Moderately severe nausea and vomiting accompanies induction therapy in approximately 80% of patients not premedicated with antiemetics. Older patients tend to have a lower incidence of emesis, perhaps due to poorer blood supply to the chemoreceptor trigger zone of the brain. Modern antiemetics, such as ondansetron [185] and granisetron [186], usually completely eliminate vomiting during induction therapy. It is not necessary to include dexamethasone in the antiemetic regimen, and it may indeed be unwise to do so since glucocorticoids inhibit anthracycline reductase activity, which may result in decreased anthracycline effectiveness.

Table 20.5 A standard remission induction regimen for adult AML

A. Idarubicin (12 mg/m^2) is given daily on each of the first 3 days of treatment. The drug is given as an injection over 10–15 min into a central venous catheter. Severe paravenous tissue damage may result from extravasation. Consider daunorubicin 60 mg/m^2 on the same schedule as an alternative anthracycline for patients <60 years old. Consider oral hydroxyurea [184] or leukapheresis for patients with a WBC > 50,000/μL prior to initiation of induction therapy
B. Cytosine arabinoside is given as a continuous 7-day intravenous infusion at the rate of 100 mg/m^2 per day beginning on the first day of idarubicin administration. The infusion must be controlled by an electronic device to ensure the proper rate of administration
C. Consider adding a FLT3-ITD inhibitor for patients with that mutation and intermediate cytogenetics

Stomatitis, esophagitis, and diarrhea are usually only of grade 1–2 intensity and can be expected in approximately 65%, 15%, and 80% of patients, respectively [158]. Oral mucosal ulceration is usually well managed with viscous xylocaine or a paste of gelatin, pectin, and carboxymethyl cellulose. Hepatic toxicity manifested by serum liver enzyme elevations occurs in half of patients and is usually unaccompanied by clinically significant hepatic dysfunction and virtually always resolves with the completion of induction therapy.

A generalized mild-to-moderate erythroderma may result from cytarabine or idarubicin treatment, and a unique cutaneous eruption has been reported after etoposide administration [187].

Profound bone marrow hypoplasia and pancytopenia are expected and desirable after induction therapy since, except in patients with the M3 subtype, complete remission is virtually never achieved without these results of therapy. Pancytopenic patients will require platelet transfusion and, very likely, packed red cell transfusion until the bone marrow recovers, usually in 3–4 weeks after the end of treatment. Transfusion support is discussed in Chaps. 56 and 57.

Response to Induction Therapy

Approximately 90% of patients who achieve complete remission will do so within the month after completion of the first induction course. Another 10% of patients who ultimately obtain a complete remission will require a second induction course to do so. The second course should be given in the same doses and schedule as the first. Patients who fail induction therapy with two courses of idarubicin and cytarabine may be candidates for regimens employing mitoxantrone [188], carboplatin [189], 2-chlorodeoxyadenosine [136], fludarabine [137], high-dose cytarabine [138], gemtuzumab ozogamicin [190], an investigational agent, or bone marrow transplantation, all of which are discussed next. Unfortunately, patients who fail initial therapy are not likely to subsequently do well, and at the present time it is difficult to recommend a standard approach to such patients [194]. Clinical trials should always be made available to patients who fail standard induction therapy.

Often the first sign of complete remission after induction therapy is a spontaneous rise in the platelet count. If the

marrow aspirate demonstrates repopulation with normal elements at that time, and leukemic cells are rare, blood counts should be observed until they are normal. At that time another marrow aspirate should be examined to diagnose complete remission or persistent leukemia. No additional induction therapy is necessary if the former pertains, whereas the second induction course should be administered if less than complete marrow remission has been achieved. If residual leukemia without any evidence of maturation in the granulocyte series appears to be present in the first postinduction marrow aspirate, another aspirate should be examined several days later, before reinstituting induction therapy. This is necessary because a marrow recovering from anthracycline drug administration may appear hypocellular and frankly leukemic, but normalize without further therapy. Indeed, an occasional blast may even be found in the blood after anthracycline therapy in a patient who subsequently manifests complete remission without further therapy. In such patients the platelet count may begin to rise, followed within a week by a rise in the granulocyte count. Progressive improvement in both to normal levels as indicated by daily blood counts is usually a harbinger of complete remission. A transient platelet count elevation, often without a concomitant rise in granulocyte count, usually indicates an incomplete response to induction therapy. This must be confirmed by bone marrow examination when the progressive platelet count improvement levels off or reverses. Almost always the marrow examination will confirm an incomplete response in that situation. However, rarely the marrow examination may lead to confusion due to the presence of a megaloblastic maturation arrest in the granulocyte and erythroid series and no evidence of leukemia. In such cases the patient may be folate depleted, especially if significant mucous membrane toxicity occurred during treatment. Such patients may have a dramatic response to daily physiologic doses of parenteral folate, with morphologically normal marrow and normal blood counts evident 10–14 days after initiation of folate therapy. In other cases, all criteria for the diagnosis of complete remission may be present except for the continuation of significant thrombocytopenia and a continuing need for platelet transfusion despite an adequate number of megakaryocytes in the marrow. Most such patients will respond with a normal platelet count to daily, oral low-dose cyclosporin A administration (100–200 mg per day) for unknown reasons [195]. In such patients, cyclosporin A may need to be continued indefinitely. Such patients are designated CRp in many studies [107, 108] and may have impaired long-term prognosis [109]. These guidelines for reassessing the marrow after induction therapy will reduce the number of patients who receive a second induction course needlessly. The common practice of reassessing the marrow at day 14 makes no sense at all [196–198] and has led to overtreatment of many patients.

Many prognostic factors influence induction therapy results. There is an inverse relationship between time to achieve complete remission after one course of chemotherapy, and disease-free and overall survival in patients with AML [199]. The patient's age has the most consistent influence on results. Elderly patients, especially those older than 70 years, are less likely to withstand the severity of treatment [200, 201]. It is not entirely clear why this is so, but other coincidental medical problems such as cardiopulmonary disease common in the elderly may make them less likely to sustain treatment without intolerable toxicity. Poor marrow reserve usually found in the aged may delay or disallow bone marrow recovery after treatment and facilitate infectious complications. In addition, poor-prognosis karyotypes are more frequent in the elderly, whereas good-prognosis karyotypes are more frequent in young adults [200]. For these reasons and others, some have advocated less intensive therapy for elderly patients [202]. Others disagree [203]. Clearly, elderly patients require the maximum in supportive care if intensive treatment is to be given. When intensive treatment is given in a setting of maximum supportive care it is likely to be successful in elderly patients and is likely to yield more benefit than less aggressive therapy without additional significant toxicity [203–205]. In the near future, peripheral blood testing for the absence of minimal residual disease by quantitating the level of molecular mutations that remain after therapy may become the accepted method of documenting response to therapy [198].

Although in many studies remission duration in the elderly treated with standard induction regimens has been poor [200], remission duration and survival have been prolonged in others [205]. Elevated blood urea nitrogen concentration, poor performance status, high peripheral blood blast count, and hepatomegaly have been reported to be particularly poor prognostic factors for survival in the elderly with AML [206]. The treatment of elderly patients is more fully discussed below.

Patients with secondary AML, discussed in Chap. 24, and AML developing after a preleukemic phase or myelodysplastic syndrome [207] have a poorer response rate, response duration, and survival than do patients with de novo AML.

The bone marrow and blood become normal morphologically and the quantities of various cellular elements normalize absolutely and relative to each other in the majority of patients when complete remission is achieved. Some complete responders, however, manifest myelodysplastic changes permanently after stem cell damage from chemotherapy but produce normal blood cells in normal numbers [208, 209]. Remission is usually explained by the premise that chemotherapy kills most of the abnormal cells and allows residual normal stem cells to repopulate the marrow and function normally. However, some evidence suggests that remission may result from maturation and

differentiation of leukemia cells induced by standard chemotherapy [210–212]. Rarely, patients in remission are noted to have Auer rods in otherwise normal granulocytes [212, 213] and some patients have been noted to degranulate mature granulocytes before other evidence of relapse is apparent. In addition, the normal leukocytes of some patients in remission express reverse transcriptase activity characteristic of leukemic cells and uncharacteristic of normal leukocytes [214]. These observations, together with the fact that a large number of agents, including many chemotherapeutic agents, are known to cause differentiation and maturation of leukemic cells in vitro [215, 216], suggest that remission does not necessarily derive from the cytotoxicity of induction therapy alone.

Postremission Therapy

It is universally agreed that postremission therapy prolongs complete remission and enhances the cure rate in AML. From the mid-1960s until recently, myriad maintenance regimens were tested. These regimens were usually given for a finite period each month, were usually less intensive than induction regimens, and usually consisted of multiple drugs most of which were not given during the induction phase of treatment. These treatments may have had a minimal favorable effect on remission duration [217], but were largely unsuccessful. The value of such treatments became even more doubtful when it was demonstrated that the frequency of their administration had no effect on remission duration [136]. Furthermore, some studies during that period suggested that remission duration was not adversely affected by omitting maintenance therapy altogether [218, 219]. Confusion was further compounded by the fact that most studies initiated after 1979 gave better remission duration results than previous studies irrespective of postremission therapy schemes. Most of those studies have employed an intensive induction regimen with an anthracycline and cytosine arabinoside in a schedule and doses similar to the treatment in Table 20.5. Not only have those studies resulted in superior response rates and durations compared with previous ones, but also the number of disease-free long-term survivors resulting from them was significantly greater [136, 138]. These observations suggest that the efficacy of induction chemotherapy is one important determinant of remission duration. This concept is further supported by several idarubicin studies [157, 159]. Such has also proved to be the case in other highly treatable hematologic neoplasms such as advanced Hodgkin's disease. Some biochemical substantiation of that contention has been offered by Rustum and Preisler [220], who found that patients with the longest remission durations were those whose pretreatment leukemic cells best activated cytosine arabinoside to cytosine arabinoside triphosphate and retained the activated compound longest intracellularly.

It has been suggested that postremission schemes as described previously are ineffective not because the concept of postremission therapy is wrong, but because the treatments were less intensive than necessary for optimal results. Therefore, a number of studies employing postremission schemes for a finite period that were at least as intensive as induction therapy were instituted [138, 221–226]. The results of such studies have been very impressive. Median durations of complete remission on the order of 18–24 months have been obtained and 20–45% or more of complete responders so treated have remained disease free for at least 15 years [227] after achieving complete remission. The intensive postremission programs, in general, produce results superior to those obtained with previously employed lower dose postremission therapy.

Four types of successful postremission therapy have emerged from studies conducted over the last 25 years. Consolidation therapy, which is usually given as one or more courses of high-dose cytarabine with or without other agents, has become a standard form of treatment [221, 222, 224, 228]. Such programs appear to be most effective when the dose of cytarabine is 1–3 g/m^2 given every 12 h, and doses of 3 g/m^2 are commonly employed on that schedule in patients under 60 years of age [164] while doses of 1.0–1.5 g/m^2 are used for elderly patients [156]. However, the optimal dose between 400 mg/m^2 and 3 g/m^2 on such schedules remains to be determined. This is important, since cytarabine toxicity escalates steeply above doses of 500 mg/m^2 given twice daily [229]. Treatment with a high-dose consolidation program is outlined as option I in Table 20.6. Other more complicated regimens have been studied [223, 230], but results are similar or inferior to those obtained with the regimen in that table.

High-dose cytarabine-based consolidation programs that employ cytarabine doses of 3 g/m^2 are toxic and associated with a death rate during remission of approximately 10%. Patients with hepatic or renal dysfunction and older patients tolerate this treatment especially poorly. Older patients are especially prone to severe neurotoxicity from this treatment [222, 266]. Whether cytarabine 3 g/m^2 in multiple doses is more effective than lower doses, such as 1 g/m^2, as consolidation therapy is the subject of much debate [267]. Others have employed lower doses of cytarabine without apparent loss of efficacy, although the lower doses have never been prospectively compared with doses of 1 g/m^2 or higher. Neither GM-CSF [141] nor G-CSF [268] has been particularly useful during the consolidation phase of treatment.

A less toxic but effective approach to postremission therapy utilizes conventional doses of cytarabine and 6-thioguanine given on an open-ended schedule until marrow hypoplasia is achieved [138] and is summarized as option II in Table 20.6. This treatment is associated with only

Table 20.6 Postremission therapy options for adult AML patients in first remission [231]

I. High-dose consolidation therapy of short duration
Example: adapted from Mayer et al. [222]
Regimen: Cytarabine, 3 g/m^2, is given as a 3-h infusion every 12 h on days 1, 3, and 5 for a total of six doses per course, beginning within 1 month of complete remission. Courses are repeated every 28–35 days, depending on marrow recovery. A total of four courses are given
Comment: This regimen resulted in a 44% projected disease-free survival at 5 years for patients 60 years of age or less [222]. Results were significantly poorer and toxicity was prohibitive in older patients. Toxicity was significant in patients over the age of 45 years. Therefore, the regimen may only be generally applicable to patients <60 years old. Serious neurotoxicity (usually cerebellar ataxia) occurred in 12% of patients and was permanent in 40% of patients who experienced it. Other serious toxicity included confluent maculopapular rash and desquamation, conjunctivitis, pulmonary fibrosis, and gastrointestinal tract ulceration. Treatment-related death occurred in 5% of patients. Most effective in patients with favorable cytogenetics
II. Intensive recurring regimen given on an open schedule for 3 years
Example: Dutcher et al. [138]
Regimen: Cytarabine, 100 mg/m^2, as an i.v. bolus and oral 6-thioguanine, 100 mg/m^2, are both given every 12 h until severe marrow hypoplasia is achieved. The treatment is given every 3 months for 3 years beginning 1 month after complete remission is established
Comment: Approximately 10 days of treatment is required to achieve marrow hypoplasia with the first several courses, but only 5–7 days of treatment is necessary after 12–18 months. Results are equal in younger and older patients up to age 75. Toxicity is virtually limited to the bone marrow, and only 1% drug-related deaths during remission have been noted in recent years. An observed 20% disease-free survival at 15 years has been reported [227]
III. Allogeneic myeloablative stem cell transplantation
Examples: Young et al. [232], Clift et al. [233], Bortin et al. [234], Zittoun et al. [235], Cassileth et al. [236], Sakamaki et al. [237]
Regimens: The patient's marrow is ablated with high doses of chemotherapy (usually alkylating agents) with or without total-body irradiation. In some studies ablation with irradiation + alkylating agent resulted in superior relapse rate, disease-free survival, and overall survival compared with alkylating agent ablation only [238]. Marrow or peripheral blood stem cells from an HLA-identical sibling or other source are used in this procedure. Long-term results have been reported to be best in patients without ABCG2 overexpression with intermediate- or poor-risk cytogenetics and age $\le$50 years [239, 240]. Long-term results are poor (67% relapse rate) in patients with molecular evidence of minimal residual disease despite morphologic remission at the time of transplant [241]. There is considerable disagreement in the literature as to which AML patients in remission should undergo this procedure [242–248]. Haploidentical donors and matched unrelated donors may give similar results [249, 250]
Comment: The probability of disease-free survival at 5 years has been estimated to be 45–60%, and treatment-related mortality in remission has been reported to be 25–40% in various studies. Results vary inversely with age, and patients over the age of 45 years do less well. For logistical and other reasons, some patients for which this therapy is planned may never receive it [251]
IV. Allogeneic reduced-intensity stem cell transplantation
Examples: McClune et al. [252], Hemmati et al. [253], Ringdén et al. [254], Pagel et al. [255]
Regimens: Less intensive chemotherapy, usually without radiation
Comment: Performed with related or unrelated donors with similar results. Less nonrelapse mortality than with myeloablative conditioning and similar disease-free survival. Three-year overall survival rates of 45% are reported [256]. This procedure is often recommended for elderly patients [257] and other poor-risk patients [240]. There are no studies comparing reduced-intensity stem cell transplantation with chemotherapy alone
V. Cord blood allogeneic stem cell transplantation
Examples: Sanz et al. [258],Verneris et al. [259], Ballen and Lazarus [260, 261]
Regimens: Cyclophosphamide plus TBI ± fludarabine, as an example
Comment: Leukemia-free survival of 40–50% at 2 years has been reported, but nonrelapse mortality has been high and as many as 1/3 of survivors have extensive chronic GVHD. Marrow recovery in the recipient may be delayed.
VI. Autologous bone marrow transplantation
Examples: Gorin et al. [262], Körbling et al. [263], Zittoun et al. [235], Cassileth et al. [236], Czerw et al [264], Mannis et al [265]
Regimens: Preparation of the patient is similar to that for allogeneic transplantation. Marrow must be harvested from the patient after complete remission is achieved and before high-dose postremission chemotherapy
Comment: Long-term disease-free survival comparable to that obtained with allogeneic marrow transplantation has been reported by various authors. Autologous transplantation is much safer than allogeneic transplantation, with only 3–5% treatment-related deaths during remission observed with the former. Autologous marrow transplantation may, therefore, be preferable for older patients. The relative merits of both major types of marrow transplantation and other high-dose cytarabine-based postremission options have been prospectively evaluated by several large cooperative group studies. Most such studies show no difference in overall survival rates. Whatever advantage in DFS is provided by stem cell transplantation is usually offset by toxic deaths

a 1% death in remission rate and can safely be given to patients up to the age of 75 years. Long-term results are excellent, but this approach has never been prospectively compared with a high-dose cytarabine-based regimen.

Allogeneic bone marrow transplantation after marrow-ablative therapy is described as option III in Table 20.6. Best results have been reported in young patients, and most reported series are heavily weighted with such patients. Preparative regimens usually consist of alkylating agents such as busulfan and cyclophosphamide or busulfan and total body irradiation. The latter was more effective than the former with respect to relapse rate, disease-free survival, and overall survival in a prospective, randomized study of patients with AML [238]. With currently available techniques, patients under the age of 60 years, who have an HLA-compatible sibling donor whose blood

lymphocytes do not react with those of the potential recipient in mixed lymphocyte culture, are considered optimal candidates for the procedure. Postremission consolidation therapy with high-dose cytarabine before allogeneic marrow transplantation for AML in first complete remission does not improve outcome compared with proceeding directly to transplantation after recovery from induction therapy [269]. Allogeneic transplants are more successful when the donor is less than 40 years old [270]. Thus, only 20% or less of patients with AML who achieve complete remission can be considered optimal candidates for allogeneic marrow transplantation using a sibling donor at this time, and some of them actually are not transplanted due to logistical and other problems [251].

Allogeneic bone marrow transplantation utilizing an HLA-matched unrelated donor has been studied in patients who do not have a sibling donor. In one study of 161 patients [271] leukemia-free survival at 5 years was 50 ± 12% for patients transplanted during first complete remission, and the relapse rate was 19% after a median posttransplant follow-up of 2.9 years. There was a direct relationship between the duration of leukemia-free survival and the dose of marrow cells infused. These results closely approach those obtained with sibling allografts and represent significant improvement in the efficacy of this procedure.

Many transplant experts think that the future of allogeneic stem cell transplantation lies with cord blood and/or reduced-intensity allogeneic transplantation [272]. Early results are encouraging, but most studies are small, and no studies in which those procedures are compared with chemotherapy alone exist to date.

Relapse after allogeneic stem cell transplantation occurs at about the same rate as in non-transplanted patients. The median time to relapse after transplantation is approximately 7 months, and less than a quarter of relapsed patients survive 1 year [273].

Autologous bone marrow transplantation, option VI in Table 20.6, has been developed more recently than allogeneic transplantation as a postremission option for AML, and in some studies [235, 236, 274], but not all [275, 276], results have been equivalent to those obtained with allogeneic transplantation. Marrow recovery seems to be more rapid after transplantation with allogeneic peripheral blood stem cells compared with marrow cells [277, 278] but there may be a higher incidence of relapse with peripheral blood stem cells [279]. Autologous bone marrow transplantation with [280, 281] and without [235, 275] ex vivo purging appears to yield similar results.

Disease-free and overall survivals for AML patients transplanted with allogeneic stem cells during first remission have been reported by innumerable investigators from around the world. The 5-year disease-free survival rate projected from actuarial analysis in most studies has ranged from 30 to 50%, and relapse rates of 15–25% have been reported. Occasionally, relapses are extramedullary [282], late [283], and possibly due to induction of leukemia in the graft [284, 285]. Most adult long-term survivors of marrow transplantation have been reasonably, if not entirely, well. In one large study, patients with no recurrence of leukemia at 2 years had an overall 82% chance of being alive in complete remission at 9 years following transplantation regardless of the type of transplant. Patients allografted, however, experienced a lower frequency of late relapse than patients autografted [286]. Females had a lower relapse rate than males, an observation also reported after chemotherapy alone [100]. In another large similar study [287] of patients who were free of AML 2 years after allogeneic transplantation, mortality remained higher than in the normal population through the ninth year post-transplantation. Recurrent leukemia was the major cause of death. Haploidentical transplants may give the same results as matched sibling donor transplants [250].

There is no doubt that both allogeneic and autologous bone marrow transplantation can cure AML. The question is the relative frequency of cure from these and other methods. In an effort to answer the question, a number of prospective studies were performed in which allogeneic or autologous bone marrow transplantation and intensive consolidation chemotherapy alone were compared [197, 221, 224, 235, 288–290, 307]. The results have been quite similar in most of these trials. Allogeneic bone marrow transplantation results in fewer leukemic relapses than consolidation chemotherapy alone, but overall survival of the two groups of patients is similar, and results with autologous transplantation are often in the middle [235] with respect to relapse rate.

The high death rate during remission after allogeneic transplantation is primarily due to acute graft-versus-host disease (GvHD). Unfortunately, treatments that reduce the incidence of acute or chronic GvHD, with the possible exception of thalidomide [291], usually lead to an increased incidence of leukemic relapse [292], since the undesired GvHD effect cannot yet be fully separated from the desired graft-versus-leukemia effect of allogeneic transplantation. Some data suggest that patients with favorable cytogenetics have longer disease-free survival after either autologous or allogeneic bone marrow transplantation than with consolidation chemotherapy alone [293, 294] and that patients with unfavorable cytogenetics fare best with allogeneic bone marrow transplantation, but these data need to be confirmed in a larger series. Chronic GVHD can be a serious problem for responders to allogeneic transplantation and its incidence has increased in recent years [295]. Recent data suggest that donor EBV+ status significantly increases the risk of chronic GVHD in the transplant recipient [296], and that low-dose interleukin-2 is highly effective in controlling steroid-refractory GVHD [297]. See Chap. 50 for information on management of the transplant patient.

Treatment of Refractory and Relapsed AML

Although significant improvement has been made in the therapy of AML and the number of potentially cured patients has increased in recent years, most patients still relapse after complete remission and ultimately die of their disease [192]. However, many relapsed patients respond to reinduction therapy with durable remissions and some of them, especially those with favorable cytogenetics such as inv(16), appear to be cured after obtaining a second complete remission. Complete responses to reinduction therapy are much more common in patients who have relapsed after an initial complete response than in patients who were refractory to initial therapy [298], and more common and more durable in patients whose first remission was longer than 1 year. Drug resistance in AML may be partially due to increased glycolysis in resistant AML cells, and this abnormality may be actionable [299].

Patients with relapsed or refractory disease are candidates for further therapy unless serious comorbidities or residual toxicity from prior therapy prevents it. Relapsed patients whose first remission was >1 year are usually retreated with the same induction regimen to which they initially responded. Others are candidates for regimens that they have not previously received followed or not by stem cell transplantation, or stem cell transplantation alone. The longer the first remission and the younger the age of the patient, the better the results with any so-called salvage therapy. Combinations of agents such as mitoxantrone and etoposide are associated with a second complete response in 25% of patients in first relapse and a median overall survival of <8 months [300–302].

A large number of studies in relapsed or refractory disease have used various doses and schedules of cytarabine with and without mitoxantrone [303]. Most yielded a complete response rate between 30% and 50%, depending on patient age and other prognostic factors. No such regimen appears to be superior to another. Although these regimens are popular in various quarters, they leave much to be desired. Relapsed or refractory patients with AML should be seriously considered for clinical trials, since to date there is no standard approach to them.

The combination of fludarabine, cytarabine, and G-CSF has been found to be quite active in poor-prognosis AML. The combination of nucleosides results in enhanced intracellular accumulation of Ara-CTP, the intracellularly active form of cytarabine, and increased DNA damage. G-CSF was thought to enhance the cytotoxicity of cytarabine by recruiting cells into the S-phase of the cell cycle and render them more sensitive to cycle-specific drugs [191, 233], but it does not appear to do this sufficiently to improve clinical results [234]. Results appear to be excellent with this regimen, with or without G-CSF, although it is quite toxic. Opportunistic infections with unusual organisms are rare but severe neurotoxicity [304–306] detracts from its appeal. Furthermore, fludarabine-based induction therapy does not overcome the negative impact of multidrug resistance proteins' overexpression [307].

The addition of gemtuzumab ozogamicin [193] to intensive reinduction therapy may improve those results and allow more patients to survive long enough to receive a stem cell transplant [308]. Recently, high-dose cytarabine, mitoxantrone, all-*trans* retinoic acid, and gemtuzumab ozogamicin was studied in 93 patients aged 18–60 years who were refractory to one cycle of standard induction therapy. The complete response rate was 51% and for patients who responded to this regimen and went on to an allogeneic stem cell transplant the 4-year survival rate was 49% [309]. These results are excellent and deserve confirmation. Others have reported similar results with a fludarabine-containing regimen [310]

Therapeutic results for patients with core-binding factor AML in first relapse are more encouraging. Such patients appear to be more sensitive to gemtuzumab ozogamicin than others, and in one study of 48 patients aged 16–76 years, patients treated with regimens including that agent had a complete second remission rate of 88% and a 5-year overall survival of 51% [311]. Unfortunately, core-binding factor AML patients account for a minority of AML patients.

New agents with major activity against relapsed or refractory AML continue to be identified and recently the specificity of new antileukemic agents has improved greatly. There is renewed interest in azacitidine, which demonstrated significant activity against de novo AML in early phase II studies [312]. Recent studies in patients who relapse after stem cell transplantation [313–316] or elderly patients are encouraging [317] as are data with a similar agent, decitabine [318, 319].

Carboplatin yields complete or partial responses in approximately 30% of relapsed or refractory AML patients [320]. No combinations including this agent have been studied in this setting, however.

Selective ablation of the leukemic clone in AML is theoretically possible with an anti-CD33—calicheamicin immunoconjugate, since CD33 is expressed by most AML cells but not by normal hematopoietic stem cells [321]. Gemtuzumab ozogamicin (GO) was such a conjugate tested clinically. A complete response was reported in 30% of 142 elderly patients with AML in first relapse with that agent [322]. However, more recent studies have been very disappointing. Martin et al. [323] reported that the addition of GO to a fludarabine, cytarabine, and idarubicin regimen failed to improve the outcome of treatment for relapsed or refractory patients. Yamaguchi et al. [324] reported that GO alone had little single-agent activity in relapsed or refractory patients, and Litzow et al. [325] reported a 12% CR rate in a phase II study of cytarabine plus GO in refractory or relapsed patients.

No patients with an initial CR of <6 months or with multiple relapses responded. Löwenberg et al. [326] reported similar results in patients ≥60 years of age in first CR. It should be mentioned that the agent has occasionally been associated with veno-occlusive disease [327]. Balaian and Ball [328] observed that CD33 upon ligation with anti-CD33 downregulates cell growth in a Syk-dependent manner, and demonstrated in vitro a correlation between GO antileukemic activity and Syk expression. Blocking Syk expression rendered AML cells unresponsive to GO, but upregulating Syk by exposing the cells to azacitidine resulted in enhanced GO activity. If these results can be confirmed it would be extremely interesting to study the sequential combination of azacitidine and GO in the clinic.

FLT3 mutations occur in approximately 30% of patients with AML and are associated with shorter disease-free and overall survival after initial or relapse therapy [329] except in patients with acute promyelocytic leukemia. These findings apply especially to younger patients [330]. Pemmaraju et al. [331] reviewed the outcome of 128 patients (22 received first salvage therapy) who received FLT3 inhibitors as part of their treatment. Median overall survival was 3.1 months and 4.2 months for those without and with FLT3 mutations, respectively, and all who had FLT3 mutations achieved CR. Mori et al. [332] demonstrated that inhibition of both FLT3-wt and mutant FLT3 is necessary for maximal antileukemic effect against cells that express both types of FLT3.

Metzelder et al. [333] treated 18 FLT3-ITD + relapsed patients with sorafenib and all had a hematological response. Lee et al. [334] reported a CR of several months' duration in an elderly relapsed male with extensive leukemia cutis. Ravandi et al. [335] reported CR in all 15 FLT3-mutated relapsed patients with a combination of idarubicin, high-dose cytarabine, and sorafenib.

Sunitinib is synergistic with cytarabine against FLT3-ITD + AML cell lines, but not cell lines with FLT-wt [336], and clinical responses have been recorded in mutated FLT3 patients [337], but the agent has not been fully studied in the clinic.

Midostaurin (PK412) is a multi-targeted kinase inhibitor with activity against mutant and wt FLT3 AML. In a study by Stone et al. [338] newly diagnosed patients under the age of 61 were induced with daunorubicin, cytarabine, and midostaurin and consolidated with high-dose cytarabine. A complete response was induced in 74% of FLT3-wt and 92% of mutant FLT3 patients, and 2-year overall survival rates were 62% for the latter and 59% for the former. These positive results led to a placebo-controlled international study (CALGB 10603) of 717 patients with FLT3 mutation. In that study at a median follow-up of 57 months the midostaurin arm reduced the risk of death by 23% [177].

Lestaurtinib (CEP-701), another FLT3 inhibitor in clinical trial, was studied in AML patients in first relapse, but results were disappointing [339]. AC220 is a second-generation FLT3 inhibitor with low nanomolar potency and exceptional kinase selectivity [340] and is currently in clinical trial [341].

FLT3 inhibitors provide us with an entirely new, more specific approach to AML treatment. However, in most studies to date, FLT3-ITD inhibition has been transient and resistance has been noted early. Resistance may be due to inadequate dosing, ligand interference, presence of residual dormant FLT3-ITD+ cells, all of these, or as-yet undiscovered mechanisms. It is too early to discard any of these agents or others not discussed, and all merit further study alone and in combination with chemotherapy and/or other agents such as mTOR inhibitors.

There are few data on post-second remission therapy that suggest that one treatment is superior to another. Robles et al. [342] demonstrated that low-dose cytarabine, 10 mg/m^2 given subcutaneously every 12 h until relapse, may have resulted in a second remission duration longer than that expected from no maintenance therapy. If these data can be confirmed, postremission cytarabine will be the first agent demonstrated to prolong second remission. A surprising finding in that study was the fact that 18% of patients in the control group also had second remissions longer than the first [343], which suggests that reinduction therapy was a more effective antileukemic therapy than initial induction and postremission therapy in that group. Therefore, it is essential to perform prospectively controlled post-second remission studies if new active therapies are to be identified, rather than simply to determine "inversion" rates from uncontrolled studies.

Farnesyl transferase inhibitors such as tipifarnib and lonafarnib have entered clinical trial in AML, but to date, results have been disappointing [344–346]. The combination of simvastatin and tipifarnib may be more active than tipifarnib alone against CD34+ AML cells [347], but clinical trials have not yet been done.

A regimen of fludarabine, cytarabine, and liposomal daunorubicin was successful in refractory and relapsed patients and produced a 44% and 56% complete response rate in them, respectively [348]. Remissions were relatively short, and a more recent study demonstrated little or no activity for liposomal daunorubicin in similar patients [224].

There is no doubt that bone marrow transplantation can cure some patients with relapsed and/or refractory AML [349–352]. However, it has been suggested by some that a bone marrow-preparative regimen without stem cell support may yield results equivalent to those reported after transplantation [353]. In a study by Forman et al. [349], 12 adults with AML who failed induction therapy were treated with an allogeneic transplant from a matched sibling and 75% achieved a complete remission. One-third of the complete responders relapsed and two-thirds (ages 20–29) remained in continuous complete remission for approximately 18–108 months. In a larger Seattle study [350] that included some

older patients, allogeneic transplantation was tested in AML patients in untreated first relapse and the 5-year disease-free survival was projected to be 23%. Only one of ten patients with AML given an allogeneic transplant in second complete remission in another study [351] survived in long-term complete remission. Ipilimumab, an immune checkpoint blockade monoclonal antibody, may restore antitumor activity through a graft-versus-tumor effect in patients who relapse after allogeneic transplantation and by this mechanism restore response in such patients. The agent is under clinical investigation [354].

Autologous bone marrow transplantation for patients in first relapse or in second complete remission was studied by Petersen et al. [352]. In all patients, marrow was harvested and cryopreserved during first complete remission. The actuarial probabilities of relapse-free survival at 2 years for patients transplanted in first relapse (21 patients) or second remission (26 patients) were 45% and 32%, respectively. The outcome in patients who were in first relapse was comparable to that of other studies in which remission was induced prior to transplantation, which suggests that there is no clinical disadvantage in proceeding directly to transplantation upon the diagnosis of relapse. Early data from the same institution suggested that the addition of IL-2 to the management of autologous transplant patients in first relapse or later stages may improve outcome [355]. However, recent data suggest no benefit for IL-2 for patients in first remission after autologous marrow transplantation [356, 357].

Some data suggest that autologous stem cell transplantation may actually be more effective than allogeneic transplantation in relapsed or refractory patients [358].

Infusion of lymphocytes from the original marrow donor is highly effective in treating chronic myelocytic leukemia patients who relapse after allogeneic marrow transplantation, but donor lymphocyte infusions are less effective in treating posttransplant relapsed patients with AML [359–361]. The major problem with this form of treatment is the frequent induction of serious GvHD, which can be fatal [362]. However, such infusions can be successful, even for relapse after unrelated donor marrow transplantation [359]. Porter et al. [363] treated 23 patients with AML who relapsed after an unrelated donor marrow transplantation and 42% obtained a complete response with an estimated 1-year disease-free survival rate of 23%. Donor lymphocyte infusions may also be able to eradicate persistent disease after allogeneic hematopoietic cell transplantation [364].

Elderly Patients

Röllig et al. [365] devised a prognostic model for elderly patients with newly diagnosed AML in which karyotype, age, NPM1 mutation status, WBC, LDH, and CD34 expression were of independent prognostic significance for overall survival. This model may be useful in other studies and may be used to stratify patients in future prospective trials. Older patients with CEBPA double mutation, NPM1 mutation, and FLT3-wild type may have significantly better survival after intensive treatment than others [366].

There is no standard treatment for relapsed or newly diagnosed elderly patients (>70 years of age) with AML. As a general rule, the same intensity of treatment used for younger patients should be considered for elderly patients because results tend to be better than with less aggressive therapy for induction. However, elderly patients do not tolerate consolidation with cytarabine 3 g/m^2 and doses half that large are commonly used. As in younger patients, for patients whose initial remission was >1 year, the same induction therapy used initially will likely yield the best results for reinduction. It should be noted that many patients with late relapse (>5 years after CR) relapse with different cytogenetics than they originally displayed [367, 368] and have a poor likelihood of long-term survival after relapse. All elderly patients should be seriously considered for a clinical trial. Some data suggest that elderly patients are less sensitive to anthracyclines than younger patients [369] and resveratrol may be helpful in overcoming this relative resistance [370].

A common approach to induction therapy of elderly patients is low-dose cytarabine (20 mg once or twice a day) by subcutaneous injection for 10 consecutive days every 4–6 weeks. Although the complete response rate with this regimen is <10%, survival is better than with no treatment other than supportive care [371]. Results with new drugs may make this approach completely obsolete. Low-dose cytarabine was studied with volasertib, a selective inhibitor of polo-like kinases, and compared with low-dose cytarabine alone in a randomized study. The combination was given to 87 patients with a median age of 75 years and the complete response rate (31%) and event-free survival rate were double that obtained with low-dose cytarabine alone. Cytogenetics did not influence response. Volasertib added to the marrow and gastrointestinal toxicity of treatment, but did not lead to more deaths.

Clofarabine, a deoxyadenosine analog, was evaluated in elderly patients with AML with good results in previously untreated patients. A complete response was obtained by Kantarjian et al. [372] in 46% of 112 patients aged 60–88 years with a median duration of response >1 year. In a study by Burnett et al. [373] of 106 elderly patients a similar response rate was observed. In both studies the drug was reasonably well tolerated. Kadia et al. [374] studied an induction regimen of clofarabine and low-dose cytarabine alternating with decitabine in 118 patients aged 60–81 years followed by consolidation and maintenance therapy with the same drugs. The complete response rate was 60% overall and 50% in those with adverse cytogenetics. Overall median survival in

the complete responders was 18.5 months. They concluded that the treatment was well tolerated and highly effective in older patients with AML. Takahashi et al. [375] compared clofarabine alone to idarubicin plus cytarabine in elderly patients and found equivalent responses and survival with the two treatments, but less toxicity with clofarabine alone. In a recent study 84 patients aged 40–75 years were treated with clofarabine and cytarabine and 67% of them went on to an allogeneic stem cell transplant that was preceded by a clofarabine-based conditioning regimen. Complete remission was achieved in 60% of patients after transplantation and the 2-year disease-free survival rate was 52%. These results are encouraging, but this was a single-arm study [376] and it is unclear whether these results are better than those that would have been obtained with other treatments. The drug needs further evaluation in combination with others.

Vosaroxin is a first-in-class quinolone derivative that acts as a topoisomerase II inhibitor and does not have the cardiac toxicity of topoisomerase II inhibitors. Its toxicity is primarily hematologic. In a phase II study of 116 previously untreated patients aged 60 years or more, several doses and schedules were studied and in the best group a 35% complete response rate was obtained, with a 1-year overall survival of 38% [377]. In another study vosaroxin was found to give results no better than low-dose cytarabine [378]. Despite other trials showing some activity for this agent [379], it seems unlikely that it will have a role in the treatment of AML.

Decitabine, alone and with other agents [381–383], is currently under evaluation for the treatment of elderly patients with AML but results are too early to fully evaluate [380, 381] or disappointing [382].

Another hypomethylating agent, azacitidine, appears to be somewhat more promising in elderly patients with AML. In one study [383] azacitidine or decitabine alone yielded essentially similar results as intensive chemotherapy in elderly patients. Another study demonstrated that hematologic improvement with azacitidine short of complete response led to improved survival [384]. In a study of 149 previously untreated patients with AML and a median age of 74, including 51 patients with de novo AML considered ineligible for intensive chemotherapy, the complete response rate with azacitidine alone was 33% and the median overall survival was 9.4 months. The 2-year overall survival was 51% in responders in this single-arm study [385]. In a study of low-dose subcutaneously administered azacitidine as maintenance therapy in elderly patients in first remission after standard induction therapy [386] the median overall survival was 20.4 months. The treatment was well tolerated and seems to have been effective. Obviously further study is needed before that impression can be confirmed.

Dombret et al. [387] performed a study of 488 elderly newly diagnosed patients randomized to receive azacitidine or several conventional treatments. Azacitidine was associated with a 3.8-month improvement in median overall survival and was well tolerated. The 1-year survival rate with azacitidine was 46.5%, compared with 34.2% for the other patients. This study provides the greatest impetus for the further study of azacitidine in elderly patients with AML. Unfortunately, to date, studies of combinations of azacitidine with intensive therapy [388] or a histone deacetylase inhibitor [389] are disappointing. On the other hand, azacitidine plus sorafenib may be effective for elderly patients with FLT3-ITD mutations [390], and in patients with FLT3-ITD and NPM1 mutation, azacitidine combined with lenalidomide may be promising postremission therapy [391]. Further studies of azacitidine in AML should take into account that low miR-29c expression by leukemic cells correlates with response to azacitidine by elderly patients [392].

In an early study of the addition of gemtuzumab ozogamicin to standard induction therapy for elderly patients the combination was found to only add toxicity without any benefit [393]. However, as a single agent gemtuzumab ozogamicin significantly improved overall survival compared with best supportive care in patients over the age of 60 years [394]. The drug remains a treatment option for elderly patients who are not candidates for more aggressive treatment if it were available.

The addition of sorafenib to standard induction therapy did not improve outcome in elderly patients, even those with FLT3-ITD mutation [395], although it does so in younger patients with that mutation [396].

A very interesting compound under investigation in elderly patients with secondary AML is CPX-351, a liposomal preparation of daunorubicin and cytarabine in a 1:5 molar ratio. In a randomized study of 309 patients aged 60–75 years comparing that agent to standard administration of daunorubicin and cytarabine in a standard schedule with standard doses, the new agent proved superior in terms of overall survival, response rate, and 60-day mortality [397]. This compound is likely to become widely used for elderly patients with AML.

At least 60% of patients with AML are 65 years of age or older. They are more likely to have an antecedent hematologic disorder, unfavorable cytogenetics, and poorer performance status at diagnosis mainly due to assorted comorbidities. Many, if not most, are judged by their physician to not be a candidate for intensive chemotherapy. Those that are treated have a significantly improved overall survival [398]. On the other hand older patients have a lower complete response rate to standard induction regimens than do younger patients and remission duration is usually shorter as well. Relapsed elderly patients rarely have useful responses to reinduction therapy although this is not always the case. Newer treatments briefly described above have not had a major impact on the results of treatment in elderly patients.

Therefore, treatment of elderly patients remains a major challenge. Hopefully, some newer agents and concepts just entering clinical trial will improve results for them. In the meantime, all elderly patients judged not eligible for standard treatment should be considered for clinical trials.

It should be noted that older patients who achieve remission after intensive or other therapy achieve significant improvements in quality of life, fatigue, and physical function as do younger patients [399].

Central Nervous System Leukemia

The diagnosis and treatment of CNS leukemia are discussed earlier in this chapter. CNS leukemia is an uncommon type of presentation or relapse in adults with AML. The incidence of CNS leukemia has decreased in AML patients since the common usage of infusional cytarabine in induction regimens due to the attainment of therapeutic levels of cytarabine in the CSF with such induction therapy. Nevertheless, about 1–2% of patients who relapse will have CNS leukemia with or without marrow evidence of relapse. These are usually young patients. Intracerebral leukemia is much less common in AML than in ALL, and virtually all adults with AML with CNS leukemia demonstrate meningeal leukemia, or cranial nerve palsy or both. Irradiation of the course of an involved cranial nerve will preserve function of that nerve if done early. Cranial nerve palsy does not respond to intrathecal chemotherapy. Patients with meningeal leukemia with cerebrospinal fluid pleocytosis usually respond to intrathecal chemotherapy, usually cytarabine, and usually do not require cranial irradiation. For reasons that are not understood, patients with AML usually have longer remissions of CNS leukemia after treatment than do patients with ALL [400].

As is the case in ALL, rapid attainment of remission of meningeal leukemia, long duration of initial marrow remission, and absence of cranial nerve palsy are favorable factors for CNS leukemia remission duration after treatment.

Mixed-Phenotype Acute Leukemia

This is an uncommon form of acute leukemia accounting for perhaps 2–3% of all pediatric and adult acute leukemias. When the leukemic blast cells display cytochemical and/or immunophenotypic features of both myeloid and lymphoid blasts the leukemia is referred to as biphenotypic and when there are two populations of cells, one clearly myeloid and the other clearly lymphoid, the leukemia is referred to as bilineal. There are few data to guide treatment for these leukemias but, in general, they are treated with ALL treatment programs and therefore will not be considered further here. For a full discussion of this “entity,” see Wolach and Stone [401].

Future Directions

There is considerable interest in developing molecular tests for the diagnosis of AML [402] and for the detection of minimal residual disease in patients who have achieved complete hematologic remission [403, 404]. Determining the presence or absence of minimal residual disease will allow for informed decisions about whether or not patients require further therapy to potentially achieve cure [405].

New drugs and new techniques are under investigation for the treatment of AML and some may improve therapeutics in the future. Arsenic trioxide and all-trans retinoic acid have been found to induce apoptosis in NPM1-mutated AML cells in the laboratory [406]. Whether this induction can be demonstrated in patients remains to be seen. An old drug, pyrimethamine, was found to have significant activity against human AML in two mice xenograft models [407]. This is an oral agent that could be tested in elderly patients not fit for intensive treatment. A dendritic cell vaccine is being developed for the potential elimination of minimal residual disease and may soon come to clinical trial [408]. Vaccination with polyvalent WT1 peptides in patients with WT1+ AML in remission has been carried out at several institutions and found to be safe and possibly effective [409]. Larger clinical trials will be required to fully evaluate the effectiveness of this promising approach. Blocking MNK kinase activity in an AML xenograft model with merestinib, an orally administered multikinase inhibitor, suppresses primitive leukemic progenitors from patients with AML [410]. Preclinical studies with the agent will continue and ultimately it may come to clinical trial. Another approach under investigation involves targeting miR-126 in leukemic stem cells with antagomiR-126 nanoparticles [411]. Higher expression of miR-126, a marker for leukemic stem cells, is associated with a poor prognosis in older patients with AML and a normal karyotype treated with conventional treatment. A similar approach has been demonstrated to be feasible against FLT3-ITD+ AML [412]. Although interesting, this concept is not yet ready for clinical exploration. Another novel concept, inhibition of certain mitochondrial proteases as a leukemia therapy, is under laboratory investigation and likely to undergo clinical study in the future [413]. In an intriguing study reported in abstract only to date, Hazenberg et al. [414] reported that AML patients cured after allogeneic stem cell transplant produce tumor-specific cytotoxic antibodies that kill AML blast cells in vitro and in mouse models. Perhaps such antibodies can be used to treat other AML patients. A trial in elderly patients would be of great interest.

New prognostic markers for the disease that may serve as therapeutic targets continue to be identified. CD11b expression in a meta-analysis of 2619 patients was shown to be associated with a poorer outcome in patients with AML [415]. CTNNA1 hypermethylation, found in 25% of patients with AML, is an independent predictor for poor relapse-free survival [416].

Recent data have confirmed that smoking may influence the onset and pathogenesis of AML [417]. Hopefully these observations will be more fully explored.

Survivors of AML have an incidence of oral and pharyngeal cancer significantly higher than that of the general population for unknown reasons [418]. Is there a common viral etiology to both diseases, such as HPV?

There is a high risk of hepatitis B reactivation among patients with acute myeloid leukemia and prophylaxis with anti-HVB vaccine has been recommended [419]. It should be noted that decades ago several studies indicated that chronic viral hepatitis had a *favorable* effect on AML prognosis [420–422]. Perhaps the relationship between viral hepatitis and AML should be reexamined.

21 Acute Promyelocytic Leukemia

Peter H. Wiernik, Robert E. Gallagher, and Martin S. Tallman

Introduction

Acute promyelocytic leukemia (APL) is designated M3 in the French-American-British (FAB) classification. Because of its unique clinical features and unique response to certain differentiation inducing agents, and because of our advanced understanding of the molecular biology of this leukemia, APL deserves to be presented and discussed in detail, apart from the other acute myeloid leukemias.

APL was first described by Hillestad in 1957 [1, 2]. Three patients were described with the characteristic morphology of hypergranular APL, hypofibrinogenemia, and a hemorrhagic diathesis [1]. Caen et al. [3] established that the hemorrhagic syndrome was directly related to the proliferation of the leukemic cells in APL, and Bernard et al. [4] provided a precise description of the disease in a presentation that included 20 patients. Bernard et al. [5] subsequently discovered the unusual sensitivity of this AML variant to daunorubicin, an important observation revisited in the all-trans retinoic acid (ATRA) era discussed in detail next. Rowley et al. in 1976–1977 described the balanced cytogenetic translocation (15;17) in APL [6, 7] and found it to be present in virtually every patient (Fig. 21.1) [8]. Kantarjian et al. [9] reported that chemotherapy could induce complete remissions (CR) in APL without inducing marrow hypoplasia and that remission was often the result of a gradual morphologic evolution, an observation later confirmed by Stone et al. [10] who suggested that the mechanism of remission in APL may be leukemic cell differentiation. Breitman et al. [11] demonstrated that maturation and differentiation of leukemic cells thought to be human APL cells (HL-60 cell line) could be accomplished in vitro by several agents including retinoids. Huang et al. [12] reported the first large series of APL patients treated with oral ATRA and demonstrated a phenomenally high rate of relatively brief CR. Fenaux and colleagues [13] treated APL with ATRA and standard chemotherapy and reported results superior to those obtained with either treatment alone, and subsequently, arsenic trioxide was identified as the most active single agent in APL [14]. Coincident with these treatment advances, there has been an explosion of knowledge of APL at the molecular level. All of these events taken together have contributed to the fact that APL is now the most curable variant of acute myeloid leukemia in adults [15, 16]. For a more detailed history of APL, the reader is referred to Bernard [17].

Molecular Biological Aspects of APL

Overall Perspective

Perhaps more is known about the molecular biology of APL, both in terms of genetic mechanism and potential for tumor cell specific therapy, than for any other specific type of human cancer. The historical background underlying this statement derives from two distinct lines of investigation. One is genetic in nature, beginning with the discovery in 1977 that the APL phenotype of AML is consistently associated with a reciprocal translocation between chromosomes 15 and 17 [7]. The second is biological, stemming from the finding in 1981 that APL cells are unique in their property of undergoing terminal differentiation after exposure in short-term tissue culture to supraphysiological concentrations of the naturally occurring metabolite of vitamin A, all-*trans* retinoic acid (ATRA) [18]. The clinical relevance of the

in vitro findings was demonstrated in 1988 when Chinese investigators reported that ATRA produces complete remissions in a high percentage of APL patients [19]. In 1990, there was a remarkable confluence of these two investigative lines with the discovery that the t(15;17) consistently produced breakage of the retinoic acid receptor-alpha (RARα) gene on chromosome band 17q11–21 [20–22]. This seminal discovery provided instant access to a wealth of molecular information that had been developed related to the RARα gene since its discovery in 1987 [23, 24], which, as a ligand-dependent nuclear transcription factor that mediates cellular responses to ATRA, had obvious implications for the selective action of ATRA in APL cells. The following year, the fusion partner of the RARα gene from chromosome 15 was identified and was originally called myl but subsequently renamed PML (for ProMyeLocytes or ProMyelocytic Leukemia) [25–27]. Thus, the two hybrid gene products which result from the reciprocal t(15;17) in APL are PML-RARα and RARα-PML (Fig. 21.1).

In the intervening years, six alternative fusion gene partners of RARα have been discovered in rare cases of APL, each associated with a unique chromosome translocation (le 23.1; see discussion that follows) [28–33]. All of the fusion proteins include the same amino-truncated portion of RARα, indicating the central role of RARα in the pathogenesis of APL. The involvement of the PML gene in >98% of APL cases implies that it also contributes some essential function to pathogenesis, which has gained support from a variety of findings. Although the alternative fusion genes, generically referred to as X-RARαs, are rare and, hence are of limited clinical impact, they have provided useful information about the molecular pathogenesis of APL and about the effect of therapeutic agents on APL cells [34, 35].

Another milestone in the history of APL were mid-1990s Chinese reports that arsenic trioxide (ATO) was, like ATRA, selectively effective for the clinical treatment of APL but that the molecular biological response was different [14, 36]. These differences are presented in some detail in the succeeding sections as they relate both to the initial APL response to ATRA and ATO and to the development of resistance in the declining fraction of patients who experience disease relapse after treatment with these highly effective agents.

Studies of the molecular biology of APL have been markedly abetted by the establishment of the fusion gene-positive APL cell line NB4 in 1991 [37]. The derivation of this cell line importantly permitted more specific molecular evaluations than possible with the antecedent ATRA-sensitive prototype cell line HL-60 that had been isolated from a patient with APL features but lacked the PML-RARα fusion gene [38, 39]. Additionally,

the development of transgenic mice (TM) bearing the fusion genes has provided an important resource for evaluating the role of the different fusion genes in APL pathogenesis and treatment [35, 40]. Recently, the TM models as well as studies with fusion gene-transduced hematopoietic progenitor cells have provided important insights into attributes of the so-called APL leukemia-initiating cell (LIC), which have important implications for treatment strategies [41–43]. However, detailed biological and molecular characterization of these LIC that are required for sustaining and propagating the disease must await their physical separation for analysis.

RARα and the Essentials of Nuclear Receptor Function

RARα is a member of the steroid/thyroid hormone receptor gene superfamily, which encodes proteins that function as ligand-dependent regulators of gene transcription [44]. Most essentially, these proteins contain two domains, a DNA binding domain (DBD) near the amino terminus and a ligand binding domain (LBD) near the carboxy terminus (Fig. 21.2). The DBD contains two characteristic zinc finger motifs that bind the receptors to specific oligonucleotide sequences, hormone response elements (HREs), in the promoter region of select genes, many of which have central effects on cell and tissue growth, differentiation, and homeostasis. RARs, which include separate genes for RARβ and RARγ in addition to RARα, belong to one major branch of the steroid/hormone receptor superfamily, along with the thyroid hormone receptors and vitamin D3 receptor. These nuclear receptors have the common property of residing in the nucleus in a bound state to their respective HREs, consisting of two direct repeats of the hexanucleotide (A/G)G(G/T) TCA (Figs. 21.2 and 21.3a). These receptors also share the property of binding to HREs as a heterodimer with common adapter proteins called retinoid X receptors (Figs. 21.2 and 21.3a), of which there are also three different genes (RXR-α, β, and γ). The discriminator for HRE specificity is the number of nucleotides between the two direct repeats, which is 2 or 5 for retinoic acid response elements (RAREs), 3 for vitamin D3 RE (VDRE), and 4 for thyroid hormone RE (TREs). Additionally, HRE spacers with one nucleotide have specificity for RXR homodimers or, in some cases, may heterodimerize with RAR in reverse polarity [45]. Through expression of different combinations of RXR/RAR heterodimers, variations in RAREs, competition between nuclear receptors and alternative transcription factors for limiting quantities of RXRs, and differences in retinoid ligand utilization, the retinoid receptor system can generate enormous heterogeneity which has been related to the discriminatory, instructive

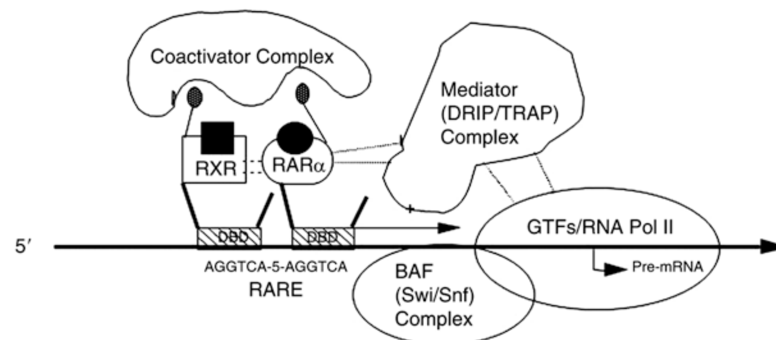

Fig. 21.3 Model for regulation of an ATRA-responsive gene promoter. (**a**) Native configuration of a RXR/RARα heterodimer bound to a canonical genomic retinoic acid response element (RARE) in the absence of ligand (ATRA). The carboxy-tail of the receptors containing the last of 12 helical motifs (*hatched oval*) is in an open position, and the receptors are engaged by a complex of corepressor proteins. A component of this complex is a histone deacetylase (HDAC) enzyme which removes acetyl (Ac) residues from the tails of select histone lysines, favoring a compact, repressed chromatin state that impedes gene transcription (*dotted arrow*). Histone methyl transferases (HMTs) directed to specific lysine residues can also contribute to the repressive effect. (**b**, **c**) Binding of ATRA to the RARα component of the heterodimer, Fig. 21.3 (continued), results in tightening of the receptor, including closure of the 12th helix over the bound ligand, associated with expulsion of the corepressor complex and recruitment of the alternative coactivator complex. This change also produces changes in the heterodimer such that the RXR component becomes permissive for binding its specific ligand 9-cis retinoic acid. The coactivator complex is nucleated by a p160/SRC family member and recruits other proteins, such as CREB-binding protein (CBP/300), with histone acetyltransferase (HAT) activity. Increased histone acetylation loosens chromatin structure, allowing access of transcription factors to promoter sites and fostering transcriptional activity. Highly site- and context-dependent methylation changes executed by specific HMTs and histone demethylases (HDMs) importantly modulate chromatin regulation of transcription. (**d**) Two additional multiprotein complexes complement or succeed the p160 coactivator complex to enhance access and functional activity of general transcription factors (GTFs) to transcribe RNA from active promoters, the mediator (DRIP/TRAP) and BAF (Swi/Snf-homologous) complexes (see text)

role of retinoids in different tissues and cells types during development [44].

In addition to the DBD and LBD domains, respectively, designated as the C and E regions, there are three other subregions of RARα (Fig. 21.2). The A/B-region has ligand-independent transcriptional activation function (AF-1). The D-region serves a rotational or "hinge" function related to heterodimer formation on RAREs. The function of the F-region, which is unique to RARs, is unknown. The E-region of RARα has been analyzed by many different methods, including site-directed mutagenesis and crystallographic analysis in the presence and absence of ligand [44, 46]. Such analysis has defined the three-dimensional structure of the region to consist of 12 α-helices and 2 β-strands linked by a series of loops. From this conformational model, it has been determined that key amino acids from various components of the LBD contribute to the formation of a binding pocket for ATRA, while those from a more restricted area stabilize a RXR/RAR dimerization interface through noncovalent bond interactions. In the absence of ligand, the apo-receptor forms a corepressor complex on RAREs in gene promoter regions, which impedes transcription of the associated gene (Fig. 21.3a). Central to this complex is the corepressor protein (SMRT or N-CoR) which directly interacts with each component of the apo-receptor and which recruits other proteins with histone deacetylase (HDAC) enzyme activity [47]. By removing negatively charged acetyl groups from lysine residues in the tails of histone proteins, HDACs increase the condensation of DNA-associated nucleosomal chromatin and inhibit gene transcriptional activity. The formation of the holoreceptor by entry of ATRA into the binding pocket produces tightening of the receptor, a prominent feature of which is a closing of the 12th, carboxy-terminal α-helix over the opening to the occupied binding site (Fig. 21.3a, b). This configurational shift results in displacement of the corepressor complex and recruitment of the coactivator complex (Fig. 21.3b, c). The core component of this complex is a p160 coactivator protein that recruits proteins with histone acetyl transferase (HAT) activity. By restoring acetyl groups on histone lysine residues in nucleosomes, these enzymes foster decondensation of chromatin and increased gene transcription. Thus, the essence of RARα function is as a sensitive switch to either repress or activate transcription from RARE-containing gene promoters in the absence or presence of ATRA, respectively.

The previously simply presented process is, in fact, highly complex and dynamic involving cell and gene promoter context-variable modifications of a multitude of molecular components that modulate transcriptional activity. At least eight classes of protein modifications have been identified that can affect the interactions and activities of these components [48]. Acetylation of histones, as described earlier, is one crucial representation of such modification. However, there is increasing documentation of the regulatory role of lysine acetylation of many nonhistone proteins, including RARα [49, 50]. Related to retinoid-mediated transcription, it has been proposed that acetylation of a p160 coactivator protein that results in disassociation of the coactivator complex from a nuclear hormone (estrogen) holoreceptor is likely commonly applicable to nuclear receptors and that this dissociation is required for engagement of the Mediator or DRIP/TRAP complex [51, 52]. The latter and another multicomponent complex, the ATP-dependent "chromatin remodeling machine" called SWI/SNF (yeast) or BAF (man), produces further chromatin decondensation essential for final engagement of the basal transcription apparatus and synthesis of mRNA by RNA polymerase II (Fig. 21.3d) [52–54]. Methylation of lysine and arginine residues in histone proteins in concert with methylation of DNA is considered to have an overall repressive effect on transcription. However, histone methylase enzymes have higher specificity than acetylases, and there is marked heterogeneity of effect depending on cellular context and the position and level of methylation (mono-, di-, or trimethylation). A defined set of histone lysine residues have been identified for which methylation or acetylation act reciprocally and in some instances in opposition to the more general effects of these protein modifications. These antagonizing "histone marks" for transcriptional repression or activation, referred to loosely as the "histone code," provide a reading guide for the chromatin modifiers involved in mediating the transcription process [55]. Protein modification by phosphorylation plays a major role in modulating retinoid-mediated transcription at all levels of the process [52]. There are at least four phosphorylation sites in RARα (Fig. 21.1), which are targeted by several different kinases, including the signaling kinases MSK1, PKA, and PKC. These and additional kinases also target RARα-associated cofactors and components of the intermediary and basal transcription complexes, most often with a stimulatory effect on transcription (but with many particular variations) [52].

PML and PML Nuclear Bodies

Structurally, PML is characterized by a conserved "tripartite motif" at the amino-terminus, which consists of a cysteine/histidine-rich (Cys3HisCys4) cluster called the RING domain, followed by two alternative cysteine/histidine clusters called B-boxes, succeeded by an α-helical coiled-coil domain (Fig. 21.4b) [56]. This RBCC structure is shared by eight other members of a large gene family, two of which in addition to PML can form oncogenic hybrid proteins as a result of tumor-associated chromosome translocations. Although all three of the cysteine/histidine clusters bind to zinc ions, which are characteristic of DNA-interacting zinc finger motifs, there is no evidence that PML directly interacts with DNA. Rather, the RING domain functions through protein–protein interactions facilitated by hydrophobic

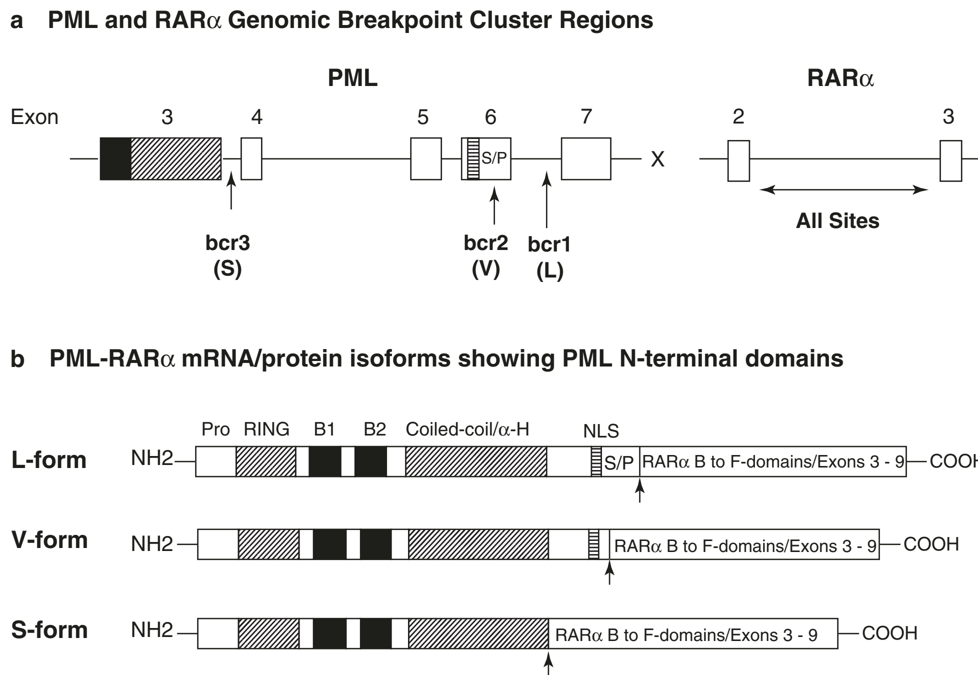

Fig. 21.4 Formation and PML region structure of PML-RARα isoforms. (**a**) DNA-level diagram is limited to the exons of PML and RARα involved in the formation of PML-RARα fusion transcript/protein. *Boxes*, numbered exons; lines, introns. Thin *arrows* indicate the intronic breakpoint cluster region (bcr) sites of DNA breakage that produce the L (bcr1), V (bcr2), and S (bcr3) isoforms of PML-RARα. (**b**) 5′-PML region linked to common RARα segment containing B–F domains shown in Fig. 21.2. The variably filled *rectangles* indicate the mRNA coding/protein regions for the proline-rich (Pro), RING, B-box (B1 and B2), coiled-coil, alpha-helical, and serine-proline-rich (S/P) domains. NLS indicates a nuclear localizing sequence in PML exon 6

amino acid heptad repeats in the coiled-coil region, which serves as a critical interface for the formation of PML homodimers and of heterodimers with PML-RARα in APL cells (see text to come). The RBCC motif, encoded by the first three exons of the PML gene, is present in all of the 18 isoforms generated by differential splicing of the succeeding 6 exons [56].

The physiological function of PML remains rather ill-defined despite many years of intensive investigation [57]. This is partly related to the lack of a compelling phenotype of PML knock-out (PML^{-}/PML^{-}) mice, which appear essentially normal under nonstressed conditions, and partly to the highly pleiotropic and complex functions that have been associated with PML. Massive experimental evidence indicates involvement in fundamental cellular processes, including proliferation, senescence, apoptosis, and differentiation and in pathological processes, including viral infections and oncogenesis. A cardinal early observation was that PML is expressed principally in nuclear structures called nuclear bodies (NB) in a wide variety of cell types [58, 59]. PML NB are quite heterogeneous ranging from 0.2 to 1 μM in size and in number from 1 to 30 per nucleus, where they often are nonrandomly distributed relative to other nuclear elements [57]. From studies using cells derived from PML^{-}/PML^{-} mice, it has been determined that PML expression is a central player in both NB structure and function [60], although there some evidence indicates that alternative NB proteins can also serve in this role [57]. An ever increasing number of proteins have been assigned to PML NBs, a recent review citing greater than 70 proteins and a recent bioinformatics study citing an interactome of 166 proteins [57, 61]. However, only a minority of the PML NB proteins have been demonstrated to directly interact with PML, importantly including a ubiquitin-related enzyme, SUMO-1 (small ubiquitin-related modifier), which produces posttranslational modification of PML required for the recruitment of many other PML NB proteins [62]. Based on the presence of several additional SUMOylation-involved proteins in PML-NBs and the presence of SUMO interaction motifs (SIMs) in the majority of PML interactome proteins, it was postulated that the on–off sumoylation status may provide a binary switch mechanism regulating the location, integrity, and activity of many PML NB components [61]. Recently, it was demonstrated that site-specific sumoylation is a prerequisite for recruitment of the ubiquitin E3 ligase RNF4, leading to degradation of PML by the proteosome [63, 64]. Several other posttranslational modifications, including phosphorylation, acetylation, and ISGylation among others have also been importantly related to PML protein biology [65]. Also, there has been a recent increased effort to dissect the specific activities of the multiple protein isoforms, including several present in the cytoplasm due to translation from mRNA

splice forms lacking the nuclear localizing sequence (NLS) encoded by exon 6.

Pathologically, PML has been defined as a tumor suppressor gene based on many experiments demonstrating an inhibitory effect on cell proliferation and a stimulatory effect on apoptosis [66, 67]. Consistent with this designation, PML knock-out (PML^{-}/PML^{-}) mice have an increased incidence of skin papillomas and lymphomas, many of high grade, after treatment with a chemical mutagen, and cells from PML^{-}/PML^{-} mice are relatively resistant to different types of apoptogenic stimuli. Also consistent decreased levels of PML protein have been demonstrated in human cancer cells [68]. Conversely, an analysis of LIC in a human chronic myeloid leukemia (CML) model in PML^{+}/PML^{+} vs. PML^{-}/PML^{-} mice indicated that greater oncogenicity was associated with higher PML expression [69]. Further, this PML-associated effect was related to the preservation of stem cell/LIC function by inducing replicative quiescence, while PML deficiency was associated with continuous cell cycle entry, eventually leading to replicative exhaustion. Notably, older nonleukemic PML^{-}/PML^{-} mice developed hematopoietic insufficiency, suggesting that one physiological role of PML is to regulate stem cell replication to maintain a lifelong reservoir. These two differing scenarios related to tumor cell behavior are likely representative of the diversity and complexity of PML activity in different cell contexts [65, 67, 70].

Structure and Generation of PML-RARα and RARα-PML

The PML-RARα fusion gene derives in each APL case from breakage of the PML gene on chromosome 15 in one of three breakpoint cluster regions (bcrs) and from breakage of the RARα gene on chromosome 17 in the second intron (Fig. 21.4a, b). PML-RARα bcr1 cases result from genomic DNA breaks in PML intron 6, producing, after mRNA processing, the long(L)-form PML-RARα fusion transcript. In bcr3 cases, the breaksite occurs in PML intron 3, producing the short(S)-form of PML-RARα mRNA. Compared to L-form mRNA, the S-form transcript lacks PML exons 4–6 which primarily encode a proline/serine-rich region with several potential phosphorylation sites. Exon 6 also contains the PML nuclear localizing sequence (NLS) and an important proteolytic site. In bcr2 cases, the PML breaksite occurs at different sites in PML exon 6, which results in deletion of variable amounts of coding sequence from the resultant variable(V)-form PML-RARα fusion transcript. Frequently, additional nucleotides derived from RARα intron 2 are incorporated at the end of the deleted PML 6 exon, which preserves the translational open reading frame (ORF) in all PML-RARα V-form cases [71–73]. Among 221 PML-RARa-positive adult cases, the frequency of L-, S-, and V-form fusion transcripts were 55%, 37%, and 8%, respectively [74]. In pediatric cases, there is a higher frequency of V-form cases, up to 27%, and a proportionate reduction in S-form cases [75, 76].

The reciprocal product of t(15;17), RARα-PML is detected in about 75% of PML-RARα-positive APL cases [77–79]. A recent study demonstrated that a significant portion of the 25% RARα-PML-negative cases can be accounted for by complex rearrangements involving a third gene, by deletions and by alternative mRNA splicing [80].

In order to try to understand the genesis of PML-RARα/RARα-PML fusion gene products, detailed DNA sequence analyses have been performed to identify the precise genomic breaksites. The RARα breaksites can occur throughout the 17 kb-long intron 2, although a few favored microcluster sites were identified, only one of which had an identifiably significant consensus sequence—a high-stringency binding site for the DNA double-strand break repair enzyme topoisomerase II [72, 73]. A similar nondescript pattern prevailed for PML intron breaksites in random APL cases. However, in a subset of APL patients who relapsed after previous treatment with anthracycline topoisomerase II inhibitors for prior cancers or multiple sclerosis, agent-specific (mitoxantrone and epirubicin) strong hotspot breaksites were identified in PML intron 6, and similar but weaker breaksite clusters were found in RARα intron 2 [81–83]. In both PML and RARa, the breaksites contained short homologous sequences suggesting that the fusion gene was generated by means of the nonhomologous end-joining pathway. Of note in these treatment-related APL cases, the median time from drug exposure to leukemia development was about 2 years, which could be consistent with the latency period observed between initial PML-RARα exposure and leukemia development in preclinical models (see text to come). Interestingly, a longer latency period was documented in a spontaneous APL case in a 10-year-old boy by demonstrating the same DNA-level PML and RARα breaksites in the blood Guthrie card obtained at birth [84]. Further study is required to assess whether alternative consensus sequences with no known relationship to DNA break repair proteins found adjacent to RARα intron 2 breaksites in spontaneous APL cases may provide insight into alternative mechanisms of PML-RARα formation [72].

Role of PML-RARα in Leukemogenesis

An early and long-standing concept has been that the primary leukemogenic activity of PML-RARα is due to a dominant-negative inhibitory effect on normal RARα, which blocks RARα-mediated terminal granulocytic differentiation at physiological ATRA concentrations [85, 86]. One basis for this concept was the observation that over-expression of transduced RARα in lineage-negative mouse bone marrow progenitor cells could produce sustained self-renewal and

arrest myeloid differentiation at the promyelocyte stage [87, 88]. These effects could also be produced by RARα with an inactivating mutation in the LBD [88], which had been demonstrated to inhibit ATRA-induced HL-60 cell differentiation by a dominant-negative mechanism [89]. Also supportive was the observation that transduction of PML-RARα into multipotential human hematopoietic progenitor/stem cells (HSC) co-opted the differentiation program, rapidly committing the transduced cells to the neutrophilic granulocyte pathway with arrest at the promyelocyte stage [90]. Two lines of experimentation provided a strong molecular rationale for the concept. First, ATRA exposure was shown to produce selective proteolytic degradation of PML-RARα, which would relieve the dominant-negative inhibition of still intact RARα, unblocking RARα-mediated differentiation [91, 92]. Second, PML-RARα was demonstrated to form a homodimer through the coiled–coiled dimerization interface of the PML region, which could usurp RARE binding sites and recruit a double dose of corepressor–HDAC complex compared to RXR:RAR heterodimers (Fig. 21.5a, b) [93–95]. This could explain the higher, pharmacological concentration of ATRA required to trigger differentiation of APL cells.

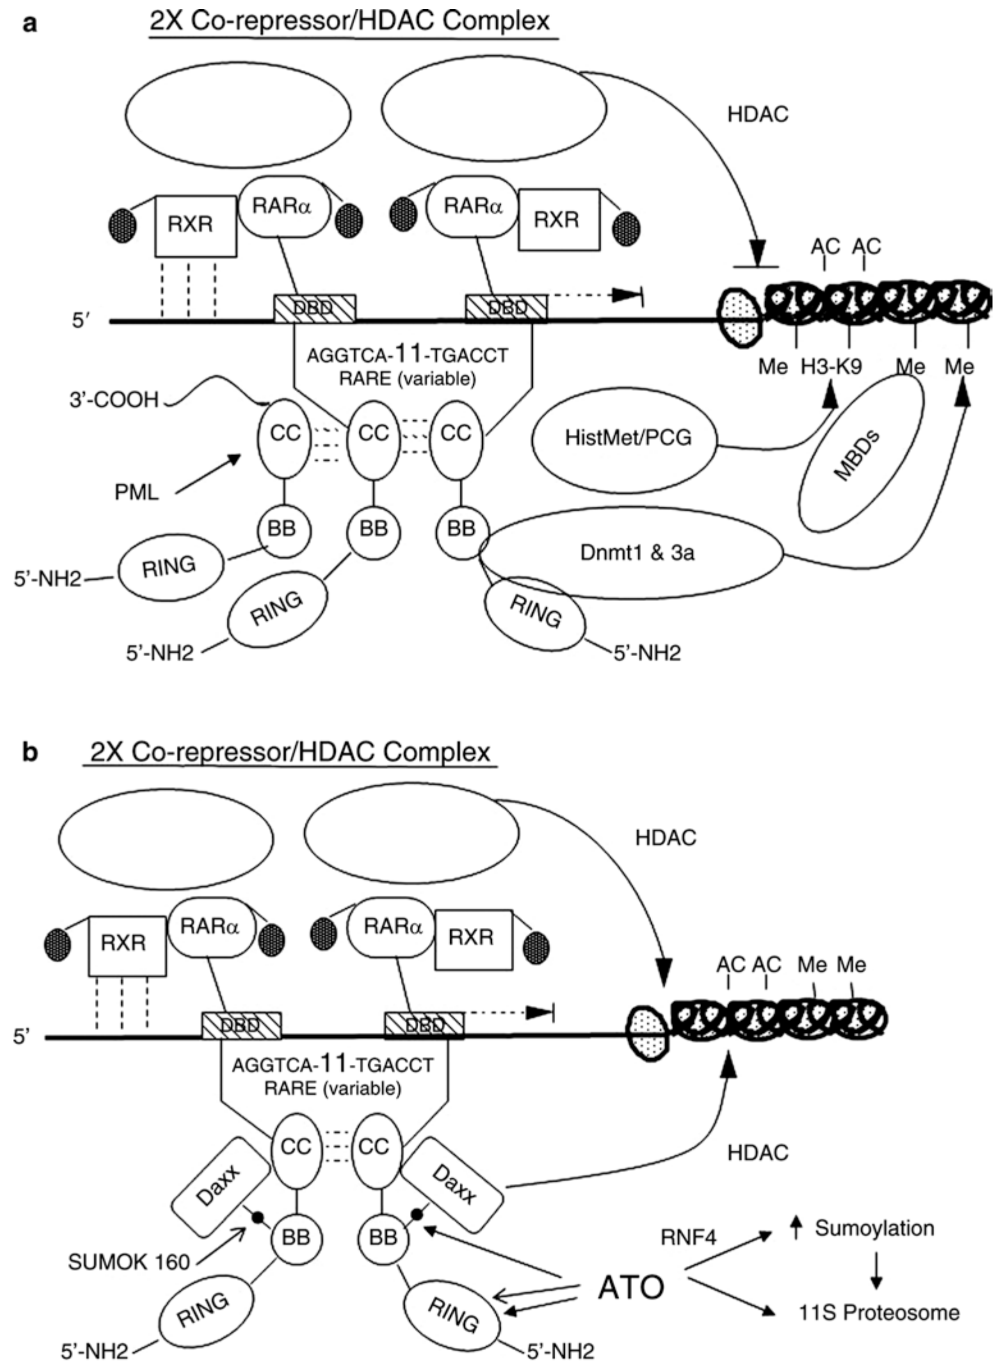

Fig. 21.5 Model illustration of the PML-RARα homodimer-nucleated hetero-oligomeric complex and action sites of arsenic trioxide (ATO). (**a**) PML-RARα homodimer situated on an atypical RARE (consisting of an inverted repeat of the right-side half-site separated from a canonical left-side half-site by 11 base pairs), stabilized by the noncovalent bonding between the two central coiled–coiled (cc) regions (*dashed lines*). Two RXR molecules form part of the complex by interacting with the interaction interface in the E-regions in the RARα portion of PML-RARα. On the lower *left side*, a normal PML molecule forms part of the complex also by interacting with the cc region of PML-RARα. On the *lower right*, several other repressor proteins have been recruited to the complex, including DNA methylases (Dnmt1 and 3a), histone methylases and demethylases (PCG, polycomb group proteins), and DNA methyl-binding proteins (MBDs). (**b**) *Lower left*: The suppressor gene Daxx is bound to the B-Box region (BB) of the PML portion of PML-RARα, which is dependent on sumoylation of lysine 160. *Lower right*: ATO degradation by the proteosome induces increased, polysumoylation of K160 by the ubiquitin E3 ligase RNF4 and also directly binds to and oxidizes vicinal cysteine residues in the PML RBCC region

It could, also, account for the effectiveness of HDAC inhibitors in complementing ATRA activity, which was particularly evident when ATRA-LBD interaction was compromised by an inactivating LBD mutation in PML-RARα [93]. A subsequent series of reports documented the staged recruitment of several additional components to PML-RARa-corepressor complex gene promoters, which are not usually evident or present at lower levels at RXR/RARα promoter sites, that can further modify chromatin structure and the level of transcriptional repression. Among these components are DNA methylases, DNA methyl-binding proteins, and histone methylases and demethylases (associated with polycomb group repressor proteins) [96–100].

This focus on the disruption of RARα-mediated transcriptional activity suggests that the PML region contribution to the fusion gene might be essentially facilitative related to homodimer formation. However, many experiments now indicate that the PML region has an active, even dominant, role in APL leukemogenesis. Most dramatically, in a TM model, a PML-RARα transgene with a mutation in the RARα-region LBD that prevented ATRA binding was equally leukemogenic compared to a nonmutant PML-RARα transgene, while a transgene with the same inactivating mutation in normal RARα was not leukemogenic [101]. These results demonstrate that PML-region activity but not RARα-region transcriptional regulatory activity is required for leukemogenesis. In accord, an artificial recombinant transgene in which an HDAC, the key effector of RARα-mediated corepressor activity (see RARα section), tethered to RARα was not leukemogenic [102]. In meticulous experiments with a variety of naturally occurring and artificially generated forms of X-RARα, it was demonstrated that homodimer formation is obligatory for leukemogenic activity and that PML-RARα homodimers were uniquely potent [103–105]. One way that PML-RARα homodimers have been considered to contribute to leukemogenicity is by interacting with the coiled–coiled region of normal PML, producing dominant-negative inhibition of this important cell regulatory molecule (Fig. 21.5a, b; see PML section) [106, 107]. In agreement, a PML-RARα transgene was more leukemogenic in PML^-/PML^- TM than PML^+/PML^+ TM, while it had an intermediate effect in $PML+/PML^-$ TM [108]. This interaction is also responsible for the signature cytological finding in PML-RARα-positive APL, as revealed by immunofluorescent staining: that PML is dispersed to myriad microspeckles throughout the nucleus in APL cells, rather than localized to discrete PML NBs as in normal cells [109]. Subsequent experiments demonstrated that a requirement for leukemogenesis in addition to the nucleating PML-RARα homodimer is the recruitment of RXR as part of a high molecular weight hetero-oligomeric complex [110–112]. Notably, the RARα region of PML-RARα is required for this interaction, since mutagenization of key amino acid sites in the LBD/E region of PML-RARα eliminates RXR recruitment and leukemogenicity [41]. Overall, these experiments indicate that the hetero-oligomeric complex can act as an inhibitor of both PML, as described previously, and of normal RARα by sequestering its heterodimerization partner RXR, as well as by competing for RARE DNA binding sites. Additional experimental evidence, however, indicates that this double dominant negative mode is still insufficient to explain the role of PML-RARα in the complex pathogenesis of APL.

A shortcoming of this presentation is that it does not consider the dynamics of the leukemogenic process. From several TM model studies a consensus conclusion is that PML-RARα is essential for the initiation of the disease process, but that additional complementary mutations are required for progression to full-blown APL-like leukemia [40]. The fundamental basis for this conclusion is a long latency period from PML-RARα initiation to leukemia development, which occurs in only a fraction of the at-risk mice (incidence, i.e., penetrance, <30%). In many molecular genetic experiments, the latency interval and penetrance fraction have been used as a measure of leukemogenic potency. A variety of evidence supports the presumption that secondary mutations required for disease progression occur during the latency interval, including cytogenetic changes indicative of clonal evolution and the divergence of gene expression patterns in leukemias arising in different TM models [113–115]. Genetic cross-breeding experiments to select TM with haploinsufficiency for genes affecting APL differentiation (*PU.1* and *CEBPA*) [43, 116] and/or other vital APL cell processes (PML; see earlier discussion) demonstrated markedly increased leukemia penetrance, suggesting that endogenous genetic or epigenetic changes that reduce the expression or activity of these molecules could be involved in disease progression. Finally, the co-expression of kinase genes with activating mutations that augment cell proliferation (*FLT3ITD* or oncogenic *RAS* mutations) had a potent effect, both decreasing latency and increasing penetrance [117, 118]. Based on these observations and evidence of cooperativity in human AML between activating kinase gene mutations that primarily affect cell proliferation and various transcription factor fusion gene mutations that primarily affect differentiation, it was proposed that these two types of mutations may be the minimal essential requirements for leukemogenesis [117], Overall, these observations indicate that the leukemogenic activity of PML-RARα must be considered on a temporal basis with respect to the disease process.

The primary leukemia initiating activity (LIA) of PML-RARα has been associated with little initial change in differentiation but, rather, with the acquisition of self-renewal capacity, a key property of LICs. Thus, during the preleukemic phase in TM, no differences in cell phenotype and very

limited gene expression differences were noted between early myeloid cells or promyelocytes from PMR-RARα-expressing TM versus control wild-type mice [115]. Similarly, minimal early phenotypic changes were observed in a more natural "knock-in" mouse model in which a single copy of PML-RARα was inserted into the promoter region of the promyelocyte expression-specific gene cathepsin G (CG) [119]. Two remarkable observations were (1) that there was a marked increase in penetrance (≤20–90%) without a change in latency compared to the corresponding CG-promoted TM model and (2) that this was associated with a very low level of PML-RARα expression (only 3% of that observed in the corresponding TM). Since the expression level of PML-RARα was less than that of normal PML or RARα, it was importantly suggested that a gain of function rather than a dominant-negative mode of action might be involved in the establishment of initiated preleukemic cells (see text to come). Recently, it was demonstrated that the most essential change in PML-RARα-initiated cells from PML-RARα CG-knock-in mice was the acquisition of self-renewal capacity at all levels of the preleukemic myeloid differentiation hierarchy from HSCs up to the promyelocyte stage [42]. There was no expansion of myeloid cell precursors or promyelocytes with self-renewal capacity, only of postreplicative neutrophils, until the leukemic stage was reached, at which time there was a marked increase in granulocyte–monocyte progenitors and promyelocytes, accompanied by normalization of neutrophil levels. Additionally, it was demonstrated that 1 in 100 cells from the leukemic promyelocyte cell population was able to generate transplantable leukemias in syngeneic mice, certifying that these normally short-lived, effete cells had acquired the crucial in vivo self-renewal property of LICs. Similar observations were reported in a TM model [43]. These results lead to at least three important conclusions. First, they indicate that the self-renewal proliferation effect imparted by PML-RARα to initiate the disease process is insufficient to account for the expanded proliferative capacity of the fully developed leukemia cells, which must be complemented by the acquisition of secondary genetic or possibly epigenetic aberrations. Second, the variable levels of differentiation block at the promyelocyte stage in different mouse genetic APL models also indicate a requirement for the acquisition of secondary aberrations to complement the inherent differentiation inhibitory effects of PML-RARα. In this regard, a potential contributory factor might be variations in the level of PML-RARα expression during disease progression [120]. Alternatively, the complementary aberrations, e.g., in oncogenes with kinase activity, might affect PML-RARα transcription complexes in a manner that alters their activity on differentiation-modulating target genes. Third, the documentation in mouse genetic models that a significant subpopulation of leukemic promyelocytes (1:100) has LIC capability suggests that the disease, once established, can be maintained by this expanded cell population, as well as by any antecedent cell in the APL hierarchy targeted by PML-RARα to initiate the disease. If applicable to human disease, this has obvious treatment implications.

As introduced previously, there is now much experimental evidence to indicate that positive gain-of-function activity of PML-RARα is at least as important as its dominant-negative inhibitory activity particularly in disease initiation but also during disease progression. An experimental model that has been very useful in studying how PML-RARα produces gain-of-function activity has been a human myelomonocytic leukemia cell line harboring a transduced and conditionally inducible PML-RARα transgene (called U937PR9) [121]. Switching on this transgene, which mimics the initiation event in APL, results in many changes in the expression of gene transcripts, as measured by oligonucleotide gene expression (RNA) array analyses. Several genes of known importance for myeloid differentiation were downregulated, consistent with the dominant repressor effect of PML-RARα on differentiation. However, in accord with a gain-of-function mode, a number of genes were upregulated, including some critically associated with increased cell proliferation and self-renewal and with reduced DNA repair that might predispose to increased mutagenesis during disease progression [121–123]. Notably, the majority of the regulated genes are not known to have a canonical RARE in the gene promoter, which argues against direct regulation via the RARα region of PML-RARα in the absence or presence of ligand (ATRA). Extensive further investigation has implicated the PML component of the fusion gene in this aberrant gene regulation, essentially, by two different mechanisms. One is based on documentation that the hetero-oligomeric complex nucleated by the PML-RARα homodimer has a markedly relaxed specificity for the sequence, orientation, and spacing of the DNA promoter RARE (Fig. 21.5a, b) [124, 125]. Recent reports document that the expanded repertoire of PML-RARα target genes compared to normal RARα target genes is extensive and, furthermore, that most are associated with epigenetic alterations, including histone acetylation and methylation and DNA methylation, indicative of functional significance [126–129]. A second general mechanism is related to protein:protein interactions of the PML region with other transcription modulators. The precise mechanism has only been documented in only one instance in which two alternative transcription factors were rendered ATRA sensitive by tethering them to the PML region of the fusion gene [130]. However, some variation of this mechanism seems probably related to observations of ATRA-modulated gene expression by PML-RARα but not by normal RARα, which include observations in APL cells of the master myeloid differentiation regulatory genes PU.1 [129, 131], CEBPA [43], and CEBPB [132]. An alternative

variation on this theme is that the dense corepressor complex formed by PML-RARα may indirectly affect the activity of alternative transcription factors by depleting modulating cofactors such as RXRs or HDACs [105]. This indirect mechanism may apply to the modulation of the AP-1 transcription factor composed of Fos and Jun [133, 134], which has been suggested to be of central importance in APL pathogenesis [135, 136].

Finally, based on evidence that sumoylation is critical for PML function (see PML section), a principal lysine sumoylation site (K160) in the B-box domain was mutagenized, and the mutant PML-RARα*K160R* was determined to retain most properties of wild-type PML-RARα but to lack the capacity to block terminal granulocytic differentiation [107]. Notably, PML-RARα*K160R* was able to form oligomeric complexes capable of binding a dense corepressor complex but, like artificial RARα homodimer fusions [103, 104], its "transforming capacity" was limited to hematopoietic cell immortalization in vitro and the generation of a expanded myeloproliferative disorder but not leukemia in an in vivo TM model. It was further demonstrated that full leukemogenic potential could be restored to PML-RARα*K160R* by linkage to the strong corepressor Daxx, previously demonstrated to require sumoylation for association with PML (Fig. 21.5a, b) [107]. Recently, Daxx was demonstrated to directly interact with and inhibit CEBPB [137] which is a key PML-RARα-specific early response gene required for differentiation after ATRA treatment [132]. Thus, the unique interaction of PML-RARα with the additional corepressor Daxx that has specific granulocyte differentiation inhibitory activity not provided by RARα-region-related corepressor complex may provide an explanation for the favored selection of PML-RARα rather than alternative RARα fusion gene partners in naturally occurring human APL [107].

Alternative RARα Genes

Six alternative RARα gene fusion gene partners in addition to PML have been reported in acute myeloid leukemia patients classified as APL by cytological criteria (Table 21.1). In all cases, the generically named X gene in the X-RARα fusion gene transcript is ligated to the beginning of the 5′-end of the third exon of RARα, as in PML-RARα. Thus, the 5′-truncated RARα segment lacks only a portion of the A/B-- region associated with ligand-independent activator function (although retaining the major phosphorylation site, Ser77). This consistent finding strongly implies that RARα is the critical factor in specification of the APL phenotype [34, 138]. As indicated in the previous section, genetic modification experiments surprisingly indicate that impairment of direct transcriptional regulatory activity of the RARα region of PML-RARα does not affect leukemogenic potency [101], but that, alternatively, this is related to mandatory recruitment of the RARα heterodimer partner RXR to the X-RARα high molecular weight hetero-oligomeric complex [110–112]. The mechanism by which recruitment of RXR contributes to the pathogenesis has not been fully determined, but it is a consistent requirement for leukemogenicity of all X-RARαs that have been tested. The recruitment of RXR enhances promoter DNA response element binding, suggesting that the constant finding of RARα in APL fusion genes is related to recruitment of RXR by X-RARα via the RARα region to aberrant RAREs selectively recognized by the X-component. The concept that the X-component adds a critical leukemogenic factor to the X-RARα-nucleated hetero-oligomeric complex is supported by the aforementioned finding that the mutagenization of a single amino acid site in the PML region of PML-RARα that did not disrupt the integrity of the hetero-oligomeric complex lost leukemogenic potential [107]. Nevertheless, the RXR sequestration effect posed by the hetero-oligomeric complex *vis-a-vis* normal RARα and alternative transcription factors, as described earlier, may provide an essential and common contribution to the transformed APL phenotype for all X-RARαs.

PLZF-RARα is the most common and most studied of the alternative X-RARαs (Table 21.1). Two studies indicate that the incidence of PLZF-RARα is <1% of APL cases: (1) in a European study of 611 cytogenetically characterized patients with a centrally evaluated consensus cytological diagnosis of APL, which included 18 PML-RARα-negative patients (2.9%), PLZF-RARα was detected in 11 patients (incidence,

Table 21.1 Alternative retinoic acid receptor-alpha fusion genes in APL

Fusion gene	X-partner name	Chromosome marker	Frequency	Reciprocal	ATRA sensitive	ATO sensitive
PLZF-RARA	Promyelocytic leukemia zinc finger	t(11;17)(q23;q21)	~0.5% of cases	Most	Weak; variable	No
NPM-RARA	Nucleophosmin	t(5;17)(q35;q21)	7 cases	Yes	Yes	Yes
STAT5b-RARA	Signal transducer and activator of transcription 5b	None or der(17)	4 cases	No	No	Not reported
NuMA-RARA	Nuclear mitotic apparatus	t(11;17)(q13;q21)	1 case	No	Yes	Not reported
PRKAR1A-RARA	cAMP-dependent protein kinase regulatory subunit R1alpha	None; FISH:del(17)(q21)	1 case	No	Not reported	Not reported
FIP1L1-RARA	Factor interacting with poly(A) polymerase	t(4;17)(q12;q21)	1 APL 1 JMML	Yes	Yes	Not reported

0.8%) [138], and (2) in 225 patients registered by the Eastern Cooperative Oncology Group (ECOG) to North American Intergroup APL trials with the clinical diagnosis of APL (no central review prior to registration), 22 patients were PML-RARα-negative (9.8%) and 1 patient was PLZF-RARα-positive (0.4%) [139]. In 10/12 of the cited cases, the PLZF-RARα fusion resulted from the reciprocal translocation t(11;17)(q23;q21), and in all cases tested, it was associated with the reciprocal fusion gene RARα-PLZF. In 1 of the 2t(11;17)-negative cases that could be tested, the PLZF-RARα fusion gene resulted from an RARα insertion in chromosome 11 and, accordingly, RARα-PLZF was absent [138, 140]. This distinction is clinically important, because the RARα-PLZF-negative case was responsive to ATRA-therapy, whereas patients with both PLZF-RARα and RARα-PLZF are relatively resistant to ATRA therapy (see clinical sections). More generally, PLZF-RARα APL is the only X-RARα reported to exhibit distinguishing cytological and immunophenotypic features—blasts with regular rather than indented nuclei, increased Pelger-like cells and expression of CD56—from those that can be common to X-RARα and PML-RARα cases [141]. Also, PLZF-RARα-positive APL is associated with a poorer prognosis than PML-RARα-positive APL. This has been ascribed both to insensitivity to ATO [142, 143] and to an inability of ATRA-containing therapy to eliminate APL LICs regardless of differentiation-inducing effect, which seems more profound than that for PML-RARα-positive APL [41, 144].

The molecular basis for the relative insensitivity of PLZF-RARα APL to ATRA therapy was initially linked to the binding of corepressor protein to the POZ domain of the PLZF region in a non-ATRA-releasable manner in addition to the common ATRA-sensitive corepressor binding to the RARα region [93–95, 145]. This conclusion was supported in these studies by in vitro and TM experiments indicating that the ATRA resistance of PLZF-RARα-positive APL cells could be at least partially overcome by co-treatment with inhibitors of HDACs recruited by the corepressors. Subsequent findings, however, have indicated that a more important factor is the absence or presence of the RARα-PLZF reciprocal gene product, as indicated previously. This relates to the structure and function of the PLZF gene, which belongs to a gene family homologous to the Droshophila transcription factor *Krüppel*. These proteins have a motif with nine zinc fingers near the carboxy-terminus that interacts with specific DNA response element sequences of select gene promoters. The PLZF intronic breaksites involved in formation of the reciprocal fusion genes usually provides seven, less frequently six, of the zinc fingers to RARα-PLZF [28, 146]. This protein was demonstrated to counter the repressive activity of normal PLZF on cell cycle progression, at least partly related to activation of the cyclin A2 gene promoter [147]. Similarly, RARα-PLZF countered the PLZF repressor activity on the promoter of CRABP1 producing a marked increase in the expression of this protein, which has been associated with increased retinoid metabolism and resistance [148]. Although it only contains two or three zinc fingers, PLZF-RARα was recently demonstrated to preferentially bind to an expanded repertoire of noncanonical RAREs that includes an APL-associated gene promoter set that is significantly overlapping with that described for PML-RARα binding [122, 125, 126, 144]. It was also demonstrated to specifically interfere with the transcriptional regulatory activity of its normal homolog PLZF [144], analogous to the interference of PML-RARα with normal PML function. A key specific effect was to increase cell proliferation in part by countering the repressive activity of PLZF to activate the cMYC gene promoter [144]. Thus, PLZF-RARα-positive APL resembles PML-RARα-positive APL by the critical contribution of the fusion gene product in countering the regulatory activity of the normal X-component, but it differs in the sense that the reciprocal PLZF-RARα and RARα-PLZF proteins are complementarily involved in the pathogenesis. These features likely account for the resistance of PLZF-RARα/RARα-PLZF APL to ATRA-induced differentiation (variably reported) and, particularly, for the ineffectiveness of ATRA in eliminating the self-renewal capacity of LICs [41, 144].

The other five X-RARαs that have been reported in APL are extremely rare, as listed in order of frequency and/or discovery in Table 21.1. Recurrent cases have been reported for NPM-RARα and STAT5β-RARα but only single cases for the other 3 X-RARαs. The FIP1L1-RARα fusion had previously been reported in a patient with juvenile monomyelocytic leukemia (JMML) [149], and, also, an alternative FIP1L1 fusion gene, FIP1L1-PDGFRA (platelet-derived growth factor receptor-alpha), has been associated with the hypereosinophilic syndrome and chronic eosinophilic leukemia [150]. Notably, the breaksite in FIP1L1 intron 15 in FIP1L1-RARα encoded a protein that could form homodimers, as characteristic of APL-associated fusion genes, while this was not so for FIP1L1-PDGFRA proteins in which the breaksite occurred in earlier introns [33]. Three of the fusion genes in which the X-partner was located outside chromosome 17 resulted from reciprocal translocations (NPM-RARα, NuMA-RARα, and FIP1L1-RARα) [33, 151, 152], while those located with RARα in chromosome 17q resulted from insertions and small deletions with (STAT5β) or without (PRKAR1A) microinversions [31, 32, 153]. Two of three translocation fusion genes were associated with the expression of the reciprocal fusions (RARα-NPM and RARα-FIP1L1); any functional role for each of these remains to be determined. Sensitivity to ATRA-induced differentiation has been established for APL cases derived from all three of the translocation-derived fusion genes [149, 152, 154, 155]. No evidence of ATRA sensitivity was observed in

any of the four STAT5β-RARα APL cases, although only one of these patients was treated with ATRA as a single agent [153]. ATO sensitivity has only been tested in NPM-RARα APL, which, like PML-RARα APL, was reported to be sensitive in both a TM model and a relapse patient [156, 157]. No testing for ATRA or ATO sensitivity related to the PRKAR1A-RARα fusion has been performed, but it was speculated that sensitivity of both of these agents is likely since reduced function of the alpha regulatory subunit (PRKAR1A) would likely result in increased catalytic activity of PKA, which has been linked to increased sensitivity to both agents [32]. More generally, the finding of recurrent cases for NPM-RARα and STAT5β-RARα implies that the X-partners in these fusions, like PML and PLZF, have some important pathogenic role beyond the formation of homodimeric and hetero-oligomeric complexes, as described earlier. Indeed, it seems likely that all of the X-RARαs contribute by as yet undetermined diverse means to the increased self-renewal properties required for LIC activity in the context of the APL phenotype imposed by X-RARα/RXRα structural complexes on a shared subset of gene promoters. Finally, in this conglomerate consideration of alternative fusion genes, it is noted that one enigmatic APL case has been reported in which only RARα-PML and no PML-RARα could be detected at disease presentation [158]. Also, in a rigorously documented set of 611 patients with characteristic features of APL, five patients (0.8%) lacked any rearrangement of RARα [138]. Overall, the previous considerations suggest that additional pathogenic elements of this disease remain to be discovered.

Role of PML-RARα in the Response to Treatment

Both ATRA and ATO, two agents that have selectively potent therapeutic effects in APL compared to other types of leukemia, have the common property of inducing proteolytic degradation of PML-RARα [36, 91]. The simplest and most direct explanation for the therapeutic effect of these agents is that by removing the dominant-negative suppressor effect of PML-RARα, normal RARα and PML (produced by the non-translocated gene loci) can re-establish physiological pathways leading to granulocyte terminal differentiation and/or apoptosis [91, 159, 160]. Although this may provide a partial explanation, the experimental details indicate that the molecular response is more complex, as well as different, for the two agents.

Exposure of APL cells to ATRA is succeeded by changes in the regulation of many hundreds of genes, leading to discernible differentiation within 24–48 h associated with a temporary increase in resistance to apoptosis [121, 126, 161–165]. The "first wave" of these reported changes in gene transcript levels occurs within 6 h of ATRA exposure [126, 165], before there has been substantial degradation of PML-RARα [91, 92]. Among these early ATRA response genes, there is no enrichment of gene promoters containing canonical RAREs required for RARα-mediated transcription, while there is some enrichment of those with atypical RAREs that can be recognized by PML-RARα [126]. Further, there were many more genes regulated in response to ATRA in U937PR9 cells (defined earlier) previously induced to express PML-RARα than in control U937 cells containing endogenous RARα [126]. These observations provide incontrovertible evidence that at least the early transcription response to ATRA is mediated predominantly by PML-RARα, not RARα. The crucial importance of PML-RARα as the primary mediator of ATRA activity in APL is also supported by the observation that after clinical relapse from ATRA-containing therapy, inactivating mutations that develop in the RARα LBD in association with acquired ATRA resistance are invariably in PML-RARα, not RARα [166–168]. Many of the early ATRA response genes are regulated in the opposite direction from that observed after PML-RARα induction in U937PR9 cells with approximately equal numbers of genes being changed from downregulated by PML-RARα to upregulated by ATRA and vice versa [122, 126]. Several important functional classes of genes are selectively regulated, including the upregulation of several key transcription factors involved in terminal granulocyte differentiation (CEBPs, PU.1, ID1&2). PU.1 is a recognized master transcription regulator of differentiation processes in hematopoietic cells, and, when it is experimentally manipulated to be switched off or on in APL cells, it has the corresponding effects of inhibiting or promoting terminal granulocyte differentiation [131]. The transcription of the PU.1 gene is activated by the binding to its promoter region of two other transcription factors, CEBPB and OCT-1 [131]. CEBPB transcription is upregulated in APL cells within 1 h of ATRA exposure, and, as previously mentioned, is activated by PML-RARα but not RARα and is inhibited by the PML-associated gene Daxx [132, 137]. This suggests a cascade activation process involving CEBPB relief from Daxx-mediated repression at an early stage, which might then be propagated by activated PU.1, a possibility supported by the finding of coincident PU.1 binding sites and nearby PML-RARα potential binding half-sites in hundreds of gene loci [129]. A key PU.1 target gene in such a cascade may be CEBPE—which as a single upregulated gene can drive terminal granulocyte differentiation in TM APL cells—since a recent report suggests that PU.1 is its principal transcriptional regulator in response to ATRA despite the presence of a classical RARE in the CEPBE gene promoter [169, 170]. Although the exact mechanism of transcriptional regulation is not known, evidence is presented for the recruitment of the histone acetyltransferase p300 to the CEBPE promoter

[170]. This observation is consistent with another recent genome-wide assessment of early epigenetic changes after exposure of APL cells to ATRA (24 h), which demonstrated marked changes in histone acetylation but not in histone or DNA methylation [128]. Thus, these findings lead to the conclusion that the early response of APL cell response to ATRA does not occur by the long-held concept that it relieves dominant negative inhibition of direct RARα-regulated genes essential for terminal granulocyte differentiation. Rather, they indicate that the RARα region of the fusion gene provides ATRA sensitivity to PML-RARα via the PML region, which affects a wide array of target genes either directly or indirectly in a gain-of-function manner.

After 6 h of ATRA exposure there is progressive degradation of PML-RARα, and, although there is considerable variation in quantitative estimates between laboratories using the NB4 cell line, this is substantial by 12–24 h and virtually complete by 48–96 h [91, 92, 159, 171, 172]. This process has been attributed to both ubiquitin/proteosome and caspase proteolytic activities directed at the RARα region of the fusion protein, although neither is sufficient for complete degradation [92, 172]. Additionally, evidence has been presented for proteolysis directed at the PML region through an alternative process called ISGylation initiated by early ATRA activation of the ubiquitin-like E1 ligase UBE1L [173]. More global proteomic studies during this ATRA exposure interval have demonstrated the associated regulation of protein systems, particularly involving signal transduction (altered), ubiquitin/proteosome activity (increased), cell cycle progression (decreased), RNA metabolism (altered), and protein synthesis (decreased) [165, 174–176]. However, reported events during this post-ATRA interval are complex and sometimes apparently contradictory, e.g., a proteomics study reported the physical downregulation of protein translation initiation factors [174], while another study focusing on phosphorylation signaling reported an increase in translational initiation [177]. Notably, at the mRNA level PML-RARα and RARα transcripts are maintained, despite degradation at the protein level [92]. Concurrently, many continuing and new gene transcript level changes are observed between 6 and 48 h, several prominently affecting cell signaling involving calcium and interferon [165]. The complex gene networks involved in executing the steps to final terminal differentiation, including a “third wave” of gene transcription regulation involving terminal differentiation marker and functional genes [165], is poorly understood. This may partially involve regulation by RARα after relief of dominant negative suppression by degradation of PML-RARα, but it likely involves other regulatory mechanisms activated during the process as well [163, 178].

The molecular mechanisms that determine the clinical response of APL cells to ATO have been less precisely defined than for ATRA. This is partly related to the complex, pleiotropic activities of ATO that can vary depending on ambient conditions [179, 180] and partly to uncertainties about translating clinically effective ATO concentrations to in vitro studies. An initial study identified dual dose-dependent effects using both fresh APL cells in short-term culture and the NB4 cell line: at ≤0.5 μM ATO, the predominant effect was the induction of partial, atypical differentiation; at >0.5 μM, the predominant effect was the induction of apoptosis [14, 181]. The probable relevance of both types of activity was supported by pharmacokinetic (PK) analyses in ATO-treated APL patients demonstrating peak plasma concentrations of total arsenic >5 μM with a biphasic excretion profile over 24 h to near basal levels [182]. However, more recent studies using more advanced technologies capable of identifying the active trivalent arsenite form, as well as the oxidized, pentavalent arsenate form and methylated metabolites, indicate that very transient peak levels of total arsenic are almost always <1 μM and the arsenite form typically <0.5 μM after standard therapy with 0.15 mg/kg ATO intravenously over a 2-h period [183, 184]. During daily treatment, there is some enrichment of the methylated metabolites, which are not effective differentiation inducers but have a greater apoptotic effect than arsenite at 0.5 μM [185]. Of note, the highest concentration of arsenic is associated with the cellular fraction, primarily with erythrocytes bound to hemoglobin [186]. Also, there is substantial ATO concentration in some cell types, especially keratinized cells such as nails and hair [182], but the level in APL cells under clinical treatment conditions has not been defined. The clinical response of patients to standard ATO therapy strongly suggests that lower ATO concentrations (<0.5 μM) are most relevant and further suggests that in vitro studies conducted at much higher ATO concentrations, e.g., >1 μM, may have limited clinical relevance. As originally described, the typical clinical response consists of the appearance of partially differentiated myeloid cells admixed with apoptotic cells in the peripheral blood, frequently appearing at increased levels more than a week after initiating treatment [14, 187]. Whether the circulating apoptotic cells are derived from the differentiated cells, as occurs following ATRA-induced differentiation of APL cells [163], or by an independent process has not been determined.

As previously noted, a primary finding was the degradation of PML-RARα (and PML but not RARα) within a few hours after ATO exposure associated with the reformation of aggregated PML nuclear bodies [36, 160]. Degradation was noted at 0.1 μM ATO, but this occurs much more slowly at this low concentration than at 1 μM [160, 181]. A series of important discoveries have been made about the details of this process. First, it was demonstrated that ATO treatment results in the sumoylation of lysine residues in the PML region of PML-RARa [188], Second, it was demonstrated that sumoylation specifically of lysine-160 (K160) is required

for recruitment along with sumoylated PML to reconstituted mature PML nuclear bodies where proteosome-dependent degradation occurs [189]. Third, it was found that polysumoylation of K160 via its SUMO interaction motifs (SIMs) recruits the RING finger ubiquitin E3 ligase RNF4, thus, defining a novel polySUMO-dependent ubiquitin-mediated proteolysis mechanism [63, 64]. Finally, it was demonstrated that within 10 min of exposure, ATO is bound to specific cysteine residues in two zinc finger motifs of the RBCC domain of the PML region [190]. Evidence was provided for the formation of octomer PML-RARα/PML complexes, including homodimers due to cross-linking between the RBCC regions of two PML-RARα/PML molecules, which could explain the rapid, aggregated PML nuclear body formation and enhanced polysumoylation required for proteosomal degradation [190].

Despite the informative detail, important questions remain about the relationship of PML-RARα degradation to the cell biological activity of ATO in APL. Is PML-RARα degradation *required* for the differentiation or apoptotic response of APL blasts to ATO? One set of experiments suggests that this could be so for differentiation: primary hematopoietic cells transduced either with the nondegradable K160-mutant PML-RARα or mutated dominant-negative RNF4 could not be induced to differentiate by 1 μM ATO, while this did occur with wild-type controls [63]. In this system, differentiation would presumably be mediated by physiological ATRA concentrations via normal RARα, which is not degraded by ATO [160], after the removal of PML-RARα dominant-negative inhibition. However, after treatment of NB4 cells with 0.1 μM ATO, the early postexposure (6 h) gene expression profile closely resembled, albeit at a lower level, that induced by ATRA [165, 181], which is primarily mediated by PML-RARα, as discussed previously. Notably, this low ATO concentration was surprisingly effective in dissociating corepressor protein (SMRT) from PML-RARα, which was attributed to SMRT phosphorylation secondary to ATO-mediated activation of the mitogen-activated protein (MAP) kinase MEK-1 [191]. Although the role of MEK-1 is controversial [192], dissociation of the corepressor in combination with delayed PML-RARα degradation at low ATO concentrations [181, 191] could result in the activation of aberrant PML-RARα-regulated gene promoters at endogenous ATRA levels [124, 125]. These results in different cell systems indicate that further studies are needed to understand how ATO mediates APL blast cell differentiation, particularly as observed in vivo. Assessment of the requirement of PML-RARα degradation for APL cell apoptosis is even more difficult, because at ≥1 μM concentrations ATO can induce apoptosis in many cell types that lack PML-RARα [193]. Thus, an alternative question is: does the presence of PML-RARα sensitize APL cells to ATO-induced apoptosis? Attempts to address this question have produced controversial results [188, 194], but a recent report suggests an intriguing mechanism by which this might occur (see text to come) [195]. Finally, is ATO-induced PML-RARα degradation *sufficient* to produce differentiation and/or apoptosis? The answer to this question is a definitive no, since studies of ATO-resistant NB4 cells effectively degrade PML-RARα without undergoing apoptosis or differentiation in response to ATO [194, 196].

Numerous studies have been performed to attempt to unravel how ATO produces apoptosis in APL cells regardless of PML-RARα contribution [179, 180]. Arsenite produces oxidative stress by binding to and decreasing the reducing capacity of the tripeptide GSH, the major intracellular buffer for reactive oxygen species (ROS), and by binding to vicinal, i.e., neighboring, sulfhydryl (thiol) groups in cysteine residues of redox-sensitive proteins [180, 197]. The relatively high sensitivity of APL cells to ATO-induced apoptosis has been attributed to low endogenous levels both of GSH and of enzymes (glutathione peroxidase, catalase, and glutathione-S-transferase) involved in regulating superoxide/free radical production from H_2O_2 [171, 198]. The importance of the GSH system in ATO sensitivity was experimentally demonstrated: increasing reduced GSH/sulfhydryl levels decreased ATO sensitivity and vice versa. Also, increased GSH levels were present in NB4 sublines selected for ATO resistance to which ATO sensitivity could be restored by depleting sulfhydryl levels [194, 198]. It was additionally proposed that postexposure ATO binding to vicinal thiols might inhibit H_2O_2-regulatory enzymes and augment endogenous APL sensitivity [171]. However, these enzymes apparently do not directly bind ATO at clinically relevant concentrations (≤1 μM), while this has been demonstrated for thioredoxin reductase (TrxR), a key regulatory enzyme in the alternative thioredoxin (Trx) ROS buffer system [199]. The oxidized (disulfide) forms of both GSH and Trx require NADPH as a reducing substrate (Fig. 21.6). Thus, it is of interest that after several days' exposure of NB4 cells to ATO at a concentration reported not to produce differentiation in these experiments (0.75 μM), gene expression analysis showed a remarkable selective increase in transcripts involved in neutrophil oxidant production, including several components of NADPH oxidase [200]. Further, this was identified as the main source of ROS. Subsequent studies found that NADPH-derived ROS are also increased in untreated NB4 cells and that aberrant regulation of NADPH oxidase is related to impairment of cyclic adenosine monophosphate (cAMP) signaling by PML-RARα [195, 201]. Although no mechanistic details about the impairment link were provided, this scenario seems a reasonable extension of the established inverse relationship of cAMP levels to NADPH oxidase activity in mature neutrophils, which is the principal source of superoxide generation in the antimicrobial response [202]. These studies implicating increased

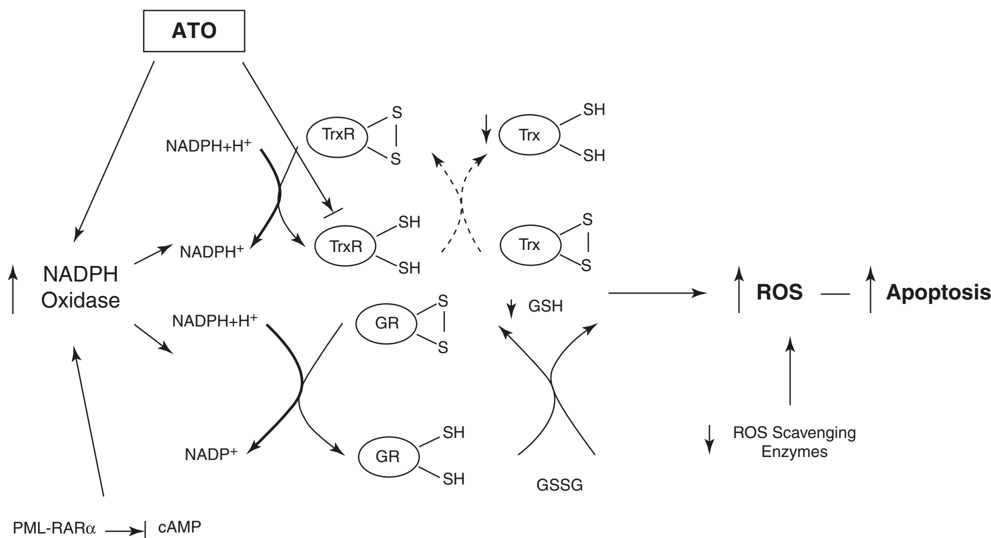

Fig. 21.6 Suggested pathways for the enhanced sensitivity of APL cells to ATO-induced apoptosis. APL promyelocytes, as committed neutrophilic lineage cells, have some increased basal levels of NADPH oxidase, a multicomponent enzyme complex involved in the antimicrobial activity of mature neutrophils. This may be enhanced by the inhibitory activity of PML-RARα on cAMP, which stimulates physiologic NADPH oxidase activity. Some studies also indicate that APL cells have constitutively diminished levels of glutathione (GSH) and reactive oxygen species (ROS) scavenging enzymes. Recent studies indicate that shortly after ATO exposure of APL cells, there are further increases in NADPH oxidase enzyme components associated with a demonstrable increase in the oxidative state. This has been related to depleted levels of NADPH, which is the principal substrate for maintaining the two main cellular antioxidant buffer molecules, GSH and thioredoxin (Trx), in an active, reduced state. ATO has also been demonstrated to strongly inhibit the key Trx system enzyme thioredoxin reductase (TrxR), further contributing to increased oxidative state that triggers the cascade of molecular events leading to apoptosis

ROS *production* due to NADPH depletion, principally after ATO treatment and specifically related to the neutrophilic lineage of APL cells, could supersede the importance of earlier-reported sources of ATO sensitization due to increased oxidative stress attributed to deficiencies in ROS scavenging with consequent decreased ROS *removal*. Regardless of attribution, the increased oxidative state generated by ATO has been linked to activation of a number of signaling pathways leading directly or indirectly to apoptosis mediated by a decrease in mitochondrial membrane potential and executed by activation of the classical caspase 3 pathway [171, 180]. Of particular note is a reportedly essential link of activation of the stress (SAPK/JNK) kinase pathway to apoptosis, possibly related to redox-sensitive conformational changes in glutathione-S-transferase pi [203, 204]. Many other potential effects due to direct interactions of ATO with vicinal sulfhydryl groups in redox sensitive proteins, e.g., with cysteines in zinc finger transcription factors, e.g., Sp1 [205], could be contributory to ATO activity, although this would presumably not be APL specific [180]. In summary, the mechanisms accounting for the high sensitivity of APL cells to ATO-induced apoptosis are complex, may involve complementary aberrations in ROS removing and producing systems, may have some PML-RARα-dependent component, can be modulated by ambient conditions that affect the APL cellular redox state—and, as mentioned before, are of uncertain importance to the clinical response of APL to ATO therapy.

Since the specific, high-sensitivity biological activities of ATRA and ATO in APL cells are dependent on differing interactions with the common target gene PML-RARα, these agents might reasonably be expected to have at least additive complementary activity. However, great variability in combined effects on differentiation and apoptosis in vitro have been experimentally demonstrated, including strong inhibitory interactions, using both sensitive and ATRA- or ATO-resistant APL cell lines and fresh APL cells [196, 206–208]. The variability is at least partly related to differing drug concentrations and schedule effects, as well as to variations in ambient conditions, each of which might affect the time-sensitive availability of PML-RARα and other protein mediators related to the differing activity kinetics of the two agents. In the only global gene transcript/protein expression study in which relatively low, differentiation-inducing concentrations of ATRA (0.1 μM) and ATO (0.5 μM) were concurrently applied to NB4 cells, the changes most closely resembled those of ATRA alone with synergistic upregulation of transcripts involved in protein degradation by the ubiquitin/proteosome system and downregulation of proteins involved in translation [165]. In contrast to the variability in vitro, in vivo studies of combined ATRA/ATO treatment in various mouse APL models have almost uniformly demonstrated positive, often strongly synergistic, antileukemia activity [143, 207, 209, 210]. A possible explanation for this difference with profound implications for the treatment of APL was recently published [41]. In this study, it was first

shown in PML-RARα-transduced mixed hematopoietic progenitor cell assays that, although a relatively low concentration of ATRA (0.1 μM) induced terminal granulocytic differentiation, it did not eliminate a subpopulation of progenitor cells that retained clonogenic replating capability, i.e., replicative self-renewal capacity. This in vitro observation suggested that there might be a dissociation of the ability of ATRA to induce differentiation in the bulk of APL cells from an inability to extinguish APL LICs that maintain propagation of the disease. In a subsequent series of in vivo experiments using various APL mouse transplantation models and selected PML-RARα mutations and leukemia initiated by the alternative APL fusion gene PLZF-RARα, further strong evidence was developed in support of dissociation of the differentiation-inducing capacity of ATRA from its anti-LIC activity. Only the latter was able to produce disease cure in the mouse models, using ATRA alone at higher concentrations (≥1 μM) or, most effectively, in combination with ATO and/or cAMP analogs. Molecularly, curative anti-LIC treatment was linked to degradation of PML-RARα under various experimental conditions, including strong inhibition in vivo of synergistic combined ATRA/ATO activity by the proteosome inhibitor bortezomib [41]. The nature of the anti-LIC activity and exactly how it is linked to PML-RARα degradation could not be determined by the functional assays used in these experiments. This must await the identification and characterization of the APL LIC, which, as previously mentioned, appear to present at about a 1:100 level in isolated APL blasts with which they may share many phenotypic properties [42, 43]. Also, these experiments do not exclude a role for ATRA-mediated transcription or distinct ATRA or ATO anti-LIC activities, which could be heterogeneous in different APL cases, partly dependent on the level of hematopoietic progenitor initiated by PML-RARα [211, 212]. The results of these experiments are, however, quite consistent with clinical observations of the curative activity of sustained high-dose ATRA in liposomal form and of combined ATRA and ATO in human APL trials (see clinical sections).

Molecular Mechanisms of Treatment Resistance to ATRA and ATO

Excluding early death from advanced disease or treatment complications, failure to achieve initial clinical remission in patients with de novo PML-RARα-positive APL has rarely been reported after treatment with ATRA [168]. If this is observed, a possible explanation is leukemic chimerism, i.e., the co-existence of APL and a second type of non-ATRA-sensitive leukemia, most frequently t(8;21) AML [213]. The high sensitivity of molecular diagnostic assays for PML-RARα has the potential of masking such chimeras if confirmatory methods such as standard cytogenetics or FISH are not employed. Another documented cause of primary ATRA-resistant disease, reported in 2V-form PML-RARα cases, is a long in-frame insertion of a sequence from RARα intron 2 at the 3′-end of a markedly truncated PML exon 6 that encodes a binding site for additional corepressor protein [71, 72]. One of these cases, additionally, had a frame-shift mutation in the normal PML gene that encoded a truncated carboxy-terminus, deleting the nuclear localizing sequence, which may have also contributed to the ATRA resistance [214]. Combined treatment of ATRA with chemotherapy and/or ATO, as is now common practice, might either overcome or forestall the manifestation of less ATRA-sensitive disease.

The development of acquired ATRA resistance was virtually universal in early clinical studies using ATRA as a single, continuous agent or with low dose chemotherapy [19, 215, 216]. However, some repeat remissions could be secured with ATRA alone if relapse/re-treatment occurred several months after discontinuing ATRA, suggesting a partially reversible systemic mechanism of ATRA resistance [217]. This was substantiated by the pharmacokinetic finding of an ATRA-induced hypercatabolic state that could diminish achievable ATRA plasma levels by up to 80% [218]. The hypercatabolic response was attributed, at least in part, to an increase in liver enzymes that could principally account for the associated increase in oxidative metabolites of orally administered ATRA and, also, to an increase in cellular retinoic acid binding protein (CRABP) in skin that could sequester ATRA to reduce systemic levels. Subsequently, it was found that the hypercatabolic resistance mechanism can be largely avoided by administering ATRA intermittently rather than continuously [219], which has become the standard schedule for administering ATRA after remission induction. A logical deduction of this systemic ATRA resistance mechanism is that alternative agents not subject to its elements should be able to induce second remissions. However, three other retinoid formulations, each with some of these characteristics—oral 9-cis retinoic acid, oral Am80, and intravenous liposomal ATRA [220–222]—were unable to induce second remissions in the majority of ATRA-resistant patients. Overall, these results suggest that other resistance mechanisms are also operative.

By analogy to drug resistance mechanisms in other malignancies, the most probable alternative source of acquired ATRA resistance is an endogenous APL cell mechanism(s). Consistent with this hypothesis, variable loss of sensitivity to ATRA-induced differentiation of fresh APL blasts from patients who relapsed after ATRA treatment in short-term tissue culture has been demonstrated in a majority of cases [167]. Several potential mechanisms of APL cellular ATRA resistance have been proposed, primarily based on investigations of established APL cell lines selected for resistance to ATRA, the most frequent of which is the clonal emergence of cells with mutations in the LBD of the RARα region of PML-RARα [168, 223]. This is, indeed, the only mechanism

of ATRA resistance so far demonstrated in APL patients who relapse after clinical ATRA therapy [166, 167]. Such mutations have been documented in 30–40% of patients at first relapse after ATRA-containing therapy, including cases of relapse long after the discontinuation of ATRA and after intervening chemotherapy [167, 224, 225]. A higher incidence of LBD mutations was observed after relapse from two or more treatment regimens containing ATRA [226]. Consistent with a functional role in ATRA resistance, the LBD mutations increase the transcriptional repressor activity of unliganded PML-RARα and diminish ATRA binding and/or its transcriptional activation [226, 227]. Although some of the mutations might be predicted to have an effect on the ability of ATRA to target PML-RARα for degradation, no specific information is available about this potential effect. Also, the downstream defects effected by the mutations in PML-RARα and their role in disease progression and relapse remain to be elucidated. Whatever, the exact mechanism, the high salvage therapy rate with ATO treatment suggests that this agent, in contrast to chemotherapy, can overcome the APL cellular resistance mechanism(s) associated with LBD mutations in many cases, although specific LBD mutations may be less ATO sensitive [225].

A second major hypothesis has been that ATRA resistance is related to altered metabolism of ATRA within APL cells (reviewed in [168]). An initial study suggested that an ATRA-triggered increase in CRABP2, which has an RARE in its gene promoter, could enhance intracellular sequestration and degradation of ATRA, reducing its effectiveness in inducing APL cell differentiation [228]. However, this result was not confirmed in a larger study, including relapse patients [229]. Further, in contrast to the negative effect of CRABP1 on ATRA activity by increasing ATRA catabolism [230], CRABP2 was subsequently determined to have a positive effect on ATRA activity by facilitating its delivery to nuclear receptors [231, 232]. To date, no evidence has been forthcoming in PML-RARα-positive APL to suggest a role of CRABP1 in ATRA resistance, as described earlier for PLZF-RARα/RARα-PLZF-positive APL [148]. Recently, however, a link was made between the ATRA-specific P450 catabolic enzyme, CYP26A1, and ATRA resistance [233]. Surprisingly, it was found that low sensitivity to ATRA-induced differentiation and to retinoid inhibition of NB4 clonal cell growth was associated with *decreased* levels of CYP26A1. It was postulated that the increased nuclear levels of ATRA found in low CYP26A1-expressing cells would increase selection pressure for ATRA-resistant cells, although the downstream resistance mechanism remained to be defined [233]. Notably, this conclusion seems at odds with the previously cited study indicating that high intracellular levels of ATRA are necessary to inhibit the self-renewal capacity of APL LIC and to effect disease cure [41]. In summary, although an attractive idea, a mechanistic role of variations in intracellular APL cell ATRA concentrations and metabolism in clinical ATRA resistance remains uncertain.

Two other potentially important mechanisms of ATRA resistance have been identified in two well-characterized sublines of the NB4 cell line after selection for ATRA resistance in vitro. In subline NB4.007/6, ATRA resistance was related to constitutive activation of the proteosome and resultant degradation of PML-RARα protein [234]. Sensitivity to ATRA could be partially restored by inhibition of proteosome activity and fully restored by forced expression of PML-RARα but not RARα, supporting other evidence that PML-RARα is required for the ATRA-mediated differentiation response. In NB4-MR2, a subcloned derivative of ATRA-resistant NB4 cells, an increased level of topoisomerase 2-beta (TOP2B) was demonstrated to decrease ATRA-mediated gene transcription and granulocytic differentiation by associating with and increasing suppression by the unliganded PML-RARα/corepressor complex [235]. The TOP2B suppressive activity was subsequently attributed to increased protein stability under regulation of protein kinase C-delta (PRKCD), the most abundant isoform of PRKC in hematopoietic cells [236]. Sensitivity to ATRA-induced differentiation could be restored in the NB4-MR2 cells by inhibiting PRKCD, an enzyme itself regulated by phosphorylation, suggesting the possible involvement of yet another upstream kinase in the pathway, possibly p38 MAP kinase. It is noted, however, that some apparently conflicting evidence regarding the role of PRKCD (and of p38 MAP kinase) in wild-type NB4 cell differentiation has been presented [237, 238]. Although neither of these in vitro ATRA-resistance mechanisms has been demonstrated in clinical circumstances, similarities to the second mechanism have been reported in other cancers. For example, ATRA resistance due to diminished ATRA-mediated RARα transcription has been linked to association with the corepressor complex by the suppressor proteins xeroderma pigmentosa-associated protein Xab2 and the tumor-associated protein Ski [239, 240]. Also, increased activation of protein kinases that can affect the activity of RARα or its transcriptional cofactors by phosphorylation, e.g., PI3K/Akt pathway enzyme components, has been implicated in ATRA resistance [241, 242].

In contrast to ATRA resistance, meager information exists about resistance to ATO under clinical conditions. From the single-agent ATO trials conducted in India, Iran, and China (see clinical sections), there is insufficient documentation to assess whether any of the patients who fail to achieve initial remission have primary refractory disease. The incidence of acquired resistance is, however, clearly much less frequent than for ATRA, since most patients with de novo disease sustain prolonged remissions with probable disease cure, even though optimal single-agent therapy has yet to be defined

[243–245]. Of these patients who relapse, almost all patients can achieve a second remission with ATO alone or in combination with other agents [246–248]. However, the second relapse rate is high associated with a significant incidence of ATO-refractory disease [243], implying the acquisition of ATO resistance. In the best documented trial with long-term follow-up, the great majority of patients who relapsed originally presented with a high APL blast count [244], which implies that acquired ATO resistance has an APL cellular basis rather than a systemic pharmacological basis. On the other hand, the observation in this study that patients with liver toxicity had superior disease-free survival raises the possibility that a pharmacogenetic factor could produce variability in ATO exposure and in the extent of response to treatment. Although no specific molecular mechanism of clinical ATO resistance has yet been identified, the recent finding of a high level of telomerase activity and telomere shortening in first relapse post-ATO treatment APL cells implies the presence of other acquired molecular abnormalities associated with disease progression [247].

In vitro studies, principally of ATO-resistant sublines of NB4 cells, have identified several molecular pathway abnormalities associated with resistance to ATO-induced apoptosis. Increased baseline levels of GSH, which can buffer the increased oxidative stress required for ATO-induced apoptosis, have been found in some ATO-resistant NB4 sublines [194, 249]. After the administration of ATO, however, the differential impact of GSH abnormalities in ATO-resistant cells was related to a more complex effect of the ratio of the reduced and oxidized forms (GSH::GSSG) on redox-sensitive proteins than control activation of JUN kinase-mediated apoptosis [204]. In another NB4 subline, ATO resistance was primarily related to increased activation of the MAP kinase ERK1/2-pathway with consequent inhibitory phosphorylation of the pro-apoptotic protein Bad [192]. In other studies, ATO resistance was related to activation of the PI3K/Akt pathway with secondary effects on the cellular redox state and modification of BCL-family proteins [250, 251]. ATO-sensitivity/resistance has also been related to the expression of the putative arsenic influx transporter aquaglyceroporin (AQP9; high expression with sensitivity) [252, 253], to the arsenic export transporter MRP1/ACBB1 (increase with resistance) [249], and of the metalloid-binding proteins, metallothioneins (increase with resistance) [254]. Detailed analysis in yeast has demonstrated ATO resistance to be a multifactorial complex process [253, 255, 256]. Overall, the in vitro results suggest that, if clinical ATO resistance in APL indeed involves reduced apoptosis, the mechanism is likely to be heterogeneous in different relapse cases and, not unlikely, multifactorial in individual relapse cases reflecting the pleiotropic nature of the agent.

APL Molecular Biology: Clinical Applications

The most essential clinical application of molecular biological knowledge in APL has been to provide a definitive diagnosis. Demonstration of the PML-RARα fusion gene (or one of the rare alternative X-RARα fusion genes) to make a genetic diagnosis is now the accepted standard requirement for certifying the diagnosis of APL [257]. The t(15;17) is also entirely specific for APL but this reciprocal translocation is not manifest by standard cytogenetic methods in up to 20% of PML-RARα-positive cases in which the gene rearrangement occurs either because insufficient APL cell metaphases are present or because more subtle intrachromosomal mechanisms are involved [138]. Fluorescence in situ hybridization (FISH) analysis using RARα- and PML-specific probes, which is not dependent on cell division, has a much lower incidence of false negative results and can provide useful supplementary information, particularly in cases with an atypical or complex derivation of PML-RARα. Another specific method, which is useful for rapidly confirming a suspected diagnosis of APL based on cytological evaluation, is a fluorescein-labeled anti-PML antibody to demonstrate the pathognomonic microspeckles in APL cells due to the displacement of PML from nuclear bodies by PML-RARα [258]. Although not entirely specific, immunophenotyping can also be valuable not only by providing early criteria for or against a suspected diagnosis but also for evaluating phenotypic variation among APL patients (see Chap. 17) [259].

A second clinical application of molecular biology relates to studies assessing the potential prognostic value of molecular markers. Most abundantly this has involved analyses of the three types of PML-RARα, the L, V, and S isoforms, which are revealed in the process of making the molecular genetic diagnosis of APL by reverse transcriptase-polymerase chain reaction (RT-PCR) procedure (Fig. 21.4a, b). Some studies have provided evidence that the minor V-form set of APL patients (3–10%) can be associated with potentially adverse risk or response factors, including higher WBC count and decreased ATRA sensitivity [72, 74, 260, 261], or with a high early relapse rate [71, 262]. However, the small number of these cases has prevented an adequate statistical assessment of potentially increased risk, which, in any event, has likely been eliminated by the increased efficacy of current treatment regimens. Much greater evidence has been presented for an association of the S-form patient set compared to the L (or combined L/V-form) patient set with adverse risk factors, including high WBC count, the microgranular (M3v) phenotype, and with internal tandem duplication mutations of the Fms-like tyrosine kinase-3 (FLT3/ITD; see text to come) [74, 261–264]. However, in most major clinical trial reports, the S isoform has not demonstrated statistical significance as a prognostic indicator of

clinical outcome independently of its association with a high WBC count [74, 265–270]. With the advent of quantitative RT-PCR procedures (RQ-PCR; described next), prognostic significance has been associated with the level of the PML-RARα transcript but this has been quite variable: in two reports, an adverse prognosis was associated with high levels [268, 271], in a third study this was associated with low levels [269] and in a fourth study, the level had no prognostic significance [272]. Technical differences likely account for these variations, including differences in housekeeping genes controls and in the adjustments in raw data made to calculate the normalized PML-RARα copy number.

The only other specific gene structural variation recurrently tested for prognostic significance in APL clinical trials is mutation of the membrane receptor tyrosine kinase *FLT3* by the in-reading-frame insertion of variable numbers of internal tandem duplications of a juxtamembrane coding segment (FLT/ITD mutations). These mutations result in Flt3 ligand-independent, constitutive activation of Flt3 kinase activity and downstream activation of signaling pathways linked to increased myeloid leukemia cell growth (recently reviewed) [273]. FLT3/ITD mutations occur in 21–38% of occidental APL patients (median >30 vs 12–25% of oriental patients), and, as noted previously, have frequently been associated with increased WBC count, the M3v phenotype, and the S-isoform of PML-RARa (11 clinical trial data recently summarized) [274]. In a minority of studies, a trend toward an association of FLT3/ITD mutations with reduced disease-free or overall survival has been observed by univariate statistical analysis [261, 263, 274–276], however, after adjustment for the associated high WBC count, no study has shown a significant reduction in postremission disease outcome (ibid; 1 study showed a significant association with increased deaths during remission induction [269, 277, 278]. In other classes of AML, quantitative assessment of ITD mutations found that only those with a high ratio of the mutant to the normal FLT3 allele were associated with poor prognosis [279]. However, no such relationship was found in two recent APL studies in which the ITD mutation was quantitatively assessed [269, 278], although in one of these studies, a long insert sequence was independently associated with an increased incidence of disease relapse [269]. In the context of the studies cited earlier, several other mutations have been tested for a possible association with APL disease outcome, including alternative FLT3 activation mutations in the tyrosine kinase domain (FLT3/RTK mutations, most affecting aspartic acid residue 835) [263, 274, 277, 278], RAS gene mutations [261], and MLL gene partial tandem duplications and Kit [263], however, the low frequency of these mutations in APL has limited statistical assessment. Finally, one study found that transcripts for the tumor-testis antigen protein PRAME (preferentially expressed antigen of melanoma) were selectively expressed in APL cells and that a low level of PRAME expression was significantly associated with reduced relapse-free survival largely independent of WBC count [280].

In summary, many studies performed to assess potential molecular prognostic markers in APL find a significant association of high presenting WBC count, hypogranular (M3V) phenotype, S-form PML-RARα, and FLT3/ITD mutations. This is consistent with the proposal that at least a subgroup of patients with these characteristics have a disease variant that significantly differs from the predominant hypergranular disease, perhaps related to different levels of initial hematopoietic progenitor cell transformation [211]. In the context of the ATRA-chemotherapy clinical trials in which this data was developed, a high WBC count clearly takes precedence over the other three elements as a prognostic indicator, although some combined features may make some additional contribution [269, 270]. In at least three recent clinical trials, however, in which frontline arsenic trioxide (ATO) was added to ATRA/chemotherapy, neither a high WBC count nor any of the previously described molecular features of PML-RARα or FLT3 were differentially related to clinical outcome [278, 281–283]. These observations suggest that in the future an alternative set of prognostic indicators will be required to identify the minor fraction of patients (probably <5%), who remain at risk of relapse after the addition of ATO to ATRA/chemotherapy-based treatment.

A third clinical application of molecular biology in APL has been molecular monitoring of subclinical disease after achieving clinical remission (referred to as minimal residual disease; MRD), using the PML-RARα gene transcript as a disease-specific marker. Two RT-PCR methodologies have been applied: (1) a conventional procedure (cRT-PCR) that provides a positive vs negative read-out determined by the presence or absence of stained gel electrophoretic bands of the DNA product derived by terminal PCR amplification of complementary DNA (cDNA) after conversion from RNA by reverse transcriptase [284]; and (2) quantitative PCR (RQ-PCR) that provides a variable read-out depending on the number of PCR cycles that are required to detect the activation of a fluorescent dye indicating the initiation of cDNA amplification (the threshold cycle or C_T), which is dependent on the concentration of the PML-RARα transcript in total cellular RNA [285, 286]. In order to assure proper primer placement for PCR amplification, both of these methods require accurate assignment of the PML-RARα isoform type at the time of diagnosis when the fusion gene is abundantly present (Fig. 21.4a, b). cRT-PCR has a detection sensitivity between 1 in 10^3 and 10^4 (determined by the ability to detect PML-RARα transcript in a serially diluted RNA from a 100% APL cell source, usually an APL cell line), while RQ-PCR sensitivity can be up to ten times more sensitive [287, 288]. A major advantage of RQ-PCR, which has now largely supplanted cRT-PCR for MRD monitoring, is that it can be more

accurately standardized. Importantly, this includes adjustment for RNA quality and efficiency of conversion to cDNA by normalization of the PML-RARα copies (calculated by comparison of the sample C_T to those for a plasmid standard curve with known copy numbers) to a constantly expressed housekeeping gene: thus, read-out is expressed as the normalized copy number (NCN) or normalized quotient (NQ).

Important lessons from the application of cRT-PCR to ATRA-chemotherapy clinical trials have included: persistence of MRD detection in the immediate postclinical remission induction period is not an indicator of long-term adverse outcome and is likely due to the slow clearance of terminally differentiated APL cells; detection of MRD after finishing consolidation therapy (molecular persistence) is a virtually certain prognostic indicator for subsequent clinical relapse if a repeat sample is also positive; and, the majority of eventual clinical relapse cases test negative at the postconsolidation checkpoint so that continued monitoring at relatively frequent intervals for 2–3 years is needed to identify most cases destined to clinically relapse [289, 290]. The clinical importance of MRD monitoring was supported by a report that the long-term outcome of patients initiated on salvage therapy based on the detection of MRD (molecular relapse) was superior to that of a historical control group in which salvage therapy was only initiated after clinical relapse [291]. This result was confirmed under internally controlled trial setting [292], and molecular relapse or persistence is now considered the equivalent of clinical relapse in calculating the relapse rate in clinical trial studies [257].

The application of RQ-PCR has confirmed the essential cRT-PCR MRD monitoring results with more accurate and refined criteria. Further, the quantitative NCN values have allowed an assessment of the kinetics of subclinical residual disease, e.g., not only whether a confirmatory, repeat test after a suspicious result is positive or negative but whether it is increasing or decreasing. From several RQ-PCR studies, it is apparent that low levels of MRD may remain detectable and yet not necessarily be a harbinger of inevitable clinical relapse, especially in the early postconsolidation treatment phase [272, 283, 287, 293, 294]. In these studies, it has been possible to define criteria—either threshold NCN values with a very high risk of subsequent clinical relapse [272, 287, 293] or compelling evidence of increasing MRD levels in serially collected samples [294]—that mandate immediate salvage therapy. In practice, prospective (rather than retrospective) RQ-PCR MRD monitoring with criteria for treatment change during the subclinical phase has only been realized in two clinical trial reports [283, 294]. In the first report, the principal clinical trial objective was to identify patients who were in subclinical relapse after ATRA-chemotherapy treatment in order to initiate early ATO salvage therapy [294]. Notable results of this study were: the clinical relapse rate after 3-years follow-up was reduced to 5% compared to 12% in an earlier similar clinical trial with no prospective MRD monitoring; there was no incidence of the differentiation syndrome when ATO salvage therapy was administered with subclinical disease which was sometimes present and problematic after hematological relapse; and MRD monitoring of bone marrow was more effective than peripheral blood. The latter is confirmation of earlier indications of this difference in studies with very limited case numbers [287, 293], although similar levels of MRD have been reported in simultaneously obtained bone marrow and blood samples, possibly related to disproportionate testing of early treatment samples [272, 287, 294]. Further, continued MRD monitoring during and after ATO salvage therapy was effective in detecting patients in incipient second relapse and in evaluating patients for transplant candidacy while the disease was still subclinical [294]. In the second report, intensive MRD monitoring was employed as a precautionary measure in an exploratory Phase II clinical trial in which frontline ATO therapy was administered with potentially insufficient, reduced-intensity chemotherapy in combination with ATRA [283]. However, among 37 patients (including 12 with high WBC counts) who completed consolidation therapy, there was only 1 relapse confined to the central nervous system and no hematological relapses (2.7% incidence of relapse with 2.7 years follow-up). Concordantly, after the completion of consolidation therapy, there were no RQ-PCR assays in bone marrow or peripheral blood that exceeded a high-risk NCN/NQ value ($>10^{-5}$; risk values defined in [272, 295]), a series of intermediate-risk values ($>10^{-6}$ but $<10^{-5}$; predominantly in blood) in the CNS relapse case, and only three assays (out of hundreds) that transiently exceeded an intermediate-risk NCN value in the remaining cases [283]. This study and other recent studies indicating that the relapse rate in APL is likely to be <5% after the addition of frontline ATO to ATRA chemotherapy even in high-risk, high WBC count patients [281, 282] bring into question the cost-to-benefit ratio of continuing to perform MRD monitoring in APL patients with primary disease. Consideration of this issue is sharpened by a recent study using mathematical modeling which concluded that to be highly effective in prospectively detecting MRD in time to implement preclinical relapse salvage therapy in APL, RQ-PCR testing would need to be performed on bone marrow samples every 2 months [296]. Thus, in the future it may be reasonable to limit MRD monitoring by RQ-PCR in primary disease to clinical trial settings in which the predicted incidence of relapse has not been established to be very low, e.g., in exploratory trials that attempt to further reduce exposure to cytotoxic chemotherapy. On the other hand, intensive application of this now highly validated method after the occurrence of increasingly rare first relapse seems indicated, since the long-term outcome of salvage therapy is less certain and molecular monitoring will likely be useful in making therapeutic adjustments to avoid secondary clinical relapses.

Clinical Features

APL accounts for about 10% of adult AML and the incidence appears to be approximately constant with respect to age [297], an observation not previously reported for any other neoplasm. The incidence in children is usually reported to be lower [298], although the incidence of APL in children diagnosed with AML and living in Italy seems to be about twice that of children living in Germany or the United States [299–301].

When Latinos develop AML they may be significantly more likely to develop APL than another AML subtype [302–305], and an investigation of the Eastern Cooperative Oncology Group database for leukemia studies E2491 and E3489 revealed that more APL patients are Latinos than are other AML patients ($P = 0.005$) [306]. Others have reported that blacks have a lower likelihood of APL than Hispanics, non-Hispanic whites, and Asians [307].

There is no difference in the incidence between the sexes [308] and the median age of patients with APL appears to be about 15 years younger than that of patients with other forms of AML (43 years vs. 59 years, $P < 0.00001$) [309]. Curiously, increasing body mass index was strongly associated with a diagnosis of APL among patients with AML ($P = 0.0003$) in one study [309] and associated with the differentiation syndrome (discussed in text to come) in another [310]. Some epidemiological studies have implicated exposure to electromagnetic fields [308] and radon exposure [308] in the etiology of APL. Therapy-related APL has been increasingly recognized [83, 311–313]. Exposure to drugs that target topoisomerase II may be especially likely to result in treatment-related APL [81]. An association with exposure to mitoxantrone for, among other diseases, multiple sclerosis, has been well established [82, 314, 315], and it has been suggested that gefitinib therapy for lung cancer may also result in secondary APL [316].

The most significant clinical feature of APL is a hemorrhagic diathesis manifested by ecchymoses, intracranial hemorrhage, or gastrointestinal bleeding, some evidence of which is present at diagnosis in the majority of patients [317, 318]. Sudden blindness due to sinus vein thrombosis has been reported [319] and other large vessel thromboses have been reported as well [320], although hemorrhage is much more common than thrombosis in APL. The most frequently documented laboratory evidence of the bleeding diathesis includes hypofibrinogenemia, increased fibrin degradation products in the serum, a prolonged prothrombin time, and, of course, thrombocytopenia [317, 318, 321]. The potential for bleeding is exacerbated by cytotoxic chemotherapy with consequent thrombocytopenia [318, 322]. The diagnosis and treatment of this important life-threatening manifestation of APL is fully discussed below.

The diagnostic hallmark of APL is the balanced cytogenetic translocation t(15;17)(q22;q11.2–12) [323] that has been discussed in detail above. However, approximately one-third of patients have additional cytogenetic abnormalities, most frequently trisomy 8 [324–326]. There may be a deleterious effect of additional cytogenetic abnormalities on the course of APL in general although the data available are conflicting. In a study of 47 APL patients, 17 with additional cytogenetic aberrations, Schoch et al. [327] found no influence of such abnormalities on prognosis. Some of their patients were treated with ATRA, others with chemotherapy. In a larger study of 161 patients treated with chemotherapy alone, Slack et al. [328] found that secondary cytogenetic changes were associated with significantly longer CR duration and event-free survival after treatment with anthracycline and cytarabine. They concluded that additional cytogenetic changes do not impair prognosis of patients with APL treated with chemotherapy. Pantic et al. [329] studied 43 APL patients treated with ATRA alone and found additional cytogenetic changes in 33%. The CR and early death rates were significantly different between those patients with and without additional abnormalities (36% vs. 76% $p = .0148$; 24 vs. 64%, $p = 0.0141$, respectively). They concluded that patients treated with ATRA who have additional cytogenetic abnormalities have a more aggressive disease than those with only t(15;17). We found this also to be true, and also that patients treated with ATRA with or without chemotherapy who had t(15;17) alone had a significantly better overall survival than did patients with additional cytogenetic abnormalities [330]. We concluded from a study of 140 patients that those with APL and t(15;17) alone were significantly more sensitive to ATRA than are patients with t(15;17) and additional cytogenetic abnormalities. Others have reported similar results in patients treated with ATRA and anthracyclines together [326] and concluded that additional cytogenetic changes may render patients less sensitive to ATRA, as suggested by the data of Pantic et al. [329] and Wiernik et al [330]. Consistent with these observations, Xu et al. [331] after a study of 284 patients with APL recently reported that relapse-free and overall survival are significantly poorer in patients with complex karyotypes compared with patients with only t(15;17). However, De Botton et al. [325] studied 292 patients treated with ATRA and chemotherapy. Additional cytogenetic abnormalities were present in 26% of cases and there was no difference in outcome between patients with and without additional cytogenetic aberrations. At present, because of conflicting data, there is no clear indication based on additional cytogenetic changes to alter what has become conventional therapy with ATRA and anthracycline-based chemotherapy [331] (discussed below). Secondary clonal cytogenetic abnormalities frequently appear in APL patients after treatment, but seem to be of no clinical importance [270, 332, 333]. Rarely, APL patients present with t(11;17) [138] as the only cytogenetic abnormality, and such patients are usually refractory to

ATRA treatment. Jansen et al. [334] induced a complete molecular remission in such a patient with the combination of ATRA plus G-CSF after demonstrating the efficacy of that regimen in vitro.

The immunophenotype of APL cells is unique among the myeloid leukemias, since they are characteristically HLA-DR-negative, CD34-negative, p-glycoprotein-negative, and CD33+ although the M3v (microgranular variant) subtype may be positive for either CD34, p-glycoprotein, or both (see Chap. 17). In addition, certain T-cell antigens, such as CD2, are frequently expressed by the FAB-M3v type of APL [318, 334, 335]. Rarely, APL cells express CD56, a neural-cell adhesion molecule. Such patients may have a poor prognosis for complete response and response duration [336].

The morphology of the leukemic cells in APL is unique and discussed in Chap. 16. Briefly, three morphological subtypes have been described. In the hypergranular type, which is the most common form of the disease, the cells appear to be abnormal promyelocytes with abundant cytoplasmic granulation that stains purple or pink with Wright's or similar stains. Auer rods are common, usually multiple, and frequently appear in bundles (haystacks) [337]. The nucleus is bilobed, folded, or reniform, suggestive of the nucleus of a monocyte [318, 337]. In the microgranular type [337], which accounts for approximately 25% of all APL cases [264, 338–340], cytoplasmic granules are difficult to see with the light microscope and Auer rods are rare. Occasional typical M3 cells are seen in the peripheral blood and are more numerous in the bone marrow. The nucleus in M3v appears similar to that of M3. M3v cells are much more commonly CD2+ than are M3 cells [335, 339] and the t(15;17) abnormality is almost always present [335, 339, 341]. A third, rare form of APL has been designated as the hyperbasophilic microgranular form [337, 342–344], by some authors. The cytoplasmic granules are intensely basophilic and prominent cytoplasmic budding is often evident in this as well as is in microgranular type. The morphology of those latter two types is reminiscent of that of micromegakaryocytes [321, 341]. Cytogenetic and immunophenotypic characteristics are typical for APL, except that in the hyperbasophilic microgranular type additional cytogenetic abnormalities such as 12p13 [344, 345], which has been described in AML with basophilic differentiation [338] may be found. At least one hyperbasophilic microgarnular patient developed hyperhistaminemia after treatment, presumably secondary to release of histamine from the basophilic granules of killed cells [346]. Both APL variants seem to have more severe bleeding at diagnosis than typical APL patients [264, 338, 342] despite higher platelet counts [339], and both are much more common in non-Whites [264, 318, 339–341, 347–349] and in females [339, 341, 343]. The determination of APL type must be made prior to therapy since arsenic trioxide therapy may induce basophilic differentiation of APL cells [350].

Histochemically, M3 cells are strongly peroxidase- and Sudan black-positive and, on occasion, strong α-naphthylacetate esterase activity sensitive to sodium fluoride may be demonstrated [337, 351–353], similar to that often observed in FAB-M4 or M5 AML. This finding is not observed in normal promyelocytes. Microgranular APL cells are less frequently peroxidase or esterase positive than typical APL cells [339, 340]. Microgranular APL may have had a poorer response to treatment and a poorer prognosis than typical APL with chemotherapy alone in the past [339], but this is no longer true when treatment includes ATRA [264].

Typically, patients with APL present with lower white blood cell counts (WBC) than do other patients with AML and counts of less than 1000 cells/μL are common [318]. Patients with microgranular APL generally present with higher WBC and leukocytosis is frequent [298, 334, 343]. Anemia is common at presentation [318] and may be severe in bleeding patients. Organomegaly, lymphadenopathy, and central nervous system (CNS) leukemia are rare in APL in the United States [298, 318], but may be more common in other countries for unknown reasons [343].

Approximately 3–5% of APL patients relapse at extramedullary sites. In the ATRA era, central nervous system (CNS) relapse appears be more common than in the pre-ATRA era and is more frequent among patients who present with a high white blood cell count [354–358]. An initial serum lactate dehydrogenase level of >3000 IU/L was recently found to be more strongly associated with CNS relapse than is an initial WBC of >10,000/μL [359]. Other factors associated with a higher incidence of CNS relapse include elderly patients, and CNS hemorrhage during induction therapy. CNS relapse is the most common form of extramedullary disease in APL [360] and usually occurs within 10 months of diagnosis. It may also rarely be diagnosed at initial presentation [361]. Other sites of extramedullary relapse include skin infiltration, [322, 349], and bone [362] after treatment with chemotherapy or ATRA [363–365], particularly among those patients who present with high a WBC. Rarely, isolated extramedullary relapse may occur after more than a decade of complete remission [362].

Most patients with APL do not have an antecedent hematologic or neoplastic disease. However, therapy-related APL with the typical t(15;17) has been reported after treatment for other neoplasms, including breast cancer, prostate cancer, non-Hodgkin's lymphoma [366], papillary thyroid carcinoma [367], and other neoplasms. In fact, most reported cases of therapy-related APL occurred in patients previously treated for breast cancer [367, 368]. This is curious because BRCA1 is located on chromosome 17 near the breakpoint involved in the formation of t(15;17) [369]. Wei et al [370] reported that ATRA inhibits a key regulator of oncogenic signaling pathways, the unique isomerase Pin1 in APL and breast cancer cells. This observation suggests some common

pathways in the etiology of both diseases.The incidence of therapy-related APL may be increasing [371]. It occurs primarily in middle-aged adults with a peak incidence at 2 years post treatment for the initial neoplasm and is more common in women [371]. Topoisomerase II inhibitors, radiation, and mitoxantrone are the most common treatments prior to the development of APL. The complete response rate and prognosis after treatment of treatment-related APL is similar to that of de novo APL [371, 372]. Prostate cancer is being recognized more frequently recently as a tumor associated with an increasing incidence of treatment-related APL [372]. In addition, karyotypically confirmed promyelocytic blast crisis of chronic myelogenous leukemia (CML) has been occasionally reported [373–376], and promyelocytic blast crisis of CML with cytogenetic abnormalities other than t(15;17), but involving chromosome 17 has been documented [377]. In fact, such a patient was the first patient with leukemia in the United States to respond to ATRA [369]. Rarely, patients with APL relapse with a cytogenetically different AML or myelodysplasia following treatment of the original leukemia [378–382]. Most such patients to date have received prior anthracycline therapy.

On rare occasion APL may be diagnosed upon relapse of other types of acute myeloid leukemia (AML) [383], and in other rare instances APL may relapse as another type of AML or myelodysplastic syndrome [384]. APL has even been reported to develop in donor cells after an allogeneic stem cell transplant [385].

Three risk groups of patients with APL have been generally recognized: low-risk, intermediate-risk, and high-risk. Low-risk patients are those with an initial WBC <10,000/μL and a platelet count >40/000/μL, intermediate risk patients are those with a WBC <10,000/μL and a platelet count <40,000/μL; high-risk patients are those with a WBC >10,000/μL irrespective of platelet count. Low-risk and intermediate-risk patients have classically been considered together for treatment purposes but therapy is usually intensified for the 10–15% of patients that are at high-risk (see below) since they are at higher risk for relapse, hemorrhage [386] and death (but usually not for lower complete response to induction therapy). Elderly patients often fall into the high-risk category [387]. Leukapheresis does not improve the prognosis for patients with hyperleukocytosis [388].

More recently, additional factors associated with therapeutic response have been identified. Patients whose leukemic blasts are CD34+, CD56+ or CD2+ are at higher risk of relapse. These antigen expressions are often associated with leukocytosis [386]. Patients with the short PML/RARα isoform as well as those with FLT3-ITD mutations (also associated with leukocytosis) are at increased risk for relapse as well in some studies [386, 389], and FLT3-ITD mutations were associated with impaired survival after treatment with ATRA and chemotherapy in one study and event-free survival in another [390]. However, importantly, FLT3-ITD mutations had no effect on outcome after treatment with ATRA plus arsenic trioxide [390]. Another study identified by multivariate analysis that the quantity of RARα transcripts in blood prior to induction therapy as the sole independent prognostic factor for relapse. At 5 years after treatment patients with >209.6 PML-RARα/ng had a cumulative incidence of relapse of >50% compared with 7.5% for those with less molecular burden of transcript [391]. Low transcript levels of KMT2E (MLL5), a gene involved in the positive control of genes involved in hematopoiesis, results in lower remission rate and shorter overall survival in patients with APL treated with ATRA and an anthracycline [392], and WT1 expression was shown to be an independent prognostic factor for overall survival of complete responders to induction therapy [393].

The TP73 gene transcript is translated into an active TAp73) and inactive (ΔNp73) isoforms. Higher inactive form/active form RNA ratios are associated with a higher risk of relapse and poorer survival of patients treated with ATRA plus anthracycline [394]. Lastly, data suggesting that ETV6 rearrangement may be an independent unfavorable prognostic factors for overall survival in patients with APL [395].

Most of the prognostic factors described above have been identified in patients treated with ATRA and anthracycline chemotherapy. Since arsenic trioxide is playing an increasingly important role in the treatment of APL it will be important to verify which, if any, of these factors still are reliable prognostic indicators that can be used to stratify patients among various therapeutic approaches. Recently, Lou et al. [396] addressed this question in 184 patients treated with arsenic trioxide-base therapy. They found no significant association between 3-year relapse-free survival and initial WBC count, FLT3-ITD status or type of PML-RARα isoform. Only CD56 in their study retained prognostic value with respect to relapse-free survival. These data suggest that arsenic trioxide-based therapy is superior to ATRA plus anthracycline treatment and that some previously important prognostic factors are no longer relevant. Further studies of this kind are needed. It may be necessary in the near future to revise commonly used risk assessment schemes for patients with APL.

The primary cause of treatment failure for patients with APL is death caused by the coagulopathy characteristic of this disease [397]. The early death rate is approximately 10% in patients <50 years of age and 30% in older patients. It is higher in patients not enrolled in clinical trials than in patients enrolled in such trials [398, 399]. Death from this cause may even occur before treatment is begun. Early death rates may be higher in uninsured patients and among minority populations [400]. Therefore, it is imperative to remove the societal obstacles to early, competent care for these subpopulations.

Treatment of APL

APL patients must be prepared for induction therapy as described for other FAB types in Chap. 22 whenever possible, but time is of the essence in APL more so than in other FAB types in that the diagnosis of APL is a medical emergency that requires immediate intervention. Once the diagnosis is suspected and while it is being confirmed by polymerase chain reaction or by immunofluorescence staining with an antipromyelocytic leukemia antibody [401], aggressive supportive care measures with blood product support should be instituted, and ATRA should be started. If the diagnosis of APL is not confirmed, ATRA should be discontinued. Concurrent with initiation of induction therapy, the hemorrhagic diathesis, which clinically or subclinically is present in virtually every patient, must be brought under control since such therapy may exacerbate the bleeding problem, particularly in patients with leukocytosis. Specific recommendations for controlling hemorrhage are given next [402, 403].

Induction Therapy

The response of APL to appropriate induction therapy is unique among the acute leukemias. As initially pointed out by Kantarjian et al. [9] and by Daly et al. [317], hematologic recovery from induction chemotherapy in at least 85% of patients is accompanied by an increase rather than a decrease of promyelocytes in the bone marrow, which spontaneously mature over several or more weeks. Postinduction therapy bone marrow specimens with increased promyelocytes have frequently been erroneously interpreted as indicative of treatment failure and retreatment has led to the death of patients. Virtually no patients who survive induction therapy will require a second course because primary resistance of leukemic promyelocytes to commonly used agents, such as ATRA and arsenic trioxide is extremely rare. Resistance to ATRA when it occurs is associated with mutations in the RARα moiety of PML-RARα and resistance to arsenic trioxide is associated with mutations in the PML moiety. Both mutation types interfere with degradation of PML-RARα, the gene that drives the disease [404]. Both agents synergistically degrade mutated NPM1 genes which results in apoptosis [405].

History of Specific Induction Chemotherapy

Anthracyclines have been the cornerstone of chemotherapy for APL since the landmark observation of Bernard et al. that daunorubicin induced a high percentage of complete responses in this leukemia [5] and that CRs were of unusually long duration, compared with those in other morphologic subtypes of AML. Since that discovery, the most common treatment reported for APL has been the standard daunorubicin and cytarabine regimen originally described by Yates and colleagues [411] and recommended by them for all FAB types. There is, however, little evidence that cytarabine is actually necessary as an induction agent in APL [407, 408]. At least 350 patients with APL treated with daunorubicin alone can be gleaned from the literature, with an overall CR rate >70% [317, 342, 345, 409–413]. This result compares very favorably with the 67% CR rate published from 1990 to 2010 for 537 patients induced with daunorubicin and cytarabine with or without other chemotherapy [318, 406–421].

In a trial of idarubicin and cytarabine compared with historical controls treated with daunorubicin and cytarabine [422, 423], the former yielded significantly greater disease-free and overall survival compared with the latter. This result may be valid, since the same advantage for idarubicin and cytarabine over standard therapy has been reported for AML in general [424, 425], and others [426] have reported an unusually high complete response rate with idarubicin alone in APL. Newer strategies have included lower doses of idarubicin in children combined with ATRA [427]. The Italian GIMEMA group and Spanish PETHEMA group have reported high complete response rates with ATRA and anthracycline, and the combination became a standard induction regimen for APL [266, 408, 428–434].

ATRA Induction Therapy

Orally administered ATRA induces complete, albeit relatively brief remissions in the vast majority of patients with APL. Unfortunately, relapse usually occurs within months if no postremission therapy is given. Complete remission with ATRA is accomplished by induction of differentiation and maturation of leukemic cells, and not by a cytotoxic mechanism [431]. Clinical evidence of this fact includes the occasional observation of mature neutrophils in responding patients that contain Auer rods, suggesting that these neutrophils are matured leukemic cells [432].

Pharmacology of ATRA

Orally administered ATRA, 45 mg/m^2, results in a peak plasma concentration in 1–2 h [433] and is rapidly eliminated from humans, with a terminal half-life of approximately 45 min after an initial dose [434]. Following long-term daily administration of the agent, plasma concentrations of ATRA decrease significantly over time [218]. The only known metabolite is 4-oxo-all-*trans* retinoic acid, which is

found in plasma and urine, but accounts for only about 10% of administered ATRA [433, 435]. ATRA does not enter the cerebrospinal fluid [433]. The mean area under the curve for plasma drug concentration of ATRA varies considerably from patient to patient [433, 434]. It was suggested that relapse on continuous administration of ATRA may be due to the progressive reduction of plasma concentration described previously to levels below those that effect leukemic cell differentiation, since leukemic cells from patients who relapsed on ATRA usually continued to be sensitive to the agent in vitro at ATRA concentrations that resulted in differentiation initially. However, it is now known that marked decreases in plasma concentration occur within days of initial administration, long before relapse occurs in virtually all patients [433]. Induction of accelerated catabolism by a cytochrome P-450-like enzyme system has been suggested as a mechanism for these peculiar aspects of ATRA catabolism [433]. This suggestion has merit, since inhibitors of oxidation by cytochrome P-450 enzymes such as ketoconazole, fluconazole [436], and liarozole [437] significantly increase plasma concentrations of ATRA and decrease concentrations of the oxo-metabolite when administered with ATRA. A recently offered possible alternative explanation for the accelerated ATRA catabolism observed after its continuous administration is that ATRA administration appears to result in increased levels of plasma lipid hydroperoxides, which accelerate the oxidative catabolism of ATRA in human microsomes in vitro [438]. And, of course, it is quite possible that ATRA blood levels correlate poorly with ATRA activity because they are irrelevant. Intracellular ATRA concentrations are much more determinant of ATRA activity [439].

Clinical Results with ATRA

Huang et al. [12] first reported on the clinical usefulness of ATRA in APL in 1988. They treated 16 previously untreated and eight previously treated patients with oral ATRA, 45–100 mg/m^2/day. All patients achieved a hematologic and clinical CR without developing bone marrow hypoplasia. Eight patients experienced early relapses within 5 months while still receiving ATRA, but the others remained in remission at the time of their publication for as long as 11+ months. This landmark observation that ATRA could induce remissions in the vast majority of patients with APL presumably by differentiation induction attracted little attention initially in the United States, but French collaborators of the Chinese investigators immediately recognized the importance of this observation and initiated their own trials, which proved to be confirmatory [440].

Chen et al. [215] observed that patients who were induced into remission with ATRA and then maintained with conventional chemotherapy could usually be successfully reinduced into second remission with ATRA after relapse, whereas patients who received both ATRA and chemotherapy as postremission treatment usually could not be induced into second remission with ATRA alone. Based on these observations, they suggested that ATRA should be discontinued upon the achievement of CR.

Subsequent studies by a large number of investigators demonstrated that, while the vast majority of patients with APL achieved CR with ATRA, some patients, perhaps 10–20%, did not respond well, primarily due to early death. In addition, a serious problem with ATRA therapy, initially termed the retinoic acid syndrome [441, 442] but now referred to as the APL differentiation syndrome, became evident (see below). This occasionally fatal, rapidly developing pulmonary distress syndrome is not related to pulmonary leukostasis, but is often but not always associated with a rapidly rising peripheral WBC count consisting of predominantly maturing cells. In initial studies, the differentiation syndrome developed in as many as one-quarter of patients within days or weeks of starting ATRA therapy. This observation, and those of Chen et al. [215] discussed earlier, led Fenaux et al. [443] to combine ATRA induction therapy with postremission chemotherapy on a flexible schedule. Their plan was to begin treatment with ATRA and switch to anthracycline-based chemotherapy after remission was achieved unless a rising WBC occurred with ATRA, a dangerous harbinger of the differentiation syndrome, in which case chemotherapy was administered early along with ATRA until CR was documented, after which chemotherapy was continued. A CR in 96% of patients was achieved with this approach in a pilot study of 26 patients and the actuarial disease-free survival of 87% at 18 months was significantly better than the 59% rate observed in their previous chemotherapy-alone study [443]. This pilot study led to a larger multi-institutional study in which 101 patients under the age of 65 years were randomized to receive daunorubicin and cytarabine alone, or those drugs preceded by ATRA treatment [444]. Both groups received two courses of daunorubicin and cytarabine as consolidation therapy after complete remission was achieved. The three-drug induction regimen yielded a 91% CR rate and a 9% death during induction rate, compared with an 81% complete response rate and an 8% death during induction rate for the two-drug regimen. Neither of the differences is significant. However, the estimated 4-year event-free survival in the ATRA plus chemotherapy induction group was 63% compared with 17% in the chemotherapy-alone group, which is a highly statistically significantly different outcome. Overall survival at 4 years for the combined modality and chemotherapy-alone groups was 76% and 49%, respectively, which is also a highly significant difference [445]. Therefore, although the addition of ATRA to standard induction chemotherapy did not result in a significantly higher CR rate or reduced early death rate, disease-free survival of complete responders was greatly enhanced.

In addition, ATRA therapy rapidly resolved the coagulopathy in most patients, an observation subsequently confirmed by others [446]. This approach to APL treatment was validated by Kanamaru et al. [447], who obtained results virtually identical to those of Fenaux et al. [444]. In that study [447], approximately 89% of 110 patients achieved CR with ATRA alone or ATRA and early chemotherapy and 6.3% developed the differentiation syndrome. With a median follow-up of 21 months, 81% of the complete responders were projected to be disease free at 23 months, which was significantly greater than the disease-free survival rate observed in a prior chemotherapy-alone study. Unlike the study reported by Fenaux et al. [445], the Japanese study demonstrated a significantly lower early mortality rate than observed in the chemotherapy-alone historical control [447]. Burnett et al. [267] demonstrated that prolonged ATRA administration starting simultaneously with chemotherapy and continuing throughout the induction period until complete response is diagnosed gave superior results compared with a short course of ATRA prior to chemotherapy. Patients in the former group had a significantly higher CR rate and fewer induction deaths, as well as superior survival at 4 years, compared with those treated with a short course of ATRA.

Liposomal ATRA given intravenously may be more active than orally administered ATRA [222, 448, 449]. When administered every other day at a dose of 90 mg/m^2, blood levels are maintained, rather than observed to decline as is the case with orally administered ATRA. Results are similar with the two formulations, but liposomal ATRA may be more likely to yield a molecular remission as determined by PCR than is oral ATRA [448]. However, liposome-encapsulated ATRA is no longer available, but a new preparation of ATRA loaded in cholesteryl butyrate solid lipid nanoparticles appears to be superior to ATRA alone against APL cell lines and may eventually come to clinical trial [450].

ATRA in conjunction with anthracycline chemotherapy or arsenic trioxide is superior to either approach alone for initial treatment of APL. The combined approach may not reduce the early death rate associated with APL therapy, however. Furthermore, CR rates with chemotherapy, ATRA, or a sequential combination of both appear to be quite similar. The major advantage for combined modality treatment with ATRA and chemotherapy is the significantly greater disease-free and overall survival achieved with the combination in virtually all controlled trials [451]. Yet another benefit appears to be a reduction in the incidence of the differentiation syndrome with concurrent therapy [452]. In addition, patients treated with ATRA prior to chemotherapy may have more rapid recovery of the peripheral granulocyte count compared with patients treated with chemotherapy alone [453].

More than 90% of newly diagnosed patients with APL initially treated with ATRA and idarubicin achieve a complete remission with that therapy. Almost all induction failures are due to death during induction from hemorrhage, infection, or differentiation syndrome which result in 5%, 2–3%, and 1–2% deaths of all treated patients, respectively. Elevated serum creatinine, increased peripheral blast count, and presence of coagulopathy correlate with an increased incidence of death from hemorrhage. Age >60 years, male sex, and fever at presentation correlate with an increased likelihood of death from infection, and poor performance score as well as hypoalbuminemia correlates with an increased likelihood of developing a fatal differentiation syndrome [454].

Whether other retinoids [221, 455–459] are superior to ATRA in the treatment of APL needs to be determined as well. Observations on the potentiation of megakaryocytopoiesis by ATRA [460, 461] and on the inhibition of marrow angiogenesis by ATRA [462] require further study, as does the observation that imatinib [463] and statins [464, 465] may potentiate ATRA activity against APL.

Retinoic Acid Toxicity

Differentiation Syndrome

The most serious toxicity associated with ATRA therapy is the APL differentiation syndrome [466] which occurs in 25% or more of patients treated with ATRA alone [467], or in combination with anthracycline chemotherapy [468]. Differentiation syndrome may also be induced by arsenic trioxide [469]. Half the patients who develop the syndrome have a severe form which can be fatal, and the others have a moderate form from which recovery is the rule [468]. Severe, life-threatening differentiation syndrome usually occurs in the first 2 weeks of treatment, while a milder form may occur later [470]. Fever and respiratory distress with or without pulmonary infiltrates on chest radiograph are the hallmarks of the syndrome. Weight gain, pedal edema, pleural and pericardial effusion, and hypotension may also occur. A bimodal incidence of the syndrome is reported with peaks occurring in the first and third weeks after the initiation of ATRA therapy [471]. Rarely, a patient may develop the syndrome during both peak incidence periods [471]. Autopsy reveals massive pulmonary parenchymal tissue infiltration with maturing myeloid cells [467]. A white blood cell count >5000/μL and a serum creatinine concentration above normal correlate with an increased risk for severe differentiation syndrome [472]. In most, but not all patients the syndrome is preceded by a rapidly rising white blood cell count. ATRA must be discontinued at once when the manifestations of the syndrome are severe and dexamethasone, 10 mg intravenously every 12 h should be administered until complete clinical resolution of the syndrome is obtained, usually in several days. Some evidence suggests that prophylactic

dexamethasone can reduce the incidence of the syndrome [472]. If the manifestations are mild, ATRA can be continued with the institution of dexamethasone. Most patients so treated will survive and, once the syndrome has resolved, ATRA therapy can usually be safely reinstituted, but it is recommended that resumption of ATRA be carried out under the coverage of steroids [467]. The syndrome rarely, if ever, occurs in patients receiving ATRA as postremission therapy [467]. Curiously, there are no data on hydroxyurea as treatment for this syndrome.

The early (concurrent) administration of chemotherapy with ATRA for induction appears to have a benefit with respect to reduction in the incidence of this syndrome [468]. Diffuse pulmonary hemorrhage may mimic the syndrome or may be a manifestation of it [473, 474].

The pathogenesis of the ATRA syndrome is not entirely known. Expression of CD13 by APL cells obtained at diagnosis significantly correlated with the development of the ATRA syndrome in one study [473, 474], which is interesting since expression of that antigen (aminopeptidase N) has previously been associated with a poor prognosis in AML and with tumor invasive capacity in some human tumor cell lines. It has been suggested that bestatin [466], a specific inhibitor of aminopeptidase N, should be tested as a possible prophylactic agent against the ATRA syndrome. It has also been demonstrated that ATRA upregulates CD54, CD11b, and CD18 on APL cells, which facilitates adhesion of them to pulmonary microvasculature, which can be reversed in vitro by anti-CD54 and anti-CD18 antibodies [475]. Furthermore, ATRA may induce chemokine production in the lung and in APL cells which enhance migration of the leukemic cells out of the vascular system [476–478].

Other ATRA Toxicity

Other toxicities associated with ATRA therapy are usually mild and include dry mucous membranes, bone pain, headache, hypertriglyceridemia, hepatic enzyme elevation, and skin rash, which may rarely evolve into erythema nodosum [479]. Pseudotumor cerebri has been reported in approximately 2% of patients receiving ATRA. The incidence is higher in children and young adults than in older patients [480, 481]. The cause is entirely unclear, but recently thrombophilic factor dysmetabolism has been implicated [482]. Treatment in APL patients usually only requires diuretics. Sweet syndrome [483, 484] has rarely been reported after ATRA administration, presumably due to a mechanism similar to that of the ATRA syndrome. Occasionally, serious thrombotic episodes may occur with ATRA therapy even when thrombocytopenia is present [485]. ATRA-induced thrombocytosis has also been observed [486, 487].

Patients treated with ATRA and anthracycline-based chemotherapy have approximately a 2% incidence of an acute myeloid leukemia or myelodysplastic syndrome developing in a median of 4 years after completing treatment for APL. The treatment-related myeloid disorder is associated with deletions of chromosomes 5 and/or 7, or 11q23 rearrangements. Patients over the age of 35 years have a higher incidence of this complication than others (approximately 5%) [488].

Clinical Results with Arsenic Trioxide

The most important new development in the treatment of APL in recent years is the introduction of arsenic trioxide (ATO) as a therapeutic agent. The drug was used in the late 1800s in the treatment of CML with some success [489]. Shen et al. [182] reported the activity of this agent in APL 2 decades ago. They administered ATO, 10 mg daily as a continuous intravenous infusion to ten patients who relapsed after ATRA induction and chemotherapy maintenance and achieved a clinical CR in 90% [17] without significant toxicity. Soignet et al. [187] subsequently treated 12 patients with APL who had relapsed after extensive prior therapy with ATO doses ranging from 0.06 to 0.2 mg/kg/day until bone marrow remission could be documented morphologically. Eleven patients achieved a complete remission after 12–39 days of treatment and a total dose of 160–515 mg. Eight of 11 patients who initially had a positive RT-PCR assay for the PML-RARα fusion transcript tested negative during remission. Three other patients remained PCR positive and relapsed early. This is an important observation, since ATRA therapy alone rarely results in a negative test. Side effects were also reported to be minimal in this study.

Investigators at the Shanghai Institute of Hematology [490] reported on 47 relapsed and 11 newly diagnosed patients with APL treated with ATO; 8 of the newly diagnosed patients (73%) and 40 of the relapsed patients (85%) achieved a CR with a median disease-free survival of 17 months. Patients received a variety of postremission treatments and those that received postremission chemotherapy plus ATO had significantly longer remissions ($P = 0.01$). Unlike previous studies, however, serious ATO toxicity was reported in this study. Seven cases of significant hepatic toxicity, including two deaths, were observed, and in other recent studies other toxic effects of ATO such as renal failure, cardiac dysfunction, and chronic neuromuscular degeneration have been observed [491]. Furthermore, the frequent occurrence of leukocytosis (58% of patients in one study [492]) and the differentiation syndrome (31% of patients in the same study [493]) after treatment with ATO is now well documented [493].

In an effort to limit exposure to ATO, Kwong et al. [494] treated eight patients with relapsed APL with ATO, 10 mg daily dose intravenously until remission was achieved and then gave three monthly cycles of idarubicin. All patients were in molecular remission after idarubicin treatment, and six have remained so after a median follow-up of 13 months. Jing et al. [207] reported that the combination of ATO and ATRA may be more effective therapy than either drug alone. Others have reported that ATO plus GM-CSF may be more effective therapy than ATO alone [495].

Recently, there has been an evolution in the induction and consolidation therapy in newly diagnosed patients with APL (including treatment-related APL) [283] with less chemotherapy and the introduction of the combination of oral ATRA and intravenous ATO [244, 245, 281, 282, 496–498], or ATO alone [499]. Results appear to be at least comparable to those obtained with ATRA and an anthracycline, and in many comparative studies of ATRA plus arsenic trioxide compared with ATRA plus anthracycline chemotherapy results have been better with the former, especially in low- and intermediate risk patients [500–506]. The North American Leukemia Intergroup study C9710 [283] randomized 481 newly diagnosed adult APL patients to either ATRA plus daunorubicin and cytarabine followed by two courses of consolidation therapy with ATRA plus daunorubicin, or the same treatment plus two 25-day courses of ATO. After that treatment patients were randomized to receive 1 year of maintenance therapy with either ATRA alone or in combination with methotrexate and 6-mercaptopurine. A complete remission was obtained in 90% of patients with each treatment and patients were eligible for postremission therapy. Event-free survival was significantly better for patients who received ATO compared with those who did not (80% and 63%, respectively at 3 years, $P \leq 0.0001$). Overall survival was also better for patients who received ATO (86 vs. 81% at 3 years, $P = 0.059$) as was disease-free survival (90% vs. 70% at 3 years) ($P < 0.0001$). The study demonstrated a significantly better outcome for patients who received ATO in addition to standard induction and consolidation therapy. Whether postremission methotrexate and 6-mercaptopurine had any influence on results is unclear. In a more recent prospective, randomized study of 263 low or intermediate-risk patients [507], ATRA plus arsenic trioxide or ATRA plus chemotherapy was given. The complete response rate (100% vs. 97%), event-free survival (97.3% vs. 80%), cumulative incidence of relapse (1.9% vs. 13.9%) and overall survival at 50 months (99.2% vs. 92.6%) all favored the ATRA plus arsenic trioxide regimen. These studies demonstrate major activity for ATO plus ATRA in newly diagnosed patients with APL.

Results with ATRA plus ATO have led some experts to recommend that that regimen be adopted as standard of care for patients with low- or intermediate-risk disease as currently defined, and that the addition of an anthracycline to induction therapy should only be considered for high-risk patients [508]. Others have reported better quality of life for patients treated without an anthracycline [509], and that the omission of chemotherapy improves the cost- effectiveness of treatment in the USA in some studies [510].

Recently, oral preparations of arsenic have been developed and early clinical trials demonstrate that oral arsenic is as effective and no more toxic than intravenous arsenic trioxide [511–513]. These results have led to a proposal that low- and –intermediate-risk APL patients could be treated entirely as outpatients with the oral combination of ATRA and arsenic [514]. However, others have wisely cautioned that treating APL patients during induction without hospitalization could be dangerous in the first few weeks, when coagulopathy and differentiation syndrome may have sudden onset and lead to early death [515].

Toxicity of Arsenic Trioxide

Long-term complications of ATO plus ATRA treatment were reported by Zhu et al. [516] in 265 patients who received arsenic trioxide plus ATRA for APL with or without chemotherapy. They compared quality of life and a number of potential long-term problems with those of 112 age and gender matched healthy controls. Signs of chronic arsenic toxicity such as cardiovascular events, chronic renal insufficiency, diabetes and neurological dysfunction were not observed in the patients at a higher rate than in the controls. Only mild liver dysfunction (15.2%) and hepatic steatosis (42.9%) were observed more frequently in patients than controls. Acute liver dysfunction occurred in 42.9% of patients during treatment and was managed primarily by suspending ATO treatment until liver function normalized. The estimated 12-year survival rate for patients with low- and intermediate-risk APL was 87.4%, compared with the high-risk group survival rate of 77.5%. No increased incidence of second malignancies was observed in treated patients in this study. Quality of life for long-term survivors in general was impaired somewhat, with more than half of patients reporting mild to moderate weakness and 41.1% reporting memory problems. The accumulation of arsenic in hair or nails was similar in patients and controls. Liver damage has been observed in other studies of ATRA plus ATO as well [517].

Of some concern is the reported serious cardiac toxicity that can be associated with ATO treatment. Ohnishi et al. [518] treated eight patients with APL with ATO, 0.15 mg/kg administered as daily 2-h infusions for a maximum of 60 days. Five patients achieved CR. Prolonged QT intervals were observed in all patients during treatment and ventricular premature contractions occurred during 75% of treatment

courses. Four patients required treatment for unsustained ventricular tachycardia. Unnikrishnan et al. [519, 520] and Naito et al. [521] reported patients who developed torsades de pointes (a form of ventricular tachycardia that has been observed in arsenic poisoning) after treatment with ATO, 10 mg total daily dose as a continuous intravenous infusion. Westervelt et al. [522] reported three sudden deaths among ten patients with relapsed APL who received ATO, 0.1 mg/kg/day intravenously. One of the patients became asystolic and died while being continuously monitored with cardiac telemetry, and the cause of death was unknown in the other two. It seems clear from these reports that the cardiac toxicity of therapeutic doses of ATO is greater than initially appreciated, and that fact must be taken into account in future studies, which must include careful cardiac monitoring [493, 523] and correction of hypokaemia and hypomagnesemia, if present, prior to ATO treatment [524].

More data need to be accumulated before we can be confident that we know the full story of arsenic short- and long-term toxicity. For instance, ATO may delay hematopoietic recovery after autologous stem cell transplantation [525], and accumulation of arsenic in thyroid tissue may have led to at least one late thyroid carcinoma [526]. Although patients who receive ATO seem to have a lower death during induction rate in some studies, it does not appear to resolve the coagulopathy associated with APL more quickly than treatments that do not contain ATO [527].

The observation that ascorbic acid can potentiate the activity of ATO in vitro [528] deserves clinical evaluation [529] in patients with APL, and the observation that ATO inhibits hepatitis C virus RNA replication deserves further exploration as well [530].

Postremission Therapy in APL

There is no question that consolidation therapy after successful induction therapy is necessary for optimal long-term results in APL, but the need for maintenance therapy after consolidation therapy is less clear. Initial studies from the Italian cooperative oncology group GIMEMA administered three courses of chemotherapy with intermittent-dose cytarabine plus idarubicin, mitoxantrone plus etoposide, and standard-dose cytarabine plus idarubicin plus 6-thioguanine [531]. Subsequently, it became apparent that cytarabine might not be important in induction and consolidation [266, 407, 532]. The Spanish cooperative oncology group PETHEMA treated patients with three courses of chemotherapy without cytarabine with excellent results [408, 429]. However, recent studies have shown that intermediate-dose or high-dose cytarabine appears effective in patients who present with high-risk disease [533–536]. The North American Intergroup, as indicated earlier, reported a prospective randomized trial showing that two cycles of early consolidation with ATO improves disease-free, event-free, and overall survival [282].

Maintenance therapy has fallen into disfavor, in general, in subtypes of AML other than APL although some studies strongly support its use [537]. Methotrexate and 6-mercaptopurine were reported to be particularly useful maintenance agents in APL years ago by Kantarjian et al. [538]. The North American Intergroup Study [539, 540] conclusively demonstrated the value of postremission ATRA therapy in one of the first large studies using ATRA. In that study, 350 patients were randomly assigned to induction therapy with standard doses of daunorubicin and cytarabine, or ATRA. Patients who achieved complete remission received another course of the successful induction regimen followed by a course of high-dose cytarabine plus standard-dose daunorubicin and were then randomized to maintenance therapy with ATRA, 45 mg/m^2 daily orally for a year, or observation. With a median follow-up of more than 6 years, the 5-year disease-free and overall survival rates for all patients induced with ATRA were substantially better than those for patients induced with chemotherapy (64% vs. 30%, $P < 0.0001$; 69% vs. 45%, $P = 0.0001$, respectively) although complete response rates were similar (73% vs. 70%, respectively). The 5-year disease-free survival was highest, 74%, in the subgroup of patients induced with ATRA and maintained with ATRA, which compared favorably to the 55% disease-free survival rate observed in those induced with ATRA who did not receive postconsolidation ATRA. Furthermore, providing ATRA maintenance to chemotherapy-induced complete responders improved the disease-free survival rate threefold, compared with observation alone. These data strongly indicate the value of ATRA therapy during remission. That study also demonstrated a low late relapse rate. With a median of almost 12 years of follow-up, only 4.6% of patients in complete remission for more than 3 years subsequently relapsed [541]. Equally compelling data on the value of maintenance therapy in APL come from Fenaux et al. [445]. In a study of 413 patients, those investigators randomized patients in complete remission to observation, intermittent ATRA (15 days every 3 months for 2 years), 6-mercaptopurine and methotrexate for 2 years, or that therapy plus intermittent ATRA for 2 years. The relapse rate at 2 years was 25% for patients who received no ATRA during remission and approximately half that for patients who did, 27% for patients who received no chemotherapy and less than half that for patients who did. The highest relapse rate (approximately 30%) was in the group that received no maintenance therapy at all. The study, therefore, confirms the value of maintenance therapy in APL with either ATRA or 6-mercaptopurine and methotrexate, and suggests that both are effective alone, but not additive. Long-term follow-up of this trial continued to show a benefit for

maintenance therapy which significantly reduced the 10-year cumulative incidence of relapse from 42.3 to 33%, 23.4%, and 13.4% with no maintenance, maintenance with intermittent ATRA, continuous 6-mercaptopurine and methotrexate, and both treatments, respectively ($P < 0.001$). However, some trials have suggested that maintenance with neither ATRA nor low-dose chemotherapy as discussed earlier nor the combination nor intensive chemotherapy [542] is effective in improving outcome among patients who are molecularly negative after intensive anthracycline-based chemotherapy.

In one large study ATO consolidation improved event-free and disease-free survival, compared with patients who did not receive ATO consolidation, but it was not clear from that study whether arsenic trioxide was better than other consolidation approaches [282, 543]. Couutre et al concluded from a study of 105 patients in molecular remission post-consolidation therapy that maintenance therapy is not helpful if ATO is included in the consolidation regimen [544]. Leech et al. demonstrated that a 4 month ATO-based consolidation program was equally effective in high-risk and lower risk APL patients [507]. Liu et al. [545] reported on a retrospective study of 18 patients that is clearly in need of confirmation, but interesting nonetheless. They induced low-risk patients with ATRA plus ATO while high-risk patients received the same plus an anthracycline. After hematologic complete remission occurred arsenic alternating with chemotherapy was given as consolidation therapy and no maintenance therapy was employed. All patients achieved a molecular complete remission and no patients died during treatment, and no patients have relapsed with a median follow-up of 5 years. All 18 remain alive and can be considered cured [541]. Other recent studies have also suggested that maintenance therapy after consolidation therapy is unnecessary for low- and intermediate-risk patients with APL [546].

In a randomized study of 344 patients reported by Shinagawa et al. [458] results of maintenance therapy with ATRA or tamibarotene, a retinoic acid derivative also known as AM80, were compared. There was no difference in relapse-free survival for low-risk patients between the treatments, but for the 52 high-risk patients the relapse-free survival rates for ATRA and tmibarotene maintenance were 58% and 87%, respectively, which was significant. These data do not help determine whether *any* maintenance therapy is necessary for low-risk patients, but they do suggest that it is necessary for high-risk patients and that tamibarotene may be a better maintenance agent than ATRA for those patients.

It is important to monitor all patients with APL in clinical remission after treatment with molecular techniques such as real-time quantitative polymerase chain reaction to detect leukemia-specific transcripts, should they reappear. Patients who are PCR negative after treatment should be retreated if such transcripts reappear and before there is clinical hematologic or cytogenetic evidence of relapse in order to have the best opportunity of achieving a second molecular remission [294, 547, 548]. Patients who do not obtain a molecular remission after planned therapy should continue treatment with a different agent, such as ATO with or without other agents. Institution of salvage therapy at molecular relapse before hematological relapse leads to a better outcome of salvage therapy [292, 547].

Hematopoietic stem cell transplantation is not recommended for patients with APL in first molecular remission.

Recommended treatment for newly diagnosed patients with APL is detailed in Table 21.2.

Table 21.2 Recommended treatment: newly diagnosed and treatment-related APL

Induction therapy
Low-, intermediate-, and high-risk patients
ATRA[a], 45 mg/m^2/day orally in two divided doses until marrow hematologic remission
Idarubicin, I.V., 12 mg/m^2/day × 4 on alternate days
OR
ATRA[a], same oral dose and schedule until hematologic remission
ATO[b], 0.15 mg/kg IV daily until hematologic remission
Perform PCR for PML/RARα before starting therapy and when bone marrow morphologic remission is achieved. Monitor for coagulation abnormalities, arsenic toxicity, and differentiation syndrome as described in the text. Consider steroid prophylaxis for differentiation syndrome for high-risk patients.
Consolidation therapy
Low- and intermediate-risk patients
ATRA[a], orally, 45 mg/m^2/day in two divided doses X 45 days
Idarubicin, I.V. 5 mg/m^2/day, days 1–4
Idarubicin I.V. 12 mg/m^2 day 45
OR
ATO[b], I.V. 0.15 mg/kg/day 5 days/week × 4 weeks every 8 weeks for 4 cycles
ATRA[a], orally, 45 mg/m^2/day in two divided doses for 2 weeks every 4 weeks for 7 cycles
High-risk patients
ATRA[a], 45 mg/m^2/daily orally in two divided doses × 45 days
Idarubicin, 5 mg/m^2 I.V. day 1
Cytarabine, 1 g/m^2 I.V. daily, days 1–4
Idarubicin, 12 mg/m^2 I.V. day 30
Cytarabine, 150 mg/m^2 I.V. daily, days 30–33
OR
ATO[b] IV 0.15 mg/kg/day × 5 days for 10 weeks, then
ATRA[a] 45 mg/m^2 orally daily × 7 days plus
Idarubicin, 12 mg/m^2 I.V. daily × 3 days. Repeat same dose and schedule of idarubicin after counts recover
Perform PCR for PML/RARα after hematologic recovery and every 3 months for 2 years. If PCR becomes positive after being negative, repeat in 1 month. If positive again, the patient requires reinduction therapy for relapse. Consider a clinical trial. If PCR remains negative for 2 years, no further therapy is recommended.

[a]All-trans retinoic acid
[b]Arsenic trioxide

Treatment of Relapsed APL

Whether to begin treatment for relapsed APL early (molecular relapse, normal morphology) or late (morphologic relapse) is the subject of debate. No prospective, randomized trials have been reported, but an important historically controlled study suggests a major advantage for treatment of molecular relapse [547]. If the relapsed patient has had no exposure to ATO for at least 6 months reinduction therapy with ATO, 0.15 mg/kg IV daily plus ATRA, 45 mg/m^2 daily in two divided doses until marrow remission is documented should be given. A number of studies have now confirmed excellent activity of ATO, either alone or combined with ATRA, in patients with relapsed APL [248, 549–553].

Consider CNS prophylaxis with intrathecal cytarabine at this point. If the marrow is in molecular remission, consider an autologous stem cell transplant [554, 555, 557]. If the patient is not a candidate for a transplant, consider consolidation with arsenic trioxide, or a clinical trial. If a second morphologic remission is achieved, but not a second molecular remission, consider a clinical trial.

If the patient relapsed within 6 months of treatment with ATRA and/or ATO without an anthracycline, reinduction with ATRA, idarubicin and arsenic trioxide is recommended, followed by the same post-remission treatment outlined above. If the early relapsed patient did previously receive an anthracycline, only ATRA and arsenic trioxide should be given as reinduction therapy, again, followed by the above post remission recommendations. Patients who do not respond to reinduction therapy with a complete remission should be considered for a clinical trial [556].

Tamibarotene (Am-80) is a synthetic retinoid that is a more active inducer of differentiation in HL-60 and NB4 cells than is ATRA [558]. Of 24 evaluable patients with relapsed APL after ATRA-induced CR treated with Am-80, 6 mg/m^2 orally daily, 58% achieved CR [221]. Four patients relapsed within 6 months, but long-term responses (>49 months) were also observed. The same group recently updated that study but, curiously, no new patients had been entered in the trial for approximately 3 years [559]. A more recent small study of tamibarotene in relapsed patients initially successfully treated with ATRA and ATO achieved a complete molecular response in 21% of patients. Most patients relapsed with a few months and the median overall survival after treatment was only 9.5 months [459]. The drug should be studied in combination with idarubicin for patients relapsing after ATRA and ATO.

Liu et al. treated 31 patients with refractory APL with compound realgar natural indigo tablets (an oral arsenic compound based on Chinese herbal medicine) and chemotherapy. The complete response rate was 90.3% and the median response duration was over 42 months. The relapse rate was <10%, with 43 months median follow-up and the treatment was apparently very well tolerated. Patients received a variety of chemotherapy regimens and it is difficult to know exactly what role the oral arsenic compound played in the results. However, these results are excellent. Hopefully they will soon be explored by others.

Chendamarai et al. [560] found CD34 expression to be significantly increased in leukemic cells from relapsed patients compared with newly diagnosed patients, and that in relapsed patients there was significant microenvironment mediated resistance to ATO which was demonstrated in vitro.

Hematopoietic stem cell transplantation for APL patients in second complete molecular remission is recommended by many investigators. Autologous stem cell transplantation is recommended rather than allogeneic transplantation [561].

APL and Pregnancy

The treatment of AML in pregnancy is discussed in general in Chap. 22. Although retinoids are well known to be teratogenic and their use during pregnancy has been advised against, reports of successful use of ATRA during the second and third trimesters in more than 40 patients have appeared [562–564] and no cases of teratogenic effects were observed. At least one case of successful pregnancy after ATO treatment has been reported [565]. Since ATRA rapidly controls the coagulopathy associated with APL, it may be an attractive induction agent for the APL patient in late pregnancy. Most women with APL treated with standard chemotherapy in late pregnancy have also survived and delivered normal children [566]. However, APL in the first trimester is likely to be associated with obstetric and fetal complications [567, 568].

APL in Children

APL in children generally has the same features as in adults, except that the incidence of leukocytosis and the microgranular variant is greater in children than in adults [569]. Children under the age of 5 years have a worse prognosis than older ones. APL in children is generally treated as in adults. The same agents used for adult APL are used in children, although many successful studies have employed lower ATRA doses (25 mg/m^2 daily), lower total anthracycline dose, and cytarbine in consolidation [427, 570]. ATRA toxicity is more frequent in children [IIII], particularly pseudotumor cerebri.

The Coagulopathy Associated with APL

A major feature distinguishing APL from all other subtypes of AML is the very frequent association with a severe life-threatening coagulopathy. The pathogenesis of

the coagulopathy is complex and includes disseminated intravascular coagulation (DIC), hyperfibrinolysis, proteolysis and exposure of tissue factor and annexin-II by leukemic blasts [571–573]. Historically, approximately 10–30% of patients with APL died of early fatal hemorrhage, often intracerebral hemorrhage [9, 409, 574–579]. Even in the modern era of therapy with *all-trans* retinoic acid (ATRA) plus idarubicin, hemorrhage remains the single most common cause of death before and after induction therapy [454]. This is particularly problematic since patients with APL historically [580–582] and now in the ATRA era are highly curable with ATRA plus anthracycline-based chemotherapy approaches or ATRA plus ATO regimens [506, 583]. Early death from coagulopathy has therefore emerged as the major obstacle to cure in APL [399, 584–590].

In every study to date, successful remission induction with ATRA has been accompanied by rapid resolution of clinical bleeding and generally, of biochemical evidence of the coagulopathy, although elevated plasma levels of sensitive markers of clotting activation may persist [446, 591, 592]. Studies of arsenic trioxide in patients with relapsed and refractory APL also show rapid correction of the clotting abnormality [182, 593]. The rapid resolution of coagulopathy in APL patients given ATRA and/or arsenic speaks to the importance of prompt treatment in order to prevent early death from coagulopathy [573, 584, 589].

Coagulopathy and Early Death in APL

Approximately 70–80% of patients with either previously untreated APL or relapsed disease have either laboratory or clinical evidence of a potentially life-threatening bleeding diathesis [9, 182, 354, 409, 415, 418, 574–578, 594]. Even in the modern era, the risk of hemorrhagic death during induction remains at about 5–9% in the controlled environment of clinical trials, and may be as high as 16–31% in population studies [399, 402, 454, 534, 542, 573, 585–587, 590, 595, 596] (Table 21.3). Clinical manifestations of coagulopathy in APL can include mucocutaneous bleeding in the form of ecchymoses, petechiae, epistaxis, and gastrointestinal hemorrhage, as well as increased bleeding at sites of minor trauma or catheter insertion [573]. Intracranial and pulmonary hemorrhages are the most feared manifestations of coagulopathy in APL, as these two sites of bleeding account for the majority of hemorrhagic deaths in most series [402, 454, 573, 584, 585, 588, 590, 597]. In the Spanish PETHEMA study, intracranial and pulmonary hemorrhage accounted for 65% and 32% of hemorrhagic deaths [454]. Similarly in the Japanese JALSG APL97 study, intracranial and pulmonary hemorrhages accounted for 66% and 22% of early deaths [597].

In addition to bleeding, some studies suggest that patients with APL are also more prone to thrombosis than patients with other leukemias [584]. Various thrombotic events have been documented in APL patients, including myocardial infarction, deep vein thromboses, pulmonary emboli, and CNS thromboses [584, 599–604]. The incidence of thrombo-embolic deaths in APL patients ranges from 5.1% to 9.6% in various studies [18, 42–44]. Thromboembolism in APL patients may be associated with procoagulant effects of ATRA and worsened by differentiation syndrome [584, 605, 606].

Pathophysiology of the Coagulopathy in APL

The etiology of coagulopathy in APL is complex, with multiple driving mechanisms including tissue factor-induced DIC and primary hyperfibrinolysis [573]. The characteristic pattern of laboratory abnormalities includes thrombocytopenia; prolongations of the prothrombin time (PT), partial thromboplastin time (PTT), and thrombin times; increased levels of fibrin degradation products; and hypofibrinogenemia [594, 607–610]. These findings are consistent with either DIC and hyperfibrinolysis or both. Notably, patients with APL can have potentially fatal bleeding even in the absence of abnormal PT and PTT. In addition, although APL patients classically experience profound hypofibrinogenemia, some individuals with APL do not have significantly decreased fibrinogen [573, 594]. Furthermore, levels of several anticoagulant proteins such as antithrombin III and protein C, often low in the setting of DIC, are usually not decreased in patients with APL [611]. Platelet survival in these patients is normal, reflecting a more complex process than DIC alone [612, 613].

Multiple procoagulant mediators have been described in patients with APL (Fig. 21.7) [622–624]. Tissue factor (TF) is the major procoagulant that initiates the extrinsic pathway of

Table 21.3 Early death rate and bleeding in APL in prospective cooperative group studies

Trial	*N*	Induction	CR%	ED%	ED from bleeding%	DFS%

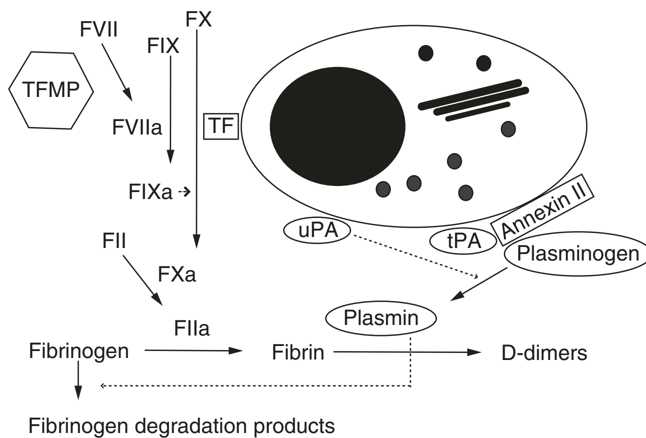

Fig. 21.7 Simplified schema of the coagulopathy associated with APL. Tissue factor present at the surface of leukemic blasts and microparticles binds to factor (F)VII, leading to activation of the latter. The TF-FVIIa complex activates FIX and FX. This leads to thrombin generation, which itself catalyzes fibrin formation. Parallel to this coagulation activation and factor consumption process, Annexin II present at the surface of malignant leukocytes binds tPA and plasminogen, resulting in the formation of plasmin, which goes on to cleave fibrin and fibrinogen. *APL* acute promyelocytic leukemia, *FII* coagulation factor II (prothrombin), *FIX* coagulation factor IX, *FVII* coagulation factor VII, *FX* coagulation factor X, *TF* tissue factor, *TFMP* tissue factor microparticle; *tPA* tissue plasminogen activator; *uPA* urokinase-type plasminogen activator. Reproduced with permission from Mantha S et al., Current Opinion in Hematology 2016 [573]

blood coagulation in vivo and is the membrane protein receptor for factor VII [614]. The resulting TF-factor VIIa complex activates factors IX and X, which leads to thrombin generation and fibrin formation. The TF gene is expressed in cells from patients with APL, and the TF promoter is activated by the PML/RARα fusion protein [615–618]. Recent work has also described tissue factor microparticles (TFMP) as potentially important for the pathogenesis of coagulopathy in APL [573, 619–621]. TFMP are cellular membrane fragments displaying TF derived from tumor cells, platelets, endothelial cells and monocytes. As in solid tumors, TFMP in APL manifest procoagulant activity as evidenced by measurements of thrombin generation [573, 619–621]. Increased expression of the cysteine proteinase cancer procoagulant (CP) protein by APL blasts has also been proposed as an additional mechanism of coagulopathy in APL [574–576]. Cytokines such as interleukin-1 (IL-1), tumor necrosis factor (TNF), and vascular permeability factor (VPF) are indirect procoagulants in APL by initiating coagulation through the induction of TF in endothelial cells and monocytes [625–627]. Interleukin-1 secreted by leukemic cells may induce DIC [628, 629]. Cytokines can generate plasminogen activator inhibitors that inhibit vessel wall fibrinolytic activity promoting coagulation [630, 631]. Interferon-γ and VPF-like mediators can induce endothelial cell procoagulant activity [632, 633].

Excessive fibrinolysis is also an important factor in the coagulopathy in APL [634, 635]. Plasminogen and alpha-2 antiplasmin levels are reduced in patients with APL [636, 637]. Furthermore, leukemic promyelocytes release plasminogen activators that cleave plasminogen and initiate fibrinolysis. Circulating tissue-type plasminogen activator can be found in the plasma of some patients with APL [638]. Decreased levels of circulating plasminogen-activator inhibitor type 1 (PAI-1) have been reported in some patients [639, 640]. APL cells contain elastases that inactivate alpha-2-plasmin inhibitor [641]. Annexin-VIII is one of a group of naturally occurring proteins that bind phospholipids and have both anticoagulant and phospholipase-A2 inhibitory properties [642]. The Annexin-VIII gene is expressed to a greater degree in cells from patients with APL compared to cells from patients with other subtypes of AML [643]. Annexin-VIII is highly expressed in the APL cell line NB4 and is significantly reduced after exposure to ATRA. Annexin-II is a cell surface receptor for plasminogen and its activator, tissue plasminogen activator (t-PA), which functions as a t-PA cofactor [644, 645]. Annexin-II is expressed in high levels on leukemic promyelocytes compared to leukemic cells from patients with other subtypes of AML [644, 645]. In APL, Annexin-II may play an important role in the formation of plasmin, serving as a driver for intense fibrinolytic activity [573, 644, 646, 647]. Studies suggest that plasmin- and elastase-induced degradation of von Willebrand factor also contributes to the hemostatic defect in APL [648].

Influence of ATRA on Coagulation Parameters

The effects of ATRA on APL coagulopathy are complex and incompletely understood. A number of studies have examined the specific changes in coagulation parameters before and after ATRA. Dombret and colleagues studied a small number of patients with APL treated with ATRA and reported that both DIC and proteolysis improved within 14 days [581]. Although proteolysis appeared to completely resolve, low-grade procoagulant activity persisted, even after patients achieved complete response, particularly in patients who developed hyperleukocytosis during treatment. Markers of thrombin generation such as thrombin–antithrombin complex (TAT), prothrombin fragment 1 + 2 (F1 + 2), and D-dimer did not completely normalize. These findings reflect a dissociation between the resolution of proteolysis (fibrinogenolysis) and DIC and may explain some reports of thromboembolic events during treatment with ATRA, particularly when ATRA is combined with antifibrinolytic therapy as prophylaxis against bleeding [584, 602, 605, 606, 649, 650].

Both TF-like and factor VII-independent (CP-like) procoagulant activity of APL blast cells is decreased after ATRA exposure [651, 652]. ATRA both upregulates thrombomodulin and downregulates TF expression in APL cells [654, 698]. However, several studies have demonstrated that retinoic acid also stimulates tissue-type plasminogen activator in human endothelial cells, which can initiate the fibrinolytic cascade and counterbalance the effects of a decrease in other procoagulant mediators [655, 656]. Levels of markers of coagulation activation including D-dimer, F1 + 2, TAT, and fibrinopeptide A have been shown to decline following exposure to chemotherapy or ATRA. Notably, plasma levels of D-dimer, F1 + 2, TAT, and fibrinopeptide-A decreased more rapidly among patients treated with ATRA compared to chemotherapy. D-dimer, TAT, and fibrinopeptide A levels also remain significantly elevated well above the upper limit of normal among the chemotherapy-treated patients [592]. Later in the course following ATRA and chemotherapy treatment, re-elevation of several molecular markers of coagulation may occur in some patients, potentially attributable to late effects of cytotoxic chemotherapy and infection [582]. Overall, most studies support the unifying hypothesis that as ATRA induces terminal differentiation of leukemic promyelocytes, markers of both procoagulant activity and fibrinolytic activity decrease with some evidence of persistent mild DIC.

Effect of the Improvement in the Bleeding Diathesis on Outcome of APL Patients Treated with ATRA or Arsenic

Nonrandomized and randomized prospective trials have examined the outcome of patients treated with ATRA alone or with ATRA and chemotherapy [267, 402, 430, 539, 657]. Before the ATRA era, the risk of early hemorrhagic death for APL patients ranged from 10 to 30% [9, 409, 574–579]. However, since the introduction of ATRA in 1988, the risk of early hemorrhagic death in prospective APL studies has decreased significantly to 5–10% [266, 402, 408, 430, 445, 539, 573, 658–661].

Arsenic trioxide also has emerged as an important agent in the treatment of APL, with recent studies demonstrating that ATRA plus arsenic trioxide is as at least noninferior and possibly superior to ATRA plus chemotherapy in the treatment of patients with low-to-intermediate-risk APL [506]. Unlike ATRA, arsenic trioxide binds the APL oncoprotein and leads to its degradation, resulting in decreased transcription of downstream target genes, suggesting that it could ameliorate the coagulopathy of APL early in its pathogenesis [63, 190, 573, 662]. Arsenic trioxide induces rapid loss of membrane procoagulant activity and TF mRNA [663]. Preliminary studies have shown that arsenic trioxide also has a beneficial effect on the coagulopathy in APL [605, 664]. Given the excellent outcomes in modern APL prospective clinical trials, it is difficult to assess the impact of arsenic in decreasing bleeding in contemporary studies. For example, there were no cases of early death in the ATRA + arsenic trioxide arm of the recent study comparing ATRA + arsenic and ATRA + chemotherapy in low-to-intermediate risk APL. However, there was only one death from hemorrhagic shock in the ATRA + chemotherapy group. Overall, patients with low-to-intermediate risk APL treated either with ATRA + arsenic or ATRA + chemotherapy had very good outcomes [506]. It is possible that there may be more room for improvement in reducing risk of early death from coagulopathy in high-risk APL. Since the mechanism of induction of remission of arsenic trioxide appears to be different from that of ATRA, new opportunities are present to explore the pathogenesis of the coagulopathy and the pathophysiologic basis for its improvement.

The Next Frontier: Management of Coagulopathy and Prevention of Early Death in APL

Despite the dramatic improvements in APL outcomes and reduced rates of hemorrhage in clinical trial settings, early death from hemorrhage remains a significant problem in population and community studies [399, 454, 573, 585, 587, 588, 590, 595] (Table 21.4). As early death in APL is driven significantly by coagulopathy, management of the coagulopathy of APL is therefore critical to ensuring high rates of cure [573, 584, 589] (Table 21.5). The most important initial step in managing the coagulopathy of APL involves suspecting the diagnosis of APL and prompt administration of ATRA. Given the rapid impact of ATRA in altering coagulation parameters

Table 21.4 Early death rate in APL in population studies

Study	*N*	ED%
Jeddi [595]	41	16
Lehmann [585]	99	31
McClellan [588]	70	26
Park [590]	1400	18

Table 21.5 Management of coagulopathy and prevention of early hemorrhagic death in APL

• Start ATRA at first suspicion of APL (based on clinical history and review of peripheral smear), BEFORE BONE MARROW AND BEFORE DIAGNOSIS CONFIRMED (in ER)
• Frequent platelet transfusion to >50,000/μL
• Cryoprecipitate to maintain fibrinogen >150 mg/dL
• No heparin, although not studied in ATRA era
• No antifibrinolytics

as noted above, ATRA should be given whenever APL is first suspected following review of the peripheral smear—without waiting for genetic confirmation of APL diagnosis and without waiting for bone marrow biopsy [257].

In addition to rapid administration of ATRA, vigilant monitoring of coagulation parameters and frequent administration of blood products are needed to prevent early hemorrhagic death in APL. Blood products serve as the cornerstone or prohemostatic treatments in APL, including platelet transfusions, fresh frozen plasma, as well as cryoprecipitate for repletion of fibrinogen [257, 573]. Guidelines support maintaining the platelet count above 30,000–50,000/μL and maintaining fibrinogen above 100–150 mg/dL (Table 21.5) [257]. Replacement therapy should be continued until all clinical and laboratory signs of coagulopathy have resolved. Although all patients presenting with APL are potentially at risk of hemorrhage, specific factors predicting high risk of fatal hemorrhage have been identified. In particular, patients with active bleeding, increased WBC or peripheral blast counts, abnormal renal function, poor performance status, hypofibrinogenemia (<100 mg/dL), or increased levels of fibrin degradation products combined with prolonged prothrombin or activated partial thromboplastin time are at increased risk of developing fatal hemorrhage [257, 267, 402, 454, 597, 660].

Beyond ATRA and blood products, there are no robust data to support the use of other prohemostatic modalities in APL. Intravenous heparin, antifibrinolytics, recombinant factor VIIa, and thrombomodulin have all been tested in APL patients, though none have been tested in randomized trials in the ATRA era [573]. Although heparin was advocated prior to the advent of ATRA, there are concerns as to the safety of heparin due to the possibility of worsening bleeding. Alternate concerns have been raised regarding the use of antifibrinolytics, due to the potential of thrombotic complications and the known predisposition of APL patients to thrombosis [584, 599–604]. Recombinant factor VIIa has been described in case reports of life-threatening hemorrhage in APL patients [665, 666]. However, the data for recombinant favor VIIa in this setting is highly limited, and recombinant factor VIIa presents similar safety concerns as antifibrinolytics in serving as a potential trigger for thrombosis. Recent retrospective postmarketing data from Japan suggests that the natural anticoagulant thrombomodulin may be useful in treating the coagulopathy of APL [667]. However, although the 3.5% rate of hemorrhagic death in APL patients who receive thrombomodulin is encouraging and lower than rates of hemorrhagic death in community studies, there are no randomized prospective trials of thrombomodulin that demonstrate clear efficacy in the treatment of coagulopathy in APL. Therefore, we would not recommend the use of thrombomodulin for treatment of APL coagulopathy outside of the context of clinical trials.

Management of coagulopathy in APL involves prompt suspicion of APL diagnosis, rapid administration of ATRA, and vigilant use of blood products. Given the disparity in rates of early hemorrhagic death between APL patients in population studies and in prospective academic clinical trials, education of community physicians in recognition and management of the coagulopathy of APL will be critical to improving overall rates of cure.

Future Treatment Research

Although tremendous progress has been made in the treatment of APL in the last two decades, problems remain. The coagulopathy characteristic of APL is not sufficiently addressed by the advent of ATRA or ATO. Mechanisms to interrupt the coagulopathy more rapidly need to be developed. Therapy, especially for high-risk patients needs to be improved. It is still unclear whether ATRA plus ATO or ATRA plus anthracycline is the best induction treatment for high-risk patients and experts have called for a randomized trial to address that issue [668]. A number of potential improvements in treatment are currently under investigation. Zoldronic acid was shown by Liu et al [669] to synergize with ATO in the inhibition of NB4 cells in vitro and should be explored clinically. Homoharringtonine [670] plus ATRA induction therapy followed by consolidation therapy and a 2-year maintenance program produced a 100% 9-year overall survival among patients with APL who were not overweight in one study, while obese patients had only a 73% 9-year survival rate. Other studies have shown that APL patients were more likely to be obese than other patients with AML. The effect of obesity on APL needs further study, and homoharringtonine as therapy for APL deserves further study as well. pVAX14DNA-mediated immunotherapy together with ATRA and ATO increased the survival of APL in mice [671]. This is an interesting observation that should also be explored further. AZD11512, a specific inhibitor of Aurora B which is overexpressed in APL, showed significant activity against NB4 cells and could lead to an entirely new approach to treatment of APL [672].

ATO degrades PML-RARα oncoprotein via the proteasome pathyway. Ganesan et al. [673] demonstrated in the laboratory that ATO and bortezomib (a proteasome inhibitor) are synergistic against arsenic sensitive and resistant cell lines. They have begun a test of this finding in the clinic. A traditional Chinese agent, tanshinone, was shown to induce differentiation in APL cells and subsequently shown to significantly prolong survival of APL-bearing mice [674]. Clinical trials should be entertained. Fucoidan, a sulfated polysaccharide from brown algae, apparently enhanced the activity of ATRA or ATO in a mouse model of APL [675] and deserves further study.

These early studies are interesting and may lead to newer approaches to the treatment of APL in the future.

Introduction

Individuals exposed to cytotoxic agents are at higher risk of developing myeloid disorders such as therapy-related myelodysplastic syndrome (t-MDS), therapy-related acute myeloid leukemia (t-AML), and therapy-related MDS/myeloproliferative neoplasms. However, all of these diseases are within the spectrum of a single disease entity, therapy-related myeloid neoplasms (t-MN), as categorized by the WHO classification system in 2008 [1]. WHO morphologic classification system defines t-MN as MDS and myeloid leukemia, which arise following the administration of chemotherapy and/or radiation for a prior malignancy. Patients who developed myeloid disorders by environmental toxins affecting hematopoiesis are not included in this disease category. Therapy-related MDS

© Springer International Publishing AG 2018
P.H. Wiernik et al. (eds.), *Neoplastic Diseases of the Blood*, DOI 10.1007/978-3-319-64263-5_22

and AML comprise the vast majority of t-MN cases. The 2008 WHO classification did not consider t-MDS and t-AML sufficiently distinctively different. However, unlike secondary AML denoting AML did not develop spontaneously or *de novo*, t-AML has clear history of prior chemotherapy or radiation therapy.

T-MN has become increasingly common. The fast rising incidence can be attributed to a variety of factors including longer survival of patients after treatment of their primary malignancy, intensified chemotherapy, radiation therapy, and broaden awareness of this disease category. This is a heterogeneous and poorly defined group of patients who have a shorter median survival than patients with *de novo* AML, MDS, or MDS/myeloproliferative neoplasia (MPN). Retrospective studies have shown that their inferior outcomes are associated with poor-risk cytogenetics, present in 50–70% of t-MDS/AML compared with 15–25% in *de novo* disease. Other studies have identified additional risk factors, including comorbidities from primary malignancy and therapy of the disease. Because of the poor outcome, t-AML is among the most feared long-term complication of cancer therapy these days.

Epidemiology

Therapy-related myeloid neoplasms (t-MN) account for approximately 10–20% of all cases of AML, MDS, and MDS/MPN. US Surveillance, Epidemiology, and End Results data of approximately 426,000 adults treated for an initial primary malignancy between 1975 and 2008 showed a 4.7-fold increased risk of AML compared with the incidence of AML expected in the general population. With the increasingly successful management of malignancies overall and improved cancer survivorship, the overall incidence of t-MN is expected to increase. The estimated incidence after therapy for any single prior diagnosis varies from less than 1 to 20% depending on the agents administered, therapy intensity, and survival, since the overall median latency time varies 1–5 years.

Patients with t-AML are seen among survivors of both solid tumors and hematologic malignancies. Smith et al. studied 306 patients who developed therapy-related myelodysplasia and myeloid leukemia with cytogenetic analyses [2]. In the study population, 25% of the patients had Hodgkin disease, 23% had non-Hodgkin lymphoma, and 38% had a solid tumor as the primary malignancy. Breast cancer was the most common among the 38% patients. Interestingly, 6% of patients had undergone cytotoxic chemotherapy for the management of immune disorders. Kayser et al. also showed similar patient characteristics in their study with 200 patients having t-AML. The group found that 71% of t-MN patients had a prior solid tumor and 27.5% patients had a prior hematologic malignancy. Breast cancer and non-Hodgkin lymphoma were the largest subsets in these two groups [3].

T-AML patients can present at any age. The risk associated with alkylating agents and radiation appears to increase with age, while the risk associated with topoisomerase II inhibitors appears to be constant across all ages [1]. Among those treated for breast cancer, younger age at the time of exposure, higher dose intensity of cytotoxic treatments, concomitant treatment with radiation, and adjuvant use of hematopoietic growth factors with cytotoxic therapy for accelerated white blood cell recovery are factors associated with an increased risk of t-AML [4, 5]. However, some t-AML/MDS individuals may have a DNA repair apparatus that is not as robust as normal, which also might predispose them to develop t-AML.

Etiology

T-AML appears to be a direct consequence of mutational events by therapy-induced DNA double-strand breaks, with a subsequent genomic instability [6]. Frequency of the mutations may vary between individuals as a result of genetic susceptibility. This susceptibility is usually not measurable or very subtle; a few exceptions include Fanconi anemia, and mismatch repair abnormalities.

The effects of some cytotoxic agents in the development of abnormal cytogenetics are well documented (Table 22.1). The latency period between first exposure to an agent (cytotoxic chemotherapy, radiation) and development of t-AML ranges from 1 to 5 years and varies by etiologic agent. T-AML after exposure to alkylating agents or radiation therapy typically presents after a latency period of approximately 4 years [7–10]. Most of these patients initially present with MDS. The chromosomal abnormalities seen in this category of t-AML often involve complex abnormalities such as deletion of the long arm or the entire chromosome 5 and/or 7. Topoisomerase II inhibitors are another etiologic agent of t-AML. It causes t-AML with a relatively shorter latency of

Table 22.1 Risk factors for therapy-related leukemia

Alkylating agent therapy: May cause MDS (preleukemic phase), could take 4–10 years to develop AML 5q or 7q deletion, bad prognosis
DNA-topoisomerase II inhibitor therapy (epipodophyllotoxins and anthracyclines): May develop t-AML without preleukemic phase; short median latency (33 months) Frequent translocation of 11q23 (MLL) or 21q22 Morphologic phenotype often M4/M5 (by former FAB classification)
Ionizing radiation therapy: similar to alkylating-related AML
G-CSF in severe congenital neutropenia

1–3 years, and the patients present with overt leukemia rather than MDS or MDS/MPN [11–13]. The cytogenetic alterations in this category of t-AML occur frequently with translocations including the MLL gene located at 11q23 or AML1 (RUNX1) gene at 21q22 [e.g., t(9;11), t(8;21), or t(3;21)]. However, no reliable way exists to determine the duration of the "at-risk" period for developing t-AML. The latency periods with other agents are not as clear as these two drugs. Exposure to multiple agents also makes it difficult to determine the risk, etiology, and latency period.

Alkylating agents are frequently used chemotherapeutic agents; more than 85% of patients who developed chemotherapy-related leukemia had received an alkylator [14]. Melphalan, chlorambucil, or cyclophosphamide is the offending agent in nearly 65% of patients. Therefore, different alkylating agents may be associated with varying risks of leukemogenesis. For example, one study compared the rates of mutagen-related leukemia in ovarian cancer patients treated with either melphalan or cyclophosphamide, and found that melphalan may be a more potent leukemogen than cyclophosphamide. Thus, the mutagenic potential may differ between the antineoplastic agents [15].

Alkylating agents interact with DNA in a variety of ways: monoadduct formation, inter- and intra-strand cross-links, as well as alkylation of free DNA bases. This can lead to cell death, but also can cause termination of DNA replication and chromosome loss, leading to mutagenesis and resulting in development of leukemia. Alkylation events can also change the stereometric configuration of DNA bases, causing them to mispair resulting in single-base mutations. Many of the alkylating agents have been clearly implicated in leukemogenesis.

Topoisomerase II helps mediate the relaxation of the DNA supercoil by making double-strand breaks. The breaks are repaired when homologous chromosome fragments realign. Topoisomerase II inhibitors, such as epipodophyllotoxins (etoposide and teniposide), doxorubicin, 4-epodoxorubicin, mitoxantrone, razosane, and biomolane, induce incorrect DNA repair by crossover recombination with nonhomologous end joining between the two DNA strands, which may result in the development of a balanced chromosomal translocation (Fig. 22.1). Balanced chromosomal aberrations involving the MLL, RUNX1, RARA, or NUP98 genes characterize unique genetic pathways of t-AML. The rearrangements between these genes and other partners provide gain-of-function fusion proteins. These topoisomerase II inhibitors are important components of chemotherapy regimens for many tumors, such as testicular cancer, ALL, NHL, lung cancer, and many others. Razoxane and bimolane, used in the treatment of psoriasis, have also been demonstrated to be leukemogenic. Those patients in whom t-AML develops after therapy with DNA-topoisomerase II inhibitors often have acute leukemia with no t-MDS phase [16, 17], and a short latency period, in contrast to alkylating agent-induced AML.

In the Polycythemia Vera Study Group (PVSG), 431 polycythemia vera patients were randomized to one of the three treatment groups: phlebotomy alone, P32 and phlebotomy, or chlorambucil and phlebotomy [18]. Higher number of AML cases occurred in both the P32 (9.6%) and chlorambucil (13%) treatment groups compared to phlebotomy-only group (1.5%), indicating a role of radiation and a cytotoxic agent in the development of AML in these patient groups [19]. French Polycythemia Study Group (FPSG) reported a leukemia incidence in polycythemia vera patients of 5–15% after 10 years of observation [20]. In a randomized trial in patients >65 years of age, the FPSG reported 12% AML at 10 years in patients receiving P32 alone. Hydroxyurea

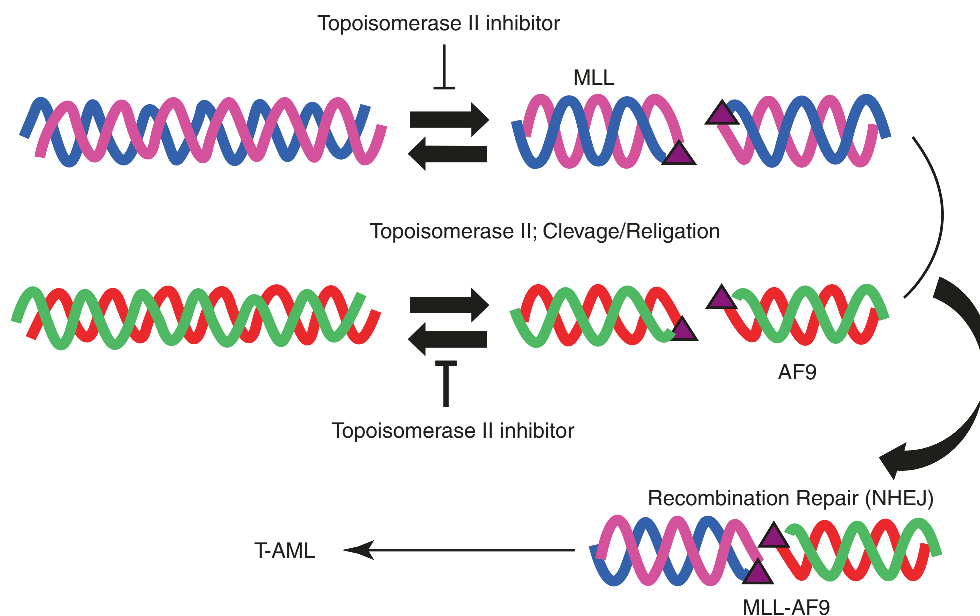

Fig. 22.1 Formation of topoisomerase II-DNA complex is necessary to perform critical cellular functions. If the amount of complexes is elevated as a result of topoisomerase II inhibitors, DNA repair/recombination process is activated, which subsequently generates chromosomal translocations or other DNA aberrations. If the fusion protein produced by chromosomal translocation results in the cells having a growth advantage, these cells may evolve and progress into t-AML

maintenance combined with initial P32 therapy also increased the risk of AML (21% at 10 years). In another case control study of MPN patients (68% of patients had polycythemia vera), the risk of AML/MDS development was significantly associated with high exposures of P32 and alkylators [21]. Taken together, a strong association exists of cytotoxic agents or radiation increasing the risk of development of AML in MPN patients.

Ionizing radiation clearly increases the risk of developing AML in humans and experimental animals. The incidence of leukemia after 400 cGy or less of radiation exposure from the Hiroshima nuclear explosion was approximately two cases of leukemia/10^6 persons/year/cGy [22]. Nearly the same incidence of leukemia was reported in patients who received 300–1500 cGy of spinal irradiation for ankylosing spondylitis. Likewise, increased rates of AML occurred in radiologists who practiced during the early years of clinical radiology before modern safety standards [23].

Animal studies confirmed the epidemiological observations in humans by showing that low-dose chronic irradiation induces leukemia in experimental animals. Half of dogs that received a daily low dose (5–10 cGy) of cobalt γ-irradiation developed AML after about 1000 days [24]. Single whole-body irradiation initiates leukemia in rodents. Myelogenous leukemia developed in 20% of mice after a single brief whole-body irradiation of 200 cGy [25]. The dose–response relationship was curvilinear; pulse irradiation of at least 300 cGy induced significantly fewer cases of leukemia than the 200 cGy dose; these doses produced marrow cell death, probably decreasing the number of cells that would otherwise have the potential to undergo malignant transformation.

Exposure to ionizing radiation can cause a DNA damage by a mechanism similar to alkylating agents. Radiation photon energy can directly lead to DNA strand breakage. Radiation is frequently used in conjunction with chemotherapy for cancer therapy, and only a few studies have specifically looked at the characteristics of myeloid neoplasms occurring after radiation alone. Recently, Nardi et al. showed that t-MDS occurring in the modern radiation therapy era, if alone, more nearly resembled *de novo* MDS/AML in cytogenetic characteristics and clinical behavior, and affected patients had better outcomes than patients with t-MDS secondary to chemotherapy [26].

Even though radiation therapy is leukemogenic [7, 27–29], studies in Hodgkin's disease suggest that the incidence of secondary leukemia in patients receiving radiation therapy alone was low compared with those receiving chemotherapy alone [30, 31]. In one study, a total of 957 patients exclusively received radiation therapy, and none developed leukemia. By contrast, 542 patients received only chemotherapy, and 12 developed leukemia. A similar finding was reported in ovarian cancer patients who received either chemotherapy or radiation therapy [32]. In most studies, the risk of AML in patients with either Hodgkin's disease or ovarian carcinoma treated exclusively with chemotherapy is not different from those treated with both chemotherapy and radiation therapy [7, 27–29, 32].

In a study of chromosomal abnormalities, only 37 of 344 patients with secondary leukemia had been treated with radiation therapy alone; the incidence of a normal karyotype was higher in patients who received only radiation than in patients who received chemotherapy either with or without radiation therapy (24.3 vs. 11.7%). Normal karyotype is associated with better response to antileukemic therapy, but with little improvement in overall survival (OS) [33]. Another study of 63 patients with either t-MDS or t-AML found that 11 of 63 had received only radiation, in most cases to ports including the pelvis or spinal bone marrow [34]. In this study, only two patients had a normal karyotype. The low risk of leukemia after currently used high-voltage irradiation may be analogous to the earlier mentioned murine model where high-dose irradiation has a lethal effect on marrow cells in contrast to lower dose exposure, which may be more likely to produce nonlethal marrow cell injury and mutations.

Although several studies examined secondary malignancies in patients with specific primary tumor types, few data have been published examining the long-term effect of pelvic radiation. Wright et al. analyzed patients with invasive tumors of the vulva, cervix, uterus, anus, and rectosigmoid treated with radiotherapy from 1973 to 2005 [35]. In a Cox proportional hazards model adjusting for other risk factors, posttreatment leukemia was increased by 72% (hazard ratio [HR], 1.72; 95% CI, 1.37–2.15) in the patients who received pelvic radiotherapy. The risk of secondary leukemia peaked at 5–10 years after primary treatment (HR, 1.85; 95% CI, 1.40–2.44) and remained elevated even 10–15 years after initial treatment (HR, 1.50; 95% CI, 1.03–2.18) [35].

Radioiodine (I-131) induces chromosomal aberrations, and theoretically can lead to leukemogenesis. However, the occurrence of t-AML after radioiodine treatment for thyrotoxicosis and thyroid cancer is infrequent. In a comprehensive meta-analysis of the currently available literature covering 16,502 patients with thyroid cancers, the relative risk of development of leukemia increased 2.5-fold in patients treated with radioiodine [36]. The latency period of t-AML associated with radiation was 5–7 years, similar to t-AML associated with alkylating agents [37].

The use of granulocyte colony-stimulating factor (G-CSF) in chemotherapy may be a risk factor for development of t-AML as shown in a meta-analysis examining data from 25 trials [38]. At a mean follow-up of 60 months, 43 t-MN cases were reported in G-CSF-treated patients, while 22 t-MN occurred in control group. G-CSF may accelerate damaged myeloid progenitors into cell cycling before repair of genetic injuries from cytotoxic therapy.

Cases of leukemic transformation in patients with severe congenital neutropenia (SCN) were prospectively studied [39]. A comprehensive analysis of the incidence of AML transformation showed that the annual risk of MDS/AML was 0.81% during the first 5 years, and 2.3% after 10 years among 374 SCN patients with G-CSF treatment. After 15 years on G-CSF, the cumulative incidence for MDS/AML was 22% in SCN, whereas none of the cyclic neutropenia patients who also received G-CSF developed MDS or AML [40]. Patients with SCN develop mutations of their G-CSF receptor, which affects the ability of the myeloid cells to differentiate.

T-MN occurring in patients with autoimmune diseases (AD) has been increasingly recognized. A large population-based study found that AD patients had significantly increased risk for AML and MDS [41], and this finding was subsequently confirmed by another study [42]. Immunosuppressive therapy may be another contributing factor for development of t-MN. Patients who received immune-suppressive agents including corticosteroids, antitumor necrosis factor (TNF) agents, sulfasalazine, and cytotoxic chemotherapeutics such as methotrexate, azathioprine, and cyclophosphamide had increased risk for hematological malignancies [43]. The development of t-APL in patients with multiple sclerosis has been reported [44, 45]. But patients receiving an antimetabolite as a single agent (e.g., fludarabine, azathioprine, and 6-thioguanine) for their autoimmune disease rarely develop t-AML [46–48]. Development of t-AML in AD patients who received immunosuppressive therapy other than cytotoxic agents could represent the importance of the immune-surveillance system in guarding against malignancies. Also, the underlying primary genetic defects in these individuals might increase susceptibility to AML.

Karyotypic Abnormalities in t-MDS/AML

Clonal chromosomal abnormalities can be detected in the blast cells of 80–95% of t-MDS/t-AML patients by routinely available techniques [7, 34, 49–53]. A hypodiploid modal number of chromosomes occur most frequently in t-MDS/t-AML patients. Hyperdiploidy, mainly trisomy 8, is rare and is often observed as an inconsistent aberration present in only a subclone of cells [52]. Chromosomes 5q and 7q probably contain critical myeloid tumor-suppressor genes in *de novo* and t-AML. The breakpoints for the deletions are variable, but a common chromosome region, the so-called critical region, is almost always deleted.

For chromosome 5, Le Beau et al. have narrowed down the critical region to 5q31.1, which includes the early growth response gene *(EGR-1)* [54]. Other genes located on the long arm of chromosome 5 include many growth factor genes, namely *granulocyte-macrophage colony-stimulating factor* (*GM-CSF*), and *interleukins-3, −4*, and *−5 (IL-3, −4, −5*) [34, 55–58], and the growth factor receptor genes known to be present on the long arm of chromosome 5, namely *macrophage colony-stimulating factor* (M-CSF or *FMS) receptor, platelet-derived growth factor (PDGF) receptor*, *glucocorticoid receptor, alpha1-adrenergic receptor, beta2-adrenergic receptor*, and *D1-dopamine receptor* [59, 60].

The breakpoints for the deletions of 7q are variable, but a common chromosome region, the so-called critical region, is located at band 7q22 proximally with the distal breakpoint varying from q31 to q36. Potentially important genes have been mapped to 7q, including genes for EZH2, erythropoietin, p glycoprotein 1/multiple drug resistance 1 (MDR-1), and MDR-3 [61]. Abnormalities of chromosome 7q are common in myeloid malignancies. Especially, homozygous EZH2 mutations were commonly found in MDS/MPN patients [61]. However, none has yet been shown to be involved in the development of t-AML [54, 59–62].

Although most of the chromosomal abnormalities reported in t-MDS/t-AML are either complete or partial deletion of chromosome 7 or 7q [del(−7/7q)], and/or 5, or 5q del(−5/5q)], in recent years recurring unbalanced translocations that also result in loss of the long arm of 7 and/or 5 have been reported with increasing frequency. These include t(1;7)(p11;q11), t(5;7)(q11.2;p11.2), and t(7;17)(p11;p11) for chromosome 7, and t(5;7)(q11.2;p11.2) and t(5;17)(p11;p11) for chromosome 5 [63]. While the loss of function of a single gene in each of these relatively large regions is possibly responsible for the development of t-MDS/t-AML, hemizygous loss of the function of several genes in each of these regions could also contribute to the disease phenotype. Another, not mutually exclusive hypothesis is that an unknown initiating abnormality causes genomic instability leading to the deletion and rearrangement of particularly susceptible chromosome regions, such as those on chromosome 5q and 7q.

A review of 431 cases of secondary leukemia found 16 nonrandom chromosomal changes involving chromosomes 3, 5, 7, 8, 9, 11, 14, 17, and 21. These changes were dependent on the type of primary disease, previous therapy, age, and gender [64]. In another single-institution study consisting of 63 patients, additional abnormalities involving chromosomes 1, 4, 5, 7, 12, 14, and 18 occurred, with significantly increased frequency of these changes in t-AML as compared to *de novo* AML [34]. Abnormalities in chromosome 17, especially translocations involving bands 17p11-p13 and 17q21, occasionally are observed in t-AML, for example, t(15;17)(q22;q11–21) [65, 66]. Other chromosomes often reported to be abnormal in t-MDS/t-AML are chromosomes 21 and 11, particularly involving balanced translocations of chromosome bands 11q23 and 21q22 in t-AML [i.e., t(4;11), t(6;11), t(9;11), t(11;19), t(3;21), and t(8;21)] [52, 59, 63, 64]. These translocations are associated with previous

therapy targeting DNA-topoisomerase II, primarily the epipodophyllotoxins and the anthracyclines. The 11q23 reciprocal translocations and interstitial deletions structurally interrupt a small region of the *MLL* (also known as *HRX, ALL-1, HTRX1*) gene that codes for a human homolog of the *Drosophila trithorax* gene [67, 68]. A fragment of the *MLL* gene translocates to more than 200 other chromosomal regions, resulting in the creation of a fusion protein with the partner gene [69].

The t(9;11) that results in a fusion between *MLL* and *AF9* is a recurring chromosomal translocation in *de novo* AML and is one of the most common recurring chromosome translocations detected in about 50% of t-AML patients who have a *MLL* translocation [70]. In addition, involvement of the *AF9* gene in the development of t-AML is linked to the treatment with topoisomerase inhibitors [6]. Interestingly, the unbalanced rearrangements of the same two bands, 11q23 and 21q22, were most often associated with therapy with alkylating agents alone or in combination with radiation therapy [59]. In Chinese patients treated for psoriasis with bimolane, t(15;17) has been frequently reported. Also, therapy with doxorubicin has been associated with an increased incidence of t-AML with balanced translocations at chromosome band 21q22, in particular t(3;21) [52, 64]. In addition to balanced translocations involving chromosome bands 11q23 and 21q22, other balanced aberrations such as inv (16), t(8;16), t(15;17), and t(6;9) have been observed in t-AML after previous therapy with drugs targeting DNA topoisomerase II (Table 22.2) [52, 63].

In a study of 491 t-MDS/t-AML patients with at least one balanced translocation, Rowley and Olney reported that 149 of the patients were positive for the 11q23 translocation (30.3%), followed by the 21q22 rearrangement seen in 15%, inv (16) in 9%, and t(15;17) in 8% of the patients [70]. Interestingly, no significant difference occurred in the gender distribution of patients within the subgroups, and patients in the 11q23 subgroup were of the youngest age at their primary and secondary diagnosis. Moreover, the translocation 11q23, inv (16), and t(15;17) subgroups had the shortest latency, with a median latency of 25.9 months for translocation 11q23, 22.0 months for inv (16), and 28.9 months for t(15;17) [70].

Table 22.2 Thirty-eight HSC gene signatures predicting development of t-MDS/AML

Thirty-eight genes differentially expressed in CD34+ HSC of t-MDS/AML patients
NR4A2, FOS, EGR1, CARD6, PEX11B, EGR3, EGR4, MRPL15, SLC7111, REEP1, FOSB, GOLGA5, ACTL6A,

LRBA, XPOT, ZYG11B, ZNF137, GEM, PGRMC2, ARL6IP6, SLC2A3P1, NR4A3, RGS2, NROP3, SLC26A2

Chromosome studies have shown that when t-MDS becomes clinically diagnosable, the preleukemic clone represents a majority of the hematopoietic cells [7, 34, 49]. Additional chromosomal abnormalities occur in the original abnormal clone in 60–70% of cases as the disease evolves to frank leukemia [71, 72]. Karyotypic evolution usually involves further deletions or losses of chromosomes and a change to a lower modal chromosome number; rarely, the evolution is associated with a gain of chromosome 8. Evidence suggests that t-MDS patients who have a mixture of karyotypically normal and abnormal cells (AN) survive longer than those who have only abnormal cells (AA) [73]. Most individuals who are AN in the preleukemic phase become AA as the disease progresses [34]. Notably, Rowley and Olney observed in their study that patients presenting with a t-MDS had significantly more frequent abnormalities of chromosomes 5 and/or 7 (49%) than did patients presenting with a t-AML (16%), and that this subgroup also presented with the highest percentage of complex karyotypes (45% vs. ca. 20% for both 1 and 2 aberrations) [70].

Genetics of Therapy-Related AML

Patients who develop t-AML may be predisposed to develop AML because of defects in DNA repair or increased susceptibility to accumulation of genetic mutations [74]. Candidate single-nucleotide polymorphisms associated with either drug metabolism or DNA repair enzymes have been identified as a mechanism by which a subset of t-AML may develop [75]. The commonly found germline variants in t-AML patients are *NQ01*, glutathione S-transferase family of enzymes, *BRCA1/2*, *TP53*, and *MDM2* [76–78]. Li-Fraumeni syndrome and Fanconi anemia also predispose to acute leukemia [79]. Tumor protein 53 (*TP53*), *RUNX1*, V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (*KRAS*), and neuroblastoma RAS viral (v-ras) oncogene homolog (*NRAS*) mutations are known mutations in the development of t-MDS/AML [80].

To understand the pathogenetic mechanisms underlying t-MDS/AML, Li et al. performed a prospective case-control study with patients undergoing autologous hematopoietic stem cell transplant for lymphoma. In the study, gene expression in CD34+ hematopoietic stem and progenitor cells (HSC) from patients who developed t-MDS/AML after autologous hematopoietic cell transplantation (autoHSCT) for lymphoma (n = 30) was compared with gene expression in CD34+ cells of control group. The authors demonstrated that the expression pattern of 38 genes was different long before the development of t-MDS/AML in the case group, and that this gene signature was involved in mitochondrial function, metabolism, and hematopoietic regulation in peripheral blood stem cells (PBSC) that could distinguish patients who developed t-MDS/AML post-autoHSCT from those who did not [81].

Table 22.3 Mutational profiles of therapy-related acute myeloid leukemia versus *de novo* AML [82, 83]

Group	More frequent in t-AML	Similar frequency in t-AML and *de novo* AML	More frequent in *de novo* AML
Genes mutated	*TP53*, ATP-binding cassette subfamily genes, *PTPN11*	*STAG2, DNMT3A, NRAS, KRAS, IDH1, IDH2, U2AF1, KIT, KHD1, PKDL2, TET2, RUNX1*	*FLT3, NPM1*

Another study assessed the bone marrow or peripheral blood samples of 70 t-MDS/AML (including 42 t-AML) patients using a next-generation sequencing of 53 targeted genes. The mutation profile of t-AML was different from those of 428 *de novo* MDS/AML patients [82]. TP53 was mutated at a significantly higher rate in t-AML than *de novo* AML (35.7% vs. 12.8%, $p = 0.002$). *PTPN11* mutations were observed in 11.9% of t-AML patients compared with 2.1% in *de novo* AML patients ($p = 0.008$). Mutations of *NPM1* and *FLT3* only occurred in 2.5% and 7.1% of t-AML patients, respectively, which was significantly lower than *de novo* AML patients (21.7% and 16.4%, respectively) (Table 22.3). Analysis of clonal evolution showed that *TP53* mutation often occurs early in the pathogenesis of t-AML, and mutations of other genes may provide a further evolution to t-AML [83].

Lindsley et al. reported the genetics of 101 t-AML patients [84]. The goal of the study was to find a distinct mutation profile of t-AML compared with secondary or *de novo* AML with comprehensive sequencing. Samples obtained from patients prior to treatment were analyzed for mutations in 82 genes and the results were compared to the genetic profiles in The Cancer Genome Atlas of *de novo* AML. The comparative analysis demonstrated three mutually exclusive patterns of mutations that were noted in the t-AML cohort. The first group had *TP53* mutations. The second group had mutations which were commonly associated with secondary AML. These "secondary" mutations at cohort included spliceosome genes (*SRSF2, SF3B1, U2AF1, ZRSR2*), chromatin remodeling genes (*ASXL1, EZH2, BCOR*), and cohesion gene (*STAG2*). The third group included those with *de novo*-type mutations (*NPM1*, CBF rearrangements, and MLL rearrangements). However, the authors did not find unique genetic profiles, associated with chemotherapy exposure other than the established link between exposure to topoisomerase II inhibitors and MLL rearrangements. The CR rate for t-AML patients with *de novo*-type mutations was less than in *de novo* AML patients with the same mutations, but t-AML with secondary-type mutations or *TP53* mutations had remission rates similar to the older *de novo* AML group with the same "secondary"-type mutations. But the t-AML cohort required more cycles of induction therapy for CR. Taken together, prior chemotherapy exposure may not produce a unique "therapy-related" genetic profile, but genetic profiles may help predict outcomes of t-AML patients [84].

Next-generation sequencing could identify mutations in the leukemic transformation of Severe Congenital Neutropenia (SCN). Mutations in *CSF3R*-T618I, *RUNX1*, and *ASXL1* were found only in the MDS/AML phase of SCN [85]. Another study revealed that 64.5% of patients of the study population had mutations in *RUNX1* and the mutation occurred in clones with earlier acquired *CSF3R* mutations [86]. A sequential analysis at stages prior to leukemia development demonstrated that the *RUNX1* mutations are late events in the AML development of SCN. The other mutations associated with leukemic transformation were *ASXL1*, *SUZ12*, and *EP300* in less frequent rate.

Several groups have tried to identify the major genetic mutations in progression of MPN to AML by performing genotypic analyses of AML cells evolved from MPN [87–92]. The process of AML transformation is considered to arise from additional mutations outside of the JAK-STAT pathway, which is supported by the findings that the canonical *JAK2*V617F mutation has not been correlated with leukemic transformation. Furthermore, this mutation can be absent in the leukemic clone [93]. In these analyses, mutations affecting epigenetic regulators and transcriptional factors (*ASXL1, TET2, EZH2, IDH1/IDH2, IKZF1*), splicing factors (*SRSF2, SF3B1, ZRSR2, U2AF1*), and *TP53* mutations were frequently observed in MPN-AML cells compared to MPN cells. While only 1.9% of PV patients had an *IDH1/2* mutation, MPN-AML patients had a high frequency (21.6%) of this mutation [94]. Among 22 patients with post-MPN AML, 45.5% of the patients had a P53-related defect. In a study of 29 post-MPN AML samples (including 162 chronic-phase PV) using SNP arrays, changes of chromosomes 1q, 7q, 5q, 6p, 7p, 19q, 22q, and 3q were associated with post-MPN AML [88].

Clinical Presentation and Diagnosis

No specific clinical presentation demarks t-AML, but most patients have symptoms similar to patients with *de novo* AML including cytopenias (i.e., anemia, neutropenia, and thrombocytopenia) associated with easy fatigue, generalized malaise, infections, and/or hemorrhagic symptoms as easy bruising, nose/gingival bleeding, menorrhagia, or petechiae. Patients may have clinical manifestations of hepatomegaly, splenomegaly, lymphadenopathy, gingival hypertrophy, skin infiltration, and neurological abnormalities.

A preleukemic or myelodysplastic phase occurs in over 70% of patients in whom AML develops following chemotherapy and/or radiation therapy for another disease [7, 27, 49–51, 95–98], whereas about 20% of patients with *de novo*

AML have a similar preleukemic phase. Indeed, the data suggest that a preleukemic period can be observed in nearly all patients with t-AML, when these patients are monitored closely. Exceptions are those individuals in whom t-AML develops after therapy with epipodophyllotoxins (VP16 and VM26) or other DNA-topoisomerase II inhibitors. In these patients, t-AML often develops with no preleukemic phase [16, 17]. The mean duration of the preleukemic phase is 11.2 months in typical t-AML. The preleukemic phase in individuals with *de novo* MDS who go on to develop AML is similar, about 14 months (Table 22.1) [95, 96, 98].

Prodromal symptoms of the emergence of t-AML may be similar. However, when a patient who has received cytotoxic agents has these symptoms, the appropriate workup to rule out t-AML should be done. The diagnostic evaluation includes a comprehensive medical history and physical examination with detailed information of exposure to cytotoxic agents (time, duration, cumulative doses). In addition, patient's age, comorbidities, performance status, organ dysfunction, and remission status of the primary disease are important for establishing management plan. A detailed family history is essential to rule out hereditary cancer syndrome. Peripheral blood smear is an important laboratory test to rule out dysplastic changes in myeloid cells. Complete blood differential counts, and metabolic panel, as well as lactate dehydrogenase and uric acid level are required for initial laboratory tests. The diagnosis of t-AML is eventually made when evaluation of the peripheral blood and bone marrow demonstrates circulating myeloblasts in peripheral blood and/or more than 20% of myeloblasts in bone marrow. This may be buttressed by typical immunophenotypic and cytogenetic changes.

The clinical manifestation of the preleukemic phase of t-AML is marked by ineffective hematopoiesis. The bone marrow morphology is characterized by trilineage dysplasia. The degree of dysplasia is usually very prominent. Interestingly, the RAEB and RAEB-t subgroups are more frequently linked to t-MDS (73%) than in *de novo* MDS (53%) [99]. Prominent abnormalities are observed in the red blood cells and their precursors. Most patients show decreased red cell production with low reticulocyte counts [27]. Oval macrocytosis and nucleated red cells are often the earliest recognizable changes observed in the peripheral blood in the preleukemic phase [100]. Macrocytosis after therapy for Hodgkin's disease was retrospectively found to be associated with a high risk of the development of leukemia [101]. Mild neutropenia is present in 75% of the individuals [27]. Neutrophils may be poorly granulated, and their nuclei can be hyposegmented (pseudo-Pelger-Hüet anomaly) [102]. Thrombocytopenia occurs in approximately 60% of patients [27], and they may be abnormally large and degranulated. Both the neutrophils and platelets can have a variety of qualitative defects. The bone marrow is often hypercellular, although hypo- and normocellular marrow can occur. Erythroid hyperplasia, megaloblastoid features, and occasionally ringed sideroblasts dominate the marrow picture [102–104]. Abnormalities of the marrow granulocytic and megakaryocytic series are usually more subtle. Micromegakaryocytes may be seen, particularly with monosomy 7. The percentage of immature granulocytic and megakaryocytic cells may be increased. The primary and specific granules of the granulocyte precursors occasionally are either deficient or abnormally large. Marrow fibrosis often is present during the preleukemic phase.

In summary, the development of unexplained pancytopenia and the finding of karyotypic abnormalities in the marrow cells of patients who received chemotherapy and/or radiation therapy for another disease are pathognomonic of preleukemia. Evolution to overt leukemia is universal if the preleukemic individual survives the complications of hemorrhage and infection. T-MDS can be viewed as an early phase of t-AML in which the malignant hematopoietic clone is established and becomes predominant.

Clinical manifestations of individuals with t-AML are typical of bone marrow failure, and their clinical course is rapidly fatal often from complications of bleeding and infection. The bone marrow morphology of t-AML has been difficult to classify according to FAB criteria for AML, as most of the leukemias demonstrate trilineage involvement and appear to bridge several subtypes. Nevertheless, the blast cells of patients with t-AML most often are myeloblastic in appearance according to AML without maturation or AML with minimal differentiation in agreement with the 2008 WHO classification. A lower frequency of acute monocytic forms of leukemia has been reported in several studies as compared to *de novo* AML [7, 105].

Auer rods are rarely observed in the blast cells in t-AML, but are seen in blast cells of 35% of patients with *de novo* AML. Many of the blast cells in t-AML lack myeloperoxidase and other granulocyte-specific enzymes. In one series, only one of ten patients with secondary AML had more than 10% peroxidase-positive blast cells compared with nearly 100% peroxidase-positive blast cells in 95% of patients with *de novo* AML [105]. In addition, less than 20% of the t-AML patients have either greater than or equal to 10% naphthol ASD chloroacetate esterase-positive blast cells compared with 47% of patients with *de novo* AML. These histochemical data suggest that the leukemic cells from secondary leukemia patients are blocked at an earlier stage of differentiation than the leukemic cells from most *de novo* AML patients.

A patient may develop t-AML after cytotoxic treatment for a *de novo* myeloid neoplasm. T-AML secondary to *de novo* myeloid neoplasm may be identified by performing cytogenetic testing and immunophenotype evaluation at

Table 22.4 Initial evaluation of a therapy-related acute myelogenous leukemia

History and physical examination	History of cytotoxic agent: cumulative doses Disease status of primary cancer Performance status Family history of cancer
Complete blood cell count, differential count	
Review of peripheral blood smear	
Serum chemistries	Liver/kidney function, LDH, uric acid
Bone marrow aspirate and biopsy	Immunophenotyping and cytogenetic analysis
HLA typing	
Organ function tests	Echocardiogram/MUGA for ejection fraction Pulmonary function tests

apparent t-AML development and by comparing with those at the time of primary disease diagnosis. The emergence of a distinctly different karyotype suggests, but does not prove, a therapy-related AML, rather than recurrence of the original leukemic clone.

For patients with good performance status, information about siblings is useful for establishing a management plan. HLA typing of patient can be done on final diagnosis and the identification of potential stem cell donor is the first step for matched related donor allogeneic transplant. To evaluate reserved organ function, echocardiogram, and pulmonary function tests is also required. Computed tomography/MRI or PET imaging can give information about the status of primary disease (Table 22.4).

Treatment

Effective treatment options for t-AML are often not available. The efficacy of various therapeutic modalities of t-AML has been difficult to assess because the number of reported cases is small. In addition, data for t-AML have been reported together with secondary leukemias following other hematological disorders such as MPN or *de novo* MDS, making the evaluation difficult. Daunorubicin in combination with cytarabine remains the standard induction chemotherapy combination for patients with AML for the last decades. All studies to date have shown that response rates, and OS, are significantly lower in whole t-AML patients compared with *de novo* AML. Complete remission rates in t-AML patients are reported in 40% of patients with median survivals of 6–8 months [106]. The treatment of patients with t-AML is a clinical challenge for multiple reasons. The patients have a greater number of comorbidities, decreased organ reserve from previous therapy or primary disease, and a higher incidence of unfavorable cytogenetic changes. The key prognostic factors in t-AML are patient age, performance status, and karyotype.

For all t-AML patients, the performance status is the first determinant for establishing a treatment plan. All medically fit patients should have HLA typing at initial diagnosis. Supportive care would be appropriate for patients with a poor performance status (ECOG PS >2) at initial diagnosis. Various attempts to improve survival in these patients have failed to change the course of the disease, with deaths due to infection, bleeding, or progression of the acute leukemia. Supportive therapy is, therefore, an important aspect of the medical care of these patients. No significant differences in survival have been shown between those patients who received chemotherapy and supportive care and those who received supportive care alone. Thus, supportive therapy with transfusions of red blood cells and platelets for symptomatic anemia or bleeding complications, or both, is often necessary as well as the treatment with antibiotics for infections. The goal of therapy in these individuals should be to maintain an acceptable quality of life. Clearly, innovative and radically novel approaches to this syndrome are required if these patients are to be cured.

Studies have suggested that no significant differences exist in clinical outcome between the t-AML and *de novo* AML in the same cytogenetic group. The therapy-related AML with favorable cytogenetic findings, such as t(8;21), t(15;17), and inv. (16), have a complete response rate, essentially the same as *de novo* AML with the same karyotype [63, 107, 108]. Similarly, patients who have secondary AML with unfavorable cytogenetic findings such as deletion of chromosomes 5 or 7 do poorly, similar to *de novo* AML individuals with the same abnormality. Therefore, though more single or complex clonal cytogenetic abnormalities are found in t-AML patients than *de novo* AML patients [3], the prognostic significance of karyotype in t-AML is similar to that in *de novo* AML.

No single form of post-remission therapy has been shown to be superior for t-AML. Post-remission therapy with high-dose cytarabine probably is appropriate in patients with favorable cytogenetic findings except for those t-APL patients with t(15;17). In contrast, because of their extremely poor outcome, patients with unfavorable cytogenetic findings should be encouraged to enter clinical trials. As part of the discussion of treatment options, t-AML patients with an extremely poor prognosis should probably be offered the spectrum of treatments from supportive care alone to intensive chemotherapy either with or without allogeneic hematopoietic stem cell transplantation.

Therapy-Related AML Patients with Favorable Cytogenetics

Therapy-related AML is a heterogeneous disease and cytogenetic profile remains prognostically relevant. Patients with t-AML and favorable cytogenetics including t(15;17), inv.(16), t(16;16), and t(8;21) generally have superior outcomes among patients with t-AML.

A European study identified 106 cases of t-APL in patients who received cytotoxic chemotherapy for breast cancer, non-Hodgkin's lymphoma, and other solid tumors over a period of 10 years [109]. These t-APL patients had a short latency time (2–3 years), and exposure to topoisomerase II inhibitors or prior radiation therapy, and shared similar clinical characteristics with *de novo* APL [110, 111]. Yin et al. demonstrated frequent dyserythropoiesis, dysmegakaryopoiesis, FLT3 mutation (43%), and frequent additional cytogenetic abnormalities (60%) in their report of 17 t-APL patients [112]. Mounting evidence supports the practice of treating t-AML with t(15;17) as *de novo* disease, even when accompanied by other karyotype abnormalities [110]. They have a good response to all-trans retinoic acid (ATRA) therapy. Induction response rates appear to be equivalent to *de novo* APL, but induction death was more common and was attributed to impaired physiologic reserves from prior therapy. Therefore, t-APL is currently treated as *de novo* APL. With the use of ATRA and arsenic trioxide (ATO) in up-front therapy, anthracyclines can be eliminated for low-risk APL, which would be particularly beneficial for patients with t-APL who have had a prior anthracycline therapy for their primary malignancy [113].

T-AML with t(8;21) is not a common type of t-AML. A review article noted 26 cases and concluded that these patients had very similar hematological characteristics and treatment response as *de novo* AML with t(8;21) [63]. The 2002 international workshop studied 72 cases of t-AML with 21q22 (RUNX1) rearrangement and found that 44 of these cases were t(8;21) [114]. In the study, patients with t(8;21) rearrangement had a more favorable outcome than patients with other rearrangements involving 21q22. Gustafson et al. observed 13 patients with t-AML having t(8;21) karyotype in a single institute and compared them to 38 patients with *de novo* AML with t(8;21) and found that patients with therapy-related t(8;21) AML were older, and had a higher frequency of *KIT* 816D mutations, and an inferior OS than their *de novo* counterparts [115]. Krauth et al. showed high frequencies of additional cytogenetic and molecular lesions in AML with t(8;21) [116]. Mutations in RAS pathway, *KIT* and *ASXL1* mutations, were the most frequent additional mutations in the study, and mutations in *KIT* D816 and *ASXL1* were strongly associated with adverse outcomes. At the chromosomal level, −Y appeared to be associated with a good prognosis whereas trisomy 8 had an inferior prognosis. In a large series of t(8;21), 22 t-AML patients showed no differences in secondary molecular genetic events from 117 *de novo* AML [116]. However, a study showed that the treatment outcomes of t(8;21) t-AML were inferior to those of *de novo* t(8;21) AML, possibly because the t-AML cohort was older and some patients had active primary cancer.

T-AML with inv (16) was often associated with prior therapy with topoisomerase II inhibitors [117]. Response rates to intensive chemotherapy in this study were comparable to those with *de novo* disease. However, t-AML with inv (16) showed a significantly shorter event-free survival than *de novo* AML. In general, secondary chromosomal aberrations as well as gene mutations are very frequent in AML with inv (16); 80–90% patients with inv (16) AML have at least one mutation involving *NRAS, KRAS, KIT*, or *FLT* [118–120]. In the German-Austrian AML Study Group (AMLSG) study, 12 patients out of 176 cases (7%) were considered to be therapy related and the secondary chromosomal abnormalities/mutations were not significantly different from *de novo* AML [120], suggesting that the additional mutation is not the reason for shorter event-free survival in t-AML patients after intensive chemotherapy.

In summary, t-AML with favorable cytogenetics shows similar response rate to their *de novo* counterpart when receiving a conventional AML treatment. However, compared to *de novo* counterparts, t-AML with favorable cytogenetics is associated with an inferior survival. This may relate to several factors such as the status of primary disease, toxicity from prior therapy, and additional genetic mutations. Considering that additional mutations in t-AML patients with favorable karyotypes may result in poor prognosis, comprehensive genetic tests may confer an appropriate decision making, especially in patients cured of the primary malignancy and who are good candidates for allogeneic HSCT.

Non-transplant Therapeutic Options for t-AML

Few retrospective studies have evaluated the efficacy of standard chemotherapy for t-AML. The German AML Cooperative Group analyzed outcomes after remission induction chemotherapy for 1511 *de novo* AML and 121 t-AML patients [121]. The study demonstrated that the survival of unfavorable and intermediate cytogenetic risk groups of t-AML was similar with the same risk groups of *de novo* AML (6 months vs. 7 months for unfavorable, 12 months vs. 16 months for intermediate-risk group, respectively). Another study, the German–Austrian AL Study Group assessed the clinical outcomes of 200 t-AML patients treated between 1993 and 2008 [3]. The survival of t-AML patients was compared with 2653 *de novo* AML patients. Although response rates to induction chemotherapy were similar, OS for t-AML patients was inferior to *de novo* AML patients.

In further analysis, patients less than 60 years old showed similar relapse rates, but their death in CR was greater, suggesting the higher toxicity of induction and post-remission therapy in this cohort. Patients older than 60 years had higher relapse rates, possibly due to lower intensity treatments, resulting in inferior survival. A retrospective study of 118 t-AML after treatment of breast cancer showed no significant difference in median OS compared with *de novo* AML (8.7 months vs. 10.2 months; $p = 0.17$) [122]. Multivariate analysis revealed cytogenetics, baseline white blood cell counts, age, and performance status as predictive factors for OS of t-AML patients.

In a prospective study of t-MDS/AML, 32 t-MDS/AML patients were treated with high-dose cytarabine and mitoxantrone induction followed by hematopoietic stem cell transplant [101]. A remarkable complete response rate of 66% was achieved. Thirteen patients who achieved CR were eventually treated with AlloHSCT for consolidation and the survival of the patients was 29% in 3 years. These studies show that patients with t-AML can achieve a comparable response with standard induction chemotherapy, and that cumulative toxicity/reserved function from prior therapy limit tolerance to induction and post-remission therapy.

T-AML patients have a higher risk of organ dysfunction due to chemotherapy and radiation-induced parenchymal and vascular toxicity, or primary malignancy. Even those with seemingly adequate organ reserves may have increased toxicity during t-AML therapy. Therefore, earlier diagnosis and treatment with less toxic therapy, while aggressively exploring transplant options, may be another critical factor in the trial of new therapeutics for t-AML. Emerging therapeutics in this area has focused on several approaches. These include novel delivery of chemotherapy as well as newer DNA-damaging agents delivered through antibody-drug conjugates, use of hypomethylating agents, and molecularly directed small molecules against specific mutations commonly occurring in t-AML.

CPX-351 is a liposomal formulation of daunorubicin and cytarabine at a fixed ratio of 5:1. The combination of these medications was developed based on in vitro data that demonstrated a synergistic effect of these two agents at the 5:1 ratio [123]. In a randomized phase II trial, CPX-351 was compared with standard daunorubicin/cytarabine in untreated patients older than the age of 60 years [124]. In a subset of secondary AML patients ($n = 52$), which included t-AML and AML evolving from myelodysplastic syndrome, patients treated with CPX-351 demonstrated a better OS (hazard ratio = 0.46, $p = 0.01$) at 24 months. Though the recovery from cytopenias was slower after CPX-351, the infection-related deaths (3.5% vs. 7.3%) or 60-day mortality (4.7% vs. 14.6%) was less than the conventional daunorubicin/cytarabine chemotherapy group. These data suggested a clinical benefit with CPX-351 in t-AML with better efficacy and tolerability.

A second approach to improving cytotoxic therapy for AML takes advantage of newer antibody-drug conjugate (ADC) technology. CD33 is a surface receptor found on more than 95% of AML cells except acute megakaryocytic leukemia. It has been a target for antibody-directed therapy. The treatment with a conjugated antibody targeting CD33 (gemtuzumab ozogamicin) as a single agent [125], and in combination with chemotherapy in untreated patients and those with relapsed AML, demonstrated clinical efficacy [126]. However, gemtuzumab ozogamicin failed to show the effectiveness in combination with standard daunorubicin/cytarabine regimen in high-risk AML patients [127]. A new ADC targeting CD33, SGN-CD33A, was developed using a novel antibody drug linkage system to a fully humanized anti-CD33 antibody. In contrast to gemtuzumab ozogamicin, SGN-CD33A exhibited a potent cytotoxicity against p53-mutated AML cells and leukemic cells with multidrug resistance-mediated drug efflux phenotypes in preclinical studies [128]. Therefore, careful clinical trials with this monoclonal antibody conjugate are appropriate for t-AML patients.

Since many cases of t-AML evolved from a preleukemic phase after being exposed to chemotherapeutics/radiation, hypomethylating agents have been evaluated as an alternative to traditional induction therapy [129]. Both azacitidine and decitabine are effective and well tolerated but the efficacy compared with cytotoxic chemotherapy is still under investigation. In a retrospective study conducted by Quintas-Cardama et al., 671 AML patients, older than 65 years, were treated with a hypomethylating agent and had a similar median survival rates with cytotoxic chemotherapy (6.5 months with hypomethylating agent and 6.7 months with chemotherapy, respectively) [130]. Moreover, a similar CR rate was observed in the subset of poor-risk cytogenetics patients carrying −5 and/or −7 (26% with hypomethylating agent vs. 28% with chemotherapy). Another retrospective study of 48 t-MDS/AML patients treated with hypomethylating agent showed 42% overall response rate including a complete response rate of 21% in a subset of patients with favorable cytogenetics, which is comparable with prospective hypomethylating agent studies for t-MDS group [131]. A phase 2 clinical trial, E1905 North American Leukemia Intergroup, studied 47 patients including 18 t-AML patients. A good response to azacitidine occurred with 46% complete hematologic response and 13 months of median OS [132]. Multivariate analyses comparing the t-MN patient with *de novo* MDS/AML patients treated with the same protocol showed no significant difference in complete hematologic response rate, and overall response rate between the two groups. However, another study of 54 t-MN patients (including 12 t-AML patients) treated with azacitidine demonstrated shorter 2-year OS (14%) compared with *de novo* MDS/AML patients (33.9%), though multivariate analysis showed that the survival was dependent on cytogenetic changes, not etiology of the AML [133].

Hypomethylating agents are frequently prescribed as an alternative to traditional AML induction chemotherapy for frail patients. They can support *de novo* and t-MDS/AML patients in order to receive a transplantation with less toxicity, and may be a safer option for low-blast-count t-AML. Response rates were equivalent to standard AML induction therapy in this population [131, 134], enhancing the likelihood of successful transplantations. A new hypomethylating agent, SGI-110, a metabolite of decitabine, is in clinical trials for treatment of MDS and AML [135].

An additional epigenetic modulator is the class of histone deacetylation (HDAC) inhibitors. They are often included in a combination regimen with a hypomethylating agent for MDS and AML patients. Valproic acid, vorinostat, pracinostat, and mocetinostat are the HDAC inhibitors being used in clinical trials in combination with hypomethylating agents [136–139].

P53 mutations and *MLL* rearrangements often occur in t-AML [140, 141]. Two agents targeting these mutations are in the drug pipeline. EPZ-5676 is a potent inhibitor of Dot1L, a histone methyl transferase which interacts with MLL oncogenic fusion protein products. In cell lines and in rat xenograft studies, EPZ-5676 significantly caused cell death and regression of MLL-rearranged leukemias [142]. It is currently in clinical trial in pediatric leukemias with MLL translocations.

Volasertib is an inhibitor of polo-like kinase (PLK). Preclinical studies demonstrated that p53-mutated cancer cells were more susceptible to PLK inhibition than p53 wild-type cancer cells [143]. In a randomized phase 2 study in untreated elderly patients with AML, volasertib, in combination with low-dose cytarabine, demonstrated a higher remission rate and improved survival compared with cytarabine alone, although median survival rates were still <1 year [144].

Hematopoietic Stem Cell Transplant for t-AML

Treatment of t-AML with conventional therapy is associated with a poor outcome. Response rate for t-AML induction therapy appears to be roughly equivalent to *de novo* AML when compared within their respective intermediate- and unfavorable-risk cytogenetic categories, but the responses on average are less durable, thereby justifying the use of transplantation in these patients.

A retrospective study of 545 t-AML patients transplanted between 1990 and 2004 found an OS of 22% at 5 years [145]. Inferior outcomes were associated with age greater than 35 years, poor-risk cytogenetics, uncontrolled disease, and use of a non-sibling-related or mismatched unrelated donor. Use of reduced-intensity chemotherapy (RIC) regimens did not decrease treatment-related mortality (TRM), which approached 50% at 5 years, but many of these patients had received a prior autologous transplant.

The European Group for Blood and Marrow Transplantation Group also reported on 461 t-MDS/AML patients, and noted an adverse impact of abnormal cytogenetics, age greater than 40 years, and uncontrolled disease [146]. Three-year relapse-free survival and OS rates were 33% and 35%, respectively. In contrast, a study of 24 breast cancer t-MN patients who underwent allogeneic stem cell transplantation for consolidation had nearly identical clinical results as female *de novo* MDS/AML patients regardless of cytogenetics [147]. In general, these studies show that transplantation can be used successfully in a fraction of t-AML patients, but it is clearly less effective than when used for *de novo* AML patients. A busulfan/cyclophosphamide conditioning regimen appears to offer one of the best 5-year relapse-free survival (43%) and lowest non-relapse mortality (28%). Relapse rates are lower with unrelated donor transplants [145, 146, 148]. After accounting for cytogenetic classification, t-AML patients have a similar outcome as *de novo* AML [149].

The Italian Network reported survival for transplant recipients of 58.8 months compared with 12.1 months for the non-transplant cohort [150]. A similar benefit was seen when the German Hodgkin Study Group reported clinical outcomes of 106 patients with t-MN after therapy for Hodgkin's lymphoma. Although the non-transplant median survival was dismal (7.2 months), the median survival for the transplanted t-MN had not been reached after a median follow-up of 41 months [151]. The survival of the patients after hematopoietic stem cell transplant at 2 years was 47% vs. 15% for the non-transplant group ($p = 0.03$). Although alloHSCT can provide a chance of long-term survival and cure in selected subgroups of patients with t-AML, major limitations of alloHSCT are availability of a donor and patients' age. Alternative treatment strategies including haploidentical donor alloHSCT or nonmyeloablative HSCT, especially for older patients, should be explored for t-AML patients.

Conclusion

Therapy-related AML (t-AML) is a recognizable subgroup of AML. Alkylating agents used in primary diseases are the most frequent etiology of t-AML. The disease arises from a series of mutations in hematopoietic stem cells, and these DNA changes provide a growth advantage to the progeny of the transformed cells. The abnormal clone of cells usually has a hypodiploid modal number of chromosomes and a deletion of part or all of chromosome 5 and/or 7. T-AML remains one of the most difficult subtypes of AML to treat. Once a patient who was treated with cytotoxic agents develops cytopenias, hematopoietic cell morphologic examination, immunophenotying, and cytogenetics should be done to detect t-AML in its early phase. The patients with t-AML have more comorbidities, decreased organ reserve, and a higher incidence of unfavorable cytogenetic phenotype than

de novo AML. The key prognostic factors in t-AML are patient age, performance status, and karyotype. As *de novo* AML, t-AML patients can be stratified based on genetics. The performance status is the first determinant for establishing a treatment plan. Supportive care at initial diagnosis would be appropriate for patients with a poor performance status (ECOG PS >2). All medically fit patients should have HLA typing at initial diagnosis. The conventional cytotoxic chemotherapy or hypomethylating agents are being used as an initial therapy. For patients in complete remission, allogeneic transplantation is the best therapeutic modality for long-term survival for the younger patients. Emerging therapeutics for AML has focused on reduced toxicity, higher efficacy, and specificity. These include novel delivery of chemotherapy in liposome as well as newer DNA-damaging agents delivered through antibody-drug conjugates, use of hypomethylating agents, and molecularly directed small molecules against specific mutations commonly occurring in t-AML.

The Myelodysplastic Syndromes

23

Kenneth Miller and Monika Pilichowska

Introduction

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal stem cell disorders characterized by impaired, and/or ineffective, proliferation and maturation of hematopoietic progenitor cells resulting in symptomatic anemia, leukopenia, or thrombocytopenia. The clinical course is very variable, ranging from a chronic, stable, mildly symptomatic disorder to a malignancy that rapidly progresses to AML. Morphological and functional cellular abnormalities involving one or more cell lines are common resulting in infections and/or bleeding. The complications from MDS and its treatment remain the major cause of morbidity and mortality. MDS shares many clinical, cytogenetic, and laboratory features with aplastic anemia, hypoplastic anemias, the myeloproliferative neoplasms, and the acute leukemias. The updated WHO classification attempts to define the diagnosis of MDS and separate it from the myeloproliferative neoplasms, reactive and secondary causes of hypoproliferative disorders and the acute leukemias. Patients with MDS may present with clinical and laboratory features suggestive of a reactive, autoimmune or other malignant stem cell disorder. Therefore, in many instances, the diagnosis of MDS is based on the exclusion of other disorders associated with dysplasia and impaired or ineffective hematopoiesis.

MDS is a progressive clonal disorder and the diagnostic studies and the initial evaluations are similar to those used to define other neoplastic and non-neoplastic stem cell disorders. However, the clinical course, prognosis, and treatment approach for a patient with a MDS is different from the other neoplastic stem cell disorders. The bone marrow and peripheral blood abnormalities in MDS can be subtle and require the cooperative efforts of pathologists, cytogeneticists, and clinicians to diagnosis, classify and define prognosis. MDS is one of most common hematologic malignancies in older populations and treatments remain controversial and limited for many patients. Treatments for many patients should be individualized and tailored to the MDS subtype, patient's age, comorbidities, and other prognostic variables.

Myelodysplasia, derived from the Greek and meaning morphological abnormality of the bone marrow, is not a new disease but it has only recently been assigned as a separate category in the classification of malignant hematopoietic disorders based on specific diagnostic criteria. The initial reports identified elderly patients with progressive cytopenias, morphologically abnormal cells, and a propensity to progress to an acute leukemia. Terms such as smoldering leukemia, or preleukemia were used to describe this condition, reflecting that patients with MDS did not meet the usual criteria of acute leukemia but presented with a syndrome which included a hypercellular bone marrow with increased blast forms and dysplastic changes in one or more cell lines. In MDS, as in the myeloproliferative neoplasms and acute leukemias an oncogenic transforming event occurs at the level of the myeloid or pluripotential stem cell. Cytogenetic studies were first to identify the genetic alterations in MDS and are important in establishing the diagnosis and prognosis in MDS. More recently numerous specific gene mutations have been identified in MDS associated genes that may define prognosis and impact treatment. While many patients with MDS have features suggestive of an early, smoldering leukemia, and rapidly evolve into one of the myeloid leukemias, most patients do not evolve into AML but die as a result of the MDS or its treatment [1, 2]. MDS therefore should not be considered as a preleukemic disorder, but as a separate neoplastic disease of the hematopoietic pluripotential stem cells that is characterized by a progressive clonal proliferation of abnormal precursors that demonstrate both impaired maturation and ineffective proliferation. The separation of MDS from AML, myeloproliferative neoplasms,

aplastic anemia, and reactive disorders continues to be problematic, which is reflected in the evolving and at times inconsistent classification systems, prognostic models, and treatment options. A proposed revised 2016 WHO classification refines the morphologic interpretation and assessment of cytopenias addresses, and applies new diagnostic terminology for MDS. The WHO classification still relies mainly on the degree of dysplasia and the percent of blasts for disease classification and specific cytopenias now have only a minor impact on the MDS classification [3, 4]. Moreover the morphologic dysplasia may not correlate with the lineage specific cytopenias. Therefore the WHO has removed terms such a refractory anemia or refractory cytopenia and replaced it with the suffix Myelodysplastic Syndrome followed by the specific abnormality. The WHO also attempted to define and incorporate identified gene mutations associated with MDS and address the controversy and limitations of incorporating distinct mutations in the new proposed classification criteria. The WHO noted that that identification of dysplasia is subjective and may vary even among experienced hematopathologists [3]. Therefore when the dysplasia is subtle or limited to a single lineage it is important to consider other possible reactive and non-neoplastic causes of the dysplasia prior to making the diagnosis of MDS.

Pathogenesis and Etiology

MDS is one of the most common hematologic malignancies in western countries with an overall incidence of 3.5–12.6/100,000/year. The median age of MDS patients in western countries is 73 years, at the time of diagnosis, and the incidence increases with age. In individuals over the age of 70 years the incidence is between 15–50/100,000/year and is increasing with the aging population [5, 6]. However, the overall incidence of MDS is likely much higher due to difficulties in reporting, diagnosis, and classification [4]. The incidence of MDS is higher in men than women with the exception of the del (5q), which has a marked female predominance. In Asian countries, notably Japan and China, the median age of patients with MDS is between 40–50 years, some two decades earlier than in western countries [5, 7, 8]. The reason for the differences in the epidemiology of MDS in Japan and China is unclear but may, in part, reflect the variability and limitations of population-based databases. However, the role of environmental factors, industrial solvents and agricultural chemicals, and smoking may contribute to the observed 20-year differences in the epidemiology of MDS [9, 10].

Environmental agents have been implicated in the etiology of MDS. In case-controlled studies, there is an association between MDS and cigarette smoking, exposure to benzene, petroleum products, organic solvents, fertilizers, pesticides, and herbicides [10]. The associated between smoking and MDS may reflect that cigarette smoke contains benzene and other suspected carcinogens [9]. The MDS risk is related to the intensity and duration of smoking and may persist for up to 15 years after cessation of smoking [9, 10]. Ionizing radiation exposure is associated with a significant increase risk for the development of MDS. In the Nagasaki atomic bomb survivors risk for developing MDS was greater in individuals exposed at a younger age and occurred 40–60 years after exposure. In contrast to the reported radiation induced leukemia in Nagasaki which occurred 10–15 years after the exposure. The long latency may reflect the proposed multistep pathogenesis model for the development of MDS with age related changes and genetic instability associated with the prior radiation exposure [11]. In epidemiologic studies there was a linear radiation dose response for the development of MDS in Nagasaki atomic bomb survivors 40–60 years after exposure.

MDS is characterized by dysplastic, ineffective hematopoiesis. The bone marrow is typically hypercellular for the patient's age with peripheral cytopenias and an increase in hematopoietic precursors in the bone marrow and/or peripheral blood. The clonal origin of MDS has been confirmed by isozyme analysis of glucose 6 phosphate dehydrogenase (G6PD) in heterozygous females and more recently by molecular analysis of other loci such as the androgen receptor gene [8, 12]. Cytogenetic analysis has demonstrated recurrent genetic alterations that are prognostically important and next generation high throughput gene sequencing has defined a number of mutated genes in MDS [12] (Table 23.1). The appearance of clonal gene mutations arise

Data from Ref. [23]

in hematopoietic stem cells and appear to be early events that are associated with clonal dominance. Specific gene mutations and the cytogenetic abnormalities can be demonstrated before the detections of morphological dysplasia or the clinical findings of MDS [13, 14]. The initial cytogenetic and somatic gene mutations are part of a multistep process that predisposes the pluripotential stem cell to secondary genetic events and the development of MDS [14]. Epigenetic alterations in one or more oncogenes including in the aberrant expression of specific tumor promotor, tumor suppressor, and transcription factor genes are associated with the progression of MDS [15, 16]. The diagnostic and prognostic role of specific gene mutations and aberrant methylation of epigenetic regulators, however, is still unclear. MDS progression is characterized by a progressive increase in chromosomal instability that leads to the development of aberrant clones and the emergence of complex karyotypes. Telomeres, noncoding repeated sequences at the ends of chromosomes, that function to stabilize chromosomes and prevent chromosomal breaks and aberrations critical in the maintaining normal hematopoiesis and are postulated to play a role in the progressive chromosomal instability in MDS [17]. Each somatic cell division is associated with loss of telomere length and the cumulative effects of telomere shortening leads to cell senescence. The shortening of telomeres is noted in patients with progressive, advanced MDS, with multiple complex karyotypic abnormalities. The genetic instability associated with shortening of telomeres may contribute, in part, to the leukemic transformation in some patients with MDS [17, 18]. Moreover, the alteration of telomere dynamics in hematopoietic stem cells may precede the clinical development of MDS [19]. However, the majority of patients that develop MDS are greater than 70 years old and loss of telomere length and function is part of the normal aging process [19].

The hematopoietic microenvironment may also play a role in the pathophysiology of MDS [20]. MDS is characterized by ineffective hematopoiesis and the increased susceptibility of hematopoietic progenitors to apoptosis. The bone marrow stroma responds to signals from the hematopoietic cells and is abnormal in some patients with MDS. Abnormalities of the bone marrow microenvironment and the hematopoietic stem cell niche may affect and promote apoptosis and telomere shortening in clonal hematopoietic cells [21]. The overexpression of TNF-a produced by MDS mononuclear cells can inhibit the growth of residual normal hematopoiesis and lead to increased cell death of normal precursors, and a growth advantage for the abnormal MDS precursors. The bone marrow in MDS patients has increased apoptotic cells which is most marked in the less proliferative, better prognosis, low risk subtypes of MDS.

Genetic, environmental, and exposure factors have been associated with an increased risk for the development of MDS [22]. Inherited constitutional genetic defects have been associated with up to 30% of children with MDS and related myeloproliferative disorders. Children with Shwachman–Diamond syndrome, Fanconi anemia, dyskeratosis congenitał, and neurofibromatosis type 1 have constitutional genetic defects that are associated with the increased risk for the development of both MDS and AML [25, 26].

Mutations of specific genes mediating DNA repair appear to predispose to the acquisition of secondary cytogenetic abnormalities that can lead to the development of MDS [23]. Somatic mutations occur in the majority of patients and may be associated with specific clinical features. Specific point mutations were associated with the clinical phenotype, specific cytopenias, disease progression, and overall survival. Genes encoding runt-related transcription factor 1 (RUNX1), tumor protein p53 (TP53), and neuroblastoma RAS viral oncogene homologue (NRAS) are associated with thrombocytopenia and an increased percent of bone marrow blast forms [23, 24]. Point mutations resulting in the activation of the specific genes (TP53, EZH2, ETV6, RUNX1, and ASXL1) are independent markers of poor prognosis and may, in part, explain the clinical heterogeneity of MDS. The TET family of genes maps to chromosome 4q24 and modulate hypomethylation by catalyzing an intermediate of DNA methylation that block the formation of silencing proteins to methylated DNA [13]. Mutations of the TET2 gene are found in a number of myeloid neoplasms including AML, MPNs, and MDS. In MDS TET2 mutation is the most frequent gene mutation occurring 20–30% of patients. Mutations of TET2 associated with loss of function may result in increased methylation and silencing of genes that are normally expressed. However, the prognostic impact of TET2 mutations on survival in MDS is unclear. The TET2 mutation is associated with a number of additional gene mutations and therefore may be one of the initial mutational events MDS. Recurrent mutations of epigenetic regulators, genes encoding the splicing machinery, spliceosomal components, and transcription factors are not unique to MDS and are found in a number of other myeloid neoplasms and occur across a spectrum of cytogenetic subgroups. It is controversial if these gene mutations are the primary events in MDS and are diagnostic and prognostic markers that are independent of other abnormalities [23, 24]. The frequency of the recurrent somatic mutations in MDS patients increases with progression of the disease and the subsequent development of secondary cytogenetic events and AML [25]. However, the etiological role of each of the somatic point mutations in the development of and progression of MDS is controversial and it is unclear if these mutations just reflect the genetic instability of the abnormal clone and its propensity to develop random genetic mutations [26, 27]. Moreover, similar somatic mutations have been noted in older normal individuals without evidence of MDS [27–29]. Somatic mutations resulting in clonal

hematopoietic cells are detected in greater than 10% of persons older than 70 years of age and the incidence of somatic mutations increases with age. These MDS associated acquired clonal mutations occur in hematopoietic cells of healthy older persons with normal blood counts and without evidence of dysplasia [29]. The presence of somatic mutations may confer an increased risk in the individual for the subsequent development of a hematological malignancy and are associated with an all cause-increased mortality [30–32]. The term "Clonal Hematopoiesis of Indeterminate Potential "(CHIP) is used describe these acquired clonal somatic mutations which are associated with hematologic malignancies in apparently healthy older individuals without any clinical features of a MDS or any myeloid malignancy. The natural history of individuals with CHIP is unclear and these persons should not be considered to have a malignancy. The revised 2016 WHO classifications addresses the controversy associated with somatic mutations and notes that the presence clonal somatic mutation alone, without other clinical manifestations of MDS, is not sufficient to make the diagnosis of MDS. While CHIP may represent a pre - malignant myeloid conditions, similar to monoclonal gammopathy of undetermined significance (MGUS) and multiple myeloma, the natural history of individuals with CHIP is not clearly defined. Testing for somatic mutations in healthy individuals should not part of routine clinical practice.

MDS patients have defects in a number of signal transduction pathways that appear to be related to the evolving ineffective hematopoiesis and epigenetic changes [33, 34]. These acquired abnormalities may contribute to the further dysregulation of progenitor cell cycle kinetics, response to cytokines, and the maintenance of DNA integrity, which results in progressive genetic instability. Abnormal regulation of microRNAs (miRNA) which function as epigenetic regulators of gene expression may play a role in the pathogenesis of MDS and alterations in miRNAs may be independent markers of prognosis [24].

MDS is associated with a number of immunoregulatory abnormalities including the development of autoantibodies and monoclonal gammopathies [35]. In subsets of patients with MDS, autoreactive T-cell clones are present that inhibit autologous erythroid and granulocytic colony growth. T-cell-mediated suppression of bone marrow growth and maturation is an important development of aplastic anemia and the hypoplastic variant of MDS [35, 36]. The incidence of MDS is increased in patients with autoimmune disorders and autoimmune disorders are more common in patients with MDS. The presence of autoimmune disorders is associated with a better overall survival and less frequent transformation to AML, The immunoregulatory abnormalities may also explain the response to immunosuppressive therapy in selected patients with MDS.

There are defined genetic predisposing factors in some MDS patients that relate to naturally occurring complex DNA polymorphisms in genes that mediate DNA repair and the metabolism of environmental carcinogens [37, 38]. In selected genetically predisposed individuals, MDS may arise as a result of cumulative environmental exposures and studies have linked the development of MDS and the nonfunction 609 C.T polymorphic allele of the NAD(P)Quinone oxidoreductase (NQO1) gene [40, 41]. These genes appear to play a critical role in detoxifying benzene and its metabolites. This association is controversial, but may explain the increased incidence of MDS in some patients exposed to organic solvents and benzene-containing compounds [39]. Similar controversial, but provocative results have been reported in the glutathione S-transferase (GST) genes that mediate the metabolism of cytotoxic and genotoxic agents [40].

A prior exposure to chemotherapy, especially alkylating agents and purine analogues is associated with an increased risk of MDS and AML (Table 23.2). The WHO identifies therapy-related MDS (t-MDS) as a separate category. Therapy related MDS represents approximately 10–20% of MDSs and MDS/MPNs [41]. The risk is, in part, related to the dose and duration of the cytotoxic therapy and generally occurs 3–7 years after the exposure. Patients who received combination radiation therapy and chemotherapy are at greater risk for the development of t-MDS [42]. Total body irradiation, administered as part of the preparative regimen for an autologous stem cell transplantation, is associated with an increased risk for MDS, and the combination of

high-dose alkylator therapy and total body irradiation was associated with a 10–15% risk of t-MDS and secondary AML [41]. The MDS that occurs after chemotherapy, has a very poor prognosis [42]. Therapy-related MDS, is associated with deletions of chromosomes 5 and/or 7 and complex karyotypes. In contrast to the cytogenetic findings in AML, balanced cytogenetic abnormalities including translocations and inversions are rare in MDS. The cytogenetic abnormalities in MDS are important independent prognostic risk factors for overall survival and risk of the development of AML (Table 23.3). However, in the majority of patients with MDS there is no history of exposure to known mutagens, cytotoxic agents, or environmental agents and therefore the etiology of the syndrome remains idiopathic or unknown.

Diagnosis and Classification

The diagnosis and classification of MDS, similar to other myeloid malignancies, is evolving and incorporates new cytogenetic and molecular findings. The updated 2016 WHO classification attempts to addresses the heterogeneity of MDS and separates MDS from reactive processes and other malignant stem cell disorders. The revised classification refines the morphologic interpretations and addresses the influence of new genetic information in MDS diagnosis, classification and prognosis. The FAB (French–American–British) group was the first to define morphological criteria in the blood and bone marrow for the diagnosis and classification of MDS and was based only on morphology, and the percentage of blast forms in the blood and bone marrow. This classification system, although generally adopted at the time, was clinically and biologically inconsistent [43]. The separation of MDS from AML and other clonal disorders was based on an arbitrary number of blast forms. Moreover, many patients with MDS had clinical and laboratory features of AML, aplastic anemia, and myeloproliferative neoplasms which were not addressed in the FAB classification [44]. The FAB criteria also did not address the clinically important cytogenetic changes in MDS and were too variable to accurately predict prognosis, survival, or transformation to AML. The FAB classification remained as a widely accepted classification system for diagnosis of MDS for two decades. The FAB group defined five categories, of MDS based on morphologic dysplasia, cytochemical stains for iron to detect ring sideroblasts, and the percent of blast forms in the bone marrow and peripheral blood and included refractory anemia (RA), or refractory cytopenia, refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), chronic myelomonocytic leukemia (CMML), and refractory anemia with excess blasts in transformation (RAEB-T). The World Health Organization (WHO), in collaboration with the Society for Hematopathology and the European Association of Hematopathology in 2001, proposed a revision of the FAB morphological approach to the classification of MDS [45]. The WHO classification was updated in 2008 and most recently in 2016 [3, 46] (Table 23.4). The revised WHO classification attempts to combine clinical, morphologic, immunophenotypic, genetic and molecular features to define clinically and prognostically important subtypes. The current WHO classification is generally accepted and is incorporated in prognostic and treatment models of MDS.

Table 23.4 WHO 2008 and WHO 2016 classification of myelodysplastic syndromes

WHO 2008	Peripheral blood key features	WHO 2016 bone marrow key features
Refractory cytopenia with With unilineage dysplasia Dysplasia (RCUD) RA anemia (RA) Refractory neutropenia (RN) Refractory thrombocytopenia (RT)	<1% blasts	MDS with single lineage dysplasia (MDS-SLD)
Refractory anemia with ring sideroblasts (RARS)	Anemia no blasts	MDS with single lineage dysplasia and ring sideroblasts(MDS-RSSLD)
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s) <1% blasts No Auer rods	MDS with multilineage dysplasia and ring sideroblast(MDS-RSMLD)
Refractory anemia with excess blasts type 1 RAEB-1(RAEB1)	Cytopenia(s) <5% blasts No Auer rods	MDS with excess blasts-1(MDS-EB1)
Refractory anemia with excess blasts type 2 RAEB-2 (RAEB2)	Cytopenia(s) 5–19% blasts ± Auer rods	MDS with excess blasts-2(MDS-EB2)
MDS associated with isolated del(5q)	Anemia normal or high platelet count	MDS with isolated del(5q)
MDS, unclassifiable MDS-U	Cytopenias ≤ 1% blasts If no dysplasia, MDS-associated karyotype	MDS-U

The WHO classification included requirements for the type of specimens to be obtained, the assessment of blasts, assessment of blast lineage, and cytogenetic or mutational studies. The assessment of blasts in the peripheral blood (PB) and bone marrow (BM) should be obtained prior to any definitive therapy. Cytogenetic analysis and flow cytometry should be obtained, with additional material saved for later molecular genetic studies as needed [12]. The WHO lowered the threshold for percent of blasts to diagnose AML from 30% (FAB) to 20%. The percent of blasts should be derived from a 200-cell differential count of the peripheral blood smear and a 500-cell differential count of all nucleated bone marrow cells. The 2016 revised WHO classification changed the diagnostic criteria for myeloid neoplasms with erythroid dominance, defined as erythroid precursors ≥50% of all bone marrow cells. In the new classification the percent of blasts is based not on non-erythroid nucleated cells but on all nucleated bone marrow cells. This new criteria will result in cases previously diagnosed as the erythroid/myeloid subtype of acute erythroid leukemia to now being classified as MDS with excess blasts.

The FAB and the subsequent WHO classifications defined MDS as a clonal stem cell disorder characterized by ineffective, dysplastic hematopoiesis, with dysplasia in one or more hematopoietic cell lines and the dysplasia should be noted in >10% of cells in either the bone marrow or the blood. The WHO noted that morphological dysplasia is not specific or diagnostic of MDS and noted the difficulty in separating MDS from other disorders associated with cytopenias and dysplasia. The 2016 WHO classification recognized that dysplasia in excess of 10% may occur in some normal individuals and in other non-malignant hematologic disorders. The hematopathologist's identification of dysplasia is also variable and not always reproducible even by expert panels [47]. The WHO classifications like the original FAB classification is based on the degree of dysplasia and percent of blast forms in the blood and bone marrow. The WHO classification noted that the cell line demonstrating the most prominent dysplasia may not correlate with the cytopenia of the most affected lineage. The 2016 WHO classification therefore changed the descriptive terms such as refractory anemia and applied the new terminology Myelodysplastic syndrome followed by the "appropriate modifiers"; single or multilineage dysplasia, ring sideroblast, excess blast or the del(5q) cytogenetic abnormality (Table 23.4). There are, however, some of he morphological abnormalities that are more characteristic of MDS and are useful in confirming the diagnosis. The neutrophil and megakaryocytic dysplastic changes are the most specific and characteristic of MDS [3, 46, 48]. In the myeloid/neutrophilic dysmyelopoiesis the presence in the peripheral blood of the acquired, pseudo, Pelger–Huët anomaly is a frequent and useful characteristic finding in the MDS. This acquired abnormality resembles the inherited Pelger–Huët anomaly, therefore the designation of pseudo, and is characterized by mature neutrophils that are hypolobated with a single lobe or two joined by a thin band of chromatin [49]. Abnormal granulopoiesis is usually evident on the peripheral smear and includes hypersegmented neutrophils, with decreased or absent cytoplasmic granules The presence of dysmegakaryopoiesis including the presence of micromegakaryocytes in the bone marrow is also very suggestive of MDS rather than a reactive process [3, 45]. The finding of micromegakaryocytes and megakaryocytes that are the size of a myeloblast with one or two abnormal small nuclei in the bone marrow is one of the most characteristic, diagnostic and recognizable morphological features in MDS.

A majority of patients with MDS are asymptomatic at presentation and are usually diagnosed when they present with an unexplained macrocytic anemia (MCV > 102) with a absolute low reticulocyte count. Anemia is the most common presenting abnormality and patients may complain of the insidious onset fatigue and progressive dyspnea on exertion. Bone pain and weight loss are uncommon. While patients may be neutropenic and have dysplastic and impaired neutrophil function, infections are unusual at presentation. The physical examination is notable for the lack of adenopathy, cutaneous lesions, prominent splenomegaly, or hepatomegaly. The diagnosis of MDS relies largely on the morphological findings in the peripheral blood and the bone marrow (Table 23.5). MDS must be differentiated from other disorders that present with abnormalities of one or more cell line including aplastic anemia, myeloproliferative neoplasms, nutritional deficiencies, and autoimmune disorders (Table 23.6). AML in elderly patients may also present with progressive pancytopenia with rare circulating blast forms [56]. The differentiation of AML with dysplasia from MDS can be difficult. Patients with acute erythroleukemia may have prominent dysplastic erythroid precursors and may initially be diagnosed with one of the MDSs. Patients with hypoplastic AML can also be confused with one of the MDS subtypes. In prospective trials of MDS up to 15% of the patients with hypoplastic MDS were later reclassified as having AML [48, 50].

The finding of a clonal cytogenetic abnormality characteristic of MDS is important in establishing the diagnosis, assessing prognosis and differentiating it from other disorders [3]. The WHO defined specific cytogenetic abnormalities, even in the absence of diagnostic morphologic dysplasia, that where sufficient to make a diagnosis of MDS (Table 23.6). In these cases the cytogenetic abnormality must be demonstrated by conventional karyotyping and not by in fluorescence in situ hybridization (FISH) or sequencing technologies. FISH analysis has facilitated an accurate cytogenetic diagnostics and compliments karyotyping. FISH can be performed on the non-dividing cells and therefore can be performed on PB cells. FISH studies may be helpful in identifying specific rearrangements not recognized by banding studies alone. FISH also provides a convenient and sensitive method for monitoring patients with a specific cytogenetic abnormality. The WHO also defined some common MDS associated cytogenetic abnormalities as not sufficiently specific to diagnosis MDS in the absence of diagnostic morphologic findings. The presence of cytogenetic abnormalities +8, −Y, and del (20q) while frequently observed in patients with MDS was noted not to be diagnostic of MDS. In the updated 2016 WHO classification del(5q) remains the only cytogenetic or molecular genetic abnormality that defines a specific MDS subtype.

The patient's clinical findings and history are helpful in guiding the pathological evaluation. An analysis of the bone marrow is essential for the diagnosis of MDS. The bone marrow is typically hypercellular for the patient's age, confirming the ineffective hematopoiesis, and shows dysplastic features in one or several cell lines. A number of other disorders can present with finding similar to MDS (Table 23.7). A history of the patient receiving chemotherapy and or radiotherapy is important. Questions about environmental and occupational exposures should be noted, including the

Table 23.5 Morphologic features of dysplasia

Lineage	Peripheral blood	Bone marrow
Erythroid	Macrocytosis	Megaloblastic changes
	Elliptocytes	Nuclear budding
	Acanthocytes	Ringed sideroblasts
	Stomatocytes	Nuclear fragments
	Teardrops	Cytoplasmic vacuolization
	Basophilic stippling	Multinucleation
	Acquired thalassemia	
Myeloid	Pseudo-Pelger-Huet anomaly	Abnormal maturation
	Auer rods Blasts	Increase in monocytoid forms
	Hypogranulation	Abnormal localization of immature precursor (AILP)
	Hypersegmentation	
	Ring shaped nuclei-circle	Hypogranulation
	Cell blasts forms	Increased blasts
Megakaryocyte	Giant platelets,Megakaryocte fragments	Micromegakaryocyte
	Hypogranular or agranular	Hypogranulation
	Platelets	Multiple small nuclei
	Thrombocytopenia	Nuclear hypolobation
	Thrombocytosis	

Table 23.6 Recurring chromosomal abnormalities considered presumptive evidence of MDS in the absence of definitive morphological features

Abnormality	WHO-estimated frequency in MDS (%)
Unbalanced	
−7 or del(7q)	10
−5 or del(5q)	10
i(17q)or t(17p)	3–5
−13 or del(13q)	3
Del(11q)	3
Del(12q) or t(12q)	3
Del(9q)	1–2
idic(x)(q13)	1–2
Balanced	
t(11;16)	3 in t-MDS
t(3;21)	2 in t-MDS
t(1;3)	<1
t(2;11)(p21;q23)	<1
Inv(3)	
t(6;9)(p23;q34)	<1

Comments: Although +8, del(20q), and –y are common chromosomal abnormalities. In MDS, the presence of one of these three abnormalities as the sole cytogenetic abnormality in cases where morphological criteria for MDS are not met is not considered to be enough for presumptive diagnosis. t-MDS-Therapy related MDS [3]

Table 23.7 Differential diagnosis of myelodysplastic syndromes

Disorder	Comments
Congenital dyserythropoietic anemia	Inherited disorder characterized by marked dyspoiesis of mature and immature erythroid elements. Granulocytes and megakaryocytes unremarkable. Unstable hemoglobins normal karyotype.
Aplastic anemia	Both congenital (Fanconi) and acquired aplastic must be distinguished from hypocellular myelodysplasia. Karyotype normal in acquired aplastic anemia, rare cases with clonal abnormalities may actually represent hypocellular myelodysplasia. Severe malnutrition.
Hypocellular neoplasms	Hypocellular MDS must be distinguished from hypocellular AML. MDS with fibrosis may resemble primary myelofibrosis.
Megaloblastic anemia	Dyspoiesis restricted to megaloblastic changes. Normal karyotype. Use of antimetabolites need to confirm normal B_{12} level. Antimetabolites, chemotherapy.
Toxic exposure	Arsenic poisoning, alcohol, chemotherapy bone marrow cellularity normal; blasts are not increased. Normal karyotype; normal vitamin B_{12} and folate levels. Neurologic and gastrointestinal manifestations may dominate clinical picture.
Disorders with ringed sideroblasts	Chemotherapy, copper deficiency, hereditary sideroblastic anemia. Pyridoxine deficiency, zinc toxicity, alcohol toxicity, and in patients receiving Antituberculosis agents, chloramphenicol. Heavy metals.
Fibrotic disorders	Acute megakaryoblastic leukemia. Metastatic carcinoma with marked fibrosis, hairy cell leukemia, and primary myelofibrosis.
Viruses	Single, double or trilineage dyspoiesis common. HIV-1. Parvovirus. Karyotype normal
Autoimmune disorders	Myelodysplasia-like picture with dyspoiesis may be found in patients with underlying immune defects. May precede evolution to red cell aplasia. SLE, rheumatoid arthritis.
Paraneoplastic syndromes	Myelodysplasia-like picture (usually resembling chronic myelomonocytic leukemia). Occasionally noted at diagnosis in patients with solid tumors (lung, colon, prostate, and gastric carcinoma and lymphomas). Distinct from therapy-induced bone marrow neoplasms in carcinoma patients.
Bone marrow regeneration	Abnormal localization of immature precursors, dyspoiesis and increased immature myeloid cells may be transient phenomena after aggressive therapy. Increased blasts from recovering bone marrow after cytoxic chemotherapy, drug toxicity or bone marrow transplantation. Karyotype normal.
Colony-stimulation factor therapy	Transient increase in blasts in blood and bone marrow. Clusters of blasts on core biopsy. Hypolobated neutrophils and toxic granule in neutrophils may be seen.
Drugs	After purine analog therapy, Zidovudine and other antivirals Dilantin, methotrexate, valproic acid, sulfasalazine, mycophenolate, etc.

patient's smoking history. An occupation history is important because excess cases of MDS have been reported in agriculcultural and industrial workers.

Clonal cytogenetic abnormalities are found in 38–78% of patients with de novo MDS and greater than 80% of t-MDS patients [50]. Cytogenetics are critical in evaluating disease progression and prognosis. All of the currently used prognostic scoring system acknowledge the importance of specific cytogenetics abnormalities to define prognosis and plan therapy. In addition, the acquisition of new cytogenetic abnormalities is generally associated with progression of the disease and a poor prognosis. Although anemia is the most common presenting laboratory feature in patients with MDS, approximately 50% of patients will demonstrate an abnormality of more than one cell line [51]. The WHO thresholds

for defining cytopenias remain the same in the new 2016 classification: hemoglobin <10 g/dL, platelets <100 × 10^9/L and a absolute neutrophil count of <1.8 × 10^9/L. Patients may be at risk for bacterial infection generally due to qualitative abnormalities of neutrophil function and platelet functional abnormalities are associated with increased risk for bleeding even with an adequate platelet count. Iron studies may demonstrate increased iron stores even in patients who have not received red cell transfusions. The use of flow cytometry to determine the percent of blasts, assessment of CD34+ cells, is not recommended by WHO criteria as a substitute for the visual inspection of the bone marrow, unless the aspirate was of poor quality. The percent of CD34+ cells generally correlates with morphologic examination of routine bone marrow aspirate and peripheral blood smear; however, the WHO noted that not all leukemic blasts express CD34 and hemodilution and processing artifacts can yield misleading results. Multiparameter flow cytometry was recommended to determine the blast lineage and to determine aberrant antigen expression. However, it remains unclear if these changes are specific for the diagnosis of MDS as they occur in other myeloid neoplasms [51].

Immunophenotyping combined with cytogenetics and morphology help in the diagnosis and assessing the possible evolution of MDS to AML [52]. An increase in the percentage of CD34+ cells or CD117+ positive cells may help in documenting the progression to AML in a low-grade MDSs. The WHO, however, while noting that aberrant antigen expression patterns are common in MDS did not consider the phenotypic abnormalities sufficient, in the absence of conclusive morphologic and/or cytogenetic abnormalities, for the diagnosis of MDS. The finding of three or more phenotypic abnormalities involving one or more of the myeloid lineages should be considering suggestive, but not diagnostic of MDS. Patients whose cells demonstrate aberrant immunophenotypic markers should be followed for morphologic features sufficient to diagnose MDS. The use of additional studies including FISH analysis and gene mutational analysis should be performed as clinically indicated. The myelodysplastic/myeloproliferative neoplasm (MDS/MPN) group is an overlap disorder reflecting that some patients have features of both MDS and MPN and patients present with a clinical picture that demonstrates both increased proliferation and dysplastic and ineffective maturation. The classification of MDS/MPN reflects difficulty-separating MDS from other myeloid neoplasms.

Patients with MDS/MPN usually present with a leukocytosis and hepatosplenomegaly. The MDS/MPN category includes four defined entities: chronic myelomonocytic leukemia (CMML), atypical chronic myelogenous leukemia (a CML-Philadelphia chromosome negative), juvenile myelomonocytic leukemia (JMML), and a more heterogenous group of unclassifiable MDS/MPN (U-MDS/MPN). The criteria for MDS/MPN with ring sideroblasts and thrombocytosis, MDS/MPN-RS-T, (previously known as RARS-T) is better defined and includes thrombocytosis, ≥450 × 10^9/L associated with anemia, erythroid dysplasia, with ring sideroblasts in ≥15% of erythroid precursors. Megakaryocytes with features of a chronic myeloproliferative neoplasm that are hyperlobulated and atypical and are increased in number with large or giant forms with lobated staghorn like nuclei and occur in lose clusters or found adjacent to the endosteum or within sinusoids and important pathologic finding [52]. The spliceosome gene mutation SF3B1, associated with ring sideroblast, is frequently present in cases of MDS/MPN-RS-T but the subtype still requires ≥15% ring sideroblasts. The JAK 2 V617F mutation has been noted in some of the cases of MPN/MDS but the proliferative potential of most cases appear to be related to aberration in the RAS/MAPK or other signaling pathways and the JAK 2 mutation is not the primary oncogenic event to explain the MPN [42, 66]. The prognosis of patients with MDS/MPN-RS-T is better than most of the MDS/MPN disorders. The transformation to AML is uncommon and unlike the MPN there does not appear to be an increase risk of thrombotic or bleeding complications associated with the elevated platelet count. The treatment options for this subtype are not clear and additional studies are needed to further define the clinical course. In addition to the JAK 2 mutation some patients demonstrate the MPL mutation and both mutations appear to correlate with the elevated platelet count. In general the MDS/MPN disorders have a variable clinical course but are generally associated with poorer prognosis than their myeloproliferative neoplastic counterpart and an increased incidence of leukemic transformation. In MDS/MPNs the karyotype is usually normal or demonstrates a typical MDS cytogenetic abnormality. Gene mutations are common in the MDS/MPNs and can be helpful in assessing difficult cases with a normal karyotype. The 2016 WHO classification, however, noted that gene mutations even of the most commonly mutated genes, SRSF2, TET2, ETV6 and ASXL1 is not sufficient proof of a neoplastic disorder because gene mutations occurs in healthy older persons with undetermined significance. While some of these mutations are prognostically important and define aggressive disease, and have been incorporated into new prognostic scoring systems they should not be the sole determinant of a neoplastic disorder [53].

The diagnosis of myelodysplastic/myeloproliferative neoplasm unclassifiable (MDS/MPN-U) includes patients with features of both myelodysplasia and myeloproliferation who cannot be assigned to a more specific category. Patients must meet the criteria of one of the categories of MDS and demonstrate prominent myeloproliferative features without a prior MPN or MDS. The WHO emphasizes that the diagnosis of MDS/MPN-U should not be made in patients who have recently recovered from cytotoxic chemotherapy or have received recent growth factor therapy.

A follow-up evaluation in these patients is essential to demonstrate that the changes in the PB and BM are independent of recent treatments or recovery from chemotherapy. The features that distinguish this subgroup include an elevated platelet count or WBC without evidence of BCR–ABL1 or rearrangement of PDGFRA, PDGFRB or FGFR1, del 5q, t (3; 3), or inv3. In most patients, the karyotype is normal and no abnormal mutational studies are noted but the JAK2 V617F mutation may be present [54].

MDS with Fibrosis and Hypocellular MDS

The WHO classifications did not define a number of MDS subtypes that are generally recognized as clinically distinct. The categories MDS with marrow fibrosis and hypocellularity MDS are distinct disorders but the WHO noted that because they lack a consensus on the precise definition or the importance of these findings as distinct entities they on not included in the current classification. A subset of patients with MDS present with a hypocellular bone marrow (less than 15% cellularity on bone marrow biopsy) and minimal dysplasia. Hypocellular MDS must be differentiated from aplastic anemia and hypocellular AML [55]. Hypocellular MDS and aplastic anemia may also be pathophysiologically related [54]. The similarity of both disorders is suggested by their response to immunosuppressive therapy. Hypocellular MDS may represent an intermediate stage in the evolution of aplastic anemia. However, hypocellular MDS in contrast to aplastic anemia tends to occur in older patients, with a more gradual onset and dysplasia involving more than one cell line. In contrast to aplastic anemia dysplastic megakaryocytes are more prominent in hypocellular MDS. Megaloblastic red cell precursors, pancytopenia, and the presence of a paroxysmal nocturnal hemoglobinuria clone (PNH)—occur in both hypoplastic MDS and aplastic anemia and are therefore not helpful diagnostic features A characteristic MDS cytogenetic abnormality sometimes helps to define hypocellular MDS but similar findings may also be present in aplastic anemia [48]. Patients with a PNH clone and hypocellular MDS respond better to immunosuppression.

MDS with fibrosis (MDS-F) can be difficult to differentiate from primary myelofibrosis (PMF), acute megakaryocytic leukemia or acute panmyelosis [55]. The bone marrow is usually not aspiratable (dry tap) and the morphological findings of dysplasia may be difficult to identify on the bone marrow biopsy. Splenomegaly and leukoerythroblastosis on peripheral smear are unusual in MDS-F and when present suggest the diagnosis of PMF. Staining the marrow biopsy and circulating blast forms with megakaryocytic lineage-specific antigens can identify abnormal megakaryoblasts [55]. The finding of diffuse fibrosis in MDS is associated with a poor prognosis and greater than 2+-reticulum fibrosis, as defined by the European consensus system, is an independent negative prognostic marker [52]. The diagnostic challenges that such cases present are discussed by the WHO with a recommendation that hematopathologists should specifically comment upon the hypocellularity or extensive fibrosis in interpretative reports. The WHO classification, however, does not recognize hypocellular MDS and MDS-F as distinct entities as the sub-classification of these cases can be problematic and there is no accepted agreement on the diagnostic features associated with these two disorders. Immunohistochemical stains for CD34 on the biopsy may demonstrate excess blasts and may help in identifying these patients. Bone marrow fibrosis is associated with a higher red cell transfusion requirement, multilineage dysplasia, pancytopenia, and a poor prognosis. The 2008 and 2016 WHO classification attempts to address these issues, about when to call a disorder a separate diagnostic entity, and raises the question of when sufficient clinical characteristics or morphologic findings are distinctive enough to warrant a separate diagnostic category.

The recognition and enumeration of blast cells is of critical importance for the diagnosis of AML, MDS and defining the subtypes of MDS and requires a differential blast count on 500 cells on the aspirate to be 20% or more for a diagnosis of AML (either de-novo or evolved from a prior MDS). If a concomitant non-myeloid neoplasm (i.e., plasma cells) is present those cells should be excluded from the count used to evaluate the percent of blast forms. If an aspirate is not available a touch preparation of the biopsy may yield valuable cytologic information, but differential counts from touch preparations may not be representative and should be confirmed on the bone marrow biopsy. The definition of a blast cell can be difficult in MDS. The WHO did not specifically define the definition of a blast, but noted that blasts can be granular or agranular [54]. Myeloblasts are defined by a high nuclear/cytoplasmic ratio, visible nucleoli and usually fine nuclear chromatin. Nuclear shape can be a variable with basophilic granule, or Auer rods, aggregates of lysozymes, may be noted but no Golgi zone is detected. Granular blast cells must be distinguished from promyelocytes and the principal distinguishing characteristic of the normal promyelocyte is the presence of a visible Golgi zone [54]. Dysplastic promyelocytes have the recognizable features of promyelocytes including round, oval or an indented nucleus that is often eccentric with decreased granules or irregular distributed granules and a poorly developed Golgi zone. Determining the overall percentage of blasts in the context of marked erythroid hyperplasia can be problematic. In the updated 2016 WHO classification the percent of blasts is based on all nucleated cells not just the non-erythroid cells. This new criteria will results in most cases previously diagnosed as the erythroid/myeloid subtype of acute erythroid leukemia in the 2008 WHO criteria now being classified as MDS with excess

blasts. In the updated 2016 WHO classification the cytogenetic abnormalities that are MDS defining remain unchanged. While acknowledging the prognostic importance of genetic abnormalities in MDS, in the 2016 WHO criteria only the del(5q) cytogenetic or molecular genetic abnormality defines a specific MDS subtype even if an there is an additional cytogenetic abnormality [3].

The 2016 WHO criteria noted the association between ring sideroblasts and an SF3B1 mutation. The SF3B1 mutation appears to be a early initiating event in the development of MDS and manifests a distinct gene expression profile and correlates with a favorable and indolent course [56]. Patients with MDS carrying the SF3B1 mutation have a more homogeneous phenotype characterized by isolated erythroid dysplasia and the presence of ring sideroblasts. Moreover, the actual percent of cells with ring sideroblast does not affect the prognosis.

The 2008 WHO classification redefined a number of new subgroups [57, 58]. Three categories of refractory cytopenia with unilineage dysplasia (RCUD) are defined: Refractory anemia (RA), refractory neutropenia (RN) and refractory thrombocytopenia (RT). These subgroups do not have an increase in blasts and involve a single lineage. In the 2016 WHO classification these subgroups are part of MDS with Single lineage Dysplasia (MDS-SLD). Other causes of dysplasia need to be addressed and excluded before the diagnosis of single lineage MDS is established (Table 23.7). The expansion of the erythroid component can occur in non-neoplastic disorders, including hemolytic anemia, iron deficiency, and B12 or folate deficiency. Erythropoietin administration may also lead to a marked expansion of the erythroid precursors. Simultaneous or chronologically close administration of erythropoietin and granulocyte growth factors may lead to erythroid hyperplasia with an increase in pronormoblasts and myeloblasts. Therefore, the pathologist must have knowledge of the patient's clinical history, including the administration of recent chemotherapy or growth factors when evaluating the bone marrow. Other causes of erythroid dysplasia include alcohol abuse (vacuolated erythroid precursors and ring sideroblasts), anti-tuberculosis medications and chloramphenicol. Isolated unilineage dyspoiesis should raise suspicion for secondary causes, including disorders not associated with prescription medications as seen in zinc over consumption leading to copper deficiency. Zinc competes with copper for its carrier, ceruloplasmin. Primary copper deficiency can present with pancytopenia with marked vacuolation of erythroid and myeloid precursors, megaloblastoid changes in red cell precursors and ring sideroblasts [59, 60] (Table 23.6). The 2016 WHO classification notes that the prognostic importance of genetic finding in MDS and the expanding knowledge of the clinical importance of recurring mutations in MDS but notes that the finding of one or more somatic mutation is not considered diagnostic of MDS even in a patient with unexplained cytopenias where these mutation may be frequently found [3].

In patients with MDS who lack the appropriate finding of any defined MDS category diagnosed with subtype, MDS, unclassifiable (MDS-U). MDS-U has no specific morphological features but includes MDS with the presence of 1% blast forms in the peripheral blood and <5% blasts in the bone marrow. An occasional blast can be found in healthy individuals and to avoid over interpreting the rare blast form the WHO notes that blasts must be noted in the peripheral blood on two or more successive evaluations to confirm the diagnosis of MDS-U. In addition the diagnosis of MDS - U can be made in cases with 1% or fewer blasts in in the blood and <5% blasts in the bone marrow with unequivocal dysplasia in <10% of one or more myeloid lineages but have a diagnostic cytogenetic abnormality. MDS-U is a very heterogenous subtype and patients have a variable clinical course and should be reclassified if they develop findings characteristic of a specific MDS subtype. The MDS-U subtype may represent the early phase of one or more specific MDS subtypes but with nonspecific morphological features of MDS.

Idiopathic Cytopenia(s) of Undetermined Significance and Idiopathic Dysplasia of Uncertain Significance

Patients who present with cytopenias but lack the diagnostic criteria of MDS, but in whom the diagnosis of MDS is suspected, are classified with the diagnosis "Idiopathic Cytopenia(s) of Undetermined Significance" (ICUS) [61]. The criteria for this group of disorders reflects the diagnostic uncertainty in these patients. A key distinction of ICUS from other potential precursor conditions such as MGUS, monoclonal B-cell lymphocytosis (MBL) and T cell clonality of undetermined is that an ICUS designation does not necessarily imply a clonal disorder. Limited data are available about the frequency or natural history of ICUS and reflects that some patients present with persistent cytopenia but lack the diagnostic features of MDS. The term idiopathic dysplasia of uncertain significance (IDUS) was proposed to describe a group of patients with dysplasia but no or only mild cytopenias [61]. In contrast to ICUS, patients with IDUS demonstrate dysplasia in >10% of cells in one or more lineage with or without a MDS-related karyotype but without persistent cytopenias. ICUS and IDUS have very variable courses and it is unclear if all the patients will ultimately develop a defined subtype of MDS or another myeloid neoplastic disorder. Moreover, it is unclear if these disorders are mutually exclusive or if the classification of a potentially premalignant disorders will provide meaningful prognostic or diagnostic information for patients in whom no cause for the cytopenia

Table 23.8 New terms for patients who do not meet the criteria for MDS

ICUS	*Idiopathic Cytopenias of Undetermined Significance*. The natural history of patients with ICUS is unclear. May have clonal or nonclonal hematopoiesis (clonal ICUS vs nc ICUS) as defined by somatic mutations or non- diagnostic cytogenetic findings by karyotype or FISH. A proportion of patients with ICUS with develop MDS or another myeloid malignancy. Much more common than MDS and most patients will not develop a myeloid malignancy.
IDUS	*Idiopathic Dysplasia of Undetermined Significance*. Dysplasia without cytopenia. Need to confirm the dysplasia over a 3–6 month period. Unclear clinical course and prognosis and frequently associated with benign conditions.
CHIP	*Clonal Hematopoiesis of Indeterminant Potential*. Age dependent somatic mutations in persons without a known hematologic disorder. The prevalence of CHIP increases greatly with age over 10% in person over the age of 70 years. Most with never develop MDS but is associated with an increased incidence of myeloid malignancies and all-cause mortality. In most persons may be an incidental findings relating to aging.
CCUS	*Clonal Cytopenias of Underdetermined Significance*. Have one or more cell line decrease, hemoglobin <11 g/dL, absolute neutrophil count (ANC), 1.5×10^9/L, platelet count < 100×10^9/L. persons have an acquired chromosomal abnormality not diagnostic of a hematologic malignancy and/or the presence of a somatic mutation with a variable allele fraction ≥2% in hematologic malignancy—Associated gene in the peripheral blood or bone marrow. Most persons had somatic mutations fraction of >10% similar to lower risk MDS patients, including mutated genes associated with high risk MDS including TP53, ASXL1,RUNX1 and DNMT3A. More frequently diagnosed than MDS but less than ICUS. No evidence of dysplasia. The natural history for most persons in unknown unlikely that all will develop MDS or other myeloid malignancy.

is found. The proposed term Clonal Cytopenia of Undetermined Significance (CCUS) has been proposed for cases with somatic mutations, or a non-diagnostic chromosomal abnormality, defining a clonal population in the bone marrow, but without dysplasia and one or more cytopenia in the blood (Table 23.8) [62].

MDS Subtypes

MDS with Ring Sideroblasts (MDS-RS)

MDS with ring sideroblasts (MDS-RS) is characterized by anemia, erythroid dysplasia and >15% ring sideroblasts of bone marrow erythroid precursors. There is generally no or minimal dysplasia in the non-erythroid precursors. Myeloblasts comprise <5% of the nucleated BM cells and are not present in the PB. In the 2016 WHO criteria MDS-RS is associated with recurrent mutations of the spliceosome gene SF3B1. The classification of MDS-RS was changed to include MDS cases with ring sideroblasts and multilineage dysplasia. This change reflected the link between ring sideroblasts and an SF3B1 mutations. In the 2016 classification if the SF3B1 mutation is identified then the diagnosis of MDS—RS can be made even if the ring sideroblast comprise only 5% of nucleated erythroid cells. If the SF3B1 mutation is lacking then ≥15% ring sideroblasts of nucleated erythroid cells is still required. MDS-RS subtype is divided into two groups; a group with single lineage dysplasia (MDS-RS-SLD), previously classified as refractory anemia with ring sideroblasts, and second group with multilineage dysplasia (MDS-RS-MLD), previously classified as refractory cytopenia with multilineage dysplasia. Patients with MDS—RS who lack the SF3B1 mutation have a more heterogenous phenotype, a high prevalence of TP53 mutations and less favorable prognosis. The SF3B1 mutation is early event in the development of MDS and may be an important therapeutic target in MDS-RS [58]. MDS-RS constitutes approximately 10% of cases of MDS. A majority of patients present with a moderate normochromic or macrocytic anemia. The PB frequently reveals dimorphic red cells due to a small population of microcytic and hypochromic red cells. Basophilic stippling and Pappenheimer bodies may be noted in red cells. Dysplasia is present in <10% of neutrophils and platelets. The bone marrow is usually hypercellular for the patient's age and demonstrates erythroid hyperplasia. The iron stain, Prussian blue staining, reveals ring sideroblasts that surround at least a third of the nuclear circumference. Iron stores are generally increased even in the absence of red cell transfusions. The number of CD 34+ cells is normal and most patients do not demonstrate a cytogenetic abnormality. Ring sideroblasts may be seen in a number of other, non- MDS-related disorders including lead poisoning, drugs including isoniazid which inhibits delta aminolevulinic acid (ALA) dehydratase activity and block hemoglobin formation resulting in ring sideroblast formation [45]. A number of acquired and hereditary conditions are associated with ring sideroblast formation and should be excluded before a diagnosis of MDS-RS is established. In RARS the ring sideroblasts and increased iron stores reflect abnormal iron metabolism in the erythroid lineage resulting from the ineffective erythropoiesis. The overall prognosis for patients with MDS-RS is 69–108 months and less than 2% of cases transform into AML. Progressive anemia requiring transfusion support is frequent and in select patients iron chelation therapy should be considered early in the clinical course to prevent iron overload and end organ failure. However, the overall beneficial effects of early iron chelation has not been demonstrated to improve survival in prospective randomized studies and therefore remains controversial [63].

MDS with Single Lineage Dysplasia and MDS with Multilineage Dysplasia

This group of disorders was previously know as Refractory anemia and refractory anemia with multilineage dysplasia in the 2008 WHO classification and is now classified as MDS-SLD and MDS-MLD. The difference between these subtypes reflects either a single or 2 or more lineages demonstrate dysplasia. These groups constitute approximately 30% of MDS cases and are characterized by one or more cytopenias and dysplastic changes in one two or more of the myeloid lineages. Blasts are rare, <1%, in the PB and <5% in the BM. Auer rods are not present in either the PB or BM. The anemia is usually macrocytic or normocytic with prominent granulocytic dysplasia including hypo granularity, nuclear shape abnormalities including hypo-lobation, acquired pseudo Pelger-Huet anomaly, and abnormal nuclear clumping. The bone marrow is usually hypercellular for age of the patient with <5% blasts. Erythroid precursors may demonstrate cytoplasmic vacuoles and marked nuclear irregularity including internuclear bridging and nuclear budding. The BM may have variable number of ring sideroblasts but less than 15%. The previously described WHO category of refractory cytopenias with multilineage dysplasia with ring sideroblasts has been omitted and incorporated in MDS-RS-MLD. Megakaryocytic dysplasia includes hypolobated and non-lobated nuclei, multinucleated and micromegakaryocyte, megakaryocytes with non-lobated or bi-lobed nuclei. Clonal cytogenetic abnormalities are present in up to 50% of patients and are important in defining the prognosis. The prognosis is related to the degree of cytopenias and cytogenetic abnormalities.

MDS with Excess Blasts 1(MDS-EB1 and MDS-EB2)

MDS-EB1 and EB2 comprises 40% of cases of MDS and is divided into MDS-EB1 and MDS-EB2 on the basis of the number of blasts and the presence or absence of Auer rods. EB 1 is defined by 5–9% blasts in the BM or 2–4% blasts in the PB and no Auer rods and EB2 is defined by 10–19% blasts in the BM or 5–19% blasts in the PB. The presence of Auer rods confirms the diagnosis of EB2 irrespective of the percent of blast forms. Most patients present with symptoms of BM failure including anemia, bleeding or neutropenia. The PB generally shows dysplastic changes in all three-cell lines and is typically hypercellular for age of the patient. Erythroid precursors may be increased with megaloblastoid changes and ring sideroblasts. The excess blasts define these subtypes. Dysmegakaryopoiesis is a frequent finding including micromegakaryocytes and abnormal megakaryocytic clustering. Blasts may form abnormal aggregates or clusters that are located away from trabeculare and vascular structures, a histologic finding previously referred to an abnormal localization of immature precursors (ALIP). Immunohistochemical staining for CD34 may help in identifying blast forms. Clonal cytogenetic abnormalities are observed in 30–50% of cases including +8, -5, del(5q),−7, del(7q), del (20q) and complex karyotypes. Fibrosis may be present and results in a dry tap. The presence of fibrosis should be noted and the finding of extensive fibrosis is an independent negative prognostic marker in MDS [3]. MDS-EB1 and 2 frequently progress to AML, 25% and 33% respectively for MDS-EB1 and MDS-EB2 respectively. The median survival is approximately 16 months for MDS-EB1 and 9 months for MDS-EB2. The survival is dependent on the number of blast forms. Cases with >5% blasts and a complex karyotype have a median survival of ≤3 months similar to AML with myelodysplastic changes.

Myelodysplastic Syndrome with Isolated del (5q)

Heterozygous, interstitial deletions of the long arm of chromosome 5 (5q) are the most common cytogenetic abnormality in patients with MDS. Del 5q is associated with a consistent clinical phenotype previously known as the 5q- syndrome in a subset of patients. Abnormalities in chromosome 5 occur in approximately 25% of MDS patients, but the incidence of the originally described 5q- syndrome is much less frequent [63]. The 5q- syndrome was originally described in patients with a macrocytic anemia, dyserythropoiesis and erythroid hypoplasia in the bone marrow and a normal to elevated platelet count, hypolobated megakaryocytes and an intestinal deletion involving the long arm of chromosome 5. In addition the 5q- syndrome in characterized by the absence of circulating myeloblast and therapeutic sensitivity to treatment with lenalidomide. The deletion of 5q in MDS does not necessarily equate to the clinical 5q- syndrome. Both the original 5q- syndrome and del (5q) MDS respond to lenalidomide and the revised WHO changed its definitions to this cytogenetically defined subset from 5q- syndrome to MDS with abnormality del(5q) [64, 65]. The deletion occur on a single chromosome resulting in a heterozygous (haploinsufficient) with the unaffected chromosome 5 contains the normal allele of all the genes contained in deleted segment. None of the genes on the nondeleted chromosome 5q are mutated or undergo homozygous inactivation in MDS patients. The recurrent haploinsufficiency for critical genes within the common deleted regions (CDR) on chromosome 5q is the basis for the unique pathological phenotype that results in the MDS subtypes del (5q). Haploinsufficiency of the RPS 14 gene on the long arm of chromosome 5 (5q) leads to activation of the P53 pathways and the development of the characteristic macrocytic anemia. The CDR on chromosome 5 and the breakpoints and size of

the deletions in the original 5q- syndrome patients and the del (5q) patients with advanced MDS and AML are variable. The CDR of the 5q–syndrome the interstitial deletion occurs in a 1.5 MB region at 5q32–33. The region contains genes for the ribosomal protein RPS14 and three micro RNAs mrR-143, miR-145, and mir-146. The non-allelic deletion of the RPS14 gene encodes for a component of the 40 s ribosome and is critical for the development of the macrocytic anemia. In contrast, patients with del (5q), and additional chromosomal abnormalities and excess blast have a different clinical course and response to treatment [85]. Patients with a deletion of 5q- and AML have large interstitial deletions that overlap the CDR of the 5q-syndrome and low risk del (5q) However, in high risk MDS and AML the deleted region was in a more distal CDR in the 5q32–33 region. Lenalidomide selectively inhibits the Del (5q) clone and results in RPS 14 inactivation of the p53 pathway. Lenalidomide exerts unique karyotype specific activity in Del (5q) MDS but does not eradicate the Del (5q) stem cell population in all patients. The inactivation RPS14 leads to defective erythropoiesis and increased apoptosis in erythroid progenitors. Moreover, in the congenital disorder Diamond- Blackfan anemia the down regulation of an another ribosomal gene (RPS19) is critical in the development of the erythroid hypoplasia and chronic anemia [65]. The down regulation of RPS14 may not be the sole genetic event underlying the del 5q- syndrome and alteration of other genes in the commonly deleted segment in 5q- may be required. The tumor suppressor SPARC (Secreted Protein Acidic and Rich in Cysteine) gene is located in the del 5q31 region. SPARC has tumor suppressor, antiproliferative, and anti angiogenesis properties and may also be important in this syndrome [64]. The loss of additional genes that code for these and other factors appear to contribute to the development of this syndrome and its unique response to the immune modulatory drug, lenalidomide. MDS with isolated del 5q syndrome is frequently associated with morphological features of MDS-SLD. Thrombocytosis and anemia is occasionally seen and when present is suggestive of the del 5q chromosomal abnormality. The bone marrow aspirate and biopsy are typically hypercellular for the patient's age with erythroid hypoplasia and dysplastic erythropoiesis. Ring sideroblasts may be present but <15% of erythroblasts. A del(5q) subtype should be suspected in patients who present with a refractory macrocytic anemia, with a normal or mildly low leukocyte counts, and thrombocytosis (a platelet count $>400 \times 10^9$/L). In contrast to the other MDS subtypes, where the mononuclear megakaryocytes are smaller (micromegakaryocytes), in the MDS with del 5q the megakaryocytes are bilobed or non-lobulated but of normal size (mono lobulated). The MDS with del 5q has a marked female predominance (70%), and rarely transforms to AML. A majority of patients have progressive anemia and become red cell transfusion dependent and rarely respond to growth factors including erythropoietin. Lenalidomide is the treatment of choice and results in transfusion independence in over two thirds of cases with durable clinical and cytogenetics responses [42].

Clinical and Laboratory Features of MDS

Blood and Bone Marrow Findings

Red Cells/Anemia

Macrocytosis or a macrocytic anemia with a low reticulocyte count is common in MDS and reflects the ineffective erythropoiesis. Impaired red cell maturation has been associated with acquired abnormalities of globin chain synthesis, and red cell enzymes. PNH has been described in the setting of MDS, and these patients have many of the typical diagnostic features of PNH including a defect in the synthesis of the glycosylphosphatidylinositol (GPI)-linked surface protein, but lack the ongoing red cell hemolysis and thrombotic complications associated with PNH. Cases may have abnormalities in the size and shape of red cells including basophilic stippling (red cell inclusions composed of ribonucleoprotein and mitochondrial remnants), Pappenheimer bodies (basophilic iron-containing granules peripherally located in red cells), macro-ovalocytes, teardrop forms, and nucleated red cells. The bone marrow may reveal multinuclear fragments, inter-nuclear bridging, and nuclear cytoplasm asynchrony.

Neutrophils

Qualitative abnormalities of neutrophil function are a common feature of MDS and may explain the increased risk for bacterial infections. Morphological abnormalities include hypo-granular and hyposegmented neutrophils, which are associated with a negative peroxidase reaction and decreased myeloperoxidase activity. The neutrophils are hyposegmented and may be confused with band forms. Nuclear fragmentation and nuclear-cytoplasmic asynchrony in early myeloid precursors may be a prominent feature in the bone marrow. Dysplastic myeloid precursors can be difficult to distinguish from blast forms and therefore a pathologist experienced in the interpretation of MDS should review the bone marrow.

Platelets

Thrombocytopenia and abnormal platelet function occur in MDS. Thrombocytopenia is an adverse prognostic feature independent of other prognostic factors [66–68]. While thrombocytopenia is associated with poor performance status and other unfavorable prognostic variable bleeding complications are underreported. Thrombocytopenia ($<100 \times 10^9$/L) has been reported in 66% of patients and was associated with a 24% incidence of deaths from hemorrhage. Impaired platelet function may also explain the

increased risk of bleeding in patients with MDS. Spontaneous bruising and bleeding after surgery or mild trauma occurs in MDS patients with a normal or slightly depressed platelet counts. Dysplastic platelets and abnormal megakaryocytes are important diagnostic features and help in distinguishing MDS from other disorders. Giant platelets, and agranular (grey platelets) and megakaryocytic fragments in the peripheral blood film are important diagnostic features of MDS.

Bone Marrow Findings

A bone marrow aspirate and biopsy is essential for the making diagnosis of a MDS and to define the MDS subtype. Abnormal distribution of cells is often present; erythroid islands may be absent or very large. Granulocytic precursors may be clustered centrally rather than their normal paratrabecular distribution. Micromegakaryocyte, mononuclear megakaryocytes, and hyperlobulated megakaryocytes are important diagnostic features of MDS and are reliable morphological findings of dysplasia. In the bone marrow the megakaryocytes may be clustered or adjacent to the bony trabecula. The del 5q syndrome has mononuclear megakaryocytes that are of normal size but with a single eccentrically placed round non-lobulated nucleus [3]. Megaloblastic changes (nuclear cytoplasm asynchrony) can be seen in the myeloid and erythroid precursors. Dysgranulopoiesis and dyserythropoiesis are more readily noted in the bone marrow aspirate smear and not the biopsy. The bone marrow smear is necessary to identify ring sideroblasts that may not be apparent on the biopsy sample. Immunohistochemistry may be a useful supplement to histology. Small mononuclear megakaryocytes can be confused with myeloid precursors. A biopsy is necessary to access the degree of reticulin fibrosis and overall bone marrow cellularity. Immunophenotyping using flow cytometry on the bone marrow and/or peripheral blood may be helpful in the diagnosis and defining prognosis and response to treatment. However, while controversial there are currently no accepted standards for the diagnosis of MDS by flow cytometry.

The finding of aberrant immunophenotyping of myeloid blasts is helpful in corroborating the diagnosis of MDS, but is not diagnostic of MDS. The aberrant expression of the lymphoid antigen CD7 on myeloid blasts is a common phenotypic abnormality and correlates with a poor prognosis [42]. Increase and/or clustering of blasts favors MDS. Immunostaining for CD34 on core biopsy is very helpful to estimate blast numbers and possible clustering. In the absence of reliable aspirate smear, CD34 immunostaining on core biopsy and/or clot section can be used for estimating percentage of blasts. The use of flow cytometry on both the PB and BM is the focus of many studies and should be part of the initial evaluation of MDS [42].

Clinical and Prognostic Features

The initial evaluation of all patients with MDS should be performed before planning treatment and should include a detailed history of prior exposures to chemotherapy, radiation therapy or toxic exposures. The cellularity should be noted from the bone marrow biopsy. The percent of blasts and the iron stain and the presence of ring sideroblasts should be performed on the bone marrow aspirate. Iron studies including a ferritin and transferrin saturation should be obtained prior to starting growth factors and on patients who are receiving red cell transfusions. A serum erythropoietin should be determined in patients with symptomatic anemia. In patients who are candidates for an allogeneic hematopoietic stem cell transplant HLA typing should be performed on the patient and their siblings.

The WHO classification system attempts to offer general prognostic guidance for each subtype but additional information is usually needed to assign prognosis and plan therapy. In an effort to determine prognosis a number of prognostic scoring systems have been developed including the International Prognostic Scoring System (IPSS), the MD Anderson Prognostic Scoring System (MDAPSS), World Health Organization –based Prognostic Scoring System (WPSS) and others models have been developed to define the prognosis and guide therapy [69, 70]. The widely used and generally accepted International Prognostic Scoring System (IPSS) developed in 1997 and recently revised, IPSS-R, addresses clinical features not included in the WHO classification and attempts to define prognosis and leukemic progression. The IPSS-R included 5 cytogenetic subsets reflecting the importance of new prognostically important cytogenetic groupings (Table 23.9). The scoring system assigns a point score for each the following variables: the number of bone marrow blast forms, karyotypic abnormalities, and number of cell lines affected (cytopenias) (Table 23.10). The combined score determines the overall risk category: very low (risk score $\leq$ 1.50), Low (risk score > 1.5–3.0), Intermediate (risk score > 3–4.5), High (risk score > 4.5–6) and very high (risk score > 6). The IPSS-R risk category and score correlates with the overall survival and probability of transformation to AML (Table 23.9).

The other prognostic scoring systems include similar parameters but the IPSS-R scoring system continues to be widely used for stratification of patients enrolled in clinical trials [69, 70]. However, the IPPS-R system has a number of important limitations. The IPPS-R system is based in part on the FAB classification of MDS and includes MDS patients with 30% blasts. The threshold for AML in the WHO classification is 20% blasts which is not reflected in the IPSS–R blast scoring system. The IPSS also does not completely address the severity of the cytopenias or the need for transfusion support and does not take into account other prognostic

Table 23.9 MDS cytogenetic scoring system: IPSS-R

Prognostic subgroup	Cytogenetic abnormalities	Percent of patients	Survival (years median)	AML evolution[a]
Very good	−Y, del(11q)	4	5.4	NR
Good	Normal, del(5q), del(12p), del(20q), double including del(5q)	72	4.8	9.4
Intermediate	Del(7q), +8, +19, i(17q) any other single or double independent clones	13	2.7	2.5
Poor	−7, inv.(3)/t(3q)/del(3q), double including- 7/del(7q),complex:3 abnormalities.	4	1.5	1.7
Very poor	Complex: >3 abnormalities	7	0.7	0.7

NR not reached

Table 23.10 IPSS-R scoring system

Prog score variable	0	0.5	1.0	1.5	2.0	3.0	4.0
Cytogenetics	Very good		Good		Intermediate	Poor	Very poor
Bone marrow %blasts	≤2		>2–<5		5–10	>10	
Hemoglobin g/dL	≥10		8–<10	<8			
Platelets cmm	≥100	50–100	<50				
Absolute neutrophil counts/cmm	≥0.8	<0.8					

Very Good −7,del(11q), Good—Normal, del(5q),del(12p), del (20q), double including del(5q) Intermediate - del(7q), +8,+19,i(17q), any other single or double independentclones. Poor—7, inv.(3)/t3q)/del 3, double including −7/del(7q). Very Poor—Complex >3 abnormalities. See Table 23.3

variables. The IPSS-R acknowledged the prognostic importance of additional variable but did not assign a point score to these factors including LDH, serum ferritin, β2-microglobulin, marrow fibrosis, patient's age, performance status and comorbidities. Other prognostic factors including disease duration or prior treatments are not part of the IPSS-R. The IPPS and IPSS-R was intended to assign prognosis at the time of diagnosis and therefore is a static score that was not intended to change with time or treatments. The IPSS–R also includes a number of uncommon cytogenetic subsets does not address the expanding role of molecular genetic studies in MDS.

MDS is often broadly separated, for treatment decisions, into low risk and high-risk disease based on overall survival and risk of AML transformation. The lower risk subtypes include MDS with single lineage dysplasia, MDS with Multilineage dysplasia, MDS with ring sideroblasts, MDS with isolated del(5q). The IPSS-R low risk categories include the very low, low and intermediate risk categories. These groups are associated with a general survival of >3 years and a low risk for transformation to AML and generally correspond to a IPPS-R score of <3.5. In contrast the higher risk MDSs groups include MDS-EB 1 and 2 and IPSS-R groups high and very high and are associated with a greater risk for transformation to AML [70].

Treatment

The treatment of a patient with MDS should be individualized based on the patient's age, subtype, IPSS-R risk category, performance status, cytogenetics and co-morbid medical problems. The majority of patients with MDS are elderly and tolerate intensive chemotherapy poorly. Moreover, standard therapies do not result in a cure and their impact on survival for most patients is unclear. Therefore any potential benefits of treatment must be weighed against the side effects and the patient's overall prognosis. The alleviation of disease-related complications and improved quality of life are important goals for most patients. The most appropriate care for many patients still remains supportive care. Although there are a number of therapeutic options available for MDS patients, none, other than an allogeneic stem cell transplantation, offers the potential for cure. The therapeutic options for patients with MDS include the use of hematopoietic growth and trophic factors, immunosuppressive agents, low-intensity cytoreductive chemotherapy including the hypomethylating agents, and intensive chemotherapy. While advances in the diagnosis and risk stratification has refined the prognosis for patients and defined gene mutations that are potential targets in MDS, no new drugs s have been approved for the treatment of MDS in over a decade.

Guidelines for evaluating the response to treatment in patients with MDS have been updated and incorporated into the criteria by the International Working Group (IWG) [71]. These guidelines attempted to define standard, criteria for complete and partial responses to treatment. Moreover, the response criteria emphasized that the goals of treatment of MDS is to alter the natural history of the disease and alleviate the disease-related complications and improve the quality

of life. Stable disease or minimal responses are difficult to interpret and make comparisons between trials difficult. In addition, the response rate in some Phase II trials did not translate into prolongation of survival, time to treatment failure, or improvement in the quality of life. The IWG criteria are a useful standard to use for comparing results across therapeutic trials and are now widely used for defining response to treatment.

Supportive Therapy

In many patients the diagnosis of MDS may require a period of observation and reevaluation. The WHO appropriately noted that in some patients reevaluating the peripheral blood and bone marrow after 3–6 months period was essential to exclude other causes of the dysplasia. In patients with indolent disease or who are asymptomatic, elderly, and frail or have co-morbidities, supportive therapy including transfusions represents a widely accepted standard of care. Patients should be followed for a change in their clinical pattern i.e., increase in red cell transfusion, declining platelet count, circulating blast forms, splenomegaly or decline in performance status. Red cell and platelet transfusions are administered for the symptomatic treatment of the anemia and thrombocytopenia. There is no one single hemoglobin cut off at which RBC transfusion should be offered to all patients but the use of transfusion support is increasing over the years in an effort to maintain a higher hemoglobin/hematocrit. Platelet transfusions are generally given when the platelet count is $<10{,}000 \times 10^9$/L but should be adjusted on the basis of individual risk factors and bleeding history. Thrombocytopenia is common in MDS and bleeding complications are exacerbated by impaired platelet function [68]. Platelet dysfunction is common and patients may bleed even with an adequate platelet count. Therefore, platelet support may be required prior to surgery and procedures to prevent excess bleeding. Patients with a platelet count of $\leq 20{,}000 \times 10^9$/L are at higher risk for bleeding. Disease modifying agents such a lenalidomide and hypomethylating agents are associated with thrombocytopenia. The repeated use of platelet transfusions is associated with allo immunization and transfusion reactions. Danazol an attenuated synthetic androgen with immune modulating activity may be effect in some thrombocytopenic patients with MDS [72]. Thrombopoietin receptor agonist (TPO) are being tested in clinical trials as single agents in low-risk MDS patients and in combination therapy with disease modifying agents (lenalidomide) in high risk MDS. Romiplostim a Fc- peptide fusion protein with no sequence homology with endogenous TPO has been evaluated in low /intermediate risk MDS patients with thrombocytopenia [73, 74]. Romiplostim reduced overall bleeding events but the trial was stopped because of concerns regarding leukemic transformation. Eltrombopag and oral nonpeptide, noncompetitive TPO receptor agonist which is indicated for the treatment of ITP was evaluated in a phase 2 randomized trial in low/intermediate risk MDS patients, Eltrombopag increased the platelet count in a limited number of patients without a increase in leukemic risk. It was unclear in the limited studies that either TPO improved survival. The TPOs are not approved at this time for treatment of thrombocytopenia in MDS patients.

Neutropenia and impaired neutrophil function are also common in MDS patients. The use of prophylactic antibiotics, however, is not warranted for most patients. Neutropenia without a history of recurrent infection is not a justification for the initiation of therapy. Granulocyte colony stimulating factor or granulocyte macrophage colony stimulating factors can transiently increase the neutrophil and blast count in many patient with MDS. However, the clinical benefit of these growth factors is unclear. The use of G-CSF did decrease the incidence of serious infections but did not favorably impact survival in a prospective controlled trial. The use of these cytokines did increase the white blood count and the number of circulating blasts but did not appear to accelerate the progression to acute leukemia. Although in selected patients with active, serious infections there may be a role for the use of these cytokines in the MDS patient with neutropenia in combination with antibiotics, at present there is no evidence to support the general use of either G-CSF or GM-CSF [74].

Patients may require multiple transfusions over many years and the potential for iron overload should be addressed early in a patient's course. Each unit of RBC contains 200–250 mg of iron and iron overload from transfusions occurs when a patient has received 25 units of packed red cells [75–79]. The benefits of chelation therapy (ICT) in MDS remains controversial. Patients with transfusion dependent low risk MDS may benefit from the early introduction of iron chelation and chelation may reduce the effects of iron overload on cardiac and possibly prevent end organ damage due to tissue iron overload [77]. Iron chelation may also reduce the risk of infections and improve survival after allogeneic hematopoietic stem cell transplantation and may delay the leukemic progression and improve hematopoiesis [78]. Some observations suggest that cytopenias in iron-overloaded patients with MDS could be mitigated by ICT, possibly by a decrease in reactive oxygen species-mediated damage to hematopoietic cells [79]. In addition hematologic improvement was seen in some patients who received deferasirox including a normalization of labile plasma iron [79]. The use of ICT may suppress ineffective erythropoiesis by reducing iron and/or oxidative stress and modulating proliferation and differentiation. However, the risk of iron overload in transfusion dependent MDS patients is unclear. Iron toxicity in MDS patients may not only depend on tissue iron accumulation but also the extent of non-transferrin bound iron. Prospective studies evaluating the clinical benefit of iron chelation in MDS patients ongoing [77]. Iron chelation is a slow process and

therefore it is important to view chelation as a preventive supportive measure. The use of deferoxamine is impractical for most patients with MDS. Deferoxamine has a short half-life and requires a prolonged parental, either subcutaneous or intravenous, infusion that is administered over 8–12 h. The rapid infusion of deferoxamine following a red cell transfusion has limited benefit and does not result effective chelation. The oral iron chelator deferasirox (Exjade, Jadenu) is administered daily and is effective in reducing the serum ferritin [79]. Deferasirox can cause reversible renal insufficiency and GI disturbances, including gastrointestinal bleeding. In a number of studies Deferasirox was poorly tolerated in MDS patients with serious renal and gastrointestinal side effects [76]. A number of guidelines on the use of chelation therapy in MDS have been reviewed and a consensus statement published recommending the use of oral chelation therapy in transfusion dependent patients with low risk MDS. Iron overload may contribute to increased morbidity and mortality in low risk MDS patients. However other studies did not demonstrate a direct correlation of the serum ferritin, numbers of transfusions and overall survival. The benefits of prolonged oral chelation therapy is low risk MDS patients remains controversial and in general the benefits should be weighed against the potential risks and its effect on quality of life. The beneficial effects of iron chelation therapy on organ function and survival in transfusion dependent MDS patients is currently lacking. But, in low risk transfusion dependent patients with a ferritin of >1000 mg/dL or patients considered eligible for an allogeneic stem cell transplant ICT should be considered and renal and hepatic function closely monitored.

Erythropoiesis Stimulating Agents (ESAs)

Recombinant hematopoietic growth factors have been used with varying degrees of success to treat the cytopenias in MDS. Recombinant human erythropoietin (rHuEPO, EPO and darbepoetin), granulocyte-colony-stimulating factor (G-CSF), and granulocyte-macrophage colony stimulating factor (GM-CSF) have a role in managing the anemia and neutropenia in selected patients with MDS. ESAs have been studied extensively and approximately 30% of anemic patients with MDS will respond to treatment [75]. The reported response rates in low risk MDS varies between 30 and 82% depending on patient selection and response criteria [80]. The best responses to erythropoiesis stimulating agents (ESA) are observed in patients with an endogenous erythropoietin level of <500 U, a transfusion requirement of less than two units of red cells a months and low risk MDS with <5% myeloblasts [81]. ESAs decrease red cell transfusion requirements and improved the quality of life (QOL). Higher doses of EPO appear to enhance the erythroid responses. The combination of EPO plus G-CSF appears to be synergistic and may optimize the response to EPO. The duration of response was 11–24 months and EPO with or without G-CSF did not increase the incidence of AML transformation. ESAs did improve the QOL but treatment did not impact on overall survival. The ESAs have been associated with an increased mortality, possible promotion of tumor growth in solid tumors and thromboembolic events in non-MDS patients. No increase in treatment related either cardiovascular or thrombotic events occurred in patients who received either EPO alone or combination cytokines EPO with G-CSF as compared to a control population. The FDA recently cited safety concerns from data in clinical studies with ESAs administered to patients with solid tumors [81]. In patients with various solid tumors the use of ESAs was associated with a shortened survival, and/or increased risk of tumor progression or recurrence as well as a increased risk for thrombotic events in patients with renal disease (http://www.fdagov/Drugs/DrugSafety/). MDS patients did not have a increase in disease progression or thrombotic complications associated with ESAs [80]. A predictive model for treatment with EPO and G-CSF demonstrated that patients with an EPO level of <500 mU/mL, and a pretreatment transfusion requirement of less than 2 units/month responded best to ESAs [81]. Best responses were noted in IPSS lower risk patients. Responses can take 8 or more weeks with most patients responding by 12 weeks and the recommended starting for the recombinant human erythropoietin alpha (rEPO) doses are 40–60,000 units administered once or twice a weekly, and increasing the dose up to 300,000 U/week depending on the response. The longer acting form, Darbepoetin, is administered starting at 50–300 mcg/weekly or every other week. Darpoetin administered every 2–3 weeks at a dose of 500 mcg is also effective. Adequate iron stores should be documented prior to starting EPO treatment and during therapy as the failure to respond or loss of response may be a manifestation of depleted iron stores. Low doses of G-CSF (1 μg/kg) with EPO can be added to patients who fail to respond and appeared to augment the response in selected patients [80]. The mechanism of the response to high doses of EPO is unclear but the growth factors may modulate apoptosis in MDS progenitors and enhance erythropoiesis. Moreover, the response to ESAs may define a more favorable group of MDS patients and in a Phase III trial MDS patients who responded to EPO had a longer overall survival versus those who did not respond [80].

Thrombocytopenia is an independent adverse prognostic factor for survival in MDS. Bleeding complications resulting from thrombocytopenia and MDS associated platelet dysfunction are major causes of morbidity and mortality in MDS. Treatments to increase the platelet count are limited. Danazol is an attenuated, synthetic androgen that has been used in the treatment of immune-mediated thrombocytopenia (ITP). Danazol may increase the platelet count in low-risk MDS patients who are thrombocytopenic [72]. The mechanism

of action is unclear, but may reflect that some patients with MDS have immune-mediated thrombocytopenia that responds to the immunoregulatory effects of danazol. Danazol, 200 mg po tid, is generally well tolerated and associated with an increase in platelets in 10–46% of treated patients. The duration of response is variable, 2–26+ months, and maintained only while the drug is administered. Patients with platelet counts greater than 15×10^9/L appear to respond best, and the impact on survival or disease progression is unknown. Two thrombopoietin receptor agonists (TPO), eltrombopag and romiplostim, are currently available to treat patient with refractory ITP. Both agents are active in patients with ITP by increasing platelet production. However, safety concerns remain including the risk of marrow fibrosis and leukemic transformation [68]. A transient increase in blasts forms has been noted in patients treated with TPO. Eltrombopag is currently being studied in higher risk MDS patients. Ongoing studies are evaluating the role of these agents in the treatment of the thrombocytopenic patient with MDS. These early trials of TPOs suggest that they are well tolerated in MDS patients and increased the platelet count and decreased the need for platelet transfusions and clinical bleeding events. But their effect on survival and disease progression is unclear.

Immunosuppressive Therapy

Patients with MDS can present with a number of immune-mediating pancytopenias that potentially respond to immunosuppressive therapy [82]. Some patients with low risk and hypocellular MDS responded to immunosuppressive regimens used for the treatment of aplastic anemia. Selected patients with hypocellular or normal cellular bone marrows responded to the administration of anti-thymocyte globulin (ATG), cyclosporine A (CSA) and steroids [83]. Antithymocyte globulin (ATG) either rabbit or hoarse derived, administered at doses similar to those used in the treatment of aplastic anemia resulted in improvement of one or more cytopenia in 30–50% of selected patients [83]. Trilineage responses were observed in some patients and the median duration of response was 10+ months. Responses were more frequent with hypocellular MDS but were even noted in patients with normocellular bone marrows. Improvements were seen in patients with low-, intermediate-, and high-risk IPSS scores. Age, 60< years, HLA- DR15 positivity, low risk disease, shorter duration of transfusion dependency, and trisomy 8 cytogenetic abnormality correlated with the response to treatment [84]. The responses did not correlate with the loss of a previously noted cytogenetic abnormality, suggesting that the treatment was not affecting the MDS clone. A majority of the patients attained a partial response and treatment did not restore normal hematopoiesis. The mechanism of action is not clear but in vitro studies suggest that the response may be mediated by a loss of cytotoxic T-lymphocyte activity which correlated with changes in the T-cell receptor profiles [84]. The response to ATG appears greatest in low-risk patients. In some patients who initially responded to ATG and then relapsed, retreatment was effective. Toxicity of ATG therapy included fevers, infusion related side effects, and infections. Age was the most important predictor of response with patients >60 years of age having a poorer outcome and increased complications associated with immunosuppressive therapy. These studies suggested that older patients with MDS may have a decreased marrow reserve associated with a diminished response to immune-suppression. CSA, alone may also be effective in hypocellular MDS patients. The combination of CSA and ATG may enhance the response in selected patients. In addition the use of alemtuzumab, an antibody against CD52, has been used in selected patients. The reported studies of ATG and CSA treated a highly selected subset of patients that represent a minority of patients with MDS. Most of the responding patients presented with hypocellular marrows (<15% cellularity) with minimal dysplasia. The responses of MDS patients to immunosuppressive therapy reflect the heterogeneity of the disorder and the relationship between the immune system, marrow suppression and MDS remains controversial. In addition it is unclear if the use of ATG with or with CSA impacted overall survival. In at least one Phase 3 trial comparing ATG + CSA versus best supportive care found no difference in overall survival or transformation to AML in the ATG + CSA arm. The use of immunosuppressive therapy to modulate the abnormal clone represents a controversial but a potential treatment that needs to be further evaluated to define the optimal group of patients who are candidates for immunosuppression.

Lenalidomide

Lenalidomide is a second generation 4-amino-gluteramide analog of thalidomide. Lenalidomide has multiple modes of action including pro-apoptotic cytokine generation, T cell stimulation or inhibition, antiangiogenesis, altering cell adhesions to bone marrow stroma, direct antiproliferative activity and the inhibition of a pro-inflammatory cytokines [85]. Lenalidomide was active in patients with del (5q) by selectively inhibiting the del(5q) clone. Lenalidomide in a phase II trial was administered at 10 mg/day for a 28 cycle or 21/28 days cycle in transfusion dependent patients with del(5q) abnormality 67% of patients became transfusion independent and 45% obtained a complete cytogenetic; complete and partial responses occurred in 84% of patients with del (5q) [63]. The finding of additional cytogenetic abnormalities, with the exception of −7/del(7q), did not significantly affect the response to lenalidomide. All patients who had a cytogenetic response became transfusion independent which was associated with improvement in overall survival. Patients who did not response to lenalidomide had higher rate of progression to AML. The median duration of response was 2.2 years (range 0.1–4.4 years)

and approximately 30% of patients remain transfusion independent after 3 years [63]. Most of the responding patients developed pancytopenia and the myelosuppression served as a surrogate marker of clonal suppression of the del(5q) clone and predictive of the response to lenalidomide. Greater than 70% of patients with the del(5q) developed thrombocytopenia within the first 4–8 weeks of treatment and the development of thrombocytopenia was significantly correlated with a favorable response and the development of transfusion independence and a cytogenetic response [63]. A platelet decline in the first 8 weeks of treatment correlated with the response to treatment and likely reflected a direct specific cytotoxic effect of lenalidomide on the MDS clone. Most patients needed dose reductions due to myelosuppression and/or thrombocytopenia and in phase III trial comparing 5 daily and 10 mg on days 1–21 on a 28-day cycle versus placebo, the 10 mg dose was superior. Long term follow up in patients treated with lenalidomide demonstrated a prolonged duration of response, with durable transfusion independence, cytogenetic responses and extended survival with improvement in quality of life [63]. In low risk, transfusion dependent MDS patient without the del (5q) cytogenetic abnormality the response rate to lenalidomide was much less and the mechanism of action appears to be very different. The overall response rate in this non del(5q) group was 33% but only 17% became transfusion independent. A majority of the responses were characterized as a decrease in RBC transfusions as compared to the baseline transfusion requirement. There were minimal or no changes in the bone marrow morphology and documented histological and cytogenetic responses were rare. Myelosuppression, grade 3/4, neutropenia and thrombocytopenia occurred only in 20–25% of patients. Moreover, the development of cytopenias including thrombocytopenia and neutropenia on lenalidomide for patients without the del(5q) was not associated with a response to treatment. The response duration of lenalidomide in the non-del (5q) patients ranged from 3 to 85 weeks with a median of 41 weeks. The median time to response was short at 4.8 weeks and response after 16 weeks of treatment were rare and alternate treatment was recommended for patients who fail to respond after 4 months of lenalidomide. Higher responses correlated with a baseline platelet count of $>150 \times 10^9$/L and shorter duration of MDS. Lenalidomide mechanism of action in MDS is clearly karyotype dependent. In del(5q) patient's lenalidomide appears to have a direct cytotoxic effect on the dysplastic clone resulting in eradication of the malignant clone. In contrast in the lower risk transfusion dependent MDs patient without the del(5q) lenalidomide effects appear to be mediated indirectly perhaps by effecting the bone marrow microenvironment or cytokine modulation.

Low-Dose Chemotherapy

Potential Differentiating Agents

Cytarabine administered at low doses (low dose Ara-C: Lo DAC) has been the most extensively used chemotherapy for elderly patients with high-risk, symptomatic MDS [86]. Cytarabine is administered daily by either continuous infusion or bolus subcutaneous injections at doses of 10–20/mg/m^2 for 14–21 days. At low dose cytarabine may induce differentiation but most likely works by a direct cytotoxicity [86]. In a prospective controlled trial patients higher risk MDS patients had the highest response rates, 20–35% (complete remission partial response [CR] + PR). The median duration of response for all subtypes was 8–15 months, with a range of 6–24 months. The response to Lo DAC correlated with its cytoreductive effect on the bone marrow. In a Phase III trial treatment with low-dose cytarabine was not superior to supportive care with regards to overall survival or leukemic transformation [86]. The role of low-dose cytarabine in the treatment of patients with high-risk MDS is controversial. In high-risk patients it remains a widely used treatment that may be effective in inducing transient responses in a subset of patients with progressive disease who are not candidates for alternative treatments. Low doses of chemotherapy may have a supportive role in selected patients with MDS. A number of trials have addressed the use of low doses of oral chemotherapy that was well tolerated and administered over a prolonged period. Low-dose oral etoposide (VP-16) and hydroxyurea were effective in controlling symptoms in some patients [87]. The use of steroids alleviated some of the cytokine-mediated symptoms associated with MDS/MPN and produced transient hematological improvements. Low-dose melphalan (2 mg/day until response or progression) in high-risk, frail patients with MDS was well tolerated and responses were noted in both hypercellular and hypocellular MDS [88]. The overall response rate to a prolonged course of low-dose melphalan in Phase II studies was approximately 40%. The duration of the responses to low-dose melphalan is unclear and additional studies are needed to determine its role in treating high risk MDS.

Histone acetylation facilitates active gene transcription and highly regulated by histone deacylases (HDACs) and histone acetyltransferases (HATs). HDAC inhibition may restore normal acetylations of histone proteins and promote cell cycle arrest and induce apoptosis in malignant cells. Normal differentiation and cell death programs are influenced by histone modification. HDAC expression is frequently deregulated in high risk MDS and AML and is therefore a potential therapeutic target. A number of HDAC inhibitors have been developed including Valproic acid, Entinostat, Belinostat, Panobinostat, Romidepsin, Vorinostat and others in various stages of development. HDAC inhibitors have multiple potential mechanism of action leading to

their pleiotropic activity and use in various disorders. The response rate for single agent HDACs is low and therefore they are combined with other agents including the DNA methyltransferase inhibitors including decitabine and azacitidine [88]. The potential synergism between demethylation and histone deacetylase inhibition made the use of combination therapy the focus of a number of ongoing trials.

DNA Methyltransferase Inhibitors

The DNA hypomethylating agents, 5-azacytidine (Azacitidine—Vidaza) and 2,5-deoxycytidine (Decitabine—Dacogen) are both analogs and the pyrimidine nucleoside cytidine. Both drugs inhibit DNA methyltransferase, reduce DNA methylation, and may induce re-expression of key tumor suppressor genes in MDS [89]. They are incorporated into the DNA of cells and result in hypomethylation of critical residues, cytosine prior to guanine sequences, (CpG) in the promoter regions in the DNA. At low doses they are believed to induce hypomethylation through depletion of cellular DNA methyltransferases and at higher doses both agents are cytotoxic by incorporation into RNA and/or DNA. The use of low doses in MDS is based on the principle that hypomethylation of DNA leads to reactivation of tumor suppressor genes expression which is passed down through subsequent generation of MDS cells.

The effect of azacitidine was evaluated in a randomized phase III trial. Azacitidine-treated patients showed a better overall response compared to those treated with supportive care only (60% versus 5%) and a longer time to progression to AML or death, but no overall survival advantage. A confirmatory international phase III trial evaluating the effects on long-term outcome with azacitidine versus conventional care (i.e., physician choice of low-dose cytarabine, standard chemotherapy, or best supportive care). Azacitidine was administered subcutaneously (75 g/m^2/day) for seven consecutive days every 28 days for patients with high risk MDS. Azacitidine treatment was associated with a significantly median overall survival 24.4 months compared to 15 months in the conventional care arm [89]. Most patients in the conventional treatment arm received low dose cytarabine. The 2 year survival was 50.8% in azacitidine as compared with 26.2% in the control, conventional treatment arm. This was the first randomized study to demonstrate a survival advantage for treatment with a hypomethylating agent. While some patients had a complete clinical response while receiving Azacitidine the durations of the complete response were short and not maintained when treatment was stopped. Myelosuppression was frequently observed in patients receiving Azacitidine and its role as a differentiating agent or de repressor of tumor suppressor genes in MDS was unclear. Responses were associated and improved quality of life in some patients. But in other trials the impact of treatment on survival was unclear. An oral formulation of 5-azacitidine is being studied in patients with low risk—intermediate risk MDS.

Decitabine (DAC) is a more potent inhibitor of DNA methyltransferase than azacitidine and is associated with greater myelosuppression. Decitabine has been effective in patients with high-risk MDS and may prolong the time to transformation to AML. The schedule of decitabine administration suggests that both the duration, dose and number of doses are important. Decitabine is given intravenously at various doses and dose schedules. The Phase I, II, and early Phase III trials DAC was administered the dose was 15 mg/m^2 over 3–4 h every 8 h for 3 days. The overall response rate in MDS was 49 and 64% in high-risk patients. The actuarial median survival time was 15 months and myelosuppression was common. In a randomized dose finding study, DAC was administered at 20 mg/m^2 IV over 1 h daily for 5 days; while not the FDA approved dosing, it is the standard of care at many institutions [89]. The CR rate in a dose finding trial was 39% and an overall response rate of 70%. The CR rate of 34% versus 9% when decitabine was given at a higher dose with fewer and less frequent cycles. Different dosing schedule have been associated with less myelosuppression and similar efficacy. Decitabine administered weekly, or 3 days a week was associated with a 60% trilineage response with minimal hematologic toxicity [90].

Phase III randomized studies however, did not demonstrate a survival benefit with DAC in a very high risk patient population. Azacitidine and decitabine generally require 3–6 treatment cycles to obtain an optimal therapeutic response, suggesting that the mechanism of action is more than just cytoreduction. For high-risk MDS, the hypomethylating agents either azacitidine and decitabine continue to be the treatments of choice [88]. MDS patients with monosomy 7(del 7) either alone or with other complex cytogenetic abnormalities may be particularly sensitive to treatment with DNMT inhibitors. High cytogenetic responses rates have been reported with both azacitidine and decitabine in retrospective analysis and both agents appear to alter the natural course of MDS and may be of benefit for selected patients. However, additional studies are needed to define the duration of therapy, dosing and their role as single agents or in combination for high risk patients with MDS. Some trials have shown a correlation between expression of methylated genes and clinical response but this finding remains controversial. Early trials using a combination of azacitidine and lenalidomide have reported acceptable toxicity and encouraging activity albeit in limited number of selected patients. In patients with low risk disease who have failed growth factors and/or lenalidomide the use of one of low dose azacitine or decitabine is associated with decrease in transfusion requirement with acceptable toxicity.

Intensive Chemotherapy

Combination, intensive cytoreductive induction chemotherapy regimens result in meaningful toxicity and modes

responses in patients with high risk MDS. The complete remission rate with intensive AML regimens is 40–60% with a 20–30% induction related mortality [88]. High risk cytogenetics, advanced age, and performance status are associated with poor response to intensive chemotherapy. In a retrospective study evaluating 510 patients with high risk MDS who received intensive chemotherapy the induction related mortality was 17% and 5 year survival probability 8% [37]. However in selected younger patients who present with poor prognosis MDS and who may proceed to an allogeneic transplant are potential candidates for intensive combination chemotherapy. Newly diagnosed patients with high risk MDS without a prior history of MDS appear to respond to standard AML induction chemotherapy in a similar fashion to de novo AML. However, patients who present with an antecedent or evolving MDS generally respond poorly to intensive AML-type induction chemotherapy [88]. The complete remission rate is 13–40% with an incidence of toxic deaths during therapy of 1–53%. Moreover, the role of post induction chemotherapy is unclear in patients with MDS who respond to treatment. In selected younger patients with MDS intensive chemotherapy including an anthracycline and cytarabine has resulted in complete remission rates of 20–60% but with a relapse rate of 90%. The remission durations are typically 6–12 months with only rare instances of prolonged disease-free survival. The poor response of MDS patients to intensive induction chemotherapy reflects the biological differences between de novo AML that occurs in younger patients and MDS. Moreover, in patients who have poor risk cytogenetics and prior MDS treatment or a longer time to progression responded poorly to induction chemotherapy with a median overall survival of less than 4 months. Moreover a CR may not impact overall survival in patients with MDS and therefore may not be the best end point for evaluating studies. The use of AML intensive induction regimens should be reserved selected younger patients with high risk disease as a bridge to an allogeneic stem cell transplant or as part of a investigational trial.

Stem Cell Transplantation

Autologous and allogeneic stem cell transplantation has been used in patients with MDS or MDS-AML. The role of autologous transplantation remains very controversial. The 3-year disease-free survival in a selected group of patients ranges from 14 to 58% in single arm or single institution studies [90]. All patients were transplanted in first remission and adequate number of stem cells were harvested. The 2-year survival in selected patients reported to the EBMT for patients in first complete remission was 39%, with a disease-free survival of 34% and a relapse rate of 64% [90]. In patients over the age of 40 years the disease-free survival was 25%. Patients younger than 40 years of age, and in first complete remission, responded better. The transplant-related mortality was high: 39% and 17% for patients over and younger than the age of 40 years, respectively. The relapse rate is higher than in patients with AML. Larger prospective studies are needed to define the potential role, if any, of an autologous stem cell transplantation for patients with MDS. However it is possible, in selected patients, to harvest polyclonal and karyotypically normal progenitors from the peripheral blood in younger patients with MDS following intensive induction chemotherapy [90].

Allogeneic stem cell transplantation represents the only potential curative therapy for patients with MDS and should be considered for patients who have an HLA compatible donor. While there are no prospective randomized trials that have compared outcomes of HSCT versus no HSCT for patients with MDS who have eligible donors it is accepted as the standard of care and generally recommended for selected low risk and all clinical eligible high risk patients with MDS [91]. However, patients with MDS have an increased incidence of transplant-related mortality as compared to patients with AML undergoing similar HSCTs [91]. The non relapse morbidity and mortality in MDS patients is high and not solely explained by the older age of the patient population [91]. Younger patients with MDS also appear to have an increased incidence of transplant-related complications. Patients with advanced disease and unfavorable cytogenetics have a higher probability of relapse and lower overall survival. The outcome is better for patients with a lower risk IPSS-R score, who are less transfusion dependent and a good performance status. Moreover, the standard risk factors that predict overall survival in MDS appear to affect the post-transplant outcome [92]. Performance status, comorbidities and fragility scores predicted overall survival [93]. Age was not the most important factor relating to transplant related morbidity and mortality [93]. The timing of the transplant for most patients remains controversial [94]. The factors that determine the overall survival and rates of relapse of an allogenic stem cell transplant include the percent of blasts, transfusion dependence, serum ferritin, comorbidities and pre transplant genetic profiles. The IPSS-R does not consider the prognostic variables associated with transplant related complications or survival but the IPSS-R score correlates with the HSCT outcome. In the IPSS-R scoring system the very high risk MDS patients had a only 10–14 months survival from the time of diagnosis and derived limited benefit from standard treatments [95]. Patients with high risk MDS should therefore be referred early in their course for consideration of an hematopoietic allogeneic stem cell transplant (HSCT) [90]. The role of HSCT in low risk MDS, while a accepted standard of care is controversial [91]. Patients with (very) low and intermediated risk IPSS-R scores with good performance status and poor, high risk features should be considered for an

allogeneic hematopoietic stem cell transplant. Low risk patients with poor risk cytogenectics, life threatening cytopenias and a transfusion requirement of ≥ units a month for 6 months should be considered for early referral to a transplant center. While the percent of bone marrow blasts did not significantly effect the overall survival cytoreductive therapy prior to HSCT is recommended for patients with ≥ bone marrow myeloblasts [96]. Patients with low risk disease have a better transplant related outcome than patients with more advanced disease [96]. However, treatment related complications is a major cause of morbidity and mortality after a HSCT transplant and must be considered in advising younger patients with low risk disease. Moreover older patients with multiple co-morbidities, very poor risk cytogenetic and mutational studies should not be offered a HSCT due to the very low chance of a successful HSCT. The patients pretransplant genetic profile and mutational findings are important predictors for overall survival and should be included in a decision to recommend a HSCT. TP 53, RAS and JAK 2 mutations were associated with a signigficantly shorter overall survival following a HSCT. Mutational studies are important predictors of overall response and should be obtained on all patients prior to performing a HSCT [96]. The use of reduced intensity regimens have decreased the early transplant related mortality and are generally recommended for patients with co morbid conditions or older age. The reduced intensity regimens are associated with a decrease in non relapse mortality but a higher risk of relapse. The reduced intensity transplant depend on the immune effects mediated by the donor derived cells and graft versus disease effect. Reduced intensity transplants, however, have not impacted the overall incidence of acute and chronic GVHD which remains the major cause of morbidity and mortality in older patients. Chronic GVHD remains a serious and life long complication of HSCTs. Studies have documented the decrease in quality of life in older patients with chronic GVHD [97]. Chronic GVHD is associated with an increase in cardiovascular disease, metabolic syndrome, diabetes, cognitive decline, fatigue, sexual dysfunction and endocrine abnormalities. However, for the younger patient with a good performance status and a suitable HLA matched donor an allogeneic stem cell transplant should be considered as it represents the only potential curative therapy and should be considered earlier in high risk patients. Determining the optimal timing of the HSCT remains a controversial issue and is the subject of a number of ongoing clinical trials [97, 98].

Future Directions and Evolving Role of Molecular Genetics

Advances in treatment will parallel our understanding of the molecular and immunological events involved in development and progression of MDS. Molecular genetic technolology may help in defining the prognosis of patients with MDS [99]. In AML the use of mutational analysis has helped define the prognosis of patients with favorable or normal cytogenetics [100]. Going forward molecular genetics, including DNA array technology and whole genome sequencing (WGS) studies are likely to play a significant role in defining more biologically based prognostic scoring system. The current MDS prognosis scoring systems stratify untreated patients at the time of diagnosis. The scoring systems do not account for changes in the prognostically important covariables over time. Currently used scoring models predict outcome at diagnosis but do not predict overall survival and transformation over time. The need for a biologically based model of MDS that can reflect the heterogenous course of high and low risk patients is needed to better define therapy and evaluate long term trials. A recent large study of patients with MDS undergoing stem-cell transplantation and evaluating the association of mutations with transplantation outcomes identified subgroups of patients with prognostic and therapeutic (conditioning regimen) implications. So for example TP53 mutations in patients with MDS were associated with sorter survival and shorter time to relapse and so was presence of RAS pathway and JAK2 mutations. Knowing mutational status of these key genes along with other biological parameters will help in clinical decision making [101] (Table 23.10).

Aberrations in gene mutations are still poorly characterized in MDS. The most common point mutations in MDS are still not specific for MDS but are associated with secondary, prognostically important mutations. In addition, most cases of MDS are genetically heterogenous with a dominant clone and many subclones and based on whole genome sequencing studies (WGS) no single gene is exclusively mutated in the funding clone [102]. The combined use of flow cytometry, mutational analysis and DNA arrays may identify the most appropriate therapy for patients with MDS. A recent Genomic classification of AML defined specific genomic categories that are biologically and prognostically important [99, 100]. Hopefully a similar classification system can be developed from the large MDS data bases. Incorporating molecular genetic studies into diagnostic and prognostic models for MDS with help in defining the role of newer agents with precise targets. A biologically based system will help evaluate studies of combination with immune based treatments for different subsets of patients. While it is till unclear how somatic mutations will be applied in cases of MDS. MDS associated genes, however not specific, appear to be relevant clinical markers for the diagnosis and prognosis but have yet to be incorporated in prognostic scoring systems. More dynamic scoring systems are needed to define biologically important subtype. A molecular diagnostic system will facilitate comparing the results of different trials and assessing treatments to specific subtypes. Newer prognostic models that incorporate molecular genetic studies are

being developed and validated. The use of molecular genetic studies in a predictive model may provide for a more dynamic scoring system that evolves over the patient's course and may help in the developing targeted therapy and the timing of HSCTs [103].

Summary

The myelodysplastic syndromes are a heterogeneous group of disorders with a variable clinical course. The incidence of MDS is increasing with the aging population and now represents the most common hematologic malignancy in patients older than 60 years. A majority of MDS patients present with lower-risk MDS and do not progress to AML and die of infections or bleeding related to their MDS. The WHO classification system remains controversial but is currently accepted at the standard criteria for defining MDS and attempts to separate MDS from reactive disorders other clonal disorders. Defining and differentiating MDS from other clonal or reactive process is critical many disorders can result in dysplasia and cytopenias. Clonal cytogenetic abnormalities are helpful in establishing a diagnosis of MDS, particularly when morphologic findings are subtle. Multilineage dyspoiesis favors MDS; however, prominent dysplasia can be seen associated with chemotherapy, immunosuppressive medications, and nutritional deficiencies. The diagnosis and management of patients with MDS require the close cooperation of clinician, cytogenetist and pathologist. The application of newer molecular studies may aide in the diagnosis and planning therapy.

MDS diagnosis and classification is currently in a transitional phase from reliance almost entirely on cell morphology supplemented by cytochemistry and G-banded karyotyping, towards a new model in which molecular and perhaps immunophenotypic findings will be fully incorporated. The revised 2016 WHO MDS classification represents the new standard for the diagnosis of MDS and reflects the complexity and heterogeneity of MDS. The trend towards greater classification complexity seems likely as additional molecular and cytogenetic lesions in MDS are characterized and incorporated into the diagnosis and prognosis. It is hoped that with additional information unifying themes will emerge that will help in defining prognosis and address new therapies.

The Peculiar Case of Thomas Alexander McBean

Saturday, Nov. 1st 1845

> *Dear Dr. Jones,*
> *–The tube contains urine of very high specific gravity. When boiled it becomes slightly opaque. On the addition of nitric acid, it effervesces, assumes a reddish hue, and becomes quite clear; but as it cools, assumes the consistence and appearance which you see. Heat reliquifies it. What is it?* [1]

This cryptic note and a urine sample were sent by a leading London general practitioner, Dr. Thomas Watson, to Dr. Henry Bence Jones, a 31-year-old physician at St. George's Hospital who had already established a reputation as a skilled chemical pathologist [2].

The patient, Thomas Alexander McBean, was a 45-year-old successful London grocer of "temperate habits and exemplary conduct," who had been married since 1825 and had numerous children [3, 4]. With the exception of two or three severe attacks of "frontal neuralgia," Mr. McBean enjoyed good health prior to his final illness. Over the course of the year 1844, Mr. McBean's family noted that he fatigued easily and appeared to stoop while walking. He also developed urinary frequency, and grew concerned that "his body-linen was stiffened by his urine" despite the absence of a urethral discharge [4]. He took a countryside holiday in September 1844 to try to regain his strength, which he felt had been impaired by overwork and a family illness.

While vaulting out of an underground cavern on his rustic vacation, Mr. McBean "instantly felt as if something had snapped or given way within the chest, and for some minutes he lay in intense agony, unable to stir" [4]. After the intense pain subsided, the patient made his way to a nearby inn where he rested for the night, and he felt considerably better the following day.

Upon his return to London, Mr. McBean saw Dr. William Macintyre, a 53-year-old Harley Street consultant and physician to the Metropolitan Convalescent Institution and to the Western General Dispensary in St. Marylebone, for an opinion regarding dyspepsia. During his consultation with Dr. Macintyre, Mr. McBean mentioned his recent accident, from which he was still somewhat sore. Dr. Macintyre applied a strengthening plaster to the patient's chest to try to reduce the pain produced by arm movement. The plaster and avoidance of exertion allowed the patient to recover enough to resume his work as a grocer, although pain and stiffness of the chest persisted. A month later, Mr. McBean consulted with a surgeon when acute chest pain and shortness of breath recurred; the surgeon removed a pound of blood (about 450 mL), and applied leeches and blistering agents. This treatment did not relieve the symptoms and was followed by several months of weakness.

In the Spring of 1845, Mr. McBean developed right-sided pleuritic pain, which was treated by cupping. Additional therapeutic bleeding induced further weakness. Wasting, pallor, and slight puffiness of his face and ankles led the patient to consult with Dr. Watson, who prescribed steel and quinine therapy, commonly used at the time for asthenic patients who had mysterious illnesses, especially if fever was present. The patient rapidly improved. By the middle of the Summer of 1845, Mr. McBean was able to travel to Scotland on holiday, where on the seacoast "he was capable of taking active exercise on foot during the greater part of the day, bounding over the hills, to use his own expression, as nimbly as any of his companions" [4]. His appetite became ravenous—so much so that he dreamed of eating dogs and cats, and ate great quantities of fish [1, 4]. His recovery was interrupted by the onset of diarrhea, "which proved obstinate, and reduced his strength considerably" [4].

In September 1845, Mr. McBean returned to London in a debilitated state, but free of pain. However, in October,

lumbar and sciatic pain developed and soon became severe. Warm baths, Dover's powder (ipecac and opium, as a purgative and for pain relief), tartrate of potash (frequently employed for rheumatism and for complex pain), acetate of ammonia (used in febrile and inflammatory conditions), camphor julep (frequently used for low-grade fevers, muscle spasms, and anxiety), and compound tincture of camphor did not help. The patient became confined to his home on Devonshire Street in the affluent Marylebone (Westminster) area of London. On October 30, 1845, Dr. Watson called in Dr. William Macintyre for a consultation.

Dr. Macintyre examined Mr. McBean's urine because of the patient's history of edema—a basic test that Dr. Watson had apparently neglected to perform. By 1845, urine examination was a well-established clinical practice, in large part because of the work of Richard Bright, a Guy's Hospital physician who linked proteinuria, "dropsy" (edema), and chronic kidney disease (thereafter known as "Bright's disease") in the 1820s [5]. Mr. McBean's urine specimen was opaque, acidic, and of high density, with a specific gravity of 1.035, but sugar was absent. When heated, the urine was found to "abound in animal matter"; with the addition of nitric acid, the turbid urine became clear, but a precipitate developed after an hour. Uniquely, this precipitate "underwent complete solution on the application of heat, but again consolidated on cooling" [1].

Upon receiving urine specimens sent by Drs. Watson and Macintyre on November 1, Bence Jones corroborated the finding that the addition of nitric acid produced a precipitate that was redissolved by heat and that formed again on cooling. He calculated that Mr. McBean was excreting more than 60 g/day of this proteinaceous material, and concluded that the protein was an oxide of albumin, specifically "hydrated deutoxide of albumen" [6]. Bence Jones calculated that there were 66.97 parts of "hydrated deutoxide of albumen" per 1000 parts of urine in the sample, and noted that this amount was equivalent to the proportion of albumin in healthy blood, so that every ounce of urine secreted was equivalent to the loss of protein from an equal volume of blood [1, 6].

Following Dr. Macintyre's visit, the patient continued to worsen. On November 3, 1845, the eminent clinical chemist Dr. William Prout (after whom Ernest Rutherford named the proton in 1920) joined Drs. Watson and Macintyre in consultation. Iron citrate and quinine were resumed, along with opiates, blistering agents, and counterirritants. Soon every movement of Mr. McBean's trunk produced excruciating pain. Great care and cautious maneuvering enabled the patient to "get in and out of bed on all fours," but he became weaker and eventually was confined to bed. He developed flatulence, and pronounced fullness and hardness in the region of the liver. He had phlegm in his chest and coughed fitfully, and suffered another episode of diarrhea.

On November 15, Dr. Bence Jones recommended treatment with alum, a substance used since ancient Egyptian times to clear turbid solutions, "with the view of checking the exhausting excretion of animal matter" [4]. The patient improved slightly in the following days and was able to sit up and enjoy his food, but on December 7 he "experienced a dreadful aggravation of lumbar pains" [4]. He had almost continual pain despite opiate treatment, became weaker, and died on January 1, 1846, exhausted but "in full possession of his mental faculties." The cause of death was listed as "atrophy from albuminuria" [3]. Involvement of the bones by the disease, aside from pain, was not recognized during the patient's illness.

Postmortem examination revealed emaciation. The ribs, which crumbled under the heel of the scalpel, were soft, brittle, readily broken, and easily cut by the knife. Their interior was filled with a soft "gelatiniform substance of a blood-red colour and unctuous feel" [4]. The sternum was soft and fragile and snapped when lifted. The heart and lungs were not remarkable. The liver was "voluminous, but of healthy structure." The kidneys appeared to be normal on both gross and microscopic examination, had "proved equal to the novel office assigned them," and were thought to have "discharged the task without sustaining, on their part, the slightest danger." The thoracic and lumbar vertebrae had the same degenerative changes as found in the ribs and sternum, but the humeri and femurs resisted "all efforts to bend or break them by manual force" [4].

John Dalrymple, surgeon to the Royal Ophthalmic Hospital, Moorfields (London), examined two lumbar vertebrae and a rib from Mr. McBean. In an 1846 paper on the "pathology of mollities ossium" (an obsolete general term for bony softness or fragility, analogous to the contemporary term "osteomalacia"), Mr. Dalrymple noted that the patient's lumbar vertebrae were markedly compressed and that they "scarcely exceed in thickness the intervertebral substance, and have lost nearly one-third of their normal bulk" [7]. The disease appeared to begin in the cancellous bone; it then grew and produced irregularly sized round dark red projections that were visible through the periosteum. Nucleated cells formed the bulk of the gelatiniform mass that filled the large cancellous cavities. Most of these cells were round or oval and about one-half to two times as large as an average blood cell. The cells contained one or two nuclei, each with a bright, distinct nucleolus. Wood engravings made from Mr. Dalrymple's drawings are consistent with the appearance of plasma cells (Fig. 24.1) [7]. Dalrymple postulated that these nucleated cells had a limited duration of life and then disintegrated, after which they were "carried out of the system by the circulation of the kidneys" [7].

In light of the autopsy findings, both Dalrymple and Macintyre believed that the disorder that Mr. McBean suffered from was a malignant disease of bone. Bright's disease

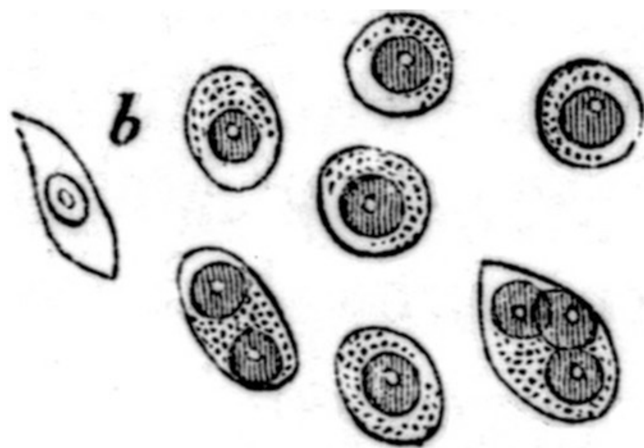

Fig. 24.1 Plasma cells obtained at the autopsy of Thomas Alexander McBean, January 1846 (wood engravings made from drawings by Mr. Dalrymple). https://commons.wikimedia.org/wiki/File:Plasmocytom-dalrymple.PNG; see also Dalrymple [7])

was considered in the differential diagnosis because of the albuminous matter in the urine, but there was no dropsy, and the kidneys appeared healthy. The diarrhea, weakness, emaciation, hepatic enlargement, flatulence, dyspepsia, edema of the ankles, puffiness of the face, and large amounts of Bence Jones proteinuria suggest to contemporary readers the possibility of amyloidosis in addition to myeloma. However, autopsy findings of a normal heart and kidneys and "voluminous liver of healthy structure" make the presence of amyloidosis less likely. Because the lardaceous or waxy changes of amyloidosis in the liver were commonly recognized during the 1840s (although not yet understood), it is unlikely that gross changes of amyloidosis would have been overlooked if present in Mr. McBean [8].

In 1967, Bristol experimental pathologist John Clamp located Mr. McBean's death certificate in the General Register Office in London, using dates and descriptions of the patient from the case reports of Drs. Macintyre and Bence Jones. Dr. Clamp suggested that the name *multiple myeloma* might instead have been *McBean's disease with Macintyre's proteinuria* [3]. However, although Dr. Macintyre first noticed the peculiar heat properties of Mr. McBean's urine, it was Bence Jones who emphasized its place in the diagnosis of myeloma—as he emphasized, "I need hardly remark on the importance of seeking for this oxide of albumen in other cases of mollities ossium"—and who can be credited with developing the first biochemical test for detection of cancer [1, 9]. The modest Dr. Macintyre stated that his "share in this part of the inquiry, it must have been seen, was very humble… I shall be content if I have succeeded in pointing out to future observers, gifted with the requisite qualifications for conducting researches of a higher order, certain definite and distinctive characters by which a peculiar and hitherto unrecorded pathological condition of the urine may be recognised and identified" [4].

Earlier Cases of Multiple Myeloma

Although the first clear description of multiple myeloma did not occur until the 1846–1850 chemical, clinical, and pathological reports of Bence Jones, Macintyre, and Dalrymple described above (all wrote single-authored publications describing the same individual patient), the disease has undoubtedly existed for centuries. It seems likely, for example, that some of the cases of "mollities ossium" reported in the eighteenth and early nineteenth centuries represent patients who had myeloma. However, without detailed microscopic description of plasma cells such as that provided by Mr. Dalrymple in Mr. McBean's case, or recognition of a unique disease-associated protein such as that first detected by Drs. Bence Jones and Macintyre, it is not possible to be certain.

When examining old skeletons, sharply demarcated spheroid skeletal lesions that are "purely lytic"—i.e., lacking gross evidence of sclerosis or formation of new bone—are suggestive of multiple myeloma, especially when such lesions are multiple and occur in the proximal long bones and axial skeleton [10]. Two male human skeletons with this bony lesion pattern, with estimated ages at death of between 40 and 60 years and dating from 3200 to 500 BCE, were identified from among 905 individuals excavated at Thebes-West and Abydos in Upper Egypt [11], while two similarly affected skeletons were found among 2547 individuals entombed in a rural South German ossuary between 1400 and 1800 AD [12].

Paleopathologists have identified additional ancient bones with features suggestive of multiple myeloma, such as the skeleton of a middle-aged Icelandic female from the eleventh to fifteenth century AD [13], two calvaria from medieval Britain [14], four American Indian skeletons from 200 to 1300 AD [15], and 14 pre-Columbian American skeletons dating back to 3300 BC [16]. The Hunterian Museum of the Royal College of Surgeons in London has in its collection the bones of an approximately 45-year-old Roman soldier with myeloma-like lesions. Suspicious rounded lytic lesions can also be seen in the remains of George Grenville (1712–1770), the Whig Prime Minister whose administration passed the notorious Stamp Act of 1765 that first alienated American colonists from England, and who was autopsied by pioneering Scottish surgeon John Hunter in 1770 [17].

Multiple myeloma with Bence Jones proteinuria occurs spontaneously in contemporary animals [18], raising the possibility that myelomatous lesions might be identifiable in prehistoric nonhuman fossils. Paleontologists have observed multiple lytic defects without evidence of bony remodeling in a few dinosaur skeletons from the Jurassic and Cretaceous periods, and these have been interpreted by some observers as evidence of an origin of multiple

myeloma in the Mesozoic era or earlier [19]. However, caution is indicated in interpreting such ancient specimens.

In any case, it is almost certain that 39-year-old Sarah Newbury, a patient described by distinguished London surgeon Samuel Solly in 1844, had multiple myeloma [20]. Mrs. Newbury had experienced increasing fatigue and, 4 years before her death, was suddenly seized with a violent pain in her back when stooping. "Rheumatic pains" in her limbs occurred a year later, and these progressed to the point where her gait became unsteady. Her limb pain increased greatly after a fall in February 1842, which resulted in inability to lift her right leg, and she was confined to her room. Two months later, her femurs fractured "into a thousand pieces" when her husband, a policeman, lifted her from the fireside to carry her to her bed. Pathological fractures of the clavicles, right humerus, and right radius and ulna followed.

Mrs. Newbury first saw Solly in consultation in October 1843, but thereafter wrote him a letter asking him not to visit her again because she was vexed that he had prescribed a bitter infusion to try to improve her poor appetite. She was then lost to medical follow-up until she was admitted at the insistence of her husband to St. Thomas's Hospital in Southwark (South London) on April 15, 1844, in an extremely debilitated state. Over the next few days she was treated with an infusion of orange peel and a rhubarb pill, fed with bland foods including arrowroot, and given an opiate at night if required. Examination of the copious amount of urine she produced revealed a "large quantity of phosphate of lime," but blood tests could not be performed because Mrs. Newbury was "too suspicious and irritable" to allow them [20]. She died suddenly on April 20, 1844, of "asphyxia" [20].

At autopsy, Mrs. Newbury's thoracic cavity was reduced to just 4 in. in transverse diameter. The right lung was compressed to about one-fourth of its natural size, and the left lung was decreased to one-half the extent of the right lung because of skeletal changes. The cancellous portion of the sternum (Fig. 24.2) had been replaced by a red substance similar to that seen in Mr. McBean [4]. A peculiar red material had also replaced much of the femur; it ranged in color "from a deep Modena red to a bright scarlet crimson" (Fig. 24.3). Solly examined this red matter with John Birkett of Guy's Hospital, a surgeon and anatomist, who described the cells within as "very clear, their edge being remarkably distinct, and the clear *oval* outline enclosing *one* bright *central* nucleus, *rarely two, never more*" [italics Solly's] [20]. John Dalrymple noted that the microscopic appearance reported by Birkett "accords very nearly" with his description of Mr. McBean's marrow [7]. Solly postulated that the process affecting Mrs. Newbury was inflammatory and had begun with an abnormality of the blood vessels, in which the "earthy matter of the bone is absorbed and thrown out by the kidneys in the urine" [20].

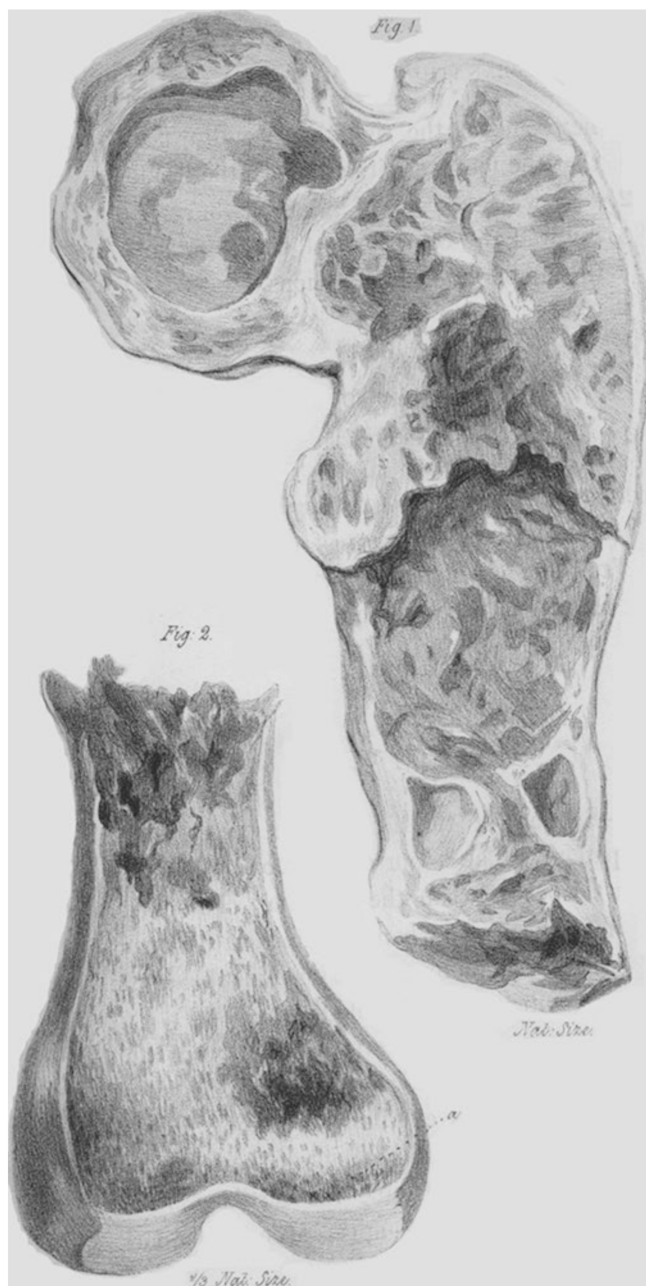

Fig. 24.3 Femur of Sarah Newbury showing destruction by myeloma tumor (from Solly [20])

Other Contributions to Bence Jones Proteinuria and Monoclonal Protein Detection

Although much has been written about the life and scientific work of Henry Bence Jones [2, 21–23], a number of other persons played a part in the evolving story of Bence Jones proteinuria.

In 1846, Johann Florian Heller, an Austrian chemist and physician working in Vienna, described a protein in the urine of a patient that precipitated when warmed a little above 50 °C and disappeared upon further heating [24]. Although Heller did not recognize the re-precipitation of the protein when the urine was cooled, it seems likely that he was observing a Bence Jones protein. Heller also distinguished this new protein from albumin and casein [24]. Richard Fleischer in Erlangen, Germany, was the first to use the term "Bence Jones protein" in writing, in an 1880 paper describing a substance with chemical characteristics of Bence Jones protein that he isolated from normal bone marrow [25].

In 1883, Wilhelm Friedrich Kühne, a prominent Berlin physiologist best known for coining the term "enzyme," described finding Bence Jones protein in the urine of a 40-year-old patient from Amsterdam who died in 1869 after an illness characterized by bone pain, spinal curvature, and cranial neuropathy, possibly from an extramedullary plasmacytoma [26]. Kühne isolated the protein and found that the carbon, hydrogen, and nitrogen levels were similar to those described by Bence Jones, and attributed any differences in results between his report and that of Bence Jones to the fact that his preparation was more pure than Bence Jones's preparation. He named the peculiar protein "albumosurie."

In 1898, Thomas R. Bradshaw of Liverpool observed that meals had little or no influence on the amount of Bence Jones proteinuria [27]. There was no nocturnal variation, and Bradshaw believed that the rate of protein excretion was "pretty constant throughout the 24 hours."

In 1899, Alexander Ellinger in Germany suggested that there might be an abnormal protein in the blood in patients with myeloma that was similar to the Bence Jones protein, but he was unable to prove this assertion [28].

Waltman Walters at Mayo Clinic in Minnesota described three carefully evaluated patients with multiple myeloma in 1921, and, like Bradshaw, reported that the quantity of Bence Jones proteinuria in these patients was independent of their oral protein intake and did not vary diurnally [29]. In one patient, intravenous injection of Bence Jones protein appeared to increase the amount of Bence Jones proteinuria. Walters also found Bence Jones protein in the blood of one patient and in the bronchial secretions of another. He concluded that Bence Jones proteins were of endogenous origin, and hypothesized that they were derived from blood proteins through some type of action of abnormal cells in the bone marrow [29].

The following year—1922—Stanhope Bayne-Jones and D.W. Wilson from Johns Hopkins made 12 preparations of Bence Jones proteins from five patients, two of whom had been included in Walters' report [30]. Bayne-Jones and Wilson immunized rabbits by intravenous injection of the Bence Jones protein, and performed precipitin tests with the Bence Jones protein preparations, concluding that Bence Jones proteins consisted of two groups of similar but not identical proteins.

Beginning in the 1930s, there was considerable debate between proponents of two schools of thought on the origin of Bence Jones protein. The first theory, championed by Adolf Magnus-Levy in Berlin, held that proteinaceous materials found in the urine were the result of overproduction of normal serum proteins by the bone marrow [31]. An alternative view was held by Maxwell Wintrobe and Mar Van Rensselaer Buell at Johns Hopkins in Baltimore. In a description of the phenomenon of cryoprecipitation in 1933, Wintrobe and Buell argued that pathologic proteins in plasma cell disorders were likely to be distinct from all normal serum components [32].

In the early 1950s, protein chemist Frank W. Putnam at the University of Chicago performed a series of experiments in myeloma patients using ^{13}C radioisotopes, which helped clarify the origin of Bence Jones proteins. Putnam first showed that the Bence Jones proteins from 18 different patients with myeloma were each biochemically unique, though as had been suggested by Bayne-Jones and Wilson they clustered into two antigenic groups. In 1955, Putnam and his coworker Sarah Hardy showed that Bence Jones proteins derived directly from the body's metabolic pool of nitrogen, rather than being a breakdown product of some sort of plasma precursor [33].

In 1956, Leonhard Korngold and Rose Lipari at New York's Sloan Kettering Institute for Cancer Research and Cornell Medical College Department of Biochemistry formally demonstrated a relationship between Bence Jones protein and the serum proteins of multiple myeloma [34]. As a tribute to Korngold and Lipari, the two major classes of Bence Jones proteins are designated by the Greek letters κ and λ.

One hundred and seventeen years after the initial description of the unique heat properties of Bence Jones protein—in 1962—Gerald Edelman and Joseph Gally at the Rockefeller Institute for Medical Research in New York demonstrated that the light chains prepared from a serum immunoglobulin G (IgG) myeloma protein and the Bence Jones protein from the same patient's urine were identical in all respects: the same amino acid sequence, similar spectrofluorometric behavior, the same molecular weight, identical appearance on chromatography with carboxymethylcellulose and on starch gel electrophoresis after reduction and alkylation, and the same ultracentrifugal pattern—as well as the same thermal solubility [35]. The light chains precipitated when heated to between 40 and 60 °C, dissolved on boiling, and reprecipitated when cooled to between 40 and 60 °C.

Shortly after Edelman and Gally's discovery, Norbert Hilschmann and Lyman Craig of the Rockefeller Institute [36] and Koiti Titani and colleagues in Putnam's laboratory [37] provided the first antibody amino acid sequences, and showed that Bence Jones proteins were not only related to the light chains of gamma globulin but also that each light chain was divided into a "variable" or V region, and a "constant" or C region. This structure accounts for the heterogeneity of normal gamma globulins and for antibody specificity and diversity.

Diagnostic Tests for Myeloma: Beyond Bence Jones Proteinuria

Arne Tiselius in Uppsala, Sweden, a 1948 Nobel Laureate in Chemistry, reported an improved method of serum electrophoresis in 1937, which allowed separation of serum globulins into three components: alpha, beta, and gamma [38]. In 1939, Tiselius isolated antibody activity to the gamma fraction [39], while Lewis Longsworth and colleagues at the Rockefeller Institute first noted the classic myeloma "M-spike" in that same year, using Tiselius' electrophoretic techniques [40].

In 1953, Pierre Grabar and Curtis A. Williams at the Institut Pasteur in Paris described immunoelectrophoresis, a technique that is infrequently practiced today but routinely facilitated the diagnosis of multiple myeloma [41]. Immunofixation or "direct immunoelectrophoresis" was reported by Armine T. Wilson from the Alfred I. duPont Institute in Wilmington, Delaware, in 1964 and is now the standard method for the recognition of monoclonal proteins [42]. Wilson applied antisera on the surface of the agar immediately after completion of electrophoresis. Immunofixation has proven useful when the results of immunoelectrophoresis are equivocal [43], and is also helpful in the recognition of small monoclonal light chains not detectable by immunoelectrophoresis [44].

Nonsecretory multiple myeloma is defined by the absence of detectable monoclonal proteins in serum and urine using immunoelectrophoresis or immunofixation; it accounts for <3% of patients with multiple myeloma. In 2001, Arthur J. Bradwell from Birmingham, England, and his colleagues reported an immunological method for detecting imbalance in the concentration of κ and λ serum free light chains, using specific antibodies that bind only to free light chains, not to light chains bound to immunoglobulin heavy chains [45]. Serum free light chain concentrations are now routinely measured in clinical practice.

Early Cases of Multiple Myeloma After Sarah Newbury and Thomas McBean

In 1867, Hermann Weber, a German physician working in London, described a 40-year-old man with mollities ossium and first linked this condition to the pathological finding of tissue deposition of amyloid [46]. The patient suffered severe sternal and lumbar pain, and movement of his head produced pain in his neck and arms. The patient died less than 4 months

after the initial onset of pain. Postmortem examination revealed that the sternum was fractured in two places, and had been almost entirely replaced by a grayish-red substance that was thought to have the microscopic appearance of a sarcoma. Several round defects in the skull were also filled with the same morbid substance as that found in the sternum, and many of the ribs, several vertebrae, and parts of the pelvis were involved by the same process. The waxy changes of amyloid were found in the kidneys and spleen.

During a meeting of the Pathological Society of London in February 1872, William Adams exhibited (on behalf of Thomas Stretch Dowse of Highgate Infirmary) specimens from the body of a 62-year-old woman with "acute rheumatism" characterized by bone pain, fractures, and fever, who died 8 days after admission to the hospital for a humerus fracture. The left femur fractured while the body was being placed on the autopsy table. Lardaceous changes consistent with amyloid were found in the liver and kidneys, and the cancellous portions of the bones had been replaced by a homogeneous, soft, gelatinoid substance. When examined microscopically, the substance filling the hollowed bone was shown to consist of small spherical and oval cells that contained one eccentric oval nucleus (rarely two) [47].

The term "multiple myeloma" was introduced in 1873 by J. von Rusitzky from Kiev, of whom little is known other than that he had once worked in Friedrich von Recklinghausen's laboratory in Strasbourg. During an autopsy, von Rusitzky noted eight separate tumors of the bone marrow in a patient, which he called "multiple myelomas" [48]. The patient, a 47-year-old man, had presented with a gradually enlarging tumor in the right temple. Subsequently, thickening of the sternal manubrium and the seventh rib developed, followed by paraplegia. At autopsy, it was revealed that a fist-sized tumor in the right frontal region extended into the orbit and had produced ophthalmoplegia. Other postmortem findings included an apple-sized tumor in the right fifth rib, a tumor in the left seventh rib that produced a fracture, a tumor of the sternum, a tumor involving the sixth to the eighth thoracic vertebrae (the cause of the paraplegia), and three tumors of the right humerus. Although von Rusitzky's description of the tumor cells in this case is vague, he described round cells with a nucleus located in the periphery near the cell membrane, suggestive of plasma cells. The report did not comment on whether Bence Jones proteinuria was found during life. In Russia and Soviet-influenced regions, myeloma was called "von Rusitzky syndrome" for much of the twentieth century.

There were few further publications about the disease until 1889, when Otto Kahler, an internist from Prague working in Vienna, described the case of a 46-year-old physician named Dr. Loos [49]. In July 1879, Dr. Loos developed sudden severe pain in the right upper thorax, which was aggravated by taking a deep breath. Six months later, this pain recurred and became localized to the right third rib, which was tender to pressure. During the next 2 years, intermittent pain aggravated by exercise occurred in the ribs, spinal column, left shoulder, upper arm, and right clavicle. Albuminuria was first noticed in September 1881. Skeletal pain, made worse by movement, continued to occur intermittently. Pallor was noted in 1883 and pneumonia developed in February 1884. In December 1885, Dr. Loos was first seen by Kahler, who noted anemia and focal tenderness of many bones. Kyphosis was so severe that when Dr. Loos stood up, his lower ribs touched his anterior iliac crest. Dr. Loos subsequently suffered from recurrent bronchial infections and intermittent hemoptysis. During the following year, Dr. Loos' kyphosis increased and height decreased monthly, to the point where his chin pressed against the sternum, resulting in skin ulceration. On August 26, 1887, Dr. Loos died, a remarkable 8 years after his initial symptoms.

Kahler's autopsy report of Dr. Loos described hepatosplenomegaly, but lardaceous change was not mentioned. The ribs were soft and could be broken with minimal effort. Soft gray-reddish masses were noted in the ribs and thoracic vertebrae. Microscopic examination showed large round cells, consistent with myeloma. It is interesting to note that the patient had a high fluid intake and took sodium bicarbonate on a regular basis; this regimen may have helped prevent renal failure. Kahler recognized that the urinary protein obtained from Dr. Loos had the same characteristics that Bence Jones had described. For many years, the eponym "Kahler's disease" was widely used in Western Europe and the United States to describe the condition once known by "mollities ossium with Bence Jones proteinuria" and now called multiple myeloma.

Detailed examination of Dr. Loos' urine by Karl Hugo Huppert, professor of medicinal chemistry at the German University in Prague, showed that a protein in the urine precipitated at 53–59 °C, cleared with heating to boiling, and then reprecipitated during cooling [50]. The patient excreted 6.7 g of the protein daily, which Huppert noted was distinct from albumin.

It is likely that A.L., the 43-year-old engineer that Joseph Coats of Glasgow reported in 1891 as having "multiple sarcoma of bone," actually had multiple myeloma [51]. The patient developed a large tumor of the sternum 5 years before his final hospitalization and death, and later noticed tumors in the right clavicle, right humerus, and left hip. He experienced back pain radiating to the lower extremities, weakness of his legs, and a pathological fracture of the right humerus. Postmortem examination revealed multiple tumors with involvement of the ribs and vertebral bodies. Microscopic examination showed round or polygonal cells "about 1/2000 in. diameter" (~13 μm, a reasonably accurate estimate of the diameter of a neoplastic plasma cell) with oval nuclei constituting more than half the diameter of the cells [51].

An 1897 Italian description of Kahler's disease by Camillo Bozzolo, a Milanese physician and pathologist working in Torino, resulted in the dual eponym "*malattia di Kahler-Bozzolo"* gaining currency in Italy in the first part of the twentieth century [52].

Other Cases of Multiple Myeloma in the Nineteenth and Twentieth Centuries

In 1894, James Bryan Herrick and Ludvig Hektoen at Rush Medical College in Chicago reported what is probably the first recognized case of multiple myeloma in the United States, just a few years after the report of Kahler [53]. A 40-year-old woman complained of lumbar pain and a nodule on the lower end of the sternum. At autopsy, there were multiple nodules attached to the sternum, right clavicle, and ribs. The sternum was thickened, irregular, and covered with tumor masses, yet was soft and flexible. Multiple nodules were found on the ribs, which bent readily without cracking. Two of the dorsal vertebral bodies were largely replaced by soft tumor masses, and fungoid masses were seen in the skull. Microscopic examination of these lesions revealed round "lymphoid" cells with large nuclei. Herrick is also credited with the first clear description of sickle cell disease (initially recognized by one of his subordinates), as well as being the first to link angina with acute coronary syndromes [54, 55].

In 1898, Frederick Parkes Weber—honorary physician to the German Hospital in Queen's Square, London, and son of Hermann Weber mentioned above—reported a case of multiple myeloma, and suggested that radiographs (discovered by Würzburg physicist Wilhelm Conrad Röntgen in 1895) would greatly facilitate the diagnosis of such cases [56]. Weber also concluded in a report of another case that Bence Jones protein was produced by the bone marrow, and that the presence of Bence Jones protein was of "fatal significance" and nearly always indicated that the patient had multiple myeloma [57]. Weber and Lister Institute bacteriologist John Charles Grant Ledingham later suggested that Bence Jones protein derived from cytoplasmic residua of karyolyzed plasma cells [58].

In 1928, C.F. Geschickter and M.M. Copeland from Johns Hopkins reviewed all 425 cases of multiple myeloma reported since 1848 [59]. They called attention to six cardinal features of the disease: multiple tumors of the axial skeleton, pathological fractures, Bence Jones proteinuria, back pain, anemia, and chronic renal disease.

Sternal aspiration of bone marrow during life, described by Soviet physician Mikhail Arinkin in Leningrad in the late 1920s, greatly increased the recognition of multiple myeloma [60]. In 1938, hematologists Nathan Rosenthal and Peter Vogel at Mt. Sinai Hospital in New York reported that only 3 cases of multiple myeloma had been recognized at the Mt. Sinai Hospital from 1916 to 1935, but that 13 cases were found in the ensuing 2 1/2 years [61]. Rosenthal and Vogel attributed this marked increase in recognition to the use of sternal puncture in patients with obscure anemia or skeletal abnormalities, and suggested that many cases of myeloma had likely been missed in the past.

In 1947, Edwin (Ned) Bayrd and Frank Heck at Mayo Clinic in Minnesota described 83 patients with histological proof of myeloma seen at their institution through December 1945 [62]. The duration of survival in the Mayo series ranged from 1 to 84 months (median, 15 months). The median survival for myeloma would not increase much beyond this until the introduction of novel agents in the early twenty-first century [63].

Plasma Cells, Hyperproteinemia, Recognition of Monoclonality, and Prognosis

The term *plasma cell* was coined by German anatomist Heinrich Wilhelm Gottfried von Waldeyer-Hartz in 1875, but his description is not characteristic of plasma cells, and it is most likely that he was instead observing tissue mast cells [64]. Plasma cells were described accurately by Spanish neuroscientist Santiago Ramón y Cajal in 1890, during the study of syphilitic condylomas. Ramón y Cajal stated that the unstained perinuclear area ("hof," from a German term meaning yard or court) contained the Golgi apparatus. In 1891, German dermatologist Paul Gerson Unna used the term *plasma cell* while describing cells seen in the skin of patients with lupus erythematosus [65]. However, it is not known whether he actually saw plasma cells. In 1895, Hungarian pathologist Tamás Marschalkó outlined the essential characteristics of plasma cells, including blocked chromatin, eccentric position of the nucleus, a perinuclear pale area ("hof"), and a spherical or irregular cytoplasm [66].

In 1900, pathologist J.H. Wright of Johns Hopkins described a 54-year-old man with multiple myeloma, and pointed out that the tumor consisted of plasma cells, proposing the new term "plasma cell myeloma" [67]. Wright emphasized that the neoplasm originated not from red marrow cells collectively but from only one type of cell, the plasma cell. Interestingly, Wright's patient was probably the first in whom radiographs revealed changes in the ribs, thus contributing to the diagnosis.

Although Victor C. Jacobson of the Peter Bent Brigham Hospital in Boston reported Bence Jones protein in the serum in a patient with chronic nephritis in 1917 [68], it was not until 1928 that biochemist William A. Perlzweig and colleagues from Duke University reported hyperproteinemia when they described a patient with multiple myeloma who had 9–11 g of globulin in his serum [69]. The patient also

had Bence Jones proteinuria and probably a small amount of Bence Jones protein in the plasma. Perlzweig and coworkers noted that it was almost impossible to obtain serum from the clotted blood because the clot failed to retract, even on prolonged centrifugation.

The concept of monoclonal versus polyclonal gammopathies was lucidly presented in the 1961 edition of the Harvey Society Lecture series (founded 1905) in New York by Jan Gösta Waldenström of Malmö General Hospital, Sweden [70]. Waldenström clearly described patients with a narrow band of hypergammaglobulinemia on electrophoresis as having a monoclonal protein. Although many of these patients had multiple myeloma, others had no evidence of malignancy and were considered to have idiopathic "essential hypergammaglobulinemia" or benign monoclonal gammopathy. Most physicians now use the term "monoclonal gammopathy of undetermined significance" (MGUS) instead, because in some of these patients, multiple myeloma, macroglobulinemia, or a related disorder will eventually develop [71–73]. Waldenström further correctly regarded the broad band in hypergammaglobulinemia as a polyclonal increase in proteins. This simple distinction is extremely important clinically because patients with a monoclonal gammopathy already have or may develop a neoplastic process, whereas patients with a polyclonal gammopathy have an inflammatory or a reactive cause of their hypergammaglobulinemia [70, 74].

In 1975, Brian G.M. Durie and Sydney Salmon proposed a three-tier myeloma staging system with prognostic value [75]. The Durie-Salmon staging system saw widespread clinical use for more than 30 years but had limitations, particularly with respect to categorization of bone lesions. In 2005, a multinational group chaired by Philip Greipp from Mayo Clinic used data from more than 11,000 patients to develop a simplified International Staging System, based on serum β (beta) 2-microglobulin and albumin levels [76]. Other important prognostic factors in myeloma defined in recent years include specific chromosomal abnormalities detectable by fluorescent in situ hybridization or conventional karyotyping, such as deletion of chromosomes 13 or 17p, abnormalities of chromosome 1, hyperdiploidy, or immunoglobulin heavy-chain translocations such as t(4;14), t(11;14), or t(14;16) [77]. A growing number of somatic mutations have been described in myeloma cells, including mutations in genes important in protein synthesis, histone modulation, coagulation, and NF-kappaB signaling [78].

Treatment of Multiple Myeloma

Treatment of multiple myeloma has progressed considerably since the nonspecific remedies attempted for Mr. McBean in 1845, especially with the introduction of highly active novel agents including immunomodulatory drugs and proteasome inhibitors [63]. Despite these novel drug therapies and the routine use of autologous stem cell transplantation for patients with myeloma [79], which have improved survival in recent years [64], the condition remains incurable.

The Urethane Distraction

In 1947, Nils Alwall, a Swedish dialysis pioneer, reported a patient with multiple myeloma who experienced a reduction in globulin levels from 5.9 to 2.2 g/dL, an increase in hemoglobin, disappearance of proteinuria, and reduction in bone marrow plasma cells from 33 to 0% when treated with urethane (ethyl carbamate) [80]. On the basis of this single report, for almost 20 years urethane was commonly used as a treatment of myeloma. The demise of urethane in myeloma therapy occurred in 1966, when James Holland and his colleagues reported results from a randomized trial of 83 patients with previously treated or untreated multiple myeloma who received either urethane or a placebo consisting of cherry- and cola-flavored syrup [81]. No difference was seen in objective improvement between the two treatment groups, and the urethane-treated patients died earlier on the average than those treated with placebo. This difference was ascribed to urethane-induced azotemia.

Alkylating Agents and Combination Chemotherapy

In 1958, a Soviet medical team led by Nikolai Blokhin reported benefit in three of six patients with multiple myeloma who were treated with "sarcolysin" (L-phenylalanine mustard, melphalan, Alkeran) [82]. Four years later, Daniel Bergsagel at the M.D. Anderson Cancer Center in Houston, Texas, and his colleagues observed improvement in 8 of 24 patients with multiple myeloma who were treated with melphalan [83].

In a 1964 report, cyclophosphamide-treated patients with myeloma had a median survival of 24.5 months, whereas a control myeloma group had a median survival of 9.5 months [84]. Objective improvement occurred in 81 of 207 cyclophosphamide-treated patients. Various combinations of alkylating agents with vinca alkaloids, anthracyclines, and corticosteroids (see below) were used for the treatment of multiple myeloma, but these combinations did not prove superior to melphalan and prednisone [85, 86].

Corticosteroids

Corticosteroids were first systematically tested in patients with myeloma by R.E. Mass in 1962, who reported the

results of a placebo-controlled double-blind trial in which single-agent prednisone decreased serum globulin and increased hematocrit, but did not improve survival [87]. In 1967, Sydney Salmon and his colleagues reported that prednisone administered at a dose of 200 mg orally every other morning produced benefit in 8 of 10 patients with poor-risk myeloma, and adverse events were uncommon [88]. In two Cancer and Leukemia Group B myeloma treatment protocols, prednisone as a single agent produced a 44% objective response rate [89]. The combination of melphalan plus prednisone (MP) was established in a randomized trial of 183 myeloma patients led by Raymond Alexanian and colleagues; patients treated with MP lived 6 months longer than those who received melphalan alone [90]. Later dexamethasone became the corticosteroid of choice in myeloma therapy.

Stem Cell Transplantation

The first report of human hematopoietic stem cell transplantation was published in 1957 by E. Donnall Thomas and Joseph Ferrebee at the Mary Imogene Bassett Hospital in Cooperstown, New York, and their colleagues [91]. Thomas and Ferrebee treated six patients (one had multiple myeloma) with total-body irradiation and chemotherapy followed by an intravenous infusion of bone marrow cells from a healthy donor. Although none of the patients lived 100 days, and transient engraftment occurred in only two of the six patients, Thomas remained convinced of the procedure's potential and continued to purse it, in collaboration with immunologists who developed the concept of tissue (human leukocyte antigen) typing [92]. Thomas moved to Seattle in 1963, and his groundbreaking research on stem cell transplantation eventually led to a Nobel Prize in 1990.

The Seattle group reported a syngeneic bone marrow transplant in a patient with multiple myeloma in 1982; the patient's physician brother served as donor [93]. Four years later, Alexander Fefer from Seattle and his colleagues described five myeloma patients who received a syngeneic bone marrow transplant [94]. In 1987, a European group led by Gösta Gahrton of Sweden reported that 10 of 14 patients with multiple myeloma who received an allogeneic bone marrow transplant from an HLA-compatible sibling donor survived for at least 6 months (median, 12 months) [95].

The first autologous bone marrow transplantation for myeloma was reported in 1983 by Tim McElwain and Ray Powles from the Institute of Cancer Research and the Royal Marsden Hospital in the United Kingdom [96]. Four years later, Bart Barlogie and his colleagues at the University of Arkansas reported the use of melphalan 140 mg/m^2 and total-body irradiation (1.5 Gy) followed by autologous allogeneic bone marrow transplantation in multiple myeloma patients refractory to chemotherapy [97]. Subsequently, Barlogie developed intense treatment programs incorporating tandem autologous transplantation, which he called "total therapy"—a term and concept pioneered for childhood leukemia at St. Jude Children's Research Hospital in Memphis. Subsequent clinical trials of transplantation regimens played a major role in establishing high-dose therapy and stem cell rescue as a standard treatment for multiple myeloma.

Novel Agents

Since the late 1990s, several exciting new agents have emerged and achieved regulatory approval, which has improved outcomes for patients with myeloma [63].

Thalidomide, Lenalidomide, and "Immunomodulatory" Agents

The tragedy of thalidomide embryopathy is widely known outside of the medical profession, but the drug's rebirth as an immunomodulatory and antineoplastic agent is less well recognized.

In 1957, German pharmaceutical company Chemie Grünenthal began marketing thalidomide (α-N-[phthalimido] glutarimide) as a sedative. By 1960, thalidomide was sold in more than 40 countries, and achieved widespread use as a sedative that was thought to be safer than barbiturates, as well as a treatment for morning sickness of pregnancy [98].

On November 18, 1961, Widukind Lenz, a German pediatrician and geneticist, reported that thalidomide exposure during the first trimester of fetal development was associated with severe teratogenic malformations [99]. In December 1961, Lenz' findings were independently confirmed by an Australian obstetrician, William G. McBride [100]. By the end of 1961, thalidomide was removed from the market in most countries, but almost 10,000 infants had already been affected. The United States was largely spared because thalidomide had been denied approval by Frances Oldham Kelsey at the US Food and Drug Administration (FDA), due to a lack of safety data.

Thalidomide persisted as a therapeutic agent due to promising activity later seen in leprosy (1964), Behçet disease (1979), graft-versus-host disease (1988), and human immunodeficiency virus (HIV)-associated oral ulcers and wasting (1989) [98]. Under pressure from activists, the FDA approved thalidomide for the treatment of erythema nodosum leprosum in July 1998, with a risk-management system to control prescribing and prevent exposure of unborn infants to thalidomide.

In 1994, the antiangiogenic properties of thalidomide in a rabbit cornea micropocket assay were reported [101].

Based on the increasing awareness of angiogenesis in the pathobiology of cancer and the evidence of increased angiogenesis in myeloma, the spouse of an affected myeloma patient convinced Barlogie and his colleagues to initiate a compassionate-use trial of "antiangiogenic therapy" at the University of Arkansas in late 1997. The idea to use thalidomide in this setting came from Harvard's Judah Folkman, an angiogenesis researcher [102]. In an Arkansas study of 84 previously treated patients, 32% responded to thalidomide. Other investigators subsequently confirmed the Arkansas results and observed activity of thalidomide in newly diagnosed myeloma as well [103]. Although it was never clear whether the mechanism of action required inhibition of angiogenesis—various drug-associated changes in cytokines and immune cell subsets led to thalidomide and its derivatives also being called an "immunomodulatory agent" (iMid)—thalidomide soon became a therapy widely used in myeloma, including in combination with corticosteroids and other agents.

The sponsor of thalidomide subsequently synthesized several analogues to try to increase clinical activity and minimize adverse events such as neuropathy. The most successful of these analogs has been lenalidomide (formerly CC-5013), a 4-amino-substituted analog of thalidomide. A Phase 1 trial in 24 relapsed refractory myeloma patients was led by Paul G. Richardson at the Dana-Farber Cancer Institute; as reported in 2002, lenalidomide reduced paraprotein levels by at least 25% in 17 of 24 patients [104].

Richardson and colleagues then conducted a multicenter randomized Phase 2 trial that enrolled 102 patients with relapsed/refractory myeloma and confirmed the drug's activity [105]. In a Mayo Clinic study of lenalidomide and dexamethasone of 34 patients with newly diagnosed myeloma, 91% achieved an objective response with lenalidomide plus dexamethasone [106]. Lenalidomide plus dexamethasone was approved by the FDA in June 2006 for the treatment of myeloma in patients who failed one prior therapy; lenalidomide had previously been approved in 2005 for treatment of lower risk myelodysplastic syndromes associated with deletions of chromosome 5q. Numerous studies showed benefit of lenalidomide in combination regimens both as initial therapy and in relapsed/refractory disease. Lenalidomide was soon widely used in maintenance regimens for at least 2 years after stem cell transplant, which prolonged relapse-free survival in several studies [107]. Another immunomodulatory agent/thalidomide analogue, pomalidomide, received accelerated approval for patients with relapsed/refractory disease in 2013 [108].

The mechanism of thalidomide and lenalidomide in myeloma was only discovered in 2014, after both drugs had been in use for many years [109]. These drugs were found to bind to cereblon, a component of an E3 ubiquitin ligase complex, altering the affinity of this complex for various proteins and thereby changing their rate of degradation. In myeloma cells, increased ubiquitin ligase-mediated degradation of the transcription factors IKZF1 and IKZF3 results in cytotoxicity, since these factors are necessary for malignant plasma cell survival.

Proteasome Inhibitors

The ubiquitin-proteasome pathway contributes to the orderly degradation of unneeded eukaryotic cellular proteins [110]. Inhibition of the proteasome leads to cellular apoptosis, especially in neoplastic and rapidly proliferating cells [111].

Bortezomib (formerly PS-341), a derivative of boronic acid, was synthesized in 1995 and selected for preclinical and clinical testing in cancer [111]. In a Phase 1 study enrolling patients with relapsed and refractory hematological malignancies led by Robert Orlowski at the University of North Carolina and published in 2002, bortezomib demonstrated striking antimyeloma activity [112]. Kenneth Anderson at the Dana-Farber Cancer Institute in Boston and his colleagues also observed promising activity of bortezomib against myeloma cells in several preclinical models [113].

In the first Phase 2 trial of bortezomib in 202 patients with relapsed refractory myeloma, approximately one-third of patients responded to bortezomib therapy, with a median response duration of 1 year [114]. These results led the FDA to approve bortezomib for multiple myeloma in May 2003. Bortezomib has also been combined effectively with corticosteroids and with lenalidomide, and used in newly diagnosed patients. Subsequently several other proteasome inhibitors were developed, including carfilzomib (FDA approved for relapsed/refractory myeloma in mid-2012) and ixazomib (FDA approved in late 2015) [115, 116]. In 2015, in a cooperative group trial, a combination regimen of bortezomib, lenalidomide, and dexamethasone (VRd) was shown to improve overall survival compared with lenalidomide and dexamethasone (Rd) alone—the first time a "triplet" combination had shown benefit compared to a "doublet" [117].

Monoclonal Antibodies and Other Agents

Following the success of the anti-CD20 antibody rituximab in non-Hodgkin lymphoma, numerous monoclonal antibodies were developed for other hematological neoplasms. Antibodies used in myeloma include elotuzumab, a humanized antibody targeting signaling lymphocytic activation molecule F7 (SLAMF7), and daratumumab, a fully human antibody against CD38, which were both FDA approved in late 2015 [118, 119]. Panobinostat, a deacetylase inhibitor, also has activity in relapsed/refractory myeloma and was FDA approved in early 2015 [120]. Several other novel

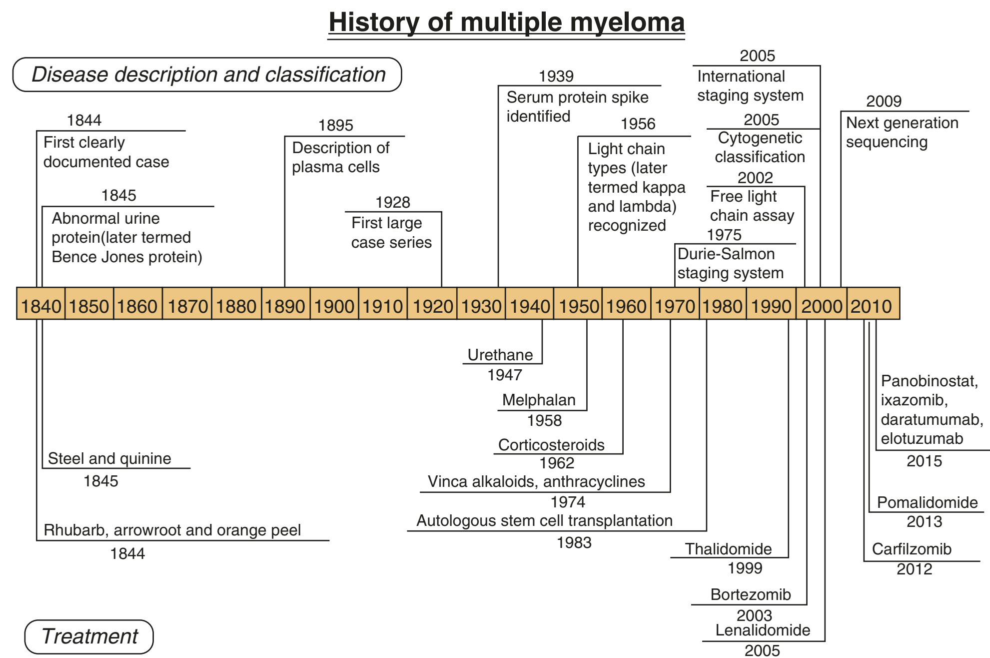

Fig. 24.4 Timeline of historical discoveries (*top*) and introduction of specific therapies (*bottom*) for multiple myeloma. For therapies approved in the twenty-first century, the date of initial FDA approval is given, rather than the first date these agents were used in humans (revised and updated from Kyle and Rajkumar [121])

agents are in various stages of development. After many years of limited therapeutic alternatives, the future looks brighter for patients with myeloma (Fig. 24.4).

25 Monoclonal Gammopathy of Undetermined Significance

Malin Hultcrantz and Ola Landgren

Introduction

The presence of a monoclonal protein on serum electrophoresis in otherwise healthy individuals was first described by Prof. Jan Waldenström who named this condition "essential hypergammaglobulinemia" in 1960 [1]. Dr. Kyle et al. later observed that individuals with a monoclonal gammopathy were at a higher risk of developing multiple myeloma and therefore coined the term "monoclonal gammopathy of undermined significance" (MGUS) [2]. The diagnostic criteria for MGUS are presence of monoclonal protein <3.0 g/dL, <10% clonal plasma cells in the bone marrow, and absence of end-organ damage that can be attributed to a plasma cell disorder [3]. MGUS can be further classified into non-IgM MGUS, IgM MGUS, and light-chain MGUS (LC-MGUS) [3]. Typically, patients with non-IgM MGUS, IgM MGUS, and LC-MGUS progress to multiple myeloma, Waldenström's macroglobulinemia, and light-chain multiple myeloma, respectively. In addition, MGUS has been associated with comorbidities that are not necessarily caused by the plasma cell dyscrasia [4]. Several host factors, e.g., gender and ethnicity, as well as external factors, e.g., exposure to pesticides, are associated with an increased risk of MGUS [5, 6]. The rate of progression to multiple myeloma is approximately 0.5–1% per year and there is evidence that multiple myeloma is consistently preceded by MGUS [7]. A number of predictive factors as well as prognostic scoring systems have been developed to estimate the risk of progression to malignant disease [7–9]. In this review chapter, we discuss the diagnosis, risk of progression, as well as clinical implications for patients with MGUS.

Diagnosis and Definition of MGUS

In the majority of patients, MGUS is diagnosed incidentally during workup for other various symptoms or disorders. The diagnostic criteria for MGUS, smoldering multiple myeloma, and multiple myeloma were updated in 2014 [3]. MGUS is defined as presence of a monoclonal protein (M-protein) <3.0 g/dL, <10% plasma cells in the bone marrow, and absence of events defining for myeloma or other plasma cell disorders; all three criteria must be met [3]. Myeloma-defining events are presence of end-organ damage that can be attributed to the plasma cell proliferation as defined by the CRAB criteria (hypercalcemia, renal failure, anemia, bone lesions, Table 25.1) or the recently added definitions of free light chain (FLC) ratio ≥100, >60% clonal plasma cells in the bone marrow, or >1 lytic bone lesion on whole-body MRI [3].

There are three different types of MGUS: *non-IgM MGUS, IgM MGUS,* and *light-chain MGUS* (Table 25.2). Non-IgM MGUS is the most common type and is diagnosed on serum electrophoresis. In non-IgM MGUS, most patients have M-proteins consisting of IgG or IgA while IgD is rare and there are only a few cases in the literature of IgE

Table 25.1 Definition of monoclonal gammopathy of undetermined significance (MGUS), smoldering multiple myeloma (SMM), and multiple myeloma (MM)

	MGUS	SMM	MM
Serum M-protein	<3.0 g/dL	≥3.0 g/dL	–
Clonal bone marrow plasma cells	<10%	≥10–60%	≥10%
Presence of myeloma-defining event[a]	No	No	Yes

[a]Myeloma-defining events are CRAB criteria (hypercalcemia [serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)], renal insufficiency [serum creatinine >177 µmol/L (2 mg/dL) or creatinine clearance <40 mL/min], anemia [hemoglobin value of >2 g/dL below the lower normal limit, or a hemoglobin value <10 g/dL], bone lesions [one or more osteolytic lesions revealed by skeletal radiography, CT, or PET-CT], or the presence of bone marrow plasma cells >60%, involved/uninvolved free-light chain ratio of ≥100, or >1 focal lesion on MRI [3]

Table 25.2 Types of monoclonal gammopathy of undetermined significance (MGUS)

Type of MGUS	Definition
Non-IgM MGUS	M-protein <3.0 g/dL Clonal bone marrow plasma cells <10% No myeloma-defining event
IgM MGUS	IgM M-protein <3.0 g/dL Bone marrow lymphoplasmacytic cells <10% No myeloma or Waldenström's macroglobulinemia-defining event
Light chain MGUS	Abnormal free light chain ratio Elevated level of involved light chains No immunoglobulin heavy chain on serum electrophoresis or immunofixation Clonal bone marrow plasma cells <10% No myeloma-defining event No amyloidosis Urine M-protein <500 mg/24 h

MGUS. In the case of progression, non-IgM MGUS in the majority of cases transforms to smoldering myeloma and multiple myeloma [10].

IgM MGUS is less common than non-IgM MGUS and is defined as monoclonal IgM protein <3.0 g/L, <10% bone marrow lymphoplasmacytic cells, and absence of end-organ damage (anemia, hyperviscosity, lymphadenopathy, hepatosplenomegaly, constitutional symptoms) attributed to a lymphoproliferative disorder. Progression from IgM MGUS commonly means transition to smoldering Waldenström's macroglobulinemia or Waldenström's macroglobulinemia but also, although more rare, to IgM multiple myeloma, chronic lymphocytic leukemia or other lymphomas [11]. The *MYD88* mutation is present in the vast majority of Waldenström's macroglobulinemia patients and is found in ~50% of individuals with IgM MGUS [12–14]. IgM multiple myeloma on the other hand is rare, only 1% of all multiple myeloma cases, and is not associated with *MYD88* mutation [12, 15].

Light-chain MGUS (LC-MGUS) was described in 2010 by Dispezieri et al. and represent approximately 20% of all MGUS cases. LC-MGUS is defined as abnormal FLC ratio (<0.26 or >1.65) in combination with elevated concentration of the involved κ or λ light chains [16]. In addition, the definition includes no immunoglobulin heavy chain on serum electrophoresis or immunofixation, <10% clonal bone marrow plasma cells, and no sign of end-organ damage [16, 17]. LC-MGUS can progress to idiopathic Bence Jones proteinuria and light-chain multiple myeloma. Furthermore, LC-MGUS is associated with amyloidosis and renal impairment [16]. Due to the possibility that polyclonal light chains may be elevated in renal disease, Dispenzieri et al. discussed whether using the renal FLC reference range would be more optimal compared to the standard reference for the LC-MGUS definition. According to their estimation, this would affect the number of κ and λ LC-MGUS cases but would not have a major effect on the overall prevalence [16]. This issue was further highlighted by Hutchison et al. who suggested adjusted FLC ratio reference ranges for certain clinical settings [18]. Moreover, polyclonal increase in free light chains can be used as a biomarker for B-cell activation in a broader clinical context. Polyclonal free light chains have been associated with disease activity in autoimmune disease, risk of non-Hodgkin lymphoma, renal impairment, and overall survival in the general population [18]. Further studies are needed to fully elucidate the optimal LC-MGUS definition, polyclonal free light chain increase, and implications for progression to malignant disease.

Epidemiology

Recently, in a large population-based study of the US population, the overall prevalence of MGUS was 2.4% in individuals over the age of 50 years [5]. The study was based on the NHANES and NHANES III studies (2000–2004) which included screening of 12,482 individuals representative for the US population [5]. The highest prevalence of MGUS was found in African-American blacks (3.7%), followed by whites (2.3%), and the lowest prevalence was observed in Mexican-Americans (1.8%) [5]. IgA MGUS was more common among Mexican-Americans and there was a lower rate of IgM MGUS in blacks and Mexican-Americans compared to whites. African-American and African blacks were also more likely to have high-risk features including a higher median level of M-protein and had a higher risk of progression [5, 19]. The overall prevalence of MGUS was lower in the NHANES studies compared to the previous estimates from the Olmsted county studies where the reported prevalence of MGUS was 3.2–3.4% in individuals over 50 years [10, 16]. The difference in reported prevalence may be caused by differences in the patient population, i.e., screened population in the NHANES studies versus referral-based Mayo Clinic cohort [5, 10, 16].

IgM MGUS is less common than non-IgM MGUS but there is limited information on the overall prevalence of IgM MGUS. LC-MGUS comprises 20% of all MGUS cases and was found in 0.7–0.8% of the population over 50 years in studies from the Olmsted County and Germany [16, 20].

The prevalence of MGUS increases with increasing age across all studies. Reported prevalence of MGUS ranged from 1.2 to 2.8% in 50–59-year-olds to 4.6–8.7% in individuals 80 years or older [5, 16, 20]. Moreover, MGUS is consistently more common in men compared to women across all age groups [5].

Etiology

The etiology of both MGUS and multiple myeloma remains largely unknown. The prevalence has been associated with various host factors, e.g., gender, age, and ethnicity, and

there was also a trend towards a higher prevalence of MGUS patients with elevated BMI [5, 19]. First-degree relatives of individuals with MGUS have an increased risk of developing MGUS and LC-MGUS [21–23]. Through genome-wide association studies, a number of single-nucleotide variants associated with an increased risk of multiple myeloma have been identified indicating a genetic susceptibility [24].

A higher risk of developing MGUS has also been reported in individuals exposed to pesticides and herbicides including Agent Orange [6, 25]. Constant immune stimulation may be a trigger of MGUS and an elevated prevalence of MGUS has been observed in patients with a prior autoimmune disorder [26].

Risk Assessment and Progression

Non-IgM MGUS typically progresses to IgG or IgA smoldering myeloma and later to multiple myeloma requiring therapy. The annual risk of progression from MGUS to multiple myeloma is 0.5–1% per year [7, 9]. Patterns of progression can vary from a steady increase in M-protein while others can have a stable M-protein level for many years and then suddenly increase [27]. On average, 75–90% of MGUS patients remain in the precursor stage and never develop malignant disease. However, the risk of progression does not decrease even after 25–35 years and hence lifelong follow-up of MGUS patients is necessary [9, 28]. Patients with smoldering myeloma have a 10% risk of progression per year during the first 5 years after diagnosis and the risk thereafter decreases to around 3% the next 5 years and then 1% per year for the 10 following years [29].

The risk assessment scores in MGUS rely largely on biomarkers. The most updated scoring system was published in 2014 by investigators from the National Cancer Institute and Nordic Myeloma Study Group (NCI/NMSG) [7]. In their population-based cohort followed up to 30 years, the overall risk of progression to multiple myeloma or other lymphoproliferative disorders was 0.5% per year [7]. The rate of progression to malignant disease was higher during the first 10 years after diagnosis, almost 1%/year, and those who remained in the precursor stage after more than 10 years had a lower progression rate. Additionally, by performing new assays on stored samples, they evaluated several biomarkers and the impact on disease progression. In the NCI/NMSG score, a higher risk of transformation to multiple myeloma and lymphoproliferative diseases was observed in patients who had an abnormal FLC ratio (<0.26 or >1.65), M-protein level >1.5 g/dL, and reduction of 1 or 2 noninvolved immunoglobulin isotype levels (immunoparesis) (Table 25.3). In MGUS patients who had all three risk factors, the 10-year risk of disease progression was 40% implying that this group of patients should be carefully monitored for disease progression [7].

Table 25.3 Comparison of the three scoring systems for risk of disease progression in MGUS from the Mayo Clinic, PETHEMA, and NCI/NMSG [7–9]

	NCI/NMSG[a]	Mayo Clinic[b]	PETHEMA[c]
Sample size (*n* MGUS patients)	728	1148	407
Risk factors	Non-IgG MGUS Abnormal FLC ratio M-protein >1.5 g/dL Immunoparesis	Non-IgG MGUS Abnormal FLC ratio M-protein >1.5 g/dL	≥95% aberrant plasma cells DNA aneuploidy
Overall risk of progression	0.5%	1%	~0.6%

FLC free light chain

[a]Population-based cohort with patients included 1964–2000. Score based on unanimously analyzed stored samples

[b]Referral center cohort with patients included between 1960 and 1994. Score based on retrospective laboratory results performed at the time of diagnosis

[c]Referral center cohort with patients included 1996–2003. Score based on flow cytometry performed at the time of diagnosis

Two additional risk scores were published in 2005 and 2007 by the Mayo Clinic and PETHEMA groups, respectively [8, 9]. The Mayo Clinic risk score is based on the type and size of M-protein as well as serum FLC ratio. High-risk criteria are defined as non-IgG M-protein, M-protein >1.5 g/dL, and an abnormal FLC ratio [9]. In this system, high-risk MGUS patients who have all the three risk factors had a cumulative risk of developing multiple myeloma of 58% during the first 20 years after the MGUS diagnosis. Patients with two, one, and no risk factors have a risk of progression of 37%, 21%, and 5%, respectively [10]. The PETHEMA group bases their prognostic system on aberrant plasma cells in the bone marrow and DNA aneuploidy both measured by flow cytometry. MGUS patients who had ≥95% aberrant plasma cells and DNA aneuploidy had a 5-year risk of progression of 46%, while individuals with one of the two risk factors had a 10% risk of progression and patients with no risk factor a 2% risk of progression at 5 years, respectively [8].

Additional markers associated with a higher risk of progression from MGUS to multiple myeloma are suppression of nonclonal bone marrow plasma cells, similar to the above-mentioned immunoparesis [7, 8, 30, 31]. A progressive increase in the M-protein level is also a prognostic marker of progression [32]. Different rates of progression were reported for IgG MGUS vs. non-IgG MGUS in the Mayo Clinic model while no such difference was seen in the NCI/NMSG and PETHEMA models. The underlying reason for this difference is not fully understood but may be related to the higher catabolic rate of IgA and IgM compared to IgG implying that at a given M-protein in serum, there may be more clonal plasma cells in the bone marrow in individuals with IgA and IgM isotype MGUS compared to those with IgG MGUS [7,

8]. Furthermore, gene expression profiling can additionally contribute to the risk assessment in MGUS and smoldering myeloma [33]. Presence of circulating plasma cells, abnormal metaphase cytogenetics, and cytoplasmic immunoglobulin measured by flow cytometry can also be valuable in predicting disease progression [34, 35]. It is on the other hand not clear if cytogenetic markers of poor risk in multiple myeloma, t(4;14) or del(17p), are associated with an increased risk of malignant transformation in MGUS patients [36].

The risk of progression from IgM MGUS to Waldenström's macroglobulinemia or other lymphoproliferative diseases is approximately 1.5% per year [37]. Risk factors for progression in IgM MGUS include M-protein size >1.5 g/dL and presence of *MYD88* mutation. Abnormal FLC ratio is not an established risk factor for progression and is not included in the recommended follow-up of patients with IgM MGUS [12, 14].

There is so far limited information on the risk of progression in LC-MGUS. Based on the two published studies so far, the risk of progression appeared to be lower than 1% per year but more information is needed in order to give an accurate estimate [16, 20]. In addition to light-chain multiple myeloma, patients with LC-MGUS are at an elevated risk of developing amyloidosis and renal disease. The latter was observed in 23% of patients and the majority of these had λ-restricted LC-MGUS [16].

The prognostic factors and existing scoring systems are valuable for risk stratification but there is a need to identify molecular markers to better predict the risks in the individual patient.

Genetic Background

Patients with multiple myeloma can be classified into two major cytogenetic groups: chromosome 14 translocations (*IGH* locus) and hyperdiploidy. In studies using fluorescent in situ hybridization (FISH), these cytogenetic aberrations were present already in MGUS and are thus considered early hits in myelomagenesis [38].

During recent years, knowledge of the genetic landscape in multiple myeloma has increased greatly through studies using modern sequencing techniques, i.e., whole-genome sequencing, whole-exome sequencing, and targeted sequencing. So far, no single disease-specific gene has been identified; the studies on the contrary revealed a complex genomic landscape including frequent somatic mutations in *KRAS*, *NRAS*, *FAM46C*, *BRAF*, *TP53*, *TRAF3*, *DIS3*, *CYLD*, and more [39–42]. There is so far limited information on driver mutations and changes in the genomic landscape during transition from precursor to malignant disease. Progression from MGUS to multiple myeloma may be caused by acquisition of additional genetic events or the expansion of preexisting clones already present at the MGUS stage. In both scenarios, interactions between the plasma cells and the bone marrow microenvironment as well as the immune system are likely to influence disease evolution [43].

Comorbidities

Through assessment of large clinical cohorts, MGUS has been associated with a number of comorbidities and mortality not only associated with the development of multiple myeloma. These include increased risk of infections, venous and arterial thrombosis, malignancies, and an inferior survival compared to the general population [21, 44, 45]. Furthermore, patients with MGUS have an increased bone turnover and an elevated risk of fractures [46, 47]. In screened cohorts, the rate of these complications tended to be lower indicating a possible role of other underlying comorbidities which may have led to the original clinical workup and diagnosis of MGUS [48, 49].

There is an increased risk of renal complications in patients with MGUS, especially LC-MGUS, and the term monoclonal gammopathy of renal significance has therefore been coined [50]. M-protein-related renal diseases include monoclonal immunoglobulin deposition disease, light-chain proximal tubulopathy, proliferative glomerulonephritis with monoclonal immunoglobulin deposits, and C3 glomerulopathy with monoclonal gammopathy. These renal diseases are characterized by deposition of monoclonal deposits in the kidney diagnosed on kidney biopsy [36, 50]. In addition, the M-protein can cause various systemic manifestations including neuropathy and skin disorders [36, 43].

Clinical Recommendations

The recommended workup for MGUS is aimed at detecting end-organ damage indicative of multiple myeloma, lymphoproliferative disorders, or amyloidosis. Workup recommended by the International Myeloma Working Group includes complete blood counts, electrolytes and renal function test, serum and urine electrophoresis, as well as serum FLC assay (Table 25.4) [3, 51]. Bone marrow biopsy and bone imaging are recommended to confirm the MGUS diagnosis and to rule out CRAB criteria of other findings of smoldering or multiple myeloma. In patients with low-risk MGUS, bone marrow biopsy and imaging can be deferred if there are no signs of high-risk MGUS, or end-organ damage indicating multiple myeloma, lymphoma, or amyloidosis [51, 52]. If amyloidosis is suspected, biopsy of the bone marrow or abdominal fat with Congo red staining should be performed [36].

Patients diagnosed with MGUS should be monitored every 4–6 months during the first year after initial diagnosis. Thereafter, evaluation every 6–12 months is recommended depending on the rate of M-protein increase. In patients with stable low-risk MGUS, evaluation every 24 months is sufficient while closer monitoring is recommended in high-risk MGUS patients [36, 52]. Patients with LC-MGUS should be evaluated regularly for development of kidney disease and amyloidosis with NT-pro-BNP and urine albumin.

Table 25.4 Clinical evaluation for newly diagnosed patients with monoclonal gammopathy of undetermined significance (MGUS)

• Complete blood count
• Chemistry including serum electrolytes, creatinine, beta-2 microglobulin, calcium, albumin, lactate dehydrogenase (LDH)
• Serum protein studies including total protein and serum electrophoresis
• Serum immunofixation
• Serum free light chain measurements
• 24-h urine collection for electrophoresis and immunofixation
• Bone marrow aspirate and biopsy for plasma cell infiltration, flow cytometry, and fluorescence in situ hybridization[a]
• Skeletal survey, low-dose CT, or PET-CT[a]

[a]These assessments can be excluded in patients who are considered low-risk MGUS (IgG MGUS, M-protein <1.5 g/dL, and normal free light chain ratio)

Recently, two independent studies have reported a better overall survival in multiple myeloma patients where the MGUS was previously known compared to multiple myeloma patients without prior knowledge of MGUS [53, 54]. This is likely an effect of earlier diagnosis and treatment and raises the question whether screening for MGUS would be beneficial. There are ongoing studies for earlier treatment of patients with smoldering myeloma, especially those with high risk, but so far treatment for patients with MGUS is not recommended.

Conclusion

MGUS is a premalignant disorder that in the majority of cases is asymptomatic and will not progress to malignant disease. The risk of progression to malignant disease persists throughout life and patients should therefore be monitored continuously. Thorough workup is needed to exclude more advanced disease stages and associated disorders. There are valuable risk-scoring systems for predicting the risk of transformation to multiple myeloma and there are ongoing research efforts to identify molecular markers that can better predict individual risk of progression.

26 Smoldering Multiple Myeloma

María-Victoria Mateos and Jesús F. San-Miguel

Introduction

Smoldering multiple myeloma (SMM) is an asymptomatic plasma cell disorder defined in 1980 by Kyle and Greipp on the basis of a series of six patients who met the criteria for multiple myeloma (MM) but whose disease did not have an aggressive course [1].

At the end of 2014, the International Myeloma Working Group (IMWG) updated the definition and SMM was defined as a plasma cell disorder characterized by the presence of ≥3 g/dL serum M-protein and/or 10–60% bone marrow plasma cells (BMPCs), but with no evidence of myeloma-related symptomatology (hypercalcemia, renal insufficiency, anemia, or bone lesions (CRAB)) or any other myeloma-defining event (MDE) [2]. According to these recent updated criteria, the definition of SMM excludes asymptomatic patients with BMPCs of 60% or more, serum free light chain (FLC) levels of ≥100, and those with two or more focal lesions in the skeleton as revealed by magnetic resonance imaging (MRI).

Kristinsson et al., based on the Swedish Myeloma Registry, have recently reported that 14% of patients diagnosed with myeloma had SMM and, accordingly, the age-standardized incidence of SMM would be 0.44 cases per 100,000 people [3].

Differential Diagnosis with Other Entities

SMM must be distinguished from other plasma cell disorders, such as monoclonal gammopathy of undetermined significance (MGUS) and symptomatic MM (Table 26.1). The MGUS entity is characterized by a level of serum M-protein of <3 g/dL plus <10% plasma cell infiltration in the bone marrow, with no CRAB and no MDE. Symptomatic MM must always have CRAB symptomatology or MDE, in conjunction with ≥10% clonal BMPC infiltration or biopsy-proven bony or extramedullary plasmacytoma [2].

End-organ damage often needs to be correctly evaluated to distinguish myeloma-related symptomatology from some signs or symptoms that could otherwise be attributed to comorbidities or concomitant diseases [4].

Due to the updated IMWG criteria for the diagnosis of MM, there are some specific assessments to which physicians have to pay attention in order to make a correct diagnosis of SMM [2].

1. For evaluation of bone disease, the IMWG recommends to perform in all patients with suspected SMM one of the following procedures: skeletal survey, ^{18}F-fluorodeoxyglucose

Table 26.1 Differential diagnosis of MGUS, SMM, and symptomatic MM

Feature	MGUS	SMM	MM
Serum-M protein	<3 g/dL and	≥3 g/dL and/or	
Clonal BMPC infiltration	<10%	10–60%	≥10% or biopsy-proven plasmacytoma
Symptomatology	Absence of CRAB[a]	Absence of MDE[b] or amyloidosis	Presence of MDE[b]

[a]CRAB includes (1) hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL); (2) renal insufficiency: serum creatinine >177 μmol/L (2 mg/dL) or creatinine clearance <40 mL/min; (3) anemia: hemoglobin value of >2 g/dL below the lower normal limit, or a hemoglobin value <10 g/dL; (4) bone lesions: one or more osteolytic lesions revealed by skeletal radiography, CT, or PET-CT

[b]*MDE* Myeloma-defining events include CRAB symptoms (above) or any one or more of the following biomarkers of malignancy: clonal bone marrow plasma cell percentage ≥60%; involved/uninvolved serum free light chain ratio ≥100; >1 focal lesions revealed by MRI studies

(FDG) positron emission tomography (PET)/computed tomography (CT), or low-dose whole-body CT, with the exact modality determined by availability and resources. The aim is to exclude the presence of osteolytic bone lesions, currently defined by the presence of at least one lesion (≥5 mm) revealed by X-ray, CT, or PET-CT. In addition, whole-body MRI of the spine and pelvis is a mandatory component of the initial workup. It provides detailed information about not only bone marrow involvement but also the presence of focal lesions that predict more rapid progression to symptomatic myeloma. Hillengass et al. reported in 2010 that the presence of more than one focal lesion in whole-body MRI was associated with a significantly shorter median time to progression (TTP) to active disease (13 months), as compared to patients without focal lesions [5]. Kastritis and colleagues reported similar results after the analysis of a subgroup of patients who underwent spinal MRI and were followed up for a minimum of 2.5 years. The median TTP to symptomatic disease was 14 months when more than one focal lesion was present [6]. Therefore, if more than one focal lesion in MRI is present in SMM patients, this entity should no longer be considered as SMM but as MM, according to the current IMWG criteria. It is important to emphasize that they should be unequivocal focal lesions of >5 mm.

2. With respect to bone marrow infiltration, the Mayo Clinic group evaluated BMPC infiltration in a cohort of 651 patients and found that 21 (3.2%) had an extreme infiltration (≥60%) [7]. This group of patients had a median TTP to active disease of 7.7 months, with a 95% risk of progression at 2 years. This finding was subsequently validated in a study of 96 patients with SMM, in whom a median TTP of 15 months was reported for the group of patients with this extreme infiltration [8]. In a third study, 6 of 121 patients (5%) with SMM were found to have ≥60% BMPC, and all progressed to MM within 2 years [9]. Therefore, if ≥60% of clonal plasma cell infiltration is present either in bone marrow aspirate or biopsy, the diagnosis of SMM should be replaced by MM. Additional assessments, for example, by flow cytometry or by identifying cytogenetic abnormalities in SMM patients, are not mandatory but can help to estimate the risk of progression to active disease.
3. With respect to the serum free light chain (FLC) assay, Larsen et al. studied 586 patients with SMM to determine whether there was a threshold FLC ratio that predicted 85% of progression risk at 2 years. They found a serum-involved/uninvolved FLC ratio of at least 100 in 15% of patients and their risk of progression to symptomatic disease was 72% [10]. Similar results were obtained in a study by Kastritis and colleagues from the Greek Myeloma Group. In their study of 96 SMM patients, 7% had an involved/uninvolved FLC ratio of ≥100 and almost all progressed within 18 months [8]. In a third study, the risk of progression within 2 years was 64% [9]. Therefore, physicians must perform the sFLC assay at the moment SMM is first suspected and, if the involved/uninvolved ratio is ≥100, a diagnosis of active MM instead of SMM should be established.

Table 26.2 Workup for newly diagnosed SMM patients

• Medical history and physical examination
• Hemogram
• Biochemical studies, including creatinine and calcium levels; beta-2 microglobulin, LDH, and albumin
• Protein studies
– Total serum protein and serum electrophoresis (serum M-protein)
– 24-h urine sample protein electrophoresis (urine M-protein)
– Serum and urine immunofixation
• Serum free light chain measurement (sFLC ratio)
• Bone marrow aspirate ± biopsy: infiltration by clonal plasma cells, flow cytometry, and fluorescence in situ hybridization analysis
• Skeletal survey, CT, or PET-CT
• MRI of thoracic and lumbar spine and pelvis; ideally, whole-body MRI

FLC free light chain, *CT* computed tomography, *PET-CT* ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT, *MRI* magnetic resonance imaging

If, after considering the specific assessments mentioned above (Table 26.2), a diagnosis of SMM is finally made, the serum and urine M-component, hemoglobin, calcium, and creatinine levels should be reevaluated 2–3 months later in order to confirm the stability of these parameters. The frequency of the subsequent follow-up exams should be adapted on the basis of risk factors for progression to symptomatic MM (see below).

How to Evaluate the Risk of Progression to MM?

The annual risk of progression from SMM to symptomatic MM is 10% per year for the first 5 years, 5% per year during the following 5 years, and only 1% per year after 10 years [11]. Though most patients diagnosed with SMM will progress to symptomatic MM and will need to start treatment, SMM is not a uniform disorder.

Several groups have reported possible predictors of progression to symptomatic MM, and this information could be useful for physicians and can help to explain to patients their risk of progression to active MM (Table 26.3).

– Size of serum M-protein and the extent of marrow involvement

Table 26.3 Smoldering MM: markers predicting progression to symptomatic MM

Features for identifying high-risk SMM patients: 50% at 2 years
• Tumor burden:
– ≥10% clonal plasma cell bone marrow infiltration plus
– ≥3 g/dL of serum M-protein and
– Serum free light chain ratio between 0.125 and 8
– Bence Jones proteinuria positive from 24-h urine sample
– Peripheral blood circulating plasma cells >5 × 10^6/L
– Peripheral blood circulating plasma cells ≥150 by flow cytometry
• Immunophenotyping characterization and immunoparesis:
– ≥95% of aberrant plasma cells by flow within the plasma cell bone marrow compartment plus
– Immunoparesis (>25% decrease in one or both uninvolved immunoglobulins relative to the lowest normal value)
• Cytogenetic abnormalities:
– Presence of t(4;14)
– Presence of del (17p)
– Gain of 1q21
– Hyperdiploidy
– Gene expression profiling risk score >−0.26
• Pattern of serum M-component or hemoglobin evolution:
– Evolving type: If M-protein ≥3 g/dL, increase of at least 10% within the first 6 months. If M-protein <3 g/dL, annual increase of M-protein for 3 years
– Increase in the M-protein to ≥3 g/dL over the 3 months since the previous determination
– Decrease of hemoglobin in ≥0.50 g/dL within 12 months of diagnosis
• Imaging assessments:
– MRI: Radiological progressive disease (MRI-PD) was defined as newly detected focal lesions (FLs) or increase in diameter of existing FL and a novel or progressive diffuse infiltration
– Positive PET/CT with no underlying osteolytic lesion

MRI magnetic resonance imaging, *PET-CT* ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET)/CT

– Mayo Clinic group [11] proposed three SMM subgroups according to BMPC infiltration and the size of the serum M-protein. Group 1 was characterized by ≥3 g/dL of M-protein and ≥10% of BMPCs, with a median TTP to symptomatic MM of 2 years. Group 2 featured ≤3 g/dL of M-protein and ≥10% BMPCs with a median TTP of 8 years. Group 3 had ≥3 g/dL of M-protein but <10% BMPC infiltration, resulting in a median TTP of 19 years.

– Serum free light chain ratio

– The Mayo Clinic group also evaluated the previously described patient population to identify the risk of progression to symptomatic myeloma on the basis of a free light chain (FLC) assay. A kappa/lambda FLC ratio between 0.125 and 8 was found to be associated with an increased risk of progression to symptomatic MM. This parameter was added to their previous score, which considered the size of serum M-protein and BMPC infiltration, to refine the Mayo risk stratification model. This yielded three groups, with a median TTP of 1.9 years for the high-risk group, whose members exhibited all three defined risk factors [12].

– The Danish Myeloma group did not found in the analysis of their registry any significant threshold for the serum free light chain ratio; therefore they do not support the recent IMWG proposal that identifies patients with a FLC ratio above 100 as having ultrahigh risk of transformation to MM [13].

– Immunophenotyping and immunoparesis

– Multiparameter flow cytometry (MFC) to identify the immunophenotypic profile of plasma cells in SMM has been evaluated by the Spanish Myeloma group. We reported that the presence of an aberrant BMPC phenotype in the vast majority of PC (≥95% phenotypically abnormal plasma cells from total PC), determined by MFC (defined as the overexpression of CD56 and CD19, CD45 negative, and/or decreased reactivity for CD38), was the most important predictor of early progression from SMM to active MM [14]. The presence of immunoparesis (i.e., a decrease in one or two of the uninvolved immunoglobulins to 25% below the lowest normal value) also emerged as a significant independent prognostic characteristic. Based on these two parameters, the Spanish group proposed a scoring system that stratified SMM patients into three categories with a median TTP of 23 months when the two risk factors were present, compared with 73 months when only one was present, and not reached when neither was present [15].

– The Danish Myeloma group has recently reported that both an M-protein ≥3 g/dL and immunoparesis significantly influenced TTP (HR 2.7 95% CI(1.5;4.7) $p = 0.001$ and HR 3.3 95%CI(1.4;7.8) $p = 0.002$, respectively) to myeloma [13].

– Peripheral blood circulating plasma cells

– The Mayo Clinic group has also evaluated the role of peripheral blood circulating PCs in 171 SMM patients, and in those (15%) who had high levels of circulating PCs (>5 × 10^6/L and/or >5% PCs per 100 cytoplasmic immunoglobulin (Ig)-positive mononuclear cells), the progression risk at 2 years was significantly higher than for patients with low levels of circulating PC (71% vs. 24%; $p = 0.001$) [16]. This group has recently improved the identification of peripheral blood circulating plasma cells in SMM using flow cytometry in 100 patients. The median TTP of patients with 150 or more circulating PCs was 9 months compared to not reached for patients with less than 150 circulating PCs ($P < 0.001$). In the

future, this may allow reclassification of such patients as having MM requiring therapy prior to them enduring end-organ damage [17].

- Pattern of serum M-component evolution
- The pattern of evolution of the monoclonal component during the course of the disease enabled to identify two types of SMM: evolving and nonevolving. Based on the analysis of 207 SMM patients, the evolving type was defined by the following criteria: (1) if the concentration of M-protein was ≥3 g/dL at baseline, the evolving type featured an increase in M-protein of at least 10% within the first 6 months following diagnosis; (2) if the concentration of M-protein was <3 g/dL at baseline, the evolving type featured a progressive increase in M-protein in each consecutive annual measurement over a 3-year period [18]. The evolving pattern was recognized in 25% of patients, and was associated with a probability of progression of 45% at 2 years, with a median TTP to active MM of 3 years, compared with 19 years for those with the nonevolving type [19]. The Mayo Clinic group has recently validated the evolving change in the monoclonal protein (eMP) in a series of 191 patients with SMM, resulting in an odds ratio of 7.26 (2.89–18.26, $p < 0.001$); moreover, they found the BMPC infiltration >20% and the evolving change in hemoglobin (eHb), defined as ≥0.5 g/dL decrease within 12 months of diagnosis, as independent prognostic markers predicting progression and a new risk model comprising these variables was constructed, with median TTP of 12.3, 4.2, 2.8, and 1.0 years in patients with none, 1, 2, and 3 risk factors, respectively ($p < 0.001$). The 2-year risk of progression was 82.8% in patients with both eMP and eHb, and increased to 90.9% in those with all three risk factors. This new risk model would identify patients with SMM candidates to be considered in the future as MM [20]. The SWOG group also found that patients with an increase in the M-component ≥3 g/dL over the 3 months since their previous determination had an associated risk of progression of approximately 50% at 2 years [21].
- Bence Jones proteinuria
- One hundred and forty-seven SMM patients were examined for the presence of Bence Jones proteinuria at diagnosis, and its effect on progression to symptomatic disease was assessed. The study showed that in SMM patients in which the M-protein was defined by a complete immunoglobulin, but who were also positive for Bence Jones proteinuria, regardless of the amount, the risk of progression to active disease was significantly higher than in Bence Jones proteinuria-negative patients (22 vs. 83 months; $p < 0.001$). In addition, when Bence Jones proteinuria in the 24-h urine sample exceeded 500 mg, the risk was even higher, with a median TTP of 7 months indicating that this parameter would be a new biomarker to identify SMM patients that could be considered as MM [22].
- Novel imaging assessments
- The novel imaging assessments have contributed to the updated criteria for the definition of MM and SMM, as has been previously mentioned. However, the new imaging assessments can also help to predict progression risk in SMM. The first studies with spinal MRI were done in SMM patients and the presence of a focal pattern was associated with a shorter TTP as compared to that of a diffuse or variegated pattern (median 6 vs. 16 vs. 22 months). Hillengass et al. have recently evaluated the role of MRI during the follow-up of patients with SMM. Radiological progressive disease (MRI-PD), which they defined as the detection of new focal lesions or the increase in diameter of existing focal lesions, and a novel or progressive diffuse infiltration, was identified as a feature for classifying SMM patients at high risk of progression to symptomatic disease [23]. The role of PET/CT has also been evaluated in SMM. The Italian group has recently reported that approximately 10% of SMM patients from a series of 73 patients had a positive result with PET/CT with no underlying osteolytic lesion, and this predicted for high risk of progression to symptomatic disease (48% at 2 years compared with 32% for PET/CT-negative patients; $p = 0.007$) [24]. The Mayo Clinic group also identified a subgroup within a series of 132 SMM patients who showed a positive result with PET/CT in which the rate of progression to MM within 2 years was 56%, as compared to 28% among PET/CT-negative patients ($p = 0.001$). The rate of progression was even higher among patients on whom PET/CT was performed within 3 months of their diagnosis of SMM (74% vs. 27% in PET/CT-negative patients) [25].
- Cytogenetic abnormalities
- The Mayo Clinic group analyzed the cytogenetic abnormalities in a series of 351 SMM patients and identified a high-risk subgroup of patients with t(4;14) and/or del(17p) with a significantly shorter median TTP (24 months) as compared to the intermediate-, standard-, and low-risk patient subgroups [26]. The high risk of progression of SMM to MM with t(4;14) may be related to the fact that this abnormality is associated with markedly high FLC ratios. However, the mechanism by which a high FLC ratio is associated with a higher risk of progression is not clear and is only partly related to renal failure from cast nephropathy. Neben et al. have identified t(4;14), gain of 1q21, or hyperdiploidy as being independent prognostic factors for a shorter TTP. The median TTP for patients with del(17p) was 2.7 years (vs. 4.9 years for those without the translocation; $p = 0.019$), 2.9 years for patients

with t(4;14) (vs. 5.2 years for those without the translocation; $p = 0.021$), and 3.7 years for patients with gain of 1q21 (vs. 5.3 years for those without the gain; $p = 0.013$). In addition, hyperdiploidy was associated with a significantly shorter median TTP of 3.9 years (compared with 5.7 years for non-hyperdiploid patients; $p = 0.036$) [27].

Finally, the South West Oncology Group (SWOG) evaluated the Gene Expression Profiling 40 (GEP40) model in a group of 105 SMM patients. A gene signature derived from four genes, at an optimal binary cut point of 9.28, identified 14 patients (13%) with a 2-year progression risk of 85.7%. Conversely, a low four-gene score (< 9.28) combined with baseline monoclonal protein <3 g/dL and albumin ≥3.5 g/dL identified 61 patients with low-risk SMM with a 5.0% risk of progression at 2 years [28]. Landgren et al. have recently performed whole exome sequencing and RNA sequencing in 12 patients with high-risk SMM and 39 patients with newly diagnosed symptomatic MM. Despite having only a few high-risk SMM patients in this study, none of them had any mutations in the recurrently mutated genes found in the symptomatic MM group, indicating that the molecular profile of SMM could be different. Therefore, these findings might have some implications for risk assessment and initiation of therapy [29].

In summary, the diagnosis of SMM is associated with a variable risk of progression to active disease, and the presence of the aforementioned prognostic factors can discriminate subgroups of patients based on their degree of risk (Table 26.3).

Stratification and Management of SMM Patients

The first step in clinical practice is to identify the risk of progression to active disease for each newly diagnosed SMM patient. The key question is which risk model is better for evaluating the risk of progression to symptomatic disease for each individual SMM patient. Both the Mayo Clinic and Spanish models have been validated in a prospective trial. However, new risk models are emerging that incorporate novel clinical and biological features [9, 11, 13, 15, 18, 21, 27, 30, 31] (Table 26.4). The components of these models are not identical, and each patient's risk should probably be defined on the basis of all the available data rather than through the use of a restricted model (Table 26.3). These models identified their risk factors as independent variables in multivariate analysis. Some of the features evaluated in each risk model can overlap, but not all of them have to be present in a SMM patient to be defined as a high-risk SMM patient.

Table 26.4 Risk models for the stratification of SMM

Risk model	Risk of progression to MM	
Mayo Clinic		*Median TTP*
– ≥10% clonal PCBM infiltration – ≥3 g/dL of serum M-protein – Serum FLC ratio between <0.125 and >8	1 risk factor 2 risk factors 3 risk factors	10 years 5 years 1.9 years
Spanish myeloma		*Median TTP*
– ≥95% of aberrant PCs by MFC – Immunoparesis	No risk factor 1 risk factor 2 risk factors	NR 6 years 1.9 years
Heidelberg		*3-year TTP*
– Tumor mass using the Mayo model – t(4;14), del17p, or +1q	T-mass low + CA low risk T-mass low + CA high risk T-mass high + CA low risk T-mass high + CA high risk	15% 42% 64% 55%
SWOG		*2-year TTP*
– Serum M-protein ≥2 g/dL – Involved FLC >25 mg/dL – GEP risk score >–0.26	No risk factor 1 risk factor ≥2 risk factors	30% 29% 71%
Penn		*2-year TTP*
– ≥40% clonal PCBM infiltration – sFLC ratio ≥50 – Albumin ≤3.5 mg/dL	No risk factor 1 risk factor ≥2 risk factors	16% 44% 81%
Japanese		*2-year TTP*
– Beta-2 microglobulin ≥2.5 mg/L – M-protein increment rate >1 mg/dL/day	2 risk factors	67.5%
Czech and Heidelberg		*2-year TTP*
– Immunoparesis – Serum M-protein ≥2.3 g/dL – Involved/uninvolved sFLC >30	No risk factor 1 risk factor 2 risk factors 3 risk factors	5.3% 7.5% 44.8% 81.3%
Barcelona		*2-year TTP*
– Evolving pattern = 2 points – Serum M-protein ≥3 g/dL = 1 point – Immunoparesis = 1 point	0 points 1 point 2 points 3 points	2.4% 31% 52% 80%
Mayo Clinic evolving model		
– eMP – eHB – ≥20% plasma cells	0 points 1 point 2 points 3 points	12.3 years 4.2 years 2.8 years 1 year
Danish		*3-year TTP*
– Serum M-protein ≥3 g/dL – Immunoparesis	No risk factor 1 risk factor 2 risk factors	5% 21% 50%

SMM patients should be classified as follows:

1. Patients at low risk of progression who are characterized by the absence of the aforementioned high-risk factors (using the validated Mayo or the Spanish risk models), with a probability of progression at 5 years of only 8%. These patients behave similarly to MGUS-like patients and should be followed annually.
2. The second group includes patients at intermediate risk of progression and they only display some of the aforementioned high-risk factors. These are probably the true SMM patients. They have a risk of progression at 5 years of 42%, and they must be followed up every 6 months (except during the first year that should be followed every 3–4 months in order to exclude an SMM evolving form).
3. The third group includes high-risk patients classified on the basis of one of the risk models mentioned before. Half of them will progress during the 2 years following diagnosis. These group of patients need a close follow-up every 2–3 months. As there is not any treatment approved yet for these high-risk SMM patients, the best approach should be to refer them to specialized centers in MM therapy and to include them in clinical trials to better understand their biology and to confirm the survival benefit of early treatment in this cohort [32].

The Spanish myeloma group (GEM/Pethema) conducted a phase 3 randomized trial in 119 SMM patients at high risk of progression to active disease (according to the Mayo and/or Spanish criteria). This trial compared early treatment with lenalidomide plus dexamethasone as induction followed by lenalidomide alone as maintenance versus observation. The primary end point was TTP to symptomatic MM, and after a median follow-up of 40 months, the median TTP was significantly longer in patients in the early treatment group than in the observation arm (not reached vs. 21 months; hazard ratio, HR = 5.59; $p < 0.001$). This trial has been recently updated, and after a median follow-up of 75 months, lenalidomide plus dexamethasone continued to provide a benefit in terms of TTP compared with observation (median TTP not reached (95% CI 47 months–not reached) vs. 23 months (95% CI 16–31 months); hazard ratio (HR) 0.24 (95% CI (0.14–0.41); $p < 0.0001$)). Progression to multiple myeloma occurred in 53 (86%) of 62 patients in the observation group compared with 22 (39%) of 57 patients in the treatment group. At data cutoff, 10 (18%) patients had died in the treatment group and 22 (36%) patients had died in the observation group; median overall survival from the time of study entry had not been reached in either group (HR 0.43 (95% CI 0.21–0.92), $p = 0.024$)) [33]. The safety profile was acceptable and most of the adverse events reported were grade 1 or 2. This study showed for the first time the potential for changing the treatment paradigm for high-risk SMM patients based on the efficacy of early treatment in terms of TTP to active disease and of OS, confirmed after long-term follow-up. Moreover, several trials currently under way are investigating the role, on high-risk SMM patients, of novel agents such as lenalidomide alone, siltuximab (anti-IL6 monoclonal antibody), elotuzumab (anti-SLAMF7 monoclonal antibody), or lenalidomide-dexamethasone plus elotuzumab. Promising efficacy results have been reported for the combination of lenalidomide plus dexamethasone with the novel proteasome inhibitor carfilzomib in a series of 12 high-risk SMM patients. All patients achieved CR and most were in immunophenotypic CR [34]. The next step will be to develop a more intensive therapeutic approach for young high-risk SMM patients, similar to the treatment planned for young symptomatic MM patients, for whom "cure" should be the objective.

Conclusion and Future Directions

The treatment philosophy for MM patients has mainly focused on symptomatic patients. This approach is clearly different from those adopted to treat other malignancies, such as breast, colon, or prostate cancer, for which early intervention is not only appropriate, but also essential for success and cure. This difference in philosophy arose for several reasons: (1) in the past, only a few drugs, most of which were alkylating agents, were available to treat MM; (2) the trials conducted in asymptomatic MM patients failed to produce a significant benefit; and (3) the risk of progression to active disease in SMM patients is relatively low (10% per year).

However, significant advances are being made in the understanding and management of SMM patients. From the biological point of view, different subgroups of SMM patients have been identified, including those patients with >60% PC or FLC ratio >100 or two or more focal lesions, that are now considered as active MM patients in which treatment should be started before myeloma-related symptoms develop. In the near future, new biomarkers will be considered to expand the inclusion of SMM patients at imminent risk of progression to active disease in order to be considered as MM.

Moreover, we will soon have the results from several current trials conducted in high-risk SMM patients, which will enable us to offer early treatment for a selected group of asymptomatic myeloma patients with the confidence that some of them will be "cured." The cure-versus-control debate is particularly pertinent in asymptomatic myeloma patients. Some physicians argue in favor of controlling the disease through continuous oral therapy mainly based on immunomodulatory agents, while others support the intensive therapy approaches, including high-dose therapy and transplant, with the objective of eradicating the disease.

Ongoing biological studies will also help us to better understand the pathogenesis of the disease and to identify the key drivers of the transition from monoclonal gammopathy to smoldering and symptomatic disease. These drivers may represent optimal targets for new therapeutic approaches.

27 Frail Patients with Newly Diagnosed Multiple Myeloma

Alessandra Larocca and Antonio Palumbo

Introduction

Multiple myeloma (MM) is a neoplastic disease deriving from an abnormal proliferation of monoclonal plasma cells in the bone marrow. MM is characterized by both intrinsic genetic alterations in the clonal plasma cells and microenvironmental changes [1].

This disease accounts for 13% of all hematological cancers, approximately 2% of all cancer deaths, and 20% of deaths caused by hematological malignancies. The annual age-adjusted incidence is 5.6 cases per 100,000 people in Western countries [1]. MM is typical of the elderly, median age at diagnosis is approximately 70 years, 37% of patients at diagnosis are less than 65 years, 27% are aged 66 to 75 years, and 37% of patients are over 75 years.

Of note, life expectancy is increasing worldwide. Indeed, the global population is rapidly aging, and the number of individuals aged ≥65 years is expected to double between 2000 and 2030. As a consequence, also the prevalence of myeloma is likely to increase [2].

The diagnosis of MM requires the presence of at least 10% of monoclonal plasma cells at the bone marrow biopsy. Myeloma is defined asymptomatic (smoldering), when no myeloma-related organ or tissue dysfunction is present, or symptomatic, when the so-called CRAB criteria are present: C: hypercalcemia (>11.5 mg/dL); R: renal failure (serum creatinine >1.73 mmol/L); A: anemia (hemoglobin <10 g/dL or >2 g/dL below the lower limit of normal); and B: bone disease (lytic lesions, severe osteopenia, or pathologic fractures) [3]. The diagnostic criteria have been recently updated, and the presence of more than 60% of monoclonal plasma cells in the bone marrow, or one or more focal lesions detected with magnetic resonance imaging (MRI), or an abnormal ratio of the serum free light chains have been added as a clinically relevant criteria to start treatment [4]. To date, treatment is started in patients with symptomatic disease, whereas only clinical observation is recommended in patients with asymptomatic myeloma. Yet, ongoing trials are evaluating the role of novel agents in delaying the progression from asymptomatic to active disease.

Treatment strategy for MM has long been based on patients' age. Patients aged 65–75 years are generally considered ineligible for autologous stem cell transplantation (ASCT). Biologic age does not always correspond to chronologic age, and this strict range may differ by approximately 5 years [5]. In Europe, current treatment for elderly patients older than 65 years or younger with significant comorbidities and ineligible for ASCT consists of the combinations of melphalan-prednisone plus either the immunomodulatory agent thalidomide (MPT) or the proteasome inhibitor bortezomib (VMP) [6, 7]. Recently the European and American regulatory authorities approved lenalidomide in combination with dexamethasone in the United States and in combination with dexamethasone or with melphalan and prednisone followed by lenalidomide monotherapy maintenance for ASCT-ineligible patients in Europe [8, 9]. In the United States, age is not the primary criterion to establish whether a patient is eligible for ASCT, and patients who are not candidates for ASCT can receive initial therapy with either bortezomib-lenalidomide-dexamethasone (VRD), bortezomib-cyclophosphamide-dexamethasone (VCD), or also Rd [10].

Usually, gentler approaches are used for patients older than 75 years, who may receive reduced-dose treatments based solely on their age [11].

Survival of MM patients varies greatly, from less than 6 months to more than 10 years, depending on both biological features of the disease at diagnosis (albumin,

beta-2-microglobulin, and cytogenetics) and patient characteristics (age, performance status, comorbidities). In patients younger than 65 years eligible for ASCT, the current expected overall survival (OS) is 5–7 years; in patients ineligible for ASCT undergoing conventional chemotherapy it is 3–4 years [1].

The introduction of novel agents thalidomide, lenalidomide, and bortezomib in the twenty-first century has substantially changed the management of MM and markedly improved OS [12]. In particular, a significant 5-year OS improvement was seen in patients aged 45–64 years, while it was lower in patients aged 65–74, and absent in patients over 75 years of age [13]. The elderly population is highly heterogeneous and the well-known biologic and genetic prognostic factors, as well as age per se, are insufficient to explain this OS difference [14–17].

Indeed, aging is a complex process characterized by a gradual, progressive decrease in physiological reserve, changes in body composition, and clinically significant reductions in organ functions. It is commonly associated with the presence of comorbidity and an increased risk of developing disability, with physical and cognitive decline [18, 19], and frailty. Frailty is a state of increased vulnerability, with cumulative deficits in several physiological systems [11], which may result in a diminished resistance to stressors, such as MM and its treatment, negatively affecting patients' quality of life (QoL), treatment efficacy, and tolerability.

In MM, the term "frail" often improperly refers to a person >75 years, which sometimes leads to an inadequate under-treatment of patients based only on age. Of note, registrational trials are performed in selected patients, whereas frail patients usually do not meet eligibility criteria and thus are usually underrepresented in clinical studies [20].

Definition of Frailty

Older people are at high risk of cardio- and cerebrovascular diseases, type 2 diabetes, dementia, and cancer [21]. In particular, persons over 65 account for about 60% of newly diagnosed malignancies and about 70% of all cancer deaths. Elderly patients with cancer and comorbidities are also more likely to develop frailty, as well as physical and cognitive decline, with negative impact on lifestyle and treatment efficacy.

Indeed, the aging process is associated with a gradual, progressive decrease in physiological reserve, with changes in body composition and clinically significant reductions in renal function, gastric function, hepatic mass and blood flow, bone marrow status, and cardiovascular function [18, 22–24]. These changes affect the pharmacokinetics and pharmacodynamics of drugs, altering clinical efficacy and potentially increasing toxicity. Therefore, age-related organ function and metabolic changes can contribute to the poor tolerability of cancer treatments seen in elderly patients that can cause an increase in treatment-related adverse events. In these patients inadequate treatments can lead to excessive toxicities, unacceptable, unfavorable QoL, and increased healthcare costs.

In geriatric medicine, three terms are commonly used to characterize vulnerable adults: *frailty; comorbidity* (or multiple chronic conditions); and *disability* [25]. These are distinct clinical entities that occur individually and commonly in elderly patients. Moreover, they are interrelated and have a cumulative effect on health and prognosis of elderly patients. Of note, the use of score tables established in geriatric medicine provides additional information to performance status: in fact, 9–38% of elderly patients with good performance status (<2) were partially or fully dependent on others to carry out ordinary activities, such as household tasks and personal care [26, 27].

Frailty is a state of increased vulnerability to poor resolution of homoeostasis after a stressor event [28, 29]. It arises from cumulative deficits in several physiological systems and results in a diminished resistance to stressors. This is a condition more frequent in older individuals, as around 25% to 50% of people over 85 years of age are estimated to be frail. As yet, there is no consensus on the definition and assessment of frailty. The original definition of frailty focused on physical weakness and wasting, but many other definitions and criteria have been postulated, incorporating different aspects of aging that contribute to diminish physiological reserves. A phenotype of the clinically frail elderly adult was recently defined, based on the presence of a critical mass of ≥3 core elements of frailty: weakness; poor endurance; weight loss; low physical activity; and slow gait speed. *Comorbidity* is the concurrent presence of two or more medically diagnosed diseases in the same individual; it is associated with polymedication and increased risk of drug interactions [26]. Comorbidity is a significant concern among the elderly and 88% of the population aged over 65 years have at least one chronic condition. Many prognostic indices for the elderly that incorporate age and/or comorbidity are available. The Charlson comorbidity index is the one most frequently used in cancer patients [30, 31]. The Charlson index is a summary measure of 19 comorbid conditions weighted 1–6 corresponding to disease severity. This gives a total score ranging from 0 to 37. It can be

adapted to account for increasing age, adding 1 point to the score for each decade over the age of 50 years. With this index, the relative risk of death that can be attributed to an increase of 1 point in the comorbidity score is equivalent to an additional decade of age. With aging, the incidence of comorbid conditions increases markedly, largely because the frequency of individual chronic conditions rises with age. As a result, 35% of men and 45% of women aged 60–69 years in the United States have ≥2 comorbid conditions; this percentage increases dramatically to 53% of men and 70% of women by age 80 years [32].

Disability (which can include both physical and mental impairments or limitations) can be defined as difficulty or dependency in carrying out activities essential to independent living, including both essential personal care and household tasks, and activities that are important to maintain an individual's quality of life [33, 34]. Physical disability is common among elderly adults and is more common in women than men. The major causes of physical disability in the elderly are chronic diseases, such as cardiovascular disease, stroke, and arthritis, highlighting the interrelationship between disability and comorbidity [35]. The incidence of disability rises steadily with age among people aged ≥65 years [34]. Of community-dwelling adults, 20–30% of those aged >70 years report some disability in mobility, tasks essential to household management (e.g., shopping, meal preparation, managing money), and basic self-care tasks (e.g., washing, dressing, eating). Disability is associated with a higher probability of hospitalization and risk of mortality [36]. In oncologic-hematologic patients, the performance status generally describes the overall fitness of patients by a systematic scoring system (KPS or Eastern Cooperative Oncology Group [ECOG]), but the use of scales established in geriatric medicine to screen for disability in self-care tasks (activities of daily living, ADL) and tasks of household management (instrumental activities of daily living, IADL) provides additional information to simpler performance status. Several organizations recommend that persons older than 70 years be screened with ADL and IADL scales on an annual basis [37].

Geriatric Assessment

Determining the optimal treatment for older patients according to their clinical characteristics and fitness is the modern challenge in geriatric onco-hematology. A personalized treatment, tailored not only to disease-specific parameters but also to patient's health status is fundamental.

To date, chronological age and performance status are the most frequently used instruments to stratify patients according to their fitness and consequently select therapy. However, geriatric impairments are highly prevalent in elderly patients with hematological malignancies (even in those with good performance status), they may not be easily detected, and may impact on the patient's ability to complete treatment [38, 39].

A comprehensive geriatric assessment (CGA)—commonly used in geriatric oncology—is a systematic procedure to objectively evaluate the health status of older people, focusing on somatic, functional, and psychosocial domains [40]. The CGA is a highly sensitive and specific tool, and it is more objective and reliable than clinical judgment. Alternatively, a brief assessment with screening tools may be adopted at diagnosis in order to help clinicians identify patients who need a deeper evaluation through a CGA [41, 42].

The International Society of Geriatric Oncology task force recommended that a CGA be implemented for older cancer patients [41]. A growing interest in the geriatric assessment has recently emerged to evaluate older patients with hematological malignancies. In particular, a geriatric assessment showed to predict survival in older AML patients [43]. A simplified geriatric assessment proved to be more accurate than the physicians' judgment to predict response, progression-free survival (PFS), and OS in older patients receiving chemo-immunotherapy in non-Hodgkin lymphomas [39].

Geriatric Assessment in Multiple Myeloma

Recently the International Myeloma Working group has conducted a pooled analysis of 869 individual newly diagnosed elderly patient data from three prospective trials and proposed a frailty score for the measurement of frailty in elderly myeloma patients [44]. At diagnosis, a geriatric assessment was performed and included three tools: the ADL and the IADL scales to assess self-care activities, tasks of household management, and independence status; and the CCI to evaluate number and severity of comorbidities (Tables 27.1 and 27.2) [31, 45]. An additive scoring system (range 0–5) based on these three tools and on patients' age was developed, and three groups of patients were identified: fit (score = 0, 39%), intermediate (score = 1, 31%), and frail (score ≥ 2, 30%). The 3-year OS was 84% in fit, 76% in intermediate (hazard ratio [HR], 1.61; P = 0.042), and 57% in frail (HR, 3.57; $P < 0.001$) patients. The cumulative incidence of grade ≥3 non-hematologic adverse events at 12 months was 22.2% in fit, 26.4% in intermediate (HR, 1.23; P = 0.217), and

34.0% in frail (HR, 1.74; $P < 0.001$) patients. The cumulative incidence of treatment discontinuation at 12 months was 16.5% in fit, 20.8% in intermediate (HR, 1.41; $P = 0.052$), and 31.2% in frail (HR, 2.21; $P < 0.001$) patients. Frailty was found to be associated with an increased risk of death, progression, non-hematologic toxicities, and treatment discontinuation, regardless of International Staging System stage, chromosome abnormalities, and treatment.

Because performing a geriatric assessment can be manpower and time consuming, a simple computer application was also created to support clinicians.

This geriatric score was also validated in the phase 3 FIRST trial [46, 47]. Patients were categorized into three severity groups as described by a proxy algorithm based on the IMWG frailty scale and including age, EQ-5D: Self Care score, EQ-5D: Usual Activities score, and CCI index. Of 1517 patients, 17% were classified as fit, 30% as intermediate, and 54% as frail. Similar breakdowns were observed across treatment arms. Frail patients were older and had higher International Staging System stage, higher Eastern Cooperative Oncology Group performance status scores, higher lactate dehydrogenase levels, and worse renal function than fit or intermediate patients. Of note, fit patients had a significantly longer OS: fit vs. intermediate (hazard ratio [HR] 0.66; $P = 0.004$), fit vs. frail (HR 0.42; $P < 0.0001$), and intermediate vs. frail (HR 0.62; $P < 0.0001$). This analysis of the FIRST trial population using a proxy of the IMWG frailty scale demonstrated predictive clinical outcomes in patients with newly diagnosed MM similar to the original scale. The majority of patients fell into the frail category, demonstrating that FIRST studied a high risk population with poor outcomes and unmet need.

Table 27.1 Scores used to perform a geriatric assessment: Activities of daily living (ADL), instrumental activities of daily living (IADL), and Charlson comorbidity index (CCI)

ADL			IADL		CCI	
Activity	Independent	Dependent	Activity	Related score	Comorbidity	Related score
BATHING Patient bathes completely autonomously or needs help in bathing only a single part of the body such as the back, genital area, or disabled extremity	1	0	**Ability to use telephone**		Myocardial infarct	1
			Patient can operate telephone on own initiative; looks up and dials numbers	1	Congestive heart failure	1
			Patient can dial a few well-known numbers	1	Peripheral vascular disease	1
			Patient answers telephone, but does not dial	1		
			Patient does not use telephone at all	0	Cerebrovascular disease	1
					Dementia	1
DRESSING Patient gets clothes from closets and drawers and puts on clothes. Patient my need help for tying shoes	1	0	**Shopping**		Chronic pulmonary disease	1
			Patient takes care of all shopping needs independently	1	Connective tissue disease	1
			Patient can do the shopping independently for small purchases	0	Mild liver disease	1
			They need to be accompanied on any shopping trip	0	Diabetes	1
			Completely unable to shop	0	Ulcer	1
TOILETING Patient goes to toilet, gets on and off, arranges clothes, cleans genital area without help (may use cane or walker for support and bedpan/urinal at night)	1	0	**Food preparation**		Diabetes with end-organ damage	2
			Patient plans, prepares, and serves adequate meals independently	1	Ictus	2
			They can prepare adequate meals if supplied with ingredients	0	Moderate-to-severe renal failure	2
			Patient heats and serves prepared meals or prepares meals but does not maintain adequate diet	0	Nonmetastatic solid tumor	2
			They need to have meals prepared and served	0	Leukemia	2

Table 27.1 (continued)

ADL		
Activity	Independent	Dependent
TRANSFERRING Patient can move in and out of bed or chair unassisted. Mechanical transferring aides are acceptable	1	0
CONTINENCE Patient exercises complete self-control over urination and defecation	1	0
FEEDING Patient gets food from plate into mouth without help. Preparation of food may be done by another person	1	0

IADL	
Activity	Related score
Housekeeping	
Patient maintains house alone with occasion assistance (heavy work)	1
They can perform light daily tasks such as dishwashing, bed making	1
They can perform light daily tasks, but cannot maintain acceptable level of cleanliness	1
Patient needs help with all home maintenance tasks	1
Patient does not participate in any housekeeping tasks	0
Laundry	
They can do personal laundry completely	1
Patient launders small items, rinses socks, stockings, etc.	1
All laundry must be done by others	0
Mode of transportation	
They can travel independently on public transportation or drives own car	1
Patient arranges own travel via taxi, but does not otherwise use public transportation	1
Patient travels on public transportation when assisted or accompanied by another	1
Travel limited to taxi or automobile with assistance of another	0
They can not travel at all	0
Responsibility for own medications	
Patient is responsible for taking medication in correct dosages at correct time	1
Patient takes responsibility if medication is prepared in advance in separate dosages	0
They are not capable of dispensing own medication	0
Ability to handle finances	
Patient manages financial matters independently (budgets, writes checks, pays rent and bills, goes to bank); collects and keeps track of income	1
Patient manages day-to-day purchases, but needs help with banking, major purchases, etc.	1
Incapable of handling money	0

CCI	
Comorbidity	Related score
Lymphoma, MM	2
Moderate-to-severe liver disease	3
Metastatic solid tumor	6
AIDS	6

Table 27.2 Definition of frail patients with MM

	Frail patients can either be:		
Age	>80 years	76–80 years	≤75 years
Geriatric assessment	Independently of ADL, IADL, CCI	Plus at least one of the following: • ADL ≤ 4 • IADL ≤ 5 • CCI ≥ 2	Plus at least two of the following: • ADL ≤ 4 • IADL ≤ 5 • CCI ≥ 2

ADL Activity of daily living, *IADL* instrumental activity of daily living, *CCI* Charlson comorbidity index
The geriatric score can be calculated through the website http://www.myelomafrailtyscorecalculator.net/

Therapy at Diagnosis for Frail Patients

Start of Treatment

Particular attention is needed with frail patients and their comorbid conditions. Frail patients may present with CRAB-like symptoms that do not lead to actual organ dysfunction and do not require immediate anti-myeloma treatment, but only a close monitoring [3, 4, 48, 49]. Patients may have age-related osteopenia, or mild renal impairment due to hypertension or diabetes, or mild anemia secondary to iron or vitamin deficiency, renal failure, chronic inflammatory diseases, or concomitant dyserythropoietic/myelodysplastic syndrome [50]. Conversely, clear clinical manifestations of serious end-organ damage attributable to myeloma should be considered as CRAB, such as a progressive worsening of serum creatinine caused by light-chain cast nephropathy or a decrease in hemoglobin levels from baseline. Creatinine clearance should be considered with caution. The methods commonly used to estimate glomerular filtration rate have not been well validated at the extremes of age. In frail patients, a progressive renal impairment rather than a fixed concentration cutoff should be considered to confirm MM diagnosis.

According to the recently updated International Myeloma Working Group criteria, clonal bone marrow plasma cell percentage ≥60%, involved/uninvolved serum free light chain ratio ≥100, and >1 focal lesions on magnetic resonance imaging (MRI) studies are associated with near-inevitable development of CRAB features and should be included among the parameters for the diagnosis of MM [4]. Even if no data are present about frail patients, the assessment of these parameters may avoid serious organ damage that could inevitably worsen patients' condition.

The initial evaluation of MM frail patients includes the analysis of their medical history, physical examination, laboratory evaluation, bone marrow biopsy, and aspirate with conventional cytogenetics and fluorescence in situ hybridization for recurring chromosomal translocations and deletions/duplications seen in MM [11]. To assess bone disease, more complex investigations, such as MRI or positron emission tomography (PET), can be unnecessary on a routine basis in frail patients, and should be used only in selected cases, whereas skeletal survey and low-dose computed tomography scan are routine investigations.

Treatment Options

In the last decade, new effective treatments including novel agents thalidomide, bortezomib, and lenalidomide have replaced the former standard melphalan-prednisone [1]. Today, MPT and VMP are the standard treatments for elderly patients ineligible for ASCT [6, 7]. Recently, Rd continuously was shown to be more effective than MPT at diagnosis [46]. It should be noted that currently approved combinations were validated in studies that included selected elderly patients, and a geriatric evaluation was not performed [29].

The benefits obtained with new drug-based combinations were limited in older patients, mainly due to an increased treatment-related toxicity. Indeed, advanced age (≥75 years), occurrence of severe adverse events, and drug discontinuation predicted shorter survival in newly diagnosed MM patients treated with melphalan-prednisone alone or in combination with thalidomide and/or bortezomib [51, 52]. Therefore, avoiding treatment interruption and reducing the risk of side effects in the initial phase of therapy are fundamental, and low-dose intensity treatments are appropriate options for frail patients.

In patients with symptomatic myeloma, patient's age and a geriatric assessment should be considered to determine the most appropriate treatment. Based on the results of the geriatric assessment, patients can be stratified into fit patients suitable for full-dose therapy with three-drug combinations, or frail patients requiring dose-adjusted therapies. Treatment strategies for frail patients should have minimal cumulative toxicity and two-drug regimens showed similar efficacy and lower toxicity as compared to multidrug combinations [53].

A recent phase 3 trial compared the triplet melphalan-prednisone-lenalidomide (MPR) and cyclophosphamide-prednisone-lenalidomide versus the doublet Rd in newly diagnosed elderly MM. The three-drug alkylator-containing combinations were not superior to the two-drug combination Rd. In addition, grade ≥3 toxicity neutropenia was significantly higher with MPR (64%) than with Rd (25%; $P < 0.0001$) [54].

In another trial, the doublet bortezomib-dexamethasone (VD) was as effective as the triplets VMP and bortezomib-thalidomide-dexamethasone in elderly patients, and induced a lower rate of non-hematologic adverse events (22% compared with 33–37% with the three-drug combinations), and thus should be preferred in this patient population. Although

all bortezomib-containing regimens produced good outcomes, VTD and VMP did not appear to offer an advantage over VD in patients with myeloma treated in US community practice [53].

A phase 2 trial evaluated three low-dose intensity subcutaneous bortezomib-based treatments in patients aged 75 years or older with newly diagnosed multiple myeloma (MM) [55]. Patients received subcutaneous bortezomib and oral prednisone (VP) or plus cyclophosphamide (VCP) or VP plus melphalan (VMP), followed by bortezomib maintenance, and half of the patients were frail. Response rate was 64% with VP, 67% with VCP, and 86% with VMP, and very good partial response rates or better were 26%, 28.5% and 49%, respectively. Median PFS was 14.0, 15.2, and 17.1 months, and 2-year OS was 60%, 70%, and 76% in VP, VCP, and VMP, respectively. At least one grade ≥3 nonhematologic adverse event occurred in 22% of VP, 37% of VCP, and 33% of VMP patients; discontinuation rates for AEs were 12%, 14%, and 20%, and the 6-month rates of toxicity-related deaths were 4%, 4%, and 8%, respectively. Yet, toxicity was higher with VMP, suggesting that a two-drug combination followed by maintenance should be preferred in frail patients [55].

These data underline the importance of avoiding treatment interruption and reducing the risk of side effects during the initial phase of therapy; thus low-dose intensity treatments should be preferred for frail patients.

Maintenance therapy showed to be effective also in elderly MM patients [1, 56]. Continuous Rd improved PFS compared with fixed-duration Rd for 18 cycles (Rd18) and significantly prolonged PFS and OS compared with MPT [46]. Continuous Rd caused a modest increase in toxicity compared with Rd18, and most of the toxicity occurred within the first 18 months and decreased over time. The superiority of continuous Rd over MPT for both PFS and OS was evident also in patients >75 years. Although toxicities were more common in patients >75 years, there was no marked difference in the rates of adverse events with continuous Rd and Rd18 within this age subgroup. Furthermore, Rd continuous resulted in PFS and OS benefits compared with MPT for patients of all frailty levels [47].

On the contrary, melphalan–prednisone–lenalidomide followed by lenalidomide maintenance (MPR-R) compared to MPR or melphalan-prednisone followed by placebo improved PFS in patients 65–75 years and not in patients >75 years [57]. This can be due to the higher toxicity of MPR and the need for more frequent dose modifications in patients >75 years. Of note, the major PFS benefit was achieved with lenalidomide maintenance therapy. In a landmark analysis, lenalidomide maintenance reduced the rate of progression by 66% as compared with placebo, regardless of age.

A main goal in frail patients is to maintain an asymptomatic disease status because older age and comorbidities may compromise subsequent salvage therapies. The benefits associated with continuous therapy should be balanced against the toxicity due to prolonged drug exposure, and this is particularly important in frail patients, who are more susceptible to treatment-related toxicities. Maintenance is a valuable option in frail patients who respond slowly to treatment and who tolerate it well. However, in case of significant adverse effects, dose reductions or treatment interruption should be considered.

Complete response has become an achievable aim also in elderly patients, yet toxicity may cancel the benefits derived from such a response [58]. Nevertheless, in frail patients the aim of therapy should not focus on the depth of response, but rather on controlling symptoms, maintaining an independence status and preserving quality of life. Therefore, the achievement of a stable disease without symptoms related to myeloma is an acceptable goal and keeping the balance between disease control and toxicity is crucial.

Dosing and Schedule

Dosing, schedule, and route of administration play a major role in the safety profile of therapy in frail patients. Once-weekly bortezomib significantly reduced the incidence of grade 3–4 adverse events (35% vs. 51%) and the rate of discontinuation due to toxicity (17% vs. 23%) compared with the twice-weekly schedule, in particular halving the rate of peripheral neuropathy. To overcome the limitations of bortezomib (intravenous administration and hospitalization), subcutaneous bortezomib is a valuable and equally effective strategy.

Lenalidomide has the advantage of the oral administration, which is more appealing in a frail patient population, and is preferable in subjects with preexisting neuropathy [46]. In particular, lenalidomide plus low-dose dexamethasone was better tolerated than lenalidomide plus high-dose dexamethasone [59]. Still, bortezomib-dexamethasone can be a valid option in case of aggressive disease, which needs a rapid cytoreduction and symptom control, and in case of acute renal dysfunction [53, 55].

In frail patients lower initial doses can be administered to minimize toxicity; dose escalation may be considered in the subsequent cycles if treatment is optimally tolerated or in case of inadequate response. The initial dose of lenalidomide should not exceed 10–15 mg/day and it can be adjusted based on renal function and blood counts to avoid profound and prolonged myelosuppression. Prophylactic growth factors and antimicrobial, at fixed dose and timing, can be used to prevent myelosuppression and infections, and thus treatment discontinuation. A previous history of cardiovascular disease or thromboembolism does not preclude the use of lenalidomide, if an adequate thromboprophylaxis is associated [11].

Corticosteroids may increase blood pressure and fluid retention; therefore they should be reduced, particularly in patients with cardiac diseases. Other adverse effects include hyperglycemia, gastritis, mood swings, insomnia, and increased risk of opportunistic infections. The dose of dexamethasone should be reduced to as little as 10 mg once a week. Alternatively, prednisone 25 mg every other day is a valid option in this setting [11].

Subcutaneous weekly bortezomib is a valid alternative option; it does not need dose reductions, although thrombocytopenia could be a concern [60–62]. This is a relevant strategy to improve tolerability, reduce treatment discontinuation, and increase the chance of disease control in frail patients. Bortezomib can cause peripheral neuropathy, differently from novel proteasome inhibitors [63, 64]. In frail patients, weekly carfilzomib, oral ixazomib, and oprozomib may be implemented in the future.

Finally, in patients with severe impairment of cognitive function or social dependency, a palliative treatment may be considered. In these cases, reduced-dose corticosteroids or melphalan-prednisone or cyclophosphamide-prednisone can be used to relieve disease symptoms.

Management of Complications

Despite the benefits associated with novel agents thalidomide, lenalidomide, and bortezomib, treatment-related toxicities are a major concern in frail patients. Full drug doses are difficult to be tolerated and side effects are frequent. In a retrospective analysis of 1435 elderly patients enrolled in four European phase III trials including thalidomide and/or bortezomib, the risk of death was increased in patients >75 years (HR 1.44, 95% CI: 1.20–1.72; $P < 0.001$); in patients with renal failure (HR 2.02, 95% CI: 1.51–2.70; $P < 0.001$); in those who had grade 3–4 infections, cardiac, or gastrointestinal adverse events during treatment (HR 2.53, 95% CI: 1.75–3.64; $P < 0.001$); and in those who discontinued therapy due to adverse events (HR 1.67, 95% CI; 1.12–2.51; $P = 0.01$). This increased risk was detected in the first 6 months after occurrence of adverse events or drug discontinuation and decreased over time [65]. More intensive approaches, such as the combination of bortezomib thalidomide, negatively affected outcome. Age 75 years or over or renal failure at presentation, occurrence of infections, and cardiac or gastrointestinal adverse events negatively affected survival.

Because frail patients are more susceptible to treatment-related side effects and treatment interruption, appropriate supportive care and an early identification of toxicities are fundamental [11].

Cytopenia is typical in hematologic patients treated with chemotherapy. It involves one or more cellular lineages of the bone marrow, due to both marrow invasion by neoplastic cells and chemotoxicity. Supportive care is essential to maintain an adequate quality of life and to enable the patient to stay on treatment [66].

Anemia is characterized by a hemoglobin level inferior to 13.5 g/dL for men and 12.0 g/dL for women. In elderly cancer patients anemia may be due to bone marrow invasion and chemotoxicity, but there are also other causes, such as renal insufficiency; iron, copper, and vitamin deficiency (folic acid, B12, and vitamin D); hypogonadism; relative erythropoietin system impairment; and possibly an underlying myelodysplasia or exhaustion of the hematopoietic progenitor. Approximately 50% of patients with anemia had two or more interconnected causes. Blood transfusions are recommended with hemoglobin levels below 7–8 g/dL. Erythropoietin-stimulating agents can improve fatigue and quality of life, and treatment could be continued until hemoglobin levels rise to 12 mg/dL [67].

Patients with neutropenia are also at risk of infections following chemotherapy, based on the severity and duration of neutropenia. Antibacterial prophylaxis can prevent febrile episodes, clinically or microbiologically documented bacterial infections including bacteremias, and hospitalization of outpatients [68]. Antibiotic prophylaxis should be started promptly when neutropenia occurs. Prophylaxis with antifungal agents (usually azoles) is recommended in cases of prolonged neutropenia. All patients undergoing chemotherapy or novel agent-based therapy should receive trimethoprim-cotrimoxazole as a prophylactic agent against the opportunistic infection of *Pneumocystis jiroveci* pneumonia.

Febrile neutropenia is characterized by an oral temperature higher than 38.5 °C or two consecutive measurements with a temperature higher than 38.0 °C for 2 h and an absolute neutrophil count of less than 0.5×10^9/L or one expected to fall below 0.5×10^9/L.

Chemotherapy-induced febrile neutropenia is a major risk factor for infection-related morbidity and death, as well as a significant dose-limiting toxicity in cancer treatment. Prognosis is worse in patients with bacteremia, with mortality rates of 18% in Gram-negative and 5% in Gram-positive bacteremia [69]. In elderly patients at high risk of developing febrile neutropenia, prophylactic granulocyte colony-stimulating factor (G-CSF) should be adopted based on age, medical history, disease characteristics, and myelotoxicity of their chemotherapy regimen. In patients with febrile neutropenia, the choice of initial antibiotic should be based on the patient's infectious disease history, prior antibiotic usage, and epidemiologic data of the area where the patient lives.

In patients receiving proteasome inhibitors, antiviral prophylaxis for herpes zoster reactivation is needed; immunomodulatory agents require an appropriate risk-based thromboprophylaxis. When corticosteroids are administered, gastrointestinal prophylaxis should be used. Antibacterial prophylaxis is recommended in case of severe myelosuppression,

and growth factors should be used in patients experiencing neutropenia and anemia. In addition, a careful review of the patient's previous medications and attention to potential drug interactions are essential [11].

When an adverse event occurs in a frail patient, prompt action is required. Therapy should be stopped in case of grade 3–4 toxicity, and can be restarted at lower doses when toxicity decreases to at least grade 1 [1]. Lenalidomide dose may be decreased from 15 to 10 mg/day, or from 10 to 5 mg/day or, if required, to 5 mg every other day on days 1–21 every 4 weeks. Bortezomib may be reduced from 1.3 mg/m^2 weekly to 1.0 mg/m^2 once weekly or 0.7 mg/m^2 once weekly.

Conclusions

Treatment of elderly patients is particularly challenging today because of the complex phenomenon of aging. Aging is in fact associated with an increased incidence of tumors and of other comorbidities, and more than two-thirds of cancer diagnoses and of cancer deaths are reported among elderly people [21].

The presence of multiple diseases in elderly patients and the availability of newer and more targeted drugs require tailored treatments according to both the disease features and the patient's status. In this setting, cancer treatment decision should be based not only on age but a careful assessment of patients' frailty is crucial. To date there is no consensus about the definition and assessment of frailty, although recently the International Myeloma Working Group has proposed a valuable tool to better stratify patients according to age, CCI, ADL, and IADL. However, the most appropriate treatment in different subgroups of patients remains to be definitively determined and further studies are necessary.

Newly Diagnosed Multiple Myeloma in Transplant-Eligible Patients

28

Rajshekhar Chakraborty and Morie A. Gertz

Introduction

Multiple myeloma (MM) is characterized by clonal proliferation of malignant plasma cells in the bone marrow. An estimated 30,280 new cases of MM will be diagnosed in the USA in 2017 [1]. The introduction of proteasome inhibitors (PIs) and immunomodulators (IMiDs) in conjunction with autologous stem cell transplantation (ASCT) has markedly improved the overall survival (OS) in MM, with the survival gap between MM patients and matched controls decreasing in the last decade [2]. The incorporation of ASCT into the frontline therapy of transplant-eligible (TE) patients in the late 1990s had shown a remarkable improvement in survival in younger myeloma patients between 2001 and 2005 [3]. Currently, PI and/or IMiD-based combinations are the standard of care for pretransplant induction therapy in TE newly diagnosed MM patients [4]. Furthermore, the addition of long-term maintenance therapy after ASCT has also led to improved progression-free and overall survival [5]. Hence, there has been a paradigm shift in the management of newly diagnosed MM, leading to the achievement of a deep and durable disease control and improved survival, with the current median OS being greater than 6 years [6].

Diagnosis and Risk Stratification

Traditionally, therapy for MM was initiated once patients developed signs of end-organ damage or *CRAB,* signifying *h*ypercalcemia, *r*enal failure, *a*nemia, and *b*one lesions. However, in 2014, the International Myeloma Working Group (IMWG) proposed an updated criteria for diagnosis of MM, so that early therapy can be initiated to prevent end-organ damage [7]. In addition to the traditional *CRAB* features as a requirement for diagnosis and initiation of therapy in MM, the new IMWG criteria added three biomarkers: bone marrow plasma cells (BMPCs) ≥60%, serum free light chain ratio (sFLCr; involved/uninvolved) ≥100, or ≥1 focal lesion on magnetic resonance imaging (MRI). Currently, the IMWG recommends initiating therapy in MM in the presence of either of the above-mentioned biomarkers even if the patient does not exhibit any of the *CRAB* features and is asymptomatic. The rationale behind early initiation of therapy in MM is twofold: firstly, there are currently multiple effective agents available for frontline therapy in MM, including PIs and IMiDs and, secondly, early therapy in asymptomatic high-risk patients could potentially reduce the risk of end-organ damage and prolong overall survival, as seen in patients with high-risk smoldering myeloma [8].

Once a diagnosis has been established, risk stratification should be performed using one of the prognostic models summarized in Table 28.1 [9–11], which are routinely used in clinical practice. In the revised International Staging System (rISS) for MM [10], chromosomal abnormalities by fluorescence in situ hybridization (FISH) and lactate dehydrogenase (LDH) have been incorporated into the ISS staging [12], which included albumin and β-2 microglobulin. Presence of deletion(17p), t(4;14), and t(14;16) by FISH has an independent negative prognostic impact on survival in MM [10]. The 5-year OS rate of patients with rISS stage I, II, and III are 82%, 62%, and 40%, respectively. Notably, the patient population in rISS staging received up-front novel agents in 95% and ASCT in 60% of cases. Other risk stratification tools like gene expression profiling [13] have also been used, but are not widely available.

Table 28.1 Risk stratification systems in multiple myeloma

Prognostic model	Variables	Risk categories	Overall survival	Ref.
rISS	ISS staging, CA [deletion(17p), t(4;14), t(14;16)] and LDH	**rISS stage I:** ISS stage I, no high-risk CA and LDH ≤ UNL **rISS stage II**: All other combinations **rISS stage III:** ISS stage III *AND* high-risk CA or LDH > UNL	5-year OS rate: rISS-I: 82% rISS-II: 62% rISS-III: 40%	
mSMART	CA, GEP, and PCLI	**Standard risk**: All others including t(11;14) or t(6;14) on FISH **Intermediate risk**: t(4;14) on FISH, cytogenetic deletion 13, hypodiploidy or PCLI ≥3% **High risk**: Del(17p), t(14;16) or t(14;20) on FISH or high-risk signature on GEP	Median OS: Standard risk: 8–10 years Intermediate risk: 4–5 years High risk: 3 years	
IMWF	ISS staging and CA	**Low risk**: ISS stage I/II *AND* absence of t(4;14), deletion(17p) and +1q21 *AND* age <55 years **Standard risk**: Others **High risk**: ISS stage II/III *AND* t(4;14) or 17p13 deletion	Median OS: Low risk: 2 years Standard risk: 7 years High risk:>10 years	
IFM	LDH, ISS (III), and cytogenetics (FISH)	**Scores 0–3** (higher score indicating poor prognostic subgroup), with 1 point each for high LDH, ISS stage III, and high-risk CA [t(4;14) and/or del(17p)]	2-year OS rate: Score 0: 93% Score 1: 85% Score 2: 67% Score 3: 55%	

Optimal Induction Regimen for Transplant-Eligible Patients

The goal of induction therapy in MM is to rapidly reduce the tumor burden for minimizing the risk of end-organ damage with minimal toxicities. Furthermore, in TE patients, stem cell toxic drugs like alkylating agents should be avoided due to the risk of inadequate stem cell mobilization. Fortunately, with the introduction of PIs and IMiDs in the treatment armamentarium of MM, a wide variety of non-stem cell toxic induction regimens with high anti-myeloma activity are available in the current era. In TE patients, the combination of bortezomib and dexamethasone (VD) was shown to be superior to alkylating agent-based vincristine-adriamycin-dexamethasone (VAD) induction regimen in terms of response rate and progression-free survival (PFS) in the phase III IFM trial, with less toxicity [14]. Subsequently, a meta-analysis of three phase III RCTs on bortezomib- versus non-bortezomib-containing induction regimen prior to ASCT showed a superior PFS and OS with bortezomib-containing induction regimens [15], the comparator being alkylating agent in two and thalidomide-based induction regimen in one trial. These studies have paved the way for several combination regimens on a backbone of VD to be widely used as induction therapy in newly diagnosed TE-MM patients [4, 16, 17]. However, with a wide variety of available induction regimens, the optimal choice for frontline induction therapy is becoming increasingly complex. The 2017 NCCN guideline recommends using a three-drug over two-drug regimen for frontline therapy in MM based on the evidence of improved response rates and survival [4]. A study on serial genomic analysis of MM has shown that the tumor can exhibit either genomic stability, linear evolution, or clonal heterogeneity with shifting clonal predominance over time [18]. Furthermore, the genome of patients with standard-risk cytogenetics showed minimal changes over time, unlike those with high-risk cytogenetics which was characterized by clonal evolution. This study provides the biological rationale for preferentially using three-drug over two-drug regimens since a suboptimal frontline therapy especially in high-risk patients may fail to eradicate the aggressive clones and lead to future relapse due to clonal evolution. In patients with high-risk cytogenetic abnormalities like deletion (17p), three-drug regimens incorporating a PI and IMiD like bortezomib-lenalidomide-dexamethasone (VRD) or carfilzomib-lenalidomide-dexamethasone (KRD) should be used for induction therapy. Bortezomib-based regimens should be used in those presenting with renal insufficiency at diagnosis [19]. Medical comorbidities, including preexisting peripheral neuropathy should also be taken into consideration while choosing the induction regimen. Intensive induction therapy with bortezomib and/or alkylating agents followed by ASCT is recommended for patients presenting with primary plasma cell leukemia (PCL) [20].

The commonly used induction regimens along with the evidence supporting their use are summarized below and the important phase II and III clinical trials on induction regimens in TE patients are shown in Table 28.2 (three-drug combinations) and Table 28.3 (two-drug combinations).

Three-Drug Combinations

Bortezomib-Lenalidomide-Dexamethasone (VRD)

VRD was initially evaluated as a frontline induction therapy in the phase I/II study by Richardson et al. [21]. The regimen was shown to be highly effective with an unprecedented post-induction partial response (PR) rate of 100% and a VGPR rate of 67%. The most common grade 2/3 AEs were sensory neuropathy and fatigue and grade 3/4 hematologic toxicities included thrombocytopenia, neutropenia, and lymphopenia. The 18-month PFS and OS rates were 75% and 97%, respectively, at a median follow-up of 21 months. Subsequently, a phase II study by the French group on VRD induction followed by frontline ASCT in newly diagnosed MM patients demonstrated a post-induction VGPR rate of 58% [22]. Notably, 16% of patients in this trial achieved post-induction MRD negativity by flow cytometry at a sensitivity level of 10^{-4}. The 3-year PFS and OS rates were 77% and 100%, respectively, at a median follow-up of 39 months. No treatment-related mortality was reported. Discontinuation due to AEs was noted in only 3% of patients during induction or consolidation phase. The most common grade 3/4 adverse events (AEs) were neutropenia and thrombocytopenia. The randomized phase II EVOLUTION study compared VRD with bortezomib-cyclophosphamide-dexamethasone (VCD) and VRCD in newly diagnosed MM patients, majority of whom were TE [23]. There was no significant difference in the incidence of post-induction VGPR and 1-year PFS rate in the either arms. AEs leading to discontinuation of therapy were seen in 19% of patients in the VRD and 12% in the VCD arm.

Currently, VRD remains the preferred induction regimen in both TE and non-TE MM patients. Although there is no data on OS benefit with VRD in TE patients, it has been shown to have a superior OS over RD in non-TE patients in the SWOG S0777 trial [24].

Bortezomib-Thalidomide-Dexamethasone (VTD)

VTD was found to be superior to TD as a pretransplant induction regimen in the phase III GIMEMA trial [25]. In this trial, 480 patients were randomized to either VTD or TD induction and consolidation therapy in the setting of tandem ASCT. The post-induction VGPR rates in VTD and TD arms were 62% and 28%, respectively ($P < 0.001$). Patients in the VTD arm had a significantly superior 3-year PFS rate compare to those receiving TD (68% vs. 56%, respectively; $P = 0.006$). However, there was no significant difference in the 3-year OS rates at a median follow-up of 36 months. Of note, VTD was shown to abrogate the negative prognostic impact of t(4; 14) cytogenetic abnormality. The incidence of grade 3/4 AEs was 56% in the VTD arm and 33% in the TD arm, with no significant difference in treatment-related mortality. Notably, the incidence of grade 3/4 peripheral neuropathy (PN) was higher in the VTD (10%) compared to TD arm (2%). However, treatment discontinuation in the VTD arm was seen in only 9% of patients developing PN, with 78% experiencing improvement or resolution of symptoms over time.

Another phase III trial by the PETHEMA/GEM group randomized 386 TE patients to receive either VTD, TD, or multiple alkylating agent-based chemotherapy with bortezomib, followed by ASCT and maintenance therapy [26]. The post-induction complete response (CR) rate was 35% in the VTD arm, compared to 14% in the TD arm ($P = 0.001$). In patients with extramedullary soft-tissue plasmacytomas, the post-induction CR rates in VTD and TD arms were 42% and 14%, respectively ($P = 0.02$). The incidence of grade 2–4 PN with VTD was 60% compared to 13% with TD. Dose reduction of bortezomib due to PN was needed in 25% of patients in the VTD arm and 2% had to discontinue therapy. Although patients in the VTD arm had a superior PFS compared to TD (median, 56 vs. 28 months; $P = 0.01$), there was no significant difference in the 4-year OS rate at a median follow-up of 35 months. Patients with high-risk cytogenetics had an inferior PFS and OS irrespective of the treatment arm.

VTD has also been compared with VCD as an induction regimen prior to ASCT in a phase III randomized trial by the IFM group [27]. The post-induction VGPR rate was higher with VTD compared to VCD (66% vs. 56%, respectively; $P = 0.05$). The posttransplant response and survival were not reported in this trial. The incidence of grade 2–4 PN was higher in the VTD compared to VCD arm and grade 3/4 hematologic toxicity was higher in the VCD arm.

VTD remains an active induction regimen in TE patients, with the potential limitation being high rates of PN. Notably, it does not need any dose modification in patients with renal dysfunction and is less expensive compared to other novel agent-based triplet regimens like VRD or KRD.

Bortezomib-Cyclophosphamide-Dexamethasone (VCD)

A phase II trial of VCD induction in newly diagnosed TE-MM patients showed a post-induction PR rate of 88%, with a VGPR rate of 61% [28]. Common grade 3/4 toxicities included hematologic toxicity, hyperglycemia, diarrhea, neuropathy, and thrombosis. Another phase II trial comparing once- versus twice-weekly bortezomib in VCD induction found similar VGPR rates of 60% and 61%, respectively in the two cohorts [29]. However, grade 3/4 AEs, including PN, were lower in the once-weekly compared to the twice-weekly cohort, favoring the use of once-weekly bortezomib with similar efficacy and improved tolerability. Long-term follow-up of VCD induction therapy followed by ASCT has shown 5-year PFS and OS rates of 42% and 70%, respectively [30]. A phase II/III German study on VCD induction

in 300 TE patients showed 84% achieving a PR or better after induction, with 10% achieving a CR [31]. Serious AEs were observed in 26% of patients, with grade 3 PN in only 2.3%. Furthermore, VCD was shown to abrogate the negative prognostic impact of t(4; 14) abnormality. The phase II EVOLUTION study showed no significant difference in the post-induction response and 1-year PFS rates between VCD and VRD, as mentioned earlier [23]. The head-to-head comparison between VCD and VTD has shown higher post-induction VGPR rate in the latter but survival outcomes have not been reported thus far [27].

A phase III randomized trial comparing VCD with bortezomib-doxorubicin-dexamethasone (PAD) in 504 newly diagnosed TE-MM patients showed similar post-induction VGPR rates in the two arms (37% and 34% in VCD and PAD arms, respectively; *P* value for non-inferiority <0.001) [32]. The incidence of grade 2–4 neuropathy was higher in the PAD arm (15%) compared to the VCD arm (8%) [$P = 0.003$]. Similarly, severe AEs due to thromboembolic events were also higher in the PAD compared to the VCD arm (2.8% vs. 0.4%, respectively; $P = 0.04$). Stem cells were adequately collected for at least one transplant in both arms in close to 90% of patients. This study confirmed the non-inferiority in terms of efficacy and a superior safety profile of VCD compared to PAD as an induction regimen in TE-MM patients.

VCD is a highly effective induction regimen in TE patients. Further studies should aim at comparison of VCD with current standard-of-care regimens like VRD and VTD in terms of PFS and OS, as frontline VCD administration is cost effective and reserves the use of IMiDs later in the disease course [9].

Bortezomib-Doxorubicin-Dexamethasone (PAD)

PAD was compared head to head with VAD as a pretransplant induction regimen in the phase III HOVON/GMMG trial [33]. In this trial 827 patients were randomly assigned to receive three cycles of either PAD or VAD followed by a single or tandem ASCT. Patients in the PAD arm received 2 years of bortezomib maintenance after ASCT and those in the VAD arm received 2 years of thalidomide maintenance. The post-induction VGPR rates in the PAD and VAD arms were 42% and 14%, respectively ($P < 0.001$). Patients randomized to the PAD arm had a superior PFS compared to those in the VAD arm (median PFS, 35 vs. 28 months, respectively; $P = 0.002$) and the 5-year OS rates were 61% and 55%, respectively ($P = 0.07$), at a median follow-up of 41 months. Notably, in the subgroup of patients with deletion (17p) cytogenetic abnormality by FISH, the median PFS was 36 months in the PAD compared to 18 months in the VAD arm ($P < 0.001$) [34]. Similarly, the 3-year OS rates in the deletion (17p) subgroup was 83% and 36% in the PAD and VAD arms, respectively (HR 2.4 for VAD; $P < 0.001$). Furthermore, administration of bortezomib both before and after ASCT (as in the PAD arm) abrogated the negative prognostic impact of deletion (17p) [34]. Patients with renal failure also had a superior PFS and OS in the PAD arm [33]. Grade 2–4 PN was observed in 18% of patients receiving VAD and 40% receiving PAD. SCC was successful in close to 90% of patients in either arm.

Since patients with deletion (17p) have poor outcomes, administration of three-drug combinations including bortezomib or carfilzomib as pretransplant induction therapy and bortezomib maintenance after ASCT is recommended in this subgroup.

Carfilzomib-Lenalidomide-Dexamethasone (KRD)

Carfilzomib is a highly selective and irreversible next-generation PI with robust anti-myeloma activity [35, 36]. It has been shown to have a single-agent activity in relapsed/refractory (R/R) MM [37] and also in combination with RD in the phase III ASPIRE trial [38]. A phase I/II study of KRD in 53 patients with newly diagnosed MM showed an ORR of 98%, with 42% achieving a stringent CR (sCR) after induction [39]. At a median follow-up of 13 months, the 1- and 2-year PFS rates were 97% and 92%, respectively. Thirty-five patients in this trial underwent successful stem cell collection and seven eventually proceeded to ASCT. Common grade 3/4 AEs included hyperglycemia (23%), hypophosphatemia (25%), anemia (21%), thrombocytopenia (17%), and neutropenia (17%). PN was observed in 12% of patients, all being grades 1–2. There was no treatment-related mortality. Another phase II study of KRD induction followed by extended lenalidomide administration in 41 newly diagnosed TE and non-TE patients showed a post-induction VGPR rate of 89%, with a sCR rate of 41% [40]. Among 17 patients with at least a near CR (nCR) who underwent MRD testing at a sensitivity level of 10^{-5}, all were found to be MRD negative. Common non-hematologic grade 3/4 AEs included electrolyte disturbances (18%), abnormal liver function tests (13%), rash or pruritus (11%), fatigue (11%), cardiovascular toxicity (8%), and dyspnea (8%). The phase II FORTE trial has compared KRD and KCD (carfilzomib-cyclophosphamide-dexamethasone) in 281 TE-MM patients [41]. The post-induction rate of achieving VGPR or better response after four cycles of induction therapy was 74% with KRD and 61% with KCD ($P = 0.05$). The incidence of grade 3/4 AEs was higher in the KCD compared to KRD arm. On the other hand, grade 3/4 dermatological AEs and elevated liver function tests were common in the KRD arm. Stem cell mobilization was successful in more than 95% of patients in both arms.

KRD is emerging as a highly effective induction regimen in MM, with a high rate of sCR and MRD negativity post-induction. However, to the best of our knowledge, there is no phase III data on frontline therapy in TE-MM patients thus far. Although the incidence of PN is lesser with carfilzomib

compared to bortezomib, cardiotoxicity observed in the clinical trials of carfilzomib is concerning. A meta-analysis of phase I/II, II, and III clinical trials on carfilzomib including 2594 patients has shown the risk of all grade and grade 3/4 cardiotoxicity (including arrhythmias, systolic congestive heart failure, and acute coronary syndrome) to be 18% and 8%, respectively [42]. Furthermore, the cardiotoxicity was dose dependent, with patients receiving carfilzomib dose ≥45 mg/m^2 having a twofold higher incidence of grade ≥3 cardiac AEs, compared to those receiving <45 mg/m^2. Hence, caution should be exercised in patients at a high risk of cardiovascular complications.

Ixazomib-Lenalidomide-Dexamethasone (IRD)

The combination of oral PI ixazomib with RD has been shown to be safe and effective in 65 TE and non-TE patients in an open-label phase I/II trial [43]. Grade 3–4 AEs were observed in 63% of patients, including disorders of skin and subcutaneous tissue (17%), neutropenia (12%), thrombocytopenia (8%), and PN (6%). The post-induction ORR was 92%, including a VGPR rate of 58% and a CR rate of 27%. At a median follow-up of 14 months, the 1-year PFS and OS rates were 88% and 94%, respectively. SCC was attempted in 45% of patients after a median of four cycles of induction therapy. Although the activity of IRD seems promising in newly diagnosed MM, further data from phase II and III clinical trials on head-to-head comparison with currently used regimens is needed prior to its incorporation in the frontline therapy for TE patients.

Two-Drug Combinations

Bortezomib-Dexamethasone (VD)

VD was the first novel agent-based induction regimen which was shown to be superior to alkylating agent-based induction prior to ASCT in newly diagnosed MM [14]. In this phase III IFM trial, 482 patients were randomized to receive VD, VAD, VD followed by consolidation with multiple alkylating agents, or VAD followed by a similar consolidation. Subsequently, all patients would proceed to a single ASCT, with tandem ASCT reserved for those achieving less than a VGPR after the first ASCT. Post-induction VGPR rate was significantly higher with VD compared to VAD (54% vs. 37%, respectively; $P < 0.001$). Patients receiving VD had a superior PFS; however, they did not reach statistical significance (median PFS, 36 months with VD vs. 30 months with VAD; $P = 0.064$). Consolidation with alkylating agents did not improve post-induction response rate. Adequate SCC was achieved in more than 95% of patients in both arms. The incidence of grade 3/4 anemia, neutropenia, and thrombosis was significantly higher in the VAD arm, as was the incidence of toxicity-related deaths. On the other hand, grade 2/3 PN was significantly higher in the VD arm. Analysis of patients with high-risk FISH cytogenetics either enrolled or treated according to the above protocol showed that induction with VD abrogated the negative prognostic impact of t(4;14) but not deletion (17p) [44]. Another phase III trial by the French group randomized patients to receive VD or reduced-dose VTD (rVTD). The post-induction VGPR rate was significantly higher in the rVTD arm compared to the VD arm (49% vs. 36%; $P = 0.05$). However, there was no significant difference in PFS or OS. Notably, the incidence of grade 2–4 PN was 34% in the VD and 14% in the rVTD arm ($P = 0.001$).

Thalidomide-Dexamethasone (TD)

Thalidomide is a first-generation IMiD and is not widely used in the USA due to the availability of lenalidomide, which has a superior safety profile and a higher potency compared to thalidomide. The 2017 NCCN guidelines have removed TD as a recommended induction regimen in TE patients [4]. However, due to low cost, it still remains valuable in resource-limited settings, where there is a lack of access to bortezomib and lenalidomide.

TD was shown to be superior to D alone as an induction therapy in newly diagnosed MM in a phase III trial. The post-induction ORR was significantly higher with TD compared to D, which translated into a superior PFS (median PFS, 14.9 months with TD vs. 6.5 months with D; $P < 0.001$) [45]. However, grade 3/4 AEs, especially thromboembolic complications (18%) and PN (3.4%), were significantly higher with TD. Of note, routine thromboprophylaxis was not administered in this trial, which is currently a standard of care in patients receiving IMiDs. VTD induction therapy has been shown to have a superior PFS compared to TD in two phase III trials, as mentioned earlier [15, 25, 26].

Lenalidomide-Dexamethasone (RD)

Lenalidomide is a second-generation IMiD with a better toxicity profile compared to thalidomide. In the randomized SWOG S0232 phase III trial, RD was shown to be superior to D alone for the treatment of newly diagnosed MM [46]. The CR rate was 22% in the RD arm and 4% in the D arm ($P = 0.001$), with the 1-year PFS rates being 77% and 55%, respectively ($P = 0.002$). The trial was halted after interim analysis due to ethical challenges with using D alone as the control arm and patients were allowed to cross over to RD. Thromboembolic events (TEE) were observed in 20% of patients receiving RD compared to 12% of those receiving D alone. However, thromboprophylaxis with aspirin 325 mg daily was added later in the trial after a high rate of TEE was noted in the RD arm.

Another phase III RCT evaluated whether RlowD (lenalidomide-low-dose dexamethasone) was non-inferior in terms of efficacy and safer compared to RD as an induction

therapy for newly diagnosed MM [47]. Patients were randomized to receive dexamethasone 40 mg for 12 out of 28 days (RD) or 4 out of 28 days (RlowD) along with lenalidomide 25 mg daily from days 1 to 21. After four cycles, the cumulative rate of PR or better was 79% in the RD arm and 68% in the RlowD arm ($P = 0.008$). However, the 1-year respective OS rates in the two arms were 87% and 96% ($P = 0.0002$), mostly driven by the increased mortality during the first 4 months of therapy in the RD arm (5.4%) compared to the RlowD arm (0.45%). Notably, the incidence of grade ≥3 AEs was higher in the RD compared to RlowD arm (52% vs. 35%, respectively; $P < 0.001$), with the most common SAEs being DVT, infection, and fatigue.

In non-TE patients, RD has been shown to be inferior to VRD in terms of PFS and OS in the SWOG S0777 trial [24]. However, survival benefit of novel agent-based triplets over RD has not been shown in TE patients. Patients receiving RD should have stem cells collected after four cycles of therapy due to reports of impaired stem cell mobilization after prolonged exposure to lenalidomide [48, 49].

Stem Cell Transplantation

Stem cell transplantation is an integral part of the treatment backbone in eligible patients with newly diagnosed MM. Several RCTs, both in the context of conventional cytotoxic chemotherapy and novel agents like PIs and IMiDs, have shown ASCT to be an effective consolidative treatment. It improves the depth of response achieved by induction therapy with PIs and IMiDs [25, 50], with a negligible transplant-related mortality (TRM) of around 1% in most studies in the current era.

Transplant Eligibility

There is a lack of clear consensus on strict eligibility criteria for ASCT in MM. However, age and comorbidities are generally taken into consideration while determining transplant eligibility. Age greater than 65 years is considered to be a contraindication for transplant in most countries. However, in the USA, ASCT is frequently offered to patients over 65 years of age in a good functional status and several retrospective studies have shown similar posttransplant PFS and OS in elderly patients who undergo transplantation [51, 52]. There was no significant difference in TRM noted in elderly patients [52]. A prospective French study on MM patients aged 64–74 years has established the feasibility of ASCT in this age group, with 89% of patients undergoing ASCT successfully [53]. Melphalan 200 mg/m^2 was used as a conditioning regimen in 64% and 140 mg/m^2 in 36% of transplanted patients. At 100 days posttransplant, there was no treatment-related mortality observed in this age group. Prior to ASCT, sufficient cardiac, renal, liver, and pulmonary function is also desirable [4]. However, in a CIBMTR study on 1492 patients undergoing ASCT, there was no difference in PFS and OS among patients with and without renal dysfunction. Furthermore, 85% of patients with severe renal insufficiency achieved dialysis independence after ASCT [54]. Hematopoietic cell transplant comorbidity index (HCT-CI) [55] has also been shown to be effective as a risk stratification tool prior to ASCT in MM, with higher HCT-CI scores indicating an inferior survival after transplant [56].

Studies on ASCT in Newly Diagnosed MM (Table 28.4)

The first RCT performing a head-to-head comparison of conventional therapy using alkylating agents with high-dose chemotherapy followed by ASCT (HDT-ASCT) was reported by the IFM group in 1996 [57]. In this study 200 patients were randomized to receive either 18 alternating cycles of VMCP/BVAP (vincristine, melphalan, cyclophosphamide, prednisone/vincristine, carmustine, doxorubicin, prednisone) or 4–6 alternating cycles of VMCP/BVAP immediately followed by HDT-ASCT, using melphalan 140 mg/m^2 and total-body irradiation (TBI; 8Gy) as a conditioning regimen. The ORR was significantly higher in the ASCT arm compared to the conventional therapy arm (81% vs. 57%, respectively; $P < 0.001$), as was the CR rate (22% vs. 5%, respectively; $P < 0.001$). The 5-year PFS rates in the ASCT and conventional therapy arms were 28% and 10% ($P = 0.01$), respectively, and the respective 5-year OS rates were 52% and 12% ($P = 0.03$). TRM was seen in 2% of patients. The MRC Myeloma VII trial also compared alkylating agent-based chemotherapy with ASCT showing similar results, with a significantly superior CR rate, PFS, and OS in the ASCT arm [58]. Death within 100 days of ASCT was seen in 3% of patients in the MRC trial, the cause being sepsis in all but one patient.

With the superiority of HDT-ASCT being established in newly diagnosed MM, the next strategic question was whether all eligible patients must undergo frontline ASCT after induction therapy or can wait for ASCT until their first relapse without compromising survival. To answer this question, Fermand et al. reported a multicenter RCT comparing patients who underwent up-front HDT-ASCT (ASCT arm) with those who had standard-dose therapy (SDT) with the option of salvage ASCT either at first relapse or in the case of primary resistance to SDT (SDT arm) [59]. With a median follow-up of around 6 years, the median PFS in the ASCT arm was 39 months, compared to 13 months in the SDT arm. However, there was no significant difference in OS, with the median OS being 64.6 months in the ASCT arm and

64 months in the SDT arm ($P = 0.92$). Around 90% of patients in the SDT arm who were TE per protocol had successfully received a salvage ASCT. Notably, the average time without symptoms, treatment, or treatment toxicity was higher in the ASCT arm compared to the SDT arm (28 vs. 22 months, respectively).

Subsequently, the phase III US Intergroup trial by Barlogie et al. randomized 516 patients to SDT or HDT-ASCT after induction with VAD and SCC with high-dose cyclophosphamide [60]. Patients in the SDT arm had received consolidation with multiple alkylating agents (VBMCP) for a total of 1 year before being randomized to interferon (IFN)-based maintenance therapy or observation. The conditioning regimen used in the ASCT arm was melphalan 140 mg/m^2 along with total-body irradiation (TBI). The cumulative response rates were identical in both arms. Furthermore, there was no significant difference in the 7-year PFS and OS rates in either arms. Notably, around 55% of patients relapsing in the SDT arm received HDT-ASCT in their first relapse. Treatment-related mortality in the SDT arm was 0.4%, compared to 1.7% in the ASCT arm. A plausible explanation proposed for the lack of superiority of ASCT seen in this study was the use of TBI as a conditioning regimen, which has been shown to be inferior to high-dose melphalan (200 mg/m^2) in MM [4, 61]. Another study comparing frontline ASCT and SDT with alkylating agents showed a nonsignificant trend towards superior PFS in the ASCT arm but no difference in OS in either arms at a median follow-up of 10 years [62]. However, the duration without symptoms, treatment, or

toxicity related to treatment was significantly longer for the ASCT compared to the SDT arm (25 vs. 17 months, respectively; $P = 0.033$).

In the era of PIs and IMiDs, two phase III studies have addressed the question of early versus delayed ASCT thus far. In a study by the Italian group, 273 patients were randomized to receive consolidation with either six cycles of melphalan-prednisone-lenalidomide (MPR) [SDT arm] or tandem autotransplantation with a total melphalan conditioning dose of 200 mg/m^2 (ASCT arm) [63]. All patients had received induction with four cycles of RD prior to randomization. The median PFS in the ASCT and SDT arms were 43 and 22 months, respectively ($P < 0.001$), and the 4-year OS rates in the respective arms were 82% and 65%, respectively ($P = 0.02$). Notably, 63% of patients in the SDT arm received salvage ASCT at relapse. Grade 3/4 hematologic, gastrointestinal, and infectious adverse events were more common in the ASCT arm. A similar question in the context of VRD induction and consolidation therapy has been answered by the phase III IFM study by Attal et al. [50]. In this study, 700 patients were randomized to receive three cycles of VRD induction followed by consolidation with ASCT and two cycles of VRD (Arm A) or five cycles of VRD alone (Arm B). All patients received 1 year of lenalidomide maintenance. A total of 323 out of 350 patients (92%) underwent up-front ASCT in Arm A. Patients undergoing up-front ASCT had a higher VGPR rate compared to those receiving VRD alone (88% vs. 77%, respectively; $P = 0.02$). The rate of MRD negativity by flow cytometry at a sensitivity level of 10^{-4} was also higher in patients receiving early ASCT (79% in Arm A vs. 65% in Arm B; $P = 0.001$). At a median follow-up of 43 months for Arm A and 44 months for Arm B, the median PFS in the respective arms were 50 and 36 months ($P < 0.001$), favoring frontline transplantation. There was no difference in OS at 4 years, which was more than 80% in both arms. Among patients in Arm B who experienced symptomatic relapse necessitating a second-line therapy, 79% were able to successfully undergo a salvage transplant. The rates of grade 3/4 neutropenia, gastrointestinal toxicity, and infections were significantly higher in the group receiving up-front ASCT. There was no significant difference in the overall incidence of second primary malignancies (SPMs) in either arm.

Hence, in the era of PIs and IMiDs, ASCT with high-dose melphalan as a conditioning regimen remains an integral part of treatment and should be offered up front to all eligible patients, based on PFS benefit in both studies [50, 63] and OS benefit in one study [63]. Furthermore, early ASCT has been shown to be cost effective [64] and prolongs the treatment-free interval [59, 62]. Patients with progressive disease after induction therapy also benefit from ASCT [65, 66]. In TE patients who do not undergo frontline ASCT, adequate stem cells should be collected for at least two transplants and ASCT should be offered at first relapse.

Role of Tandem Transplantation

Tandem ASCT is defined as a planned course of treatment with high-dose therapy followed by stem cell infusion within 6 months of the first transplant [4]. The rationale behind a second ASCT is to improve the depth of response and potentially prolong long-term outcomes like PFS and OS. A list of RCTs comparing single and double ASCT in newly diagnosed MM has been summarized in Table 28.5.

In the USA, tandem transplant for newly diagnosed MM was pioneered by the University of Arkansas group. Tandem ASCT was shown to be feasible and superior to historical controls receiving standard therapy in terms of response rate, PFS, and OS [67]. A multicenter randomized trial by the French group (IFM94) in the era of alkylating agent-based induction therapy has shown a superior PFS and OS with double ASCT compared to single ASCT, despite no significant difference in the depth of response [68]. The 7-year OS rates with single and double ASCT in the study were 21% and 42%, respectively ($P = 0.01$), at a median follow-up of over 6 years. Notably, the subgroup of patients who did not achieve at least a VGPR after the first ASCT derived the most benefit from a second ASCT. However, a limitation of this trial was the suboptimal conditioning regimen used in the single-transplant arm. The cumulative melphalan dose in the tandem arm was 280 mg/m^2 compared to 140 mg/m^2 in the single-transplant arm. Seventy-eight percent of patients in the tandem arm were successfully able to undergo two transplantations with no significant difference in hematologic toxicity or TRM compared to patients who received a single transplant. In the HOVON24 trial comparing single and double ASCT after VAD-based induction therapy, the CR rate was significantly higher in patients receiving double transplant [69]. However, there was a marginal difference in the median PFS between the two groups and no significant difference in OS at a median follow-up of 56 months. Similarly, in the Bologna96 randomized trial, there was no significant difference in OS between the single- and double-transplant arms, despite an increase in response rate and PFS duration by 18 months in the double-transplant arm [70]. The cumulative melphalan dose in this trial was 200 mg/m^2 in the single-transplant and 320 mg/m^2 in the double-transplant arm, with no significant difference in TRM in the two arms. Similar to the IFM94 trial [68], patients who did not achieve nCR after the first ASCT benefitted the most from a second transplant, with a trend towards OS benefit in this subgroup of patients.

Two randomized trials have compared single and double transplants in the context of PI and IMiD-based induction and maintenance therapy. The StaMINA trial randomized 758 TE patients who had received 2–12 months of induction therapy to receive either a single ASCT (Arm A), single ASCT followed by four cycles of VRD consolidation therapy (Arm B), or tandem ASCT (Arm C) [71]. The conditioning

dose of melphalan was 200 mg/m^2 for each transplant. All arms received lenalidomide maintenance until progression. At a median follow-up of 38 months, there was no significant difference between the PFS and OS rates in the three arms. The 38-month probabilities of OS was 83%, 86%, and 82% in Arm A, Arm B, and Arm C, respectively. The cumulative incidences of first SPM were 4%, 6%, and 5.9%, respectively, in the three arms. The phase III EMN02/HO95 trial randomized 614 TE patients to either VMP (bortezomib-melphalan-prednisone) consolidation, single-ASCT, or double-ASCT arm after induction therapy with 3–4 cycles of VCD [72]. All patients received lenalidomide maintenance until progression or toxicity. At a median follow-up of 27 months, the 3-year PFS rates in patients receiving a single and double ASCT was 60% and 73%, respectively ($P = 0.03$). The PFS benefit of double ASCT was evident in all predefined subgroups, including those with high β-2 microglobulin, bone marrow plasma cells >60%, lactate dehydrogenase above upper normal limit, revised ISS-II, and high-risk cytogenetic abnormalities by FISH. OS data was not mature at the time the study was reported. Based on these studies, there is a lack of convincing evidence to perform tandem ASCT in the era of PI- and IMiD-based induction and post-transplantation therapies. Randomized trials are currently under way to determine whether patients achieving less than a VGPR after the first transplant can benefit from a second transplant in the novel agent era.

Optimal Conditioning Regimen

The IFM group had tested high-dose melphalan (200 mg/m^2) with low-dose melphalan (140 mg/m^2) plus 8 Gy total-body irradiation (TBI) as a conditioning regimen in 282 patients in the context of induction therapy with four cycles of VAD [61]. Patients receiving high-dose melphalan had a superior 45-month OS rate of 66%, compared to 46% in patients receiving low-dose melphalan plus TBI ($P = 0.05$). Furthermore, patients receiving high-dose melphalan had a faster hematologic recovery, shorter duration of hospitalization, and lower rates of severe oral mucositis. This study paved the way for high-dose melphalan to be the optimal conditioning regimen in MM.

Recently, there has been some evidence on the benefit of combining bortezomib with melphalan during the conditioning phase [73, 74]. Administration of bortezomib within 24 h

following melphalan was shown to induce robust plasma cell apoptosis in pharmacodynamics studies, with 51% achieving VGPR or better [73]. A phase II IFM study on the combination of melphalan 200 mg/m^2 with bortezomib at a cumulative dose of 4 mg/m^2 (Mel-Vel) showed a post-ASCT VGPR rate of more than 70%, with no increase in hematologic toxicity [74]. A matched control analysis with patients receiving melphalan alone showed that Mel-Vel led to higher rates of CR after transplant. However, RCTs comparing melphalan alone or combined with novel agents are needed before incorporation of such strategies in practice. Other alkylating agents like busulfan in addition to melphalan have shown PFS benefit but no difference in OS, with a higher TRM [75, 76]. Hence, high-dose melphalan (200 mg/m^2) remains the standard of care currently, except in patients with renal dysfunction where lower dose (140 mg/m^2) should be used [19].

Stem Cell Mobilization

The three most common stem cell mobilization strategies include growth factor, growth factor plus plerixafor, and chemotherapy. Strategies for mobilization vary among different institutions. Growth factor (granulocyte-colony-stimulating factor [G-CSF]) is one of the most common mobilization strategies currently. Factors predicting suboptimal mobilization with G-CSF include advanced age, low platelet count at mobilization, use of filgrastim instead of pegfilgrastim, and longer duration of lenalidomide therapy prior to mobilization [77]. Plerixafor, when added to G-CSF, leads to adequate stem cell mobilization in patients receiving lenalidomide-based induction therapy [78]. However, the efficacy of added plerixafor is similar to adding low-dose cyclophosphamide (1.5 mg/m^2) to G-CSF in the novel agent era [79]. Hence, due to low cost of cyclophosphamide, it should be preferred over plerixafor for use in conjunction with G-CSF in patients with prior exposure to lenalidomide. The threshold of stem cell infusion dose for a single transplant in Mayo Clinic is 3×10^6 CD34+ cells/kg [80].

Role of Allogeneic Transplantation

With the advent of effective and well-tolerated anti-myeloma agents and excellent activity of ASCT as a consolidative therapy, allogeneic stem cell transplantation (Allo-SCT) is not routinely used in newly diagnosed MM. In the IFM trials comparing ASCT → Allo-SCT (auto-allo) with tandem ASCT after induction therapy with VAD, the median PFS was similar in both arms and there was a nonsignificant towards a superior OS in the tandem ASCT arm [81]. Notably, 24% of patients developed grade 2–4 acute graft-versus-host disease (GVHD) after allo-SCT and 36% of evaluable patients developed extensive chronic GVHD. Another study on 162 TE newly diagnosed MM patients biologically randomized to either a non-myeloablative allo-SCT or ASCT after induction therapy with VAD and a single ASCT showed a superior PFS and OS in the allo-SCT arm [82]. The BMT-CTN and PETHEMA trials have shown comparable survival between ASCT and Allo-SCT, with a higher rate of TRM in the allo-SCT arms [83, 84]. Due to a high treatment-related morbidity and mortality, allo-SCT in newly diagnosed MM should be restricted to clinical trials in high-risk patients and can be an option in certain situations, including primary refractory disease or lack of response to ASCT [4].

Post-transplantation Maintenance and Consolidation

Despite increasing the depth of response and the rate of MRD negativity, ASCT is not curative in MM and most patients eventually relapse. Hence, post-transplantation maintenance or consolidation therapy is administered with the intent of further improving the depth and prolonging the duration of response, to eventually improve long-term outcomes, including PFS and OS. A pooled analysis of studies involving head-to-head comparison of continuous and fixed-duration therapy in MM has shown a superior PFS and OS with continuous therapy, with the 4-year OS rate being 69% with continuous and 60% with fixed-duration therapy ($P = 0.003$) [85]. Maintenance therapy involves prolonged treatment with an anti-myeloma agent, usually until progression or unacceptable toxicity. Consolidation involves a short course of single agent or combination therapy for a fixed duration after ASCT [86].

Prior to the introduction of PIs and IMiDs, glucocorticoid [87] and interferon [88, 89] were used for posttransplant maintenance therapy. Two large meta-analysis of interferon maintenance showed an OS benefit ranging from 4 to 7 months [88, 89]. However, currently, there is no role of interferon-based maintenance therapy in MM due to the toxicity profile and its impact on quality of life. With the advent of novel agents, thalidomide was tested as a maintenance therapy in various randomized trials [90–97]. A meta-analysis however showed that thalidomide maintenance in the context of ASCT significantly improved PFS (HR 0.67, 95% CI, 0.61–0.74; $P < 0.001$), but not OS (HR 0.90, 95% CI, 0.73–1.11; $P = 0.343$) [98]. The toxicity profile of thalidomide is unfavorable for long-term maintenance therapy due to high rates of PN and poor health-related quality of life (HRQOL) [97]. Furthermore, the UK MRC IX trial has shown worse OS with thalidomide maintenance in patients with high-risk cytogenetic abnormalities by FISH ($P = 0.01$)

Table 28.6 Phase III studies on lenalidomide and bortezomib maintenance

[99]. Hence, lenalidomide has largely replaced thalidomide as a posttransplant maintenance therapy due to better tolerability and data on improved OS, which will be described below.

Here, we discuss the lenalidomide and bortezomib-based maintenance strategies in MM in the posttransplant setting. The phase III studies on lenalidomide and bortezomib maintenance have been summarized in Table 28.6.

Lenalidomide Maintenance

Lenalidomide has been shown to be an effective maintenance therapy in MM in the posttransplant setting in four independent phase III RCTs [63, 100, 101]. The CALGB100104 was the first US trial showing a survival advantage with lenalidomide maintenance [100]. In this trial, 460 patients who had a stable disease or better 100 days post-transplantation were randomized to receive lenalidomide or placebo at a starting dose of 10 mg/day (range, 5–15 mg). Induction regimen other than bortezomib, lenalidomide, or thalidomide prior to ASCT was used in only 6% of patients. Lenalidomide was administered until disease progression or unacceptable toxicity. At a median follow-up of 34 months, the median PFS of patients in the lenalidomide group was 46 months compared to 27 months for those in the placebo group ($P < 0.001$). Furthermore, the 3-year OS rate was also significantly superior in the lenalidomide compared to the placebo group (88% vs. 80%, respectively: $P = 0.03$). Grade 3/4 hematologic AEs were significantly higher in the lenalidomide compared to the placebo group as expected. The cumulative incidence of SPMs was 8% in the lenalidomide and 3% in the placebo group ($P = 0.008$). The simultaneously released IFM trial randomized 614 patients with nonprogressive disease after ASCT to lenalidomide maintenance or placebo [101]. The starting dose of lenalidomide was 10 mg daily for the first 3 months, with subsequent escalation to 15 mg if well tolerated. Approximately 50% of patients had received VAD induction therapy pre-ASCT and the other half received VD. Maintenance was continued until relapse. At a median follow-up of 30 months, the median PFS was higher in the lenalidomide compared to the placebo group (41 vs. 23 months, respectively; $P < 0.001$). However, there was no significant difference in the 3-year OS rates, which was more than 80% in both arms. The cumulative incidence of SPMs was 3.1 per 100 patient-years in the lenalidomide and 1.2 per 100 patient-years in the placebo group ($P = 0.002$). Grade 3/4 hematologic toxicity including thromboembolic events was more frequent in the lenalidomide group, with no difference observed in the rate of grade 3/4 PN. The GIMEMA trial randomized 251 patients to lenalidomide or no maintenance after induction therapy with four cycles of RD and consolidation with either six cycles of MPR or tandem ASCT [63]. At a median follow-up of 51 months, the median PFS was significantly longer with lenalidomide maintenance compared to no maintenance (42 vs. 22 months, respectively; $P < 0.001$). However, there was no significant difference in the 3-year OS rates in the two arms. Grade 3/4 hematologic and dermatologic toxic effects were significantly higher in the lenalidomide arm.

A prospectively planned individual patient-level meta-analysis of the three studies (CALGB, IFM, and GIMEMA) showed a significant OS benefit with lenalidomide maintenance compared to no-maintenance therapy [5]. The 7-year OS rate was 62% with lenalidomide maintenance versus 50% with no-maintenance therapy ($P = 0.001$) at an updated median follow-up of 80 months. The OS benefit was evident in most subgroups; however, patients with ISS stage III disease and high-risk cytogenetics did not derive survival benefit from lenalidomide maintenance. The cumulative incidence of both hematologic and solid SPMs was higher with lenalidomide maintenance therapy. Notably, the HRQoL score of patients receiving lenalidomide maintenance in the real world has been shown to be similar to those receiving no-maintenance therapy [102].

The Myeloma XI study from the UK had randomized patients to lenalidomide maintenance or observation after induction therapy with CRD (cyclophosphamide-lenalidomide-dexamethasone) or CTD (cyclophosphamide-thalidomide-dexamethasone) and consolidation with ASCT. At a median follow-up of 36 months, the median PFS was 50 months in patients receiving lenalidomide maintenance compared to 28 months in those on observation. Furthermore, the PFS benefit with lenalidomide maintenance was evident in all prespecified subgroups, including in those with high-risk cytogenetic abnormalities and ISS stage III disease. The most common grade 3/4 AE was neutropenia.

In summary, given the OS benefit noted in the meta-analysis including three large RCTs, lenalidomide maintenance is currently the standard of care in all patients posttransplant. However, OS benefit has not yet been demonstrated in patients with high-risk cytogenetic abnormalities, in whom bortezomib maintenance should be preferred based on data from the HOVON trial, which will be described below. Furthermore, it is unclear whether a fixed duration of lenalidomide maintenance after ASCT is as good as prolonged maintenance until disease progression, and it needs to be answered by future RCTs.

Bortezomib Maintenance

There is a lack of placebo-controlled randomized trials evaluating bortezomib maintenance after ASCT in literature. However, the HOVON-65/GMMG-HD4 trial performed a head-to-head comparison of bortezomib-based induction and maintenance therapy with VAD induction followed by posttransplant maintenance with thalidomide [33]. It should be noted that patients were not randomized to bortezomib or thalidomide maintenance after ASCT and the study was not designed for direct comparison between bortezomib and thalidomide. Nevertheless, patients receiving bortezomib-based induction and maintenance therapy had a superior OS in the entire cohort and also in the subgroups with deletion (17p) and renal failure. Notably, in patients with deletion (17p), the median PFS was 18 months without bortezomib and 36 months with bortezomib-based therapy, which also translated into a superior OS [3-year OS 83% with bortezomib and 36% without bortezomib in deletion (17p) subgroup; $P < 0.001$] [34]. An updated report of this trial at a median follow-up of more than 7 years showed that the negative prognostic impact of deletion (17p) was abrogated in the bortezomib arm but not in the standard arm [103]. The plausible explanation for the excellent activity of bortezomib in deletion (17p) patients is the induction of apoptosis in myeloma cells by altering the balance between proteasome load and proteasome capacity in a p53-independent fashion [104]. The median duration of bortezomib maintenance at a starting dose of 1.3 mg/m^2 every other week was 23 months, compared to 14 months for thalidomide, indicating that bortezomib was well tolerated and feasible for long-term posttransplant maintenance therapy. Emergence of grade 3/4 PN during bortezomib maintenance therapy was seen in 5% of patients, with the rate of treatment discontinuation due to any toxicity being 11%.

Hence, lenalidomide should be used for posttransplant maintenance in the vast majority of MM patients, except in those with high-risk cytogenetics especially deletion (17p) and t(4;14), where bortezomib maintenance should be considered.

Posttransplant Consolidation Therapy

The goal of consolidation therapy in MM is to improve the depth of response and possibly long-term outcomes. A phase III trial evaluating VTD versus TD consolidation after ASCT showed a significant increase in CR rates after consolidation with VTD, which translated into a superior PFS but not OS at a median follow-up of 30 months [105]. Grade 2/3 PN was more frequent with VTD compared to TD (8.1 vs. 2.4%, respectively). Notably, high-risk cytogenetic abnormalities, including deletion(17p) and/or t(4;14), retained their negative prognostic impact on PFS in the TD arm but not in the VTD arm. Another study by the Nordic myeloma group randomized 370 patients 3 months after ASCT to receive either 21 weeks of bortezomib or no-consolidation therapy [106]. Consolidation with bortezomib led to an improvement in PFS by 7 months ($P = 0.05$), but did not have any impact on OS. Pooled results from two phase III studies comparing bortezomib consolidation and observation after ASCT in MM also showed only PFS but no OS benefit, with a significant PFS benefit seen only in patients achieving less than a VGPR after ASCT [107]. Finally, the StaMINA trial on 758 TE patients in the era of novel agent-based induction and post-transplantation therapy did not show any PFS or OS benefit from four cycles of VRD consolidation after ASCT [71].

Based on the data presented above, there is a lack of convincing evidence for use of consolidation therapy after ASCT, especially in the context of PI- and/or IMiD-based induction therapy and lenalidomide maintenance until progression.

Supportive Care and Toxicities

Peripheral Neuropathy

Peripheral neuropathy is one of the most common serious AEs of PI bortezomib and is also seen with IMiDs thalidomide and lenalidomide. Drug-induced PN by bortezomib or thalidomide can present with sensory, motor, and autonomic symptoms, with the potential targets being small fibers, dorsal root ganglia, and afferent sensory and efferent motor fibers [108]. Important predisposing conditions for drug-induced neuropathy are preexisting PN and medical comorbidities, including diabetes mellitus, vitamin deficiencies, alcohol abuse, or viral infections [108]. Subcutaneous bortezomib has been shown to be non-inferior to intravenous bortezomib in terms of efficacy, with a lower incidence of grade 2–4 PN (24% with subcutaneous and 41% with intravenous formulation; $P = 0.012$) [109]. Changing the route of administration of bortezomib to subcutaneous and the frequency from twice weekly to once weekly have led to deceased rates of bortezomib-induced PN (BiPN) in clinical practice. For moderate BiPN (grade 2), dose should be reduced from 1.3 to 1 mg/m^2, and for severe PN (grade 3), dose should be temporarily withheld and can be resumed at a lower dose of 0.7 mg/m^2, once symptoms resolve. Bortezomib should be discontinued if patients develop a disabling PN (grade 4) [110]. BiPN has been shown to resolve or improve in about two-thirds to three-quarters of patients, with median time for reversal or improvement being 2–3 months. On the other hand, recovery in thalidomide-induced PN (TiPN) is limited to about a quarter of patients and takes around 4–6 years [108]. Hence, dose modification guidelines should be strictly followed in the setting of drug-induced PN to maximize the chances of reversal or improvement.

Infections

The 2017 NCCN guidelines state that prophylaxis for *Pneumocystis jirovecii* pneumonia (PJP) can be considered in myeloma patients [4]. Similarly, intravenous immunoglobulin should be considered in life-threatening infections [4]; however, routine use is not recommended [17]. In the phase III APEX study comparing bortezomib-dexamethasone with dexamethasone alone, the incidence of herpes zoster virus infections was significantly higher in the bortezomib arm [111], which led to the recommendation of using acyclovir or valacyclovir prophylaxis in all patients receiving PI-based therapies [17]. Immediate therapy with broad-spectrum antibiotics and supportive care is needed.

Thromboembolic Phenomenon

Patients with MM have a higher base rate of thromboembolic phenomena compared to general population, with the baseline risk of venous thromboembolic (VTE) events being 3–4% [17]. The rate of thrombosis has been shown to be higher in patients receiving high-dose dexamethasone and IMiDs. The ECOG trial comparing RD with RlowD in newly diagnosed MM showed greater than a twofold higher rate of thromboembolic phenomena in the high-dose dexamethasone compared to the low-dose dexamethasone arm (26% vs. 12%, respectively; $P = 0.0003$) [47]. This study led to the routine use of low-dose dexamethasone in combination regimens. Aspirin at a dose of 100 mg daily is currently recommended for VTE prophylaxis in myeloma patients on IMiDs [4, 17, 112]. Full-dose anticoagulation with warfarin or low-molecular-weight heparin should be initiated in the setting of a clot, without any urgent need to discontinue IMiDs.

Bone Disease

Osteolytic bone disease due to the activation of osteoclasts is one of the most common clinical manifestations of MM and also causes significant worsening of HRQoL [113]. Bisphosphonates are the mainstay of therapy for myeloma bone disease, with their mechanism of action being inhibition of osteoclasts and subsequently bone resorption. A double-blind placebo-controlled trial on 392 MM patients with at least one lytic bone lesion showed a significantly reduced incidence of skeletal events in patients receiving pamidronate compared to those receiving placebo (24% vs. 41%; $P < 0.001$) [114]. Furthermore, pamidronate was well tolerated and led to decrease in bone pain. Another double-blind RCT on patients with hypercalcemia of malignancy compared zoledronic acid and pamidronate head-to-head [115]. Zoledronic acid was superior to pamidronate in terms of the rate of normalization of serum calcium level by day 4 and duration of response. The UK MRC Myeloma IX trial comparing zoledronic acid with clodronic acid in both TE and non-TE newly diagnosed MM patients showed a significant improvement in the median OS by 5.5 months in the zoledronic acid arm [116]. Current NCCN guidelines

recommend addition of bisphosphonates to the treatment regimen in all symptomatic MM patients, regardless of the evidence of bony lesions. Monitoring of renal function, baseline dental examination, and monitoring for osteonecrosis of jaw while on bisphosphonates are also recommended [4].

Miscellaneous

In patients with myeloma-associated anemia, erythropoietin therapy can be used [117, 118] to maintain a target hemoglobin around 12 gm/dl. Granulocyte colony-stimulating factor (G-CSF) may be administered in patients with severe neutropenia during therapy [17]. In patients with symptomatic hyperviscosity, plasmapheresis can be used to reduce the risk of end-organ damage [4, 119]. For impending spinal cord compression, high-dose dexamethasone and radiation therapy should be emergently initiated [17]. Orthopedic consultation should be sought for pathological fractures. Certain patients with symptomatic vertebral compression fractures might benefit from kyphoplasty or vertebroplasty [4].

Bortezomib-based therapy should be used initially in those with renal insufficiency since bortezomib does not need dose modification in renal dysfunction [19]. Furthermore, it leads to a rapid reduction of tumor burden, which decreases the nephrotoxic effects of paraproteins. In TE patients with renal dysfunction, melphalan should be used at a dose of 140 mg/m^2 [19]. A high-cutoff hemodialysis (HD) technique to remove free light chains has shown a higher rate of dialysis independence compared to HD with conventional high-flux dialyzers in MM patients presenting with myeloma cast nephropathy receiving initial therapy with bortezomib-dexamethasone [120].

Role of Hematopoietic Cell Transplantation for Myeloma

29

Heather Landau and Sergio Giralt

Introduction and Historical Perspective

More than 30 years ago McElwain and Powles demonstrated that dose intensification of melphalan could result in significant responses in patients with relapsed and refractory multiple myeloma (MM) [1]. However, significant myelosuppression occurred which limited the utility of this treatment strategy [2]. Barlogie et al. demonstrated that high-dose melphalan therapy followed by infusion of autologous bone marrow was feasible and resulted in predictable hematologic recovery within 28 days [3]. Subsequent confirmatory trials in the setting of relapsed disease were followed by the use of high-dose therapy (HDT) with autologous hematopoietic cell transplantation (HCT) as consolidation of initial remissions in patients with newly diagnosed MM [4–14]. Randomized trials in the front-line setting compared treatment outcomes of patients receiving multiagent chemotherapy regimens (usually combinations of vinca alkaloids, anthracyclines, alkylators, nitrosoureas, and steroids) to patients who received consolidation with HDT and auto-HCT [7–14]. The preponderance of evidence showed that HDT was associated with improved outcomes including event-free (EFS), progression-free (PFS), and in some but not all studies overall survival (OS) [7–14]. Depth of response, particularly achievement of a complete response (CR), was associated with longer PFS and OS in MM and was likely responsible for the initial success of HDT and autologous HCT [15].

The advent of proteasome inhibitors (bortezomib and carfilzomib) and the immunomodulatory (IMID) drugs (thalidomide and lenalidomide) have rendered all prior randomized trials of HDT versus chemotherapy in MM less relevant since induction therapy with these agents has been shown to be associated with more frequent and deeper responses than the traditional vincristine, adriamycin, and dexamethasone (VAD) induction [16]. In this chapter we review the basics of HCT for myeloma, current results, and future direction of this important treatment modality.

Basics of Hematopoietic Cell Transplantation (HCT) for Myeloma [17]

HCT is a complex procedure. The patient receives a combination of chemical and physical agents to eliminate a malignant disorder or a poorly functioning bone marrow supported by reinfusion of HSC from the patient or a third-party source (related or unrelated). As with solid organ transplantation HCT candidates should meet a set of organ function and psychosocial criteria that may vary from transplant center to transplant center but are aimed at determining the risk-benefit ratio of HCT versus other treatment approaches.

Depending on the source of stem cells, HCT can be categorized as either autologous (hematopoietic stem cells (HSCs) are obtained from patient) or allogeneic (HSCs are obtained from a third party). HSCs can be obtained from the marrow cavity or can be mobilized in large quantities into the peripheral blood using medications such as filgrastim or plerixafor and collected through apheresis techniques.

Transplant Eligibility

MM is the most common indication for autologous HCT in the world today with more than 6000 procedures performed in the United States every year [18]. Which MM patient is an appropriate candidate for HCT has been a subject of continued discussion in the HCT and MM literature. Table 29.1 lists the current criteria being utilized to determine HCT eligibility for both autologous and allogeneic HCT in MM patients according to recently published guidelines from the American Society of Blood and Marrow Transplantation (ASBMT) [19].

Table 29.1 Criteria used to determine HCT eligibility for MM

Criteria	Autologous HCT	Allogeneic HCT	Comments and references
Age	No age limit but rarely performed over age 80	No age limit but rarely performed over age 70	[18–20]
Performance status	KPS ≥ 70	KPS ≥ 80	[18, 21]
HCT-CI	No limit	≤ 1	Patients with KPS < 80 and high HCT-CI should be considered for alternative therapies rather than autologous HCT
Response to therapy	At least a PR	At least a PR	Patients with "primary" refractory disease are an exception for autologous HCT
Social support	Required	Required	Older myeloma patients undergoing HCT may require help for activities of daily living during the early post-HCT period to ensure compliance with medications and adequate hydration and nutrition
Patient wishes	Required	Required	

Initially limited to younger patients (less than 65 years of age), multiple retrospective analyses have demonstrated that outcomes for patients over the age of 65 are not statistically significantly different than outcomes for younger patients and thus age alone should not be considered a contraindication for HCT [20–24]. Notwithstanding, few autografts are performed in patients over the age of 80 and few allografts for MM are performed in patients over 70 years of age.

The hematopoietic cell transplantation comorbidity index (HCT-CI) developed by Sorror et al. to predict nonrelapse mortality after allogeneic HCT incorporates various measurements of organ function (cardiac, pulmonary, renal, hepatic) together with existence of other comorbidities into one score. Patients with HCT-CI scores of 0 to 1 have significantly less NRM than those with scores of 2 or greater with either a myeloablative or reduced-intensity conditioning regimen (RIC) [25].

The HCT-CI has been validated in the setting of autologous HCT and is a valuable tool to determine the risk–benefit ratio of this procedure. The Center for International Blood and Marrow Transplant Research (CIBMTR) recently analyzed the outcomes of 1156 MM patients reported to the registry who underwent auto-HCT after high-dose melphalan. NRM rates were similar for patients with HCT-CI scores of 0 to 1 versus 2 or greater and were 2%. However, on multivariate analysis, OS was inferior in groups with HCT-CI score of 1 to 2 (relative risk, 1.37, [95% CI, 1.01 to 1.87]; $P = 0.04$) and HCT-CI score of greater than 2 (relative risk,1.5 [95% CI, 1.09–2.08]; $P = 0.01$). OS was also inferior with Karnofsky performance status <90 ($P < 0.001$) [26]. Patients with KPS of less than 80 and high HCT-CI had 100-day NRM rates after HDT with autologous HCT of approximately 10%. Therefore the risk–benefit ratio of HDT should be balanced against the benefits of continued nontransplant therapies. In general, for older patients with high HCT-CI and KPS of less than 80 we have recommended proceeding to autologous HCT only if they have failed to achieve at least a very good partial response (VGPR) to induction therapy. End-stage renal disease is not an absolute contraindication to HCT in MM with many centers routinely performing autografting for MM in patient dialysis [27, 28].

Although response to induction therapy has been associated with HCT outcomes most retrospective data suggests that patients with primary induction failure (i.e., less than a partial response to induction therapy) still benefit from HDT with autologous HCT [29–32]. Whether this still holds true for patients failing modern induction therapy is uncertain but retrospective analysis of CIBMTR data suggests that although additional lines of therapy may improve response prior to autologous HCT this did not result in improved outcomes over proceeding directly to HDT [33].

Stem Cell Procurement

Autologous HSCs for MM patients are most frequently obtained through peripheral blood stem cell mobilization utilizing either chemotherapy in combinations with cytokines or cytokines alone. In North America autologous HSC mobilization is most commonly performed with granulocyte colony-stimulating factor (GCSF-filgrastim) alone or in combination with the CXCR4 antagonist plerixafor [34, 35]. In a randomized trial the combination of plerixafor and GCSF resulted in significant improvement in stem cell collection yields a total of 106 of 148 (71.6%) patients in the plerixafor group and 53 of 154 (34.4%) patients in the placebo group met the primary endpoint ($P < 0.001$). A total of 54% of plerixafor-treated patients reached target after one apheresis, whereas 56% of the placebo-treated patients required four aphereses to reach target [36]. Because of cost considerations many centers only use plerixafor in the event that CD34 peripheral blood counts are low (usually less than 10 CD34 cells/microliter) after 4 days of filgrastim therapy. This "just-in-time" plerixafor strategy has been shown to be cost effective [37]. A number of risk factors for poor mobilization in MM patients have been described and are summarized in Table 29.2.

Conditioning Regimen

The conditioning regimen is the combination of agents given to eliminate malignant cells exploiting the dose–response phenomena that most cancer cells exhibit and in the setting of allogeneic SCT suppress the host immune system to allow engraftment of donor cells. For allogeneic HCT conditioning regimen intensity has been classified according to their myelosuppressive effects into myeloablative, reduced intensity, and non-myeloablative [17].

For MM the most commonly utilized conditioning regimen for autologous HCT is melphalan 200 mg/m^2 throughout the world. Moreau et al. performed the only randomized trial comparing melphalan 200 mg/m^2 to melphalan and total-body irradiation. A total of 282 evaluable patients were randomized. The median duration of event-free survival was similar in both arms (21 vs. 20.5 months, $P = 0.6$), but the 45-month survival was 65.8% for high-dose melphalan and 45.5% for melphalan and total-body irradiation (TBI) ($P = 0.05$) [38]. The addition of busulfan or bortezomib to the standard melphalan has in retrospective analysis been proposed as potentially superior than high-dose melphalan but prospective comparative trials need to be done [39–42].

For allogeneic HCT, RIC is the most frequently utilized unless in the context of a CD34 selected peripheral blood stem cell graft (PBSC) [43]. However, the role of myeloablative conditioning for allografting continues to be explored particularly in the context of CD34 selected allografts [44].

Table 29.2 Risk factors for poor mobilization in myeloma patient

Patient factors	Treatment factors	Procedure factors
Age—older age reduces mobilization yields	Treatment with melphalan or bendamustine	Poor catheter flow
Extent of marrow infiltration	More than four cycles of lenalidomide	Low apheresis volumes
Platelet count (measurement of marrow reserve)	Radiation to pelvis- or marrow-bearing bones	
	Extensive prior therapy	

Complications of High-Dose Therapy in Myeloma

HDT is associated with significant morbidity due to the effects of intense myelosuppression and the effects of the conditioning regimen on normal tissues. The HCT procedure can be divided into five phases [17]:

Phase I: Chemotherapy phase
Phase II: Cytopenic phase
Phase III: Early recovery phase
Phase IV: Early convalescence phase
Phase V: Late convalescence

Although considered the least intense and less toxic of all conditioning regimens high-dose melphalan is associated with a variety of complications that are summarized in Table 29.3.

Despite being associated with low mortality rates (less than 3%), high-dose melphalan is associated with significant morbidity and a high treatment-related symptom burden as documented by Campagnaro et al. Fatigue, insomnia, loss of appetite, weakness, and feeling sick were the most common described symptoms that interfered with patients' quality of life and activity level. The peak symptom burden

Table 29.3 Randomized trials of early vs. delayed HCT in up-front therapy for myeloma

Author (ref)	*N*	Median PFS	OS at 4 years	Comments
Palumbo (2014)	273	HDT 43.3 months No HDT 22.4 months	HDT 81.6% No HDT 65.3%	No proteosome inhibitor Second randomization to lenalidomide maintenance
Gay (2015)	389	HDT 43.3 months No HDT 28.6 months	HDT 77% No HDT 68%	No proteosome inhibitor exposure
Attal (2015)	700	HDT Not reached 61% at 3 years Delayed HDT 46% at 3 years	3-year OS 88% for both groups

occurred at the time of white blood cell count nadir and approximately a third of the patients had not recovered to baseline a month posttransplant [45]. Increased plasma levels of interleukin 6 have been correlated with increasing symptom burden and could be a potential target for reduction of symptom burden [46].

Current Controversies in HCT for Myeloma

Optimal Induction Regimen

The optimal induction regimen should be effective, well tolerated, spare hematopoietic stem cell, and not negatively impact HDT outcomes. A detailed discussion of optimal induction therapy for MM patients is addressed in other chapters of this book. In brief, randomized trials have demonstrated that for transplant-eligible patients optimal induction therapy will include a IMID (thalidomide or lenalidomide) and a proteosome inhibitor (bortezomib or carfilzomib). Deeper and quicker responses are typically achieved with three-drug regimens such as thalidomide-bortezomib-dexamethasone (VTD), cyclophosphamide-bortezomib-dexamethasone (CyBorD), bortezomib-adriamycin-dexamethasone (PAD), or lenalidomide-bortezomib-dexamethasone (VRD) versus two-drug regimens, thalidomide-dexamethasone (TD), lenalidomide-dexamethasone (RD), or bortezomib-dexamethasone (VD) although the impact on OS has not been established until recently. In the United States the most commonly used induction regimens are the combination of RVD or CyBorD [47].

Carfilzomib-based combinations are emerging as some of the most potent induction regimens in MM. Carfilzomib has been combined with lenalidomide-dexamethasone (CRD), and in 53 newly diagnosed patients with MM, 38% achieved at least a near-complete response (nCR) after four cycles [27]. Stem cells were successfully collected in 34/35 patients. CRD was well tolerated with minimal neuropathy, allowing for prolonged administration with deeper responses over time. After a median of 24 cycles and 47.5 months of follow-up the 4-year PFS was 64% with a 93% OS rate [48]. Subsequently 76 patients received the same induction for four cycles and underwent autologous HCT after high-dose melphalan consolidation followed by CRD consolidation and prolonged maintenance. Median age was 59 years (range 40–76), with 57% of patients with ISS stage II/III and 36% with high-risk cytogenetics. Response rates after four cycles of CRD consolidation post-auto-HCT were 96% VGPR, 73% CR, and 69% sCR. Among CR patients tested 82% of them were MRD negative by flow and 66% by next-generation sequencing (NGS). With a median follow-up of 17.5 months 2-year PFS was 97% and 2-year OS was 99% for all 76 patients. These excellent results need to be confirmed and compared head to head with bortezomib, lenalidomide, and dexamethasone before CRD can be considered standard of care. CRD was well tolerated with few grade 3 or 4 toxicities generally lymphopenia (28%), neutropenia (18%), and infections (8%). Only two patients were reported to have an asymptomatic decrease of ejection fraction to 45–50%.

Timing of HCT

The achievement of major responses (CR and VGPRs) to induction therapy with IMIDs and proteasome inhibitors, especially in combination, has called into question the role of HDT and HCT as consolidation of first remission for all patients with MM. Yet, even in the context of modern induction regimens where over 90% respond the quality of response continues to improve following HCT and PFS approaches or exceeds 3 years [15, 16]. Four large randomized trials have now been performed comparing early versus delayed HCT in the context of modern induction treatment and are summarized in Table 29.4.

Palumbo et al. randomized 273 newly diagnosed MM patients to receive an autologous HCT after melphalan at a

Table 29.4 Common toxicities associated with high-dose melphalan

Toxicity	Incidence	Time peak occurrence	Preventive measures
Cytopenias	100%	5–7 days post-HCT infusion	Filgrastim or Peg-filgrastim will reduce duration of neutropenia Transfusion support not universally required Cell dose of greater than 5×10^6 CD34+ cells not effective in reducing cytopenias
Mucositis	30%	5–7 days post-infusion	Cryotherapy effective in reducing incidence of severe mucositis Keratinocyte growth factor not effective nor indicated Incidence increases with prior exposure to cytotoxic chemotherapy
Infections	40–50%	During cytopenic fever	Neutropenic fever common Severe sepsis and life-threatening infections rare. HSV reactivation rare with acyclovir prophylaxis CMV reactivation rare (<5%), thus monitoring not indicated Fungal infection rare, but fluconazole prophylaxis during neutropenia required

dose of 200 mg/m^2 or continued treatment with melphalan-prednisone-lenalidomide (MPR) followed by a second randomization to lenalidomide maintenance therapy. After a median follow-up of 51.2 months the PFS was significantly longer with high-dose melphalan plus HCT compared to MPR (43.0 months vs. 22.4 months $P < 0.001$). Overall survival at 4 years was also superior for high-dose melphalan and auto-HCT (81.6% vs. 65.3%; $P = 0.02$). Median progression-free survival was significantly longer with lenalidomide maintenance than with no maintenance (41.9 months vs. 21.6 months; $P < 0.001$), but 3-year overall survival was not significantly prolonged (88.0% vs. 79.2%) [49].

Gay et al. recently reported on 389 newly diagnosed MM patients less than 65 years of age receiving induction with four 28-day cycles of lenalidomide (25 mg, days 1–21) and dexamethasone (40 mg, days 1, 8, 15, and 22). Patients were randomized to consolidation with either chemotherapy plus lenalidomide (six cycles of cyclophosphamide [300 mg/m^2, days 1, 8, and 15], dexamethasone [40 mg, days 1, 8, 15, and 22], and lenalidomide [25 mg, days 1–21]) or two courses of high-dose melphalan (200 mg/m^2) and auto-HCT with a second randomization to maintenance with lenalidomide (10 mg, days 1–21) plus prednisone (50 mg, every other day) or lenalidomide alone. With a median follow-up of 52 months PFS was significantly shorter with chemotherapy plus lenalidomide compared with high-dose melphalan and ASCT (median 28·6 months vs. 43·3 months $P < 0{\cdot}0001$). Fewer grade 3 or 4 adverse events were recorded with chemotherapy plus lenalidomide than with high-dose melphalan and HCT. At 4 years, overall survival was 86% for autologous HCT with lenalidomide maintenance vs. 73% with chemotherapy plus lenalidomide maintenance [50].

The Intergroup Francophone du Myeloma-Dana-Farber Cancer Institute (IFM-DFCI) study of bortezomib, lenalidomide, and dexamethasone with or without high-dose melphalan consolidation and HCT was presented in December of 2015 at the American Society of Hematology meeting. A total of 700 patients were randomized to receive either eight cycles of RVD followed by lenalidomide maintenance or three cycles of the same induction followed by high-dose melphalan consolidation and followed by two cycles of the same chemo as consolidation with subsequent lenalidomide maintenance. With a median follow-up of 39 months HCT improved the complete response rate (58% vs. 46%) and 3-year PFS from 48% in the delayed HCT arm to 61% in the early HCT arm ($P < 0.0002$). The PFS benefit was observed in all subgroups. The 3-year post-randomization OS rate of overall survival was 88% in both groups [51].

Cavo et al. recently updated the results of EMN02/HO95 MM Trial in which patients were randomized to either four 42-day cycles of bortezomib-melphalan-prednisone (VMP) vs. either a single course or two sequential courses of melphalan at 200 mg/m^2 (HDM) with autologous stem cell support. All patients received induction therapy with CyBorD for 3–4 cycles. A second randomization to consolidation therapy with RVD vs. no consolidation was performed after intensification, to be followed by lenalidomide maintenance until progression or toxicity in both arms. From February 2011 to April 2014, 1510 patients 65 years or less were registered. Of these, 1192 were randomly assigned to receive either VMP ($n = 497$ patients) or HDM (1 ± 2 courses) ($n = 695$ patients). Median age was 58 years in both groups, ISS stage III was 21% in VMP and 20% in HDM, while revised ISS stage III was 9% in both groups. With a median follow-up from registration of 26 months median PFS was 44 months in the VMP arm and was not yet reached in the HDM arm; 3-year estimates of PFS were 57.5% and 66%, respectively ($P = 0.003$). PFS benefit with HDM was retained across predefined subgroups, including patients with ISS stage, cytogenetic risk category. The probability of achieving a very good partial response or higher quality response was 85.5% in the HDM group vs. 74% in the VMP group ($P < 0.001$). In a multivariate Cox regression analysis stratified by ISS, randomization to HDM and absence of high-risk cytogenetic abnormalities were the most important independent predictors of prolonged PFS. No difference in OS has been seen among the groups but the limited follow-up and small numbers of events make any conclusions difficult at this time [52].

Role of Tandem Transplants

Two studies have suggested that two courses of high-dose melphalan are superior to a single SCT, but the benefit appears to be limited to patients who had not achieved VGPR after the first transplant [53, 54]. Neither of these studies included induction therapies with either an IMID or a proteasome inhibitor and therefore may not be relevant today. More recently, patients who received bortezomib-based induction therapy and either single or double SCT on European phase III trials were analyzed. In comparison with patients for whom a single SCT was planned by study design, those who were assigned to receive tandem SCT had significantly longer PFS (median: 38 vs. 50 months, $P < 0.001$) and OS (5-year estimates: 63% vs. 75%, $P = 0.002$). From this dataset, the benefit of tandem ASCT was greatest for patients with high-risk cytogenetics defined as t(4;14) and/or del 17p and also for those who had not attained CR following bortezomib-based induction [55].

More recently, Cavo et al. presented the first interim analysis of the European Myeloma Network 02 (EMN02). Six hundred and fourteen eligible patients who received the diagnosis of MM in centers with a double-intensification policy were randomly assigned to either VMP ($n = 199$) or to a single ($n = 208$) or a tandem ($n = 207$). With similar patient and disease characteristics and a median follow-up of

27 months the median PFS was 45 months in the single-HCT group and has not been reached in the tandem HCT group. Three-year PFS were 60% and 73%, respectively ($P = 0.030$). Tandem HCT was found to be associated with an increased PFS in all predefined subgroups. In a multivariate Cox regression analysis stratified by ISS stage, randomization to tandem HCT and high-risk cytogenetics (any of the five pre-specified abnormalities) were the leading independent predictors of PFS. No difference in OS was seen between the two treatment groups [56].

In contrast the Blood and Marrow Transplant Clinical Trials Network (BMT-CTN) StAMINA Trial randomized 758 patients to one of the three consolidation strategies after an initial melphalan 200 mg/m^2 autologous HCT. A third of the patients (n = 254) received four cycles of consolidation with RVD, another third (n = 247) underwent a second autograft also with melphalan 200 mg/m^2, and the last third (n = 257) received no further consolidation. All three groups received lenalidomide maintenance 5–15 mg daily. At 38 months post-randomization the PFS was 52% for lenalidomide maintenance, 57% for RVD consolidation, and 56% for tandem transplant. OS at 38 months was excellent in all three groups (83, 86, and 82%). It is important to note that in the BMT CTN trial 32% of patients randomized to the tandem transplant arm did not received their "per-protocol" therapy which could explain some of the differences with the HOVON EMN trial of Cavo et al. [57].

Role of Allogeneic HCT

Although a graft-versus-MM effect has been well documented allogeneic HCT as frontline therapy for MM should be limited to younger patients with very-high-risk features due to high treatment-related mortality (TRM) and the risk of graft-versus-host disease even with non-myeloablative regimens. The European Group for Blood and Marrow Transplantation Non-Myeloablative allogeneic stem cell transplantation in MM 2000 study compared tandem HCT and reduced-intensity conditioning (RIC) allogeneic transplantation to HCT (single or tandem optional) alone in 357 patients that were biologically randomized based on the availability of an HLA-identical sibling. At a median of 96 months of follow-up, PFS and OS were 22% and 49% vs. 12% (P = 0.027) and 36% (P = 0.030) with HCT/RIC allogeneic HCT and autologous HCT, respectively [58]. The largest study including 625 patients performed through the BMT-CTN biologically assigned patients to tandem ASCT or RIC allogeneic and showed that at 36 months of follow-up there was no difference in PFS or OS [59].

Two other prospective studies, from the HOVON and Italian Study groups with somewhat different trial designs, have failed to conclusively show a benefit for allogeneic HCT in the up-front treatment of MM despite some suggestion of a better outcome with RIC allogeneic SCT in the Italian study [60, 61]. However, the tandem HCT arm of that study has a curiously short survival (median 48 months). Recent registry data assessing the role of allogeneic HCT in over 1200 patients with MM reported 5-year PFS and OS of 14% and 29%, respectively, with older age, longer interval from diagnosis to transplantation, and unrelated donor grafts adversely affecting OS [62].

Role of Salvage HCT

With the increasing number of patients opting for delayed HCT the optimal treatment for patients relapsing after primary therapy that did not include HCT, re-induction treatment with combination chemotherapy is the standard and most experts agreed that high-dose therapy consolidation should be considered the standard of care for this patient population. Data from both the CIBMTR and the EBMT show increasing use of salvage HCT, but prospective trials are urgently needed in this setting [63].

Cook et al. reported the first prospective randomized trial studying autologous HCT versus less intensive alkylating agent consolidation (weekly cyclophosphamide). Patients were eligible if they had relapsed after an initial autologous HCT and had at least an 18-month remission. Re-induction therapy included bortezomib, doxorubicin, and dexamethasone induction therapy. Eligible patients (with adequate stem cell harvest) were randomly assigned (1:1) to either high-dose melphalan 200 mg/m^2 plus salvage HCT or oral cyclophosphamide (400 mg/m^2 per week for 12 weeks). Time to progression was longer for patients who underwent salvage HCT (19 vs. 11 months ($P < 0.0001$) [64].

Salvage allogeneic HCT is being routinely performed particularly in younger patients with either multiply relapsed MM or short initial remission after autologous HCT. Freytes et al. performed a large registry analysis comparing the outcomes of a second autotransplant to those of a salvage allograft with a reduced-intensity conditioning regimen. NRM at 1 year after transplantation was higher in the allograft group 13% vs. 2%. Three-year PFS and OS were 6% and 20% for the allograft group and inferior to the outcomes for the autologous HCT 12% and 46%, respectively. [65]. In contrast, Patriarca et al. analyzed outcomes in patients relapsing after an initial autograft. The 2-year NRM was 22% among the 75 patients who had an identified HLA-compatible donor (donor group) versus 1% for those without a donor (no-donor group). The 2-year PFS was 42% in the donor group and 18% in the no-donor group ($P < 0.0001$) with similar 2-year OS of 54% and 53% for the donor and no donor groups, respectively [66].

De Lavallade et al. compared the outcomes of 32 relapsed MM patients. Nineteen had an HLA-identical sibling donor ("donor" group), while 13 patients had no donor ("no-donor" group). There were no significant differences between these two groups as for prognosis risk factors. With a median follow-up of 36 months, OS was similar between both groups; however, PFS was significantly higher in the "donor" group as compared to the "no-donor" group (46 vs. 8% at 3 years) [67].

Role of Maintenance Therapy and Consolidation Post-HCT

Post-HCT consolidation therapy was initially reported by Ladetto et al. who showed that four cycles of VTD consolidation following tandem HCT in patients with MM who achieved at least a VGPR ($N = 39$) increased the frequency of CR from 15 to 49% and molecular remissions from 3 to 18% [68].

Post-HCT consolidation has traditionally included similar drugs given during the induction phase. Cavo et al. reported on 480 newly diagnosed MM patients who received induction with VTD or TD that was followed by tandem HCT and two cycles of VTD or TD consolidation according to the induction arm [69]. Following HCT, the CR rate was 61% after VTD and 47% after TD consolidation ($P = 0.012$). To date, PFS but not OS is longer in the VTD arm.

The Nordic Myeloma Study Group randomized 370 bortezomib-naïve patients to 20 weekly doses of bortezomib or no consolidation at 3 months post-transplantation [70]. Again, response rates improved in patients who received consolidation with 71% vs. 57%, ($P < 0.01$) achieving at least VGPR and PFS was extended (27 vs. 20 months, $P = 0.05$), but the advantage was only seen in patients with <VGPR after HCT. There was no difference in OS between the groups. In contrast, the BMT-CTN StAMINA trial did not show a benefit for RVD consolidation followed by lenalidomide maintenance when compared to lenalidomide alone [57].

An extensive review of the different strategies and drugs tried as maintenance therapy after autologous HCT is beyond the scope of this chapter. Table 29.5 summarizes the three randomized trials demonstrating a PFS benefit for lenalidomide maintenance. The role of lenalidomide maintenance post-autologous HCT is fairly established [71–74]. The CALGB 100104 study examined 462 MM patients who were randomized to lenalidomide or placebo without consolidation until disease progression [71]. A significant increase in TTP was seen for patients in the lenalidomide arm compared with those receiving placebo (46 vs. 27 months, $P < 0.0001$). All patients benefitted from lenalidomide maintenance regardless of remission status or prior exposure to IMID therapy; at 48 months of follow-up despite crossover of 71% of placebo patients, the risk of death on lenalidomide maintenance is lower than on placebo (20% vs. 30%; $P = 0.008$) [71].

Table 29.5 Lenalidomide maintenance (versus placebo) following ASCT

	CALGB 100104 [71]	IFM 2005-02 [72]	RV-MMP 1209 [73]
N	460	614	200 (randomized to HCT)
Initial dosing	10 mg (5–15 mg) daily	10 mg (5–15 mg) daily	10 mg (5–15) 21/28 days
Duration	Until progression	24 months	Until progression
TTP/PFS	TTP: 46 vs. 27 months ($P < 0.001$)	PFS: 41 vs. 23 months ($P < 0.001$)	PFS 54.7 vs. 37.4 months
OS	3-year OS: 88% vs. 80% ($P = 0.028$)	5-year OS: 68% vs. 67%	5-year OS 78.4% vs. 66.6%
SPM total	18 vs. 6 cases	23 vs. 8 cases	11 cases (5 in lenalidomide)

The IFM 2005–02 trial reported on 614 patients who were randomized to lenalidomide or placebo after single (79%) or tandem (21%) and two cycles of lenalidomide consolidation [72]. Lenalidomide maintenance improved median PFS (41 months vs. 23 months) compared to placebo ($P < 0.001$). However, the 5-year post-randomization OS is similar (68% vs. 67%). A higher incidence of secondary primary malignancies (SPM) in the lenalidomide arm was detected in both studies.

Palumbo et al. randomized 200 patients who had been randomized to receive high-dose melphalan consolidation to lenalidomide maintenance given 21 out of 28 days. Similar to the other two trials a significant benefit on PFS was seen in patients randomized to the lenalidomide arm (54 vs. 37 months from diagnosis) but without an increase in SPM [73].

A recent meta-analysis of the three large randomized trials was recently presented at the American Society of Clinical Oncology Meeting in Chicago in July 2016. A total of 1209 patients were randomized from 2005 to 2009 to receive either lenalidomide or placebo. With a median follow-up of 6.6 years the median OS for lenalidomide maintenance had not been reached vs. 86 months for patients in the control arms ($p = 0.001$). All patients benefitted from lenalidomide maintenance regardless of response [74].

Future Directions

Despite doubling of the remission duration with post-autologous HCT lenalidomide maintenance, MM recurrence remains the most important cause of treatment failure. Depth of response has been shown to impact remission duration and survival; notwithstanding, even patients achieving a CR will relapse and progress [75, 76].

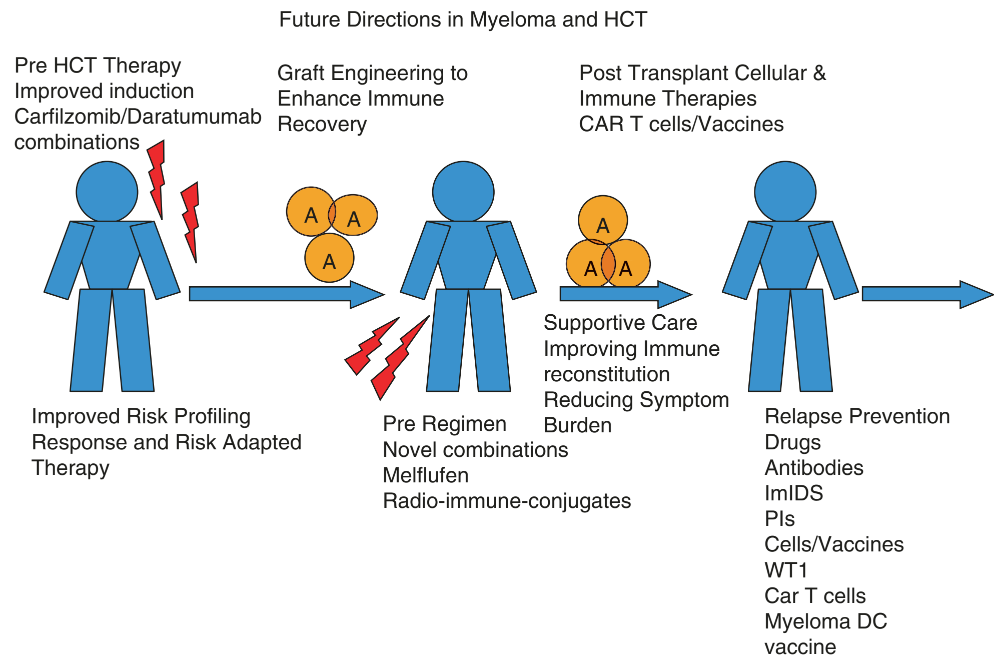

Fig. 29.1 Future directions in myeloma hematopoietic cell transplantation

Minimal residual disease detection (MRD) either by multiparameter flow cytometry (MFC) or next-generation sequencing (NGS) has been shown to be an important marker for long-term disease control in patients achieving a CR (reviewed in [77]).

Thus strategies aimed at increasing the proportion of patients that can attain an MRD-negative state are being actively explored and are summarized in Fig. 29.1. These include novel induction regimens incorporating carfilzomib and/or daratumumab as well as novel posttransplant immunotherapies such as CAR T cells, vaccines, and checkpoint blockade [78–81]. Likewise, incorporation of MRD assessment as part of a risk-adapted strategy was considered a “high-priority area to study” at the recent State of the Science Symposium of the BMT-CTN and will probably dictate treatment paradigms in the future [81–83].

As molecular techniques evolve, the goal is to individualize therapy based on predictive markers that provide insight into the likelihood of response and/or toxicity to certain drugs or regimens. Robust data already exists regarding the benefit of proteosome inhibition in the treatment of high-risk MM [84]. More recently, venetoclax a BCL 2 inhibitor has been shown to be extremely active in MM patients with the 11,14 translocation [85]. Thus the era of targeted therapies for specific MM subtypes has begun.

Finally, the burden of treatment both in regard to symptom burden cost of therapy will become a major issue in MM therapy and will be important endpoints to consider when choosing the treatment strategy that will provide patients with the longest life and the best quality of life with the least treatment burden.

30 Solitary Plasmacytomas and Soft-Tissue Involvement in Multiple Myeloma

Joan Bladé and Laura Rosiñol

Localized Plasmacytomas

Localized plasmacytomas are plasma cell tumors, histologically indistinguishable on multiple myeloma that develop as single tumors either in bone (solitary plasmacytoma of bone—SPB) or in soft tissues (extramedullary—EMP) [1]. Both are uncommon disorders accounting for less than 5% of all plasma cell malignancies [2–15].

Solitary Plasmacytoma of Bone

Clinical Findings and Diagnostic Criteria

Solitary plasmacytoma of bone (SPB) was first recognized almost one century ago and since then single-case reports as well as a number of series have been reported [2–15]. The diagnostic requirements have been revised by the International Myeloma Working Group [1]. SPB consists of a single plasma cell tumor localized in bone and it is an uncommon disorder with a frequency ranging from 3 to 5% of all plasma cell neoplasms. Typically the histopathological pattern shows a diffuse involvement by mature plasma cells identical to those observed in multiple myeloma (MM). SPB is more frequent in males than in females (ratio 2:1) and the median age is about 10 years less than that observed in patients with MM. The most frequent complain at presentation is pain at the site of the skeletal lesion. The bones more commonly involved are vertebrae followed by sternum, pelvis, and proximal long bones. Thoracic vertebrae are more commonly involved than lumbar and cervical. Back pain or features of spinal cord compression are the most frequent presenting features. Soft tissue from a plasmacytoma, as in the sternum, may result in a palpable mass. The diagnostic criteria are shown in Table 30.1. To ensure that there are no other plasmacytomas radiological imaging techniques are necessary. Classically, it was required that a complete skeletal survey did not show other lesions. Today the skeletal survey must be completed with a PET/CT to exclude other lesions. The bone marrow aspirate must contain less than 10% bone marrow plasma cells. Theoretically, there should be no serum or urine M-protein. However, more than 50% of the patients have a small M-component. Of course, it should be no evidence of CRAB (i.e., hypercalcemia, renal function impairment, or anemia related to the plasma cell proliferation) features apart from those resulting from localized bony plasmacytoma [1].

Table 30.1 Solitary plasmacytoma of bone: diagnostic criteria

Criteria
– Single area of bone destruction due to the plasma cell proliferation
– Bone marrow with <10% plasma cells
– Absence of other skeletal lesions on PET/CT
– No anemia, hypercalcemia, or renal impairment
– Absence of serum and urine M-protein[a]

[a]50% of patients have a small serum M-component

Prognostic Features

The prognosis of SPB depends on the risk of transformation to MM since progression to MM is observed in up to 75% of cases. The median time to progression is 2–4 years and the median overall survival ranges from 8 to 12 years [2–15]. The most frequent features associated with progression to MM are (1) involvement of the axial skeleton versus long bones, (2) older age, (3) persistence of the M-protein after treatment with radiation therapy, (4) plasmacytoma size larger than 5 cm, (5) low levels of uninvolved immunoglobulins, (6) abnormal free light chain (FLC) ratio at diagnosis, (7) presence of focal lesions at magnetic resonance imaging (MRI) or more than one

Table 30.2 Solitary plasmacytoma of bone. Adverse prognostic features

– Older age
– Involvement of axial skeletal versus long bones
– Plasmacytoma size ≥5 cm
– Immunoparesis
– Persistence of the M-protein after radiation therapy
– Abnormal free light chain ratio
– Presence of focal lesions on MRI or >1 metabolic lesion at PET
– Abnormal bone marrow flow cytometry

metabolic lesion at PET examination, and (8) abnormal bone marrow flow cytometry (Table 30.2). In a recent study, only immunoparesis emerged as negative predictor for progression to MM at the multivariate analysis [16]. In this study, classical prognostic factors such as age, disappearance of the M-protein after radiation therapy, location, or tumor size did not have impact on outcome. In an MD Anderson series of 60 patients, 45 (75%) had a serum M-protein at diagnosis. Most of the 32 in whom the M-protein persisted after radiation therapy evolved to MM while only 1 of the 13 patients in whom the M-protein disappeared with therapy developed MM [17]. Of note, in all these 13 patients the M-protein disappeared within the first year beyond radiation therapy was finalized and 7 of them were free from progression to myeloma between 16 and 25 years of follow-up [17]. The Mayo Clinic group reported the impact of serum FLC on the transformation rate to MM in a series of 116 patients diagnosed between 1960 and 1995 with SPB [18]. Forty-three patients progressed to MM after a median of 1.8 years. Fifty-four patients had an abnormal sFLC ratio and the progression rate at 5 years was 44% in patients with an abnormal sFLC ratio and 26% for those with normal sFLC ratio. The abnormal sFLC ratio at diagnosis had an adverse effect on both time to progression to MM and overall survival. The persistence beyond 1–2 years from diagnosis of a serum M-protein value of 5 g/L or higher was an additional factor associated with progression. Combining the FLC ratio at diagnosis and an M-protein of less than 5 g/L at 1 or 2 years beyond diagnosis a simple staging system with low (no features), intermediate (one risk factor), and high risk (both risk factors) was developed showing a 13, 26, and 62% rate of progression to MM at 5 years of follow-up [18]. In a recent study involving 43 patients, 48% had abnormal involved sFLC value and 64% an abnormal sFLC ratio while 33% had two or more hypermetabolic lesions at the PET/CT examination [19]. In a multivariate analysis, abnormal involved sFLC, and presence of at least two hypermetabolic lesions on PET/CT were the two predictors for early evolution to MM [19]. Finally, multiparameter flow cytometry (MFC) has recently been shown as a valuable biomarker to predict both high risk and low risk of progression. In this regard, Paiva et al. [20] studied 35 patients with SPB and 29 with EMP through MFC. Bone marrow clonal PCs were observed in 17 of the 35 (49%) patients with SPB and in 11 of the 29 (38%) of patients with EMP. Seventy-one percent of patients with positive flow versus only 8% of flow-negative SPB evolved to MM with a median time to progression of 26 months. In contrast, no significant differences in progression depending on the MFC findings were observed among patients with EMP. Of interest, MFC may also help to identify the so-called true SP characterized by flow-negative bone marrow and the absence of M-protein with an exceedingly rare rate of progression to MM [20]. Furthermore, almost identical results with MFC were reported by Hill et al. [21], in 50 patients with SPB. Aberrant PC phenotype was observed in 34 patients (68%). Progression to MM was observed in 72% of flow-positive patients versus in 12.5% for those flow negative, with a median time to progression of 26 months. In this study, the presence of urinary light chains was also highly predictive of the outcome with a progression rate of 91% for those with urine light-chain protein excretion versus 44% for those without. Using both parameters the authors identified a subset of patients (flow negative, no urine light chains) with a probability of progression as low as 7.7% and a high-risk subset with a bone marrow-positive flow and/or urine light-chain protein excretion with a progression rate of 75%. It is very likely that the patients with a bone marrow-positive MFC have in fact an "early myeloma" rather than a true SPB. In summary, the current most important predictors of progression to MM in patients with SPB are bone marrow MFC, serum FLC values, and finding of more than one hypermetabolic lesions on PET imaging [18–21].

Treatment Approach

In many instances patients have had surgery, with complete or partial tumor removal, as part of the diagnostic procedure. Apart from the diagnostic approach, the indications for surgery are internal fixation of fractures or as prevention of fractures, urgent decompressive laminectomy, or stabilization of spine using Harrington rods.

The treatment of choice is local radiation therapy involving the entire tumor volume with a margin of health tissue of at least 2 cm [2, 16, 22–24]. In case of vertebral plasmacytomas the irradiation field should include the proximal and distal uninvolved vertebrae. The recommended dose is between 40 and 50 Gy fractionated in over 4–5 weeks. It has been recommended that in plasmacytomas larger than 5 cm the radiation dose should be 50 Gy. However, the relationship between radiation therapy dose and tumor response is controversial when the radiation dose is higher than 35 Gy

[12, 13, 17, 23], since no clear relationship between the doses of local radiation therapy and the progression to MM has been clearly shown. It is considered that in the vast majority of cases adjuvant chemotherapy is of no benefit. The Greek group reported no improvement using either conventional chemotherapy or novel agents including bortezomib [16]. However, in this retrospective study, it might be a bias (i.e., poorer prognosis for the subset given adjuvant therapy versus radiation alone). In any event, the authors of this chapter strongly believe that in nonresponders to radiation therapy as well as in patients with bulky masses (i.e., >5 cm) located in pelvis, sternum, or a large bone such as humera or femora a multiple myeloma treatment approach should be considered, including high-dose melphalan followed by autologous hematopoietic stem cell rescue for younger patients. Currently, the response should be assessed by PET/CT imaging at least 3 months after radiation therapy is completed. For complete response all metabolic activity suggestive of active disease must have disappeared.

Multiple Solitary Plasmacytomas, Recurrent Plasmacytomas, and Macrofocal Myeloma

Among all patients diagnosed with "SPB," about 5% have more than one bone lesion with or without soft-tissue involvement and with no features consistent with MM [1]. Although patients with two or more "solitary" plasmacytomas can be treated with radiation therapy alone, we would favor a multiple myeloma treatment approach. In case of early recurrence (i.e., <2 years) either as a new lesion or as a local recurrence in an irradiated area a MM treatment approach is mandatory. In case of late recurrence (>2 years) as a new single lesion rechallenge with radiation therapy is reasonable.

The Greek group reported a variant of MM characterized by multiple lytic lesions with or without soft-tissue masses, less than 10% bone marrow plasma cells, and small M-protein in younger patients and associated with a favorable outcome [25]. This form of multiple myeloma had been previously recognized in patients younger than 30 years [26, 27]. The treatment approach is the same as for general multiple myeloma, including high-dose melphalan followed by autologous stem cell rescue whenever possible.

Extramedullary Plasmacytoma

Extramedullary plasmacytoma is an uncommon plasma cell disorder consisting of a plasma cell soft-tissue tumor. EMP may originate in many anatomical sites, although more than 90% developed in the head or neck area, particularly in the upper respiratory structures [2–4].

Clinical Findings and Diagnostic Criteria

The incidence of EMP is about 3% of all plasma cell malignancies. It is more frequent in males than in females (2:1) and the median age at diagnosis is 60 years [2–4]. The clinical features depend on the site and organ involved. As a result of the frequent locations in the upper respiratory tract patients usually present with symptoms such as nasal obstruction or discharge, epistaxis, hoarseness, or hemoptysis. Pain and tenderness at the plasmacytoma site may occur. EMP can develop in any organ including gastrointestinal tract, brain, thyroid, breast, testes, or lymph nodes [2, 4–6]. There is a predominance of IgA immunoglobulin type. The diagnosis is based on the finding of a plasma cell proliferation in an extramedullary site in the absence of MM (Table 30.3).

Treatment and Outcome

As in SPB, the treatment consists of fractionated radiation therapy at the total dose of 40–50 Gy over 4–5 weeks. Radiation therapy on local lymph nodes may be considered since up to 25% of patients with EMP of the head and neck may develop lymph node involvement. EMPs localized in the upper respiratory tract have a better outcome than those arising outside the head and neck area. Involvement of the adjacent bone has been reported as an adverse factor. Local relapses, including lymph node involvement, occur in up to 15% of cases. Progression to MM is uncommon with a reported frequency ranging from 8 to 30% [3, 4, 6–8, 10, 14, 16, 24]. The most prominent features of SPB and EMP are shown in Table 30.4.

Table 30.3 Extramedullary plasmacytoma: diagnostic criteria

– Single extramedullary tumor of clonal plasma cells
– Normal bone marrow
– Absence of other lesions on PET/CT
– No anemia, hypercalcemia, or renal impairment
– Absence of serum and urine M-protein[a]

[a]Some patients may have a small serum M-component

Table 30.4. Clinical features

	SBP	EMP
Median age (years)	55	55
M:F	2:1	3:1
Main location	Axial skeleton (vertebral)	Head and neck
M-protein (%)	50	<25
Progression to MM (%)	≥75	8–30
10-year survival (%)	40–50	70

Solitary plasmacytoma of bone (SPB) versus extramedullary plasmacytoma (EMP)

Soft-Tissue Plasmacytomas in Multiple Myeloma

Multiple myeloma (MM) is characterized by a proliferation of plasma cells (PCs) with a strong dependence on the bone marrow (BM) microenvironment. However, in up to one-third of the patients the plasma cells escape the microenvironment influences resulting in soft-tissue plasmacytomas [28]. The existence of soft-tissue involvement in MM is long-term known and old autopsy studies have shown an extra-skeletal involvement in up to 70% of patients [29–32]. In patients with multiple myeloma, the soft-tissue masses can have two different origins: (1) direct growth from skeletal lesions by disrupting the cortical bone and (2) plasma cell tumors resulting from hematogenous spread. The mechanisms involved in the extramedullary myeloma dissemination are not well understood. However, possible explanations are (1) decreased expression of adhesion molecules, (2) low expression of some cytokine receptors or downregulation of CXCR4 and its ligands, and/or (3) increased angiogenesis [33–42]. It is likely that the physiopathologic mechanisms of the two variants of plasmacytomas (hematogenous spread versus direct growth from lytic lesions) are different. Hopefully, future studies matching and comparing the characteristics of malignant BMPCs with those growing at soft tissues help to better understand the mechanisms of myeloma dissemination outside the bone marrow.

Definition

Pasmantier and Azar reported in 1969 the findings of 57 autopsy cases and proposed a classification in three stages according to the presence or absence of macroscopic tumor outside bones [43]. Stage I or intraskeletal: disease confined to the bone marrow or bone, stage II or paraskeletal: presence of soft-tissue masses arising directly from bones extending to paraskeletal areas, and stage III or extraskeletal resulting from metastatic or hematogenous spread. Of interest, in most patients in stage I and II the plasma cells were well differentiated (plasmacytic myeloma) whereas in the majority of patients in stage III the plasma cells were poorly differentiated (plasmablastic myeloma). However, the definition of extramedullary involvement in MM has not been uniform. Recently, the International Myeloma Working Group (IMWG) agreed on that two different types must be considered. (1) paraskeletal consisting of soft-tissue masses arising from skeletal lesions and (2) pure extramedullary resulting from hematogenous spread and involving only soft tissues with no contact with bone (Rosiñol et al., manuscript in preparation). Some patients develop simultaneously or successively the two types of plasmacytomas.

Incidence and Location

The reported incidence of paraskeletal plasmacytomas at diagnosis is from 7 to 34.4% [28, 44–48] while the reported rate of pure extramedullary involvement ranges between 1.7 and 4.5% [49, 50]. At relapse, the incidence of paraskeletal involvement remains similar to that observed at the time of diagnosis [44–48] while the frequency of extramedullary disease increases ranging up to 3.4–10% [49–53]. In two recent studies, 45 and 56% of patients with plasmacytomas at the time of diagnosis had paraskeletal or extramedullary disease at relapse [45, 54]. It has been suggested that patients undergoing allogeneic transplantation, particularly with dose-reduced intensity conditioning and those treated with novel antimyeloma agents, such as thalidomide, bortezomib, or lenalidomide, may have a higher incidence of plasmacytomas [55–57]. However, there is no evidence that the incidence of plasmacytomas increases at relapse after allogeneic transplantation or after exposure to novel antimyeloma agents [45, 48, 52, 54]. However, a better control of medullary disease with novel drugs can result in a more prolonged survival with a higher risk of extramedullary progression.

The extramedullary myeloma spread may consist of (1) single or multiple highly vascularized large red-purple subcutaneous nodules; (2) multiple small nodules located at any organ, particularly skin, liver, breast, or kidney; (3) pleura with myelomatous pleural effusion; (4) lymph nodes; and (5) central nervous system (CNS). Skin is the most frequent location at diagnosis whereas there is an increased incidence of liver, pleural, and CNS involvement at the time of relapse [49]. Leptomeningeal involvement occurs in about 1% of the patients [58–63]. The more common presenting features are confusion, paraparesis, and cranial nerve palsies. The cerebrospinal fluid (CSF) shows increased protein value and positive immunofixation for the myeloma M-protein as well as plasma cells usually with plasmablastic features. CNS involvement is associated with poor prognostic features such as high-risk cytogenetics, plasma cell leukemia, and high LDH serum levels. CNS involvement is usually seen in advanced phases of the disease along with the involvement of other extramedullary locations. However, in some instances CNS involvement can present at diagnosis or as isolated relapse in patients in complete remission. The prognosis is very poor with median survivals shorter than 3 months, even when novel agents are used [64]. Treatment of CNS involvement with intrathecal therapy with methotrexate, hydrocortisone, and cytosine arabinoside is unsatisfactory. Craniospinal radiation can be considered. It has been reported in a multicenter study that local plus systemic therapy can improve the prognosis [63].

Paraskeletal involvement is the most frequent cause of plasmacytomas in MM and, as previously mentioned, consists of soft-tissue masses arising from lytic skeletal

lesions [28]. The most common locations are vertebrae, ribs, sternum, skull, and pelvis. Plasmacytomas arising from vertebrae can cause spinal cord compression, the most common neurological complication of MM occurring in up to 10% of the cases [65]. The dorsal spine is the most frequently involved with a clinical picture consisting of back pain and paraparesis that can evolve to paraplegia in a matter of hours or days. The complication is a medical emergency that requires confirmation by an immediate MRI. Treatment with high-dose dexamethasone at a loading dose of 100 mg followed by 25 mg every 6 h with subsequent progressive tapering plus radiation therapy should be immediately started [66]. Plasmacytomas can be triggered by surgical invasive procedures usually performed during the course of the disease [67–70]. They can originate from laparotomy scars or catheter insertions and can even precede systemic relapses. Extensive extramedullary involvement resulting from bone surgery or fractures has also been reported [68].

Plasma Cell Characteristics in Soft-Tissue Plasmacytomas

Plasma cells from extramedullary disease commonly show immature or plasmablastic features. In contrast, myeloma cells from paraskeletal masses arising from focal bony lesions are less undifferentiated and show a more mature or plasmacytic morphology [28, 43]. CD56 expression is usually downregulated in plasma cells at extramedullary sites [71, 72]. However, more studies are needed to establish the role of CD56 in the extramedullary myeloma dissemination. The information on genetic abnormalities in extramedullary myeloma is limited. The frequency of high-risk cytogenetics, particularly 17p deletion, at extramedullary sites is usually higher than that reported in BMPCs [73–78]. It also seems that the hematogenous spread is more frequent in patients with gene expression profile (GEP)-defined high-risk myeloma [49]. However, molecular genetic studies on paired samples from medullary and extramedullary sites in the same patients are required in order to identify potential extramedullary disease-associated genes and to understand the mechanisms of extramedullary myeloma dissemination [49].

Assessment of Plasmacytomas

In some patients plasmacytomas consist of palpable masses which can be assessed by physical examination. However, in many instances radiographic imaging techniques are needed [79, 80]. Magnetic resonance imaging (MRI) is useful when spinal cord or nerve root compression is suspected and it is the best imaging technique to assess leptomeningeal or cerebral involvement [81]. The typical findings are leptomeningeal enhancement and/or meningeal based lesions resembling intracerebral masses [81]. Fluorodeoxyglucose (FDG) positron emission combined with computed tomography (PET/CT) is the most valuable whole-body technique in patients in whom the presence of plasmacytomas is suspected [82–86]. The main limitation of the PET/CT is that it is not standardized and the potential lack of interobserver reproducibility. A PET/CT should be done when myeloma soft-tissue involvement is suspected on the basis of clinical manifestations and in patients at high risk such as in those with high LDH serum levels as well as at the time of relapse in patients with previous history of plasmacytomas given the high frequency of plasmacytomas at relapse in this population [45, 54]. It is crucial and mandatory to include the plasmacytoma assessment when evaluating the response to therapy in patients with MM. The IMWG criteria requires the disappearance of plasmacytomas for CR and a decrease equal or higher to 50% for PR. Progression is defined by either the increase in at least 25% of preexisting masses, recurrence of a plasmacytoma that had disappeared with therapy, or development of any new soft-tissue involvement [87]. Ideally, the same imaging technique should be used at baseline and during follow-up [88].

Prognosis

The presence of soft-tissue involvement in MM is associated with a shorter survival. Thus, the Pavia group showed that the presence of soft-tissue involvement at any time during the course of the disease was associated to shorter PFS and OS [45] and the Royal Marsden group reported that the presence of plasmacytomas was associated to worse prognosis in patients treated with conventional chemotherapy [44]. Of interest, in the above two series [44, 45] as well as in a recent South Korea study [89] the administration of high-dose therapy followed by autologous stem cell rescue was able to overcome the negative impact of the presence of plasmacytomas. In contrast, in a PETHEMA transplant trial the OS of patients with paraskeletal involvement was significantly shorter in those with plasmacytomas [90]. It must be taken into account that in all the above studies the majority of patients had paraskeletal disease and only few pure extramedullary disease. In fact, the Arkansas group reported that patients with extramedullary disease had a significantly shorter PFS and OS even in the era of novel agents and treated in the context of the total therapy approaches [49]. Pour et al. [51] reported that in relapsed patients the presence of plasmacytomas was associated with a poorer outcome. Of interest, the survival of patients with extramedullary disease was significantly shorter than that of those with paraskeletal involvement [51]. The prognosis of patients with CNS disease is ominous even in the era of novel agents [64].

Treatment

In the frontline setting, alkylating agents, particularly high-dose melphalan, are of benefit in patients with paraskeletal disease while their efficacy in patients with hematogenous extramedullary disease is doubtful [28, 44, 45]. Bortezomib seems to be of benefit in patients with paraskeletal involvement with less evidence for hematogenous dissemination [91–93]. There is no published data on the efficacy of other proteasome inhibitors such as carfilzomib or ixazomib. The efficacy of IMIDs seems limited. In this regard, thalidomide is not effective in any type of plasmacytomas [94–98]. There is no published data on the efficacy of lenalidomide. The Mayo Clinic reported that 31% (4 out of 13) patients with extramedullary involvement responded to pomalidomide plus low-dose dexamethasone [50]. However, the authors of this chapter have treated nine patients with advanced MM and plasmacytomas with pomalidomide and low-dose dexamethasone and no response in plasmacytomas was observed. It is of interest that a dissociation between paraproteinemic and plasmacytoma response has been reported in patients treated with both thalidomide and bortezomib [93–96, 98]. The small sample size and the absence of controlled studies are important limitations to draw durable conclusions on the efficacy of bortezomib and IMiDs on soft-tissue involvement in MM. There are no reports on the potential efficacy of monoclonal antibodies such as elotuzumab and daratumumab on paraskeletal or extramedullary myeloma.

Considering that alkylating agents and bortezomib seem the most effective agents in patients with soft-tissue masses, although the evidence is lower for extramedullary than for paraskeletal disease, the treatment of choice for patients non-eligible for ASCT would be a combination of melphalan and prednisone with bortezomib (MPV) [99, 100]. Taking into account that high-dose therapy, particularly high-dose melphalan, can overcome the poor prognosis of paraskeletal involvement, a triple bortezomib-based regimen (VTD, PAD, or VRD) followed by ASCT could be the treatment of choice for younger patients [101, 102]. For transplant-eligible patients with extramedullary disease a combined anti-myeloma/anti-lymphoma regimen such as VTD/PACE followed by an allogeneic stem cell transplantation in patients younger than 50 years or by a tandem ASCR followed by dose-reduced intensity conditioning allogeneic transplantation (Allo-RIC) in those aged 50–65 years should be considered [103].

The prognosis of patients with MM relapsing with soft-tissue involvement (i.e., paraskeletal or extramedullary) is very poor [48–53]. Since these patients have already received previous bortezomib and/or IMiD-based regimens, the most effective treatment consists of lymphoma-like regimens such as PACE, Dexa-BEAM, or HyperCVAD [28, 104, 105]. The response rate is about 50%; however, the median duration of response is of only 4 months [105]. For this reason, in patients who are eligible for ASCT the best approach would be the administration of two or three cycles immediately followed by the high-dose procedure.

Local radiation therapy should be urgently administered in case of spinal cord compression and also considered in patients with severe compressive pain, bulky plasmacytomas, and persistent local disease after systemic therapy. There are not yet data on the potential efficacy of monoclonal antibodies such as elotuzumab or daratumumab, the new proteasome inhibitors carfilzomib and ixazomib, or the new IMiDs or other drugs still in their early development.

31 Supportive Care in Multiple Myeloma

Simit Mahesh Doshi, Tom T. Noff, and G. David Roodman

Myeloma Bone Disease

Multiple myeloma (MM) is the second most common hematologic malignancy, affecting more than 60,000 patients in the United States with 30,000 patients diagnosed in 2016 [1, 2]. Multiple myeloma (MM) is the most frequent cancer to involve bone with almost 70% of patients presenting with bone lesions at diagnosis [3]. Twenty percent of patients present with a pathologic fracture at diagnosis and until recently up to 60% of patients developed a pathologic fracture over the course of their disease [7]. This is extremely important since pathologic fractures increase mortality of MM patients by 20% [8]. In addition, MM bone disease can cause excruciating bone pain that remains undertreated in many patients, and hypercalcemia that can be life threatening, as well as require surgery and/or radiation to bone to control bone pain, treat impending or repair fractures, and relieve spinal cord compression. Further, in the vast majority of patients, MM bone lesions rarely heal even when patients are in long-term remission [10], and MM patients continue to suffer from the sequelae of their bone disease, even when their MM is under excellent control. Tremendous progress has been made in the treatment of MM, with a median survival of patients increasing to more than 6.1 years in the last decade and a much better overall survival for patients over the age of 65 [9]. Thus, treatment and repair of MM bone disease are increasingly important, both for enhancing the quality of life of patients, increasing their survival, prevention of hypercalcemia or fracture, and suppressing the growth of MM cells in the bone marrow.

Pathophysiology of Myeloma Bone Disease

During the normal bone-remodeling process, osteoclastic bone resorption is coupled to osteoblastic bone formation, so that bone removal and formation are balanced (Fig. 31.1). However, in MM the normal bone-remodeling process is essentially uncoupled, with markedly increased bone resorption at sites of MM and absent or severely decreased bone formation. This is due to suppression of osteoblast differentiation that can persist even when patients are in long-term remission [10]. Thus, little or no repair of lytic lesions occurs in the vast majority of patients with MM, although there have been anecdotal reports of healing of bone lesions in patients receiving bortezomib-based therapy. However, once a patient's bone density is below the fracture threshold, the patient continues to be at an increased risk of fracture and experience persistent bone pain.

A multiplicity of osteoclast stimulating factors are produced by MM cells and induced by MM cells in the bone marrow microenvironment [10]. These factors include MM cell production of Rank ligand, a highly potent osteoclast-stimulating factor, or induction of Rank ligand production by marrow stromal cells and osteocytes in the MM microenvironment. Furthermore, production of MIP-1 α by MM cells, interleukin 3 production by both MM cells and T-lymphocytes in the MM microenvironment, and IL-6 production by marrow stromal cells, osteoclasts, and other cells in the bone microenvironment also occur [10]. In addition, osteoclastic bone resorption and increased osteoclast numbers enhance the growth of MM cells. This process has been described as the vicious cycle hypothesis, in which MM cells induce osteoclastic bone resorption, and the bone resorption process releases growth factors, such as IGF1 and TGF-beta from bone matrix, which in turn stimulate the growth of MM cells (Fig. 31.2). In addition, MM cells induce polarization of T cells in the tumor microenvironment, which reverses the ratio of Th17 to Th1 T cells to 10:1 com-

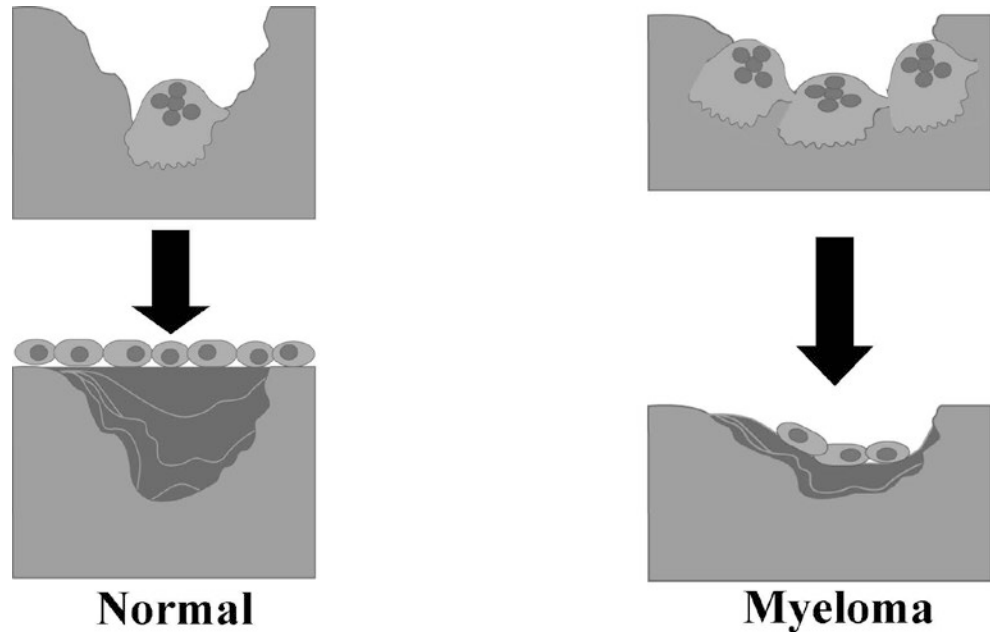

Fig. 31.1 Bone remodeling is uncoupled in myeloma. The normal bone-remodeling process in which bone resorption is followed by new bone at the same site is uncoupled in myeloma with increased bone resorption followed by little or no bone formation. Adapted by permission from Macmillan Publishers Ltd: Hattner R et al. Nature. 1965;206:489

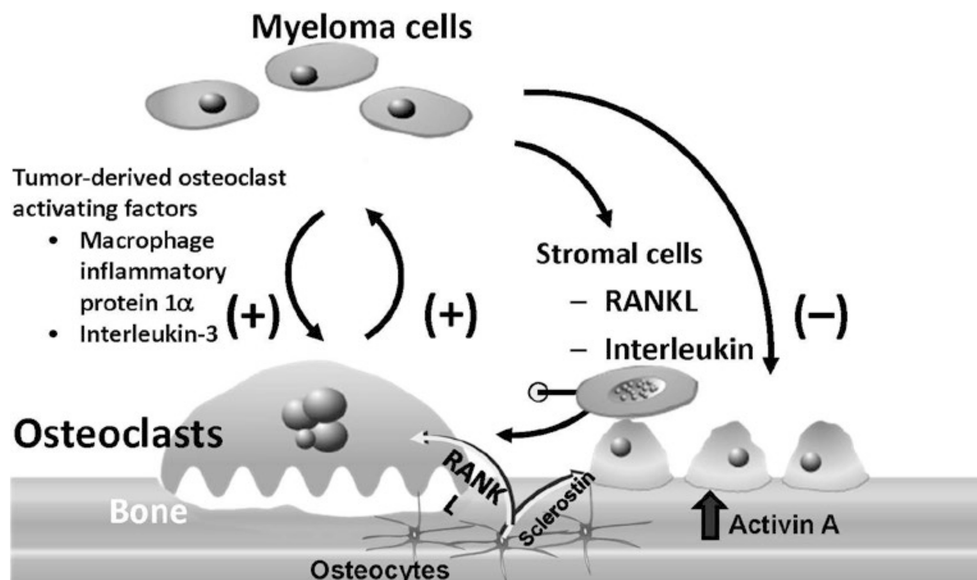

Fig. 31.2 Reciprocal interactions between myeloma cells and bone microenvironment contribute to progression of myeloma. Myeloma cells colonize the marrow and some of the cells engage the endosteal niche and become dormant, while other cells remain active myeloma cells. Active myeloma cells produce factors and induce factors by cells in the bone microenvironment to increase osteoclast formation and resorption. The increased bone resorption in turn releases growth factors from bone matrix to stimulate the growth of myeloma cells. Myeloma cells also suppress osteoblast differentiation to block new bone formation. In addition, myeloma cells directly interact with osteocytes in the bone matrix and these interactions increase myeloma cell growth and osteoclast formation as well as block osteoblast differentiation. Finally, osteoclastic resorption also releases dormant myeloma cells to become active myeloma cells, further contributing to myeloma progression. Adapted from Roodman GD. N Engl J Med. 2004;350(16):1655–1664. Copyright © 2004 Massachusetts Medical Society. Reprinted with permission

pared to the normal ratio of 1:10. Th17 cells produce IL17 that induces dendritic cell differentiation toward the osteoclast lineage, as well as enhance induction of Rank ligand.

MM cells, osteoclasts, and marrow stromal cells in the microenvironment also produce angiogenic factors that further increase the growth of MM cells [11]. In addition, the increased numbers of osteoclasts directly support MM growth. Yaccoby and coworkers demonstrated that primary MM cells from patients can be passaged over feeder layers of osteoclasts for long periods of time [12]. Abe and coworkers found that osteoclasts support the growth of primary MM cells through the production of IL-6 and osteopontin [13].

Finally, direct interactions between osteoclasts and osteocytes enhance bidirectional Notch signaling between the cells to increase the growth of MM cells, induce osteocyte apoptosis, and increase production of sclerostin and Rank ligand by osteocytes that suppresses osteoblast differentiation and stimulates osteoclastogenesis [14]. In addition, osteoclasts produce Annexin II, BAFF, and April that support MM cell growth [15, 16].

Recently, osteoclastic bone resorption has also been shown to play an important role in activating dormant MM cells in the MM microenvironment to active MM cells. Activation of dormant MM cells results in increased tumor burden, bone destruction, and distant colonization of bones. Lawson et al. recently showed by intravital imaging that treatment of mice with Rank ligand increases osteoclast numbers and decreases the numbers of dormant MM cells colonizing the osteoblast niche [17]. Thus, osteoclasts play multiple roles in progression of MM, including activation of dormant MM cells, bone destruction that results in release of matrix-bound growth factors to stimulate tumor growth, and enhancement of MM growth by factors derived from osteoclasts.

Studies in preclinical models of MM found that blocking osteoclastic bone resorption decreases tumor burden in addition to bone destruction [18]. However, until recently this phenomenon has not been demonstrated in patients. The MM IX trial showed that treating newly diagnosed MM patients with zoledronate, a potent bisphosphonate that blocks osteoclastic bone resorption, rather than with clodronate, a weaker bisphosphonate, enhances survival of MM patients. This increase in survival occurred regardless if the patients had detectable bone disease at diagnosis [19]. However, the greatest benefit in survival was seen in patients with detectable bone disease. Based on preclinical and clinical studies, the International Myeloma Working Group (IMWG) guidelines now support targeting osteoclastic bone resorption in all patients with MM [20].

Osteoblast Suppression in Myeloma

As noted above, bone formation is markedly suppressed in patients with MM and persists even when the MM is under excellent control. This explains why bone scans, which measure reactive bone formation, frequently under-represent bone disease in MM patients, making bone scans inappropriate for imaging bone disease in MM patients [21]. Multiple factors produced by MM cells or induced by MM cells in the MM microenvironment block osteoblast precursor differentiation to mature osteoblasts. A large number of inhibitors of osteoblast differentiation have been identified in MM patients, including TNFα, MIP-1 α, IL-3, activin A, sclerostin, DKK1, hepatocyte growth factor, TGF-beta, and IL7 [22]. All these factors can directly suppress osteoblast differentiation and are potential therapeutic targets for treating MM bone disease (see below). However, none of these factors can explain why osteoblast suppression persists in patients even in the absence of MM cells. The mechanisms responsible for the long-term suppression of osteoblast differentiation in MM are just beginning to be understood. D'Souza and all demonstrated that epigenetic changes in the Runx2 promoter in pre-osteoblasts, the master gene controlling osteoblast differentiation, are induced by MM cells [23]. These changes in the Runx2 promoter result from induction of Gfi1 in pre-osteoblastic marrow stromal cells exposed to MM cells. Gfi1 acts as a transcriptional repressor of Runx2 and blocks osteoblast differentiation. Increased expression of Gfi1 persists in marrow stromal cells from MM patients, even when the stromal cells are passaged for long periods of time in the absence of MM cells. Furthermore, knockdown of Gfi1 in marrow stromal cells from MM patients allows them to undergo osteoblast differentiation. These insights into the mechanisms responsible for long-term suppression of osteoblast differentiation have provided potential new therapeutic targets for repairing bone lesions in MM patients. Furthermore, Li and coworkers reported that mature osteoblasts could suppress MM cell growth through the production of decorin [24]. These results suggest that in addition to repairing bone lesions, inducing osteoblast differentiation may also suppress the growth of MM cells in patients.

Imaging of Myeloma Bone Disease

Imaging of MM bone disease has become increasingly important with the development of new criteria for the diagnosis of active MM. These criteria include presence of at least one lytic lesion detected by conventional radiography, whole-body low-dose CT or PET/CT, or presence of more than one focal bone marrow lesion greater than or equal to 5 mm on MRI studies [25]. Skeletal surveys have been the gold standard for detecting MM bone disease. The lesions appear as punched-out lytic bone lesions with the absence of reactive new bone formation and can occur in any bone. However, conventional radiographs are relatively insensitive for detecting bone disease in MM, since more than 30% of bone must be removed before a lesion is detectable. Conventional radiographs are also not useful for following disease progression or response to therapy, because lytic lesions rarely heal in these patients and enumerating new lesions can frequently be difficult in patients with extensive bone disease. In addition, it is often difficult to distinguish between osteoporotic and MM-induced vertebral fractures. Finally, skeletal surveys take a great deal of time to perform, which can be difficult for patients who have severe bone pain.

Low-dose whole-body CT has been recently shown to be superior to conventional radiographs for detecting osteolytic lesions in MM patients, and is especially useful for detecting lesions in the spine or pelvis [26]. Low-dose whole-body CT

can take less than 5 min to perform, and has the advantage that it can also demonstrate extraosseous lesions. Because of these advantages, low-dose whole-body CT is becoming the standard screening method for MM bone disease in Europe. However, although low-dose whole-body CT exposes the patients to a higher dose of radiation than standard skeletal surveys, the higher resolution and speed of the examination outweigh the disadvantages. Many experts predict that low-dose whole-body CT will replace skeletal surveys as the new gold standard for detecting MM bone disease [26].

Magnetic resonance imaging (MRI) is also more sensitive than standard skeletal radiographs for detecting MM bone disease, and also detects bone marrow infiltration by MM cells. A large study from the University of Arkansas showed that MRI detected focal lesions in 74% of MM patients, compared to 56% of patients who were examined with whole-body radiographs [27]. MRI is particularly useful for distinguishing between asymptomatic smoldering MM and symptomatic MM. Patients who were thought to have smoldering MM but had more than one focal lesion on MRI had a 70% probability of progression to active MM within 2 years [28]. These results form the basis for adding the presence of more than one focal criteria on MRI to the updated criteria for active MM [25]. The International Myeloma Working Group recommends, at a minimum, MRI examination of the spine and pelvis as part of the evaluation for smoldering MM, if whole-body MRI cannot be done [29]. However, MRI limited to the spine and pelvis will not detect lesions in the peripheral skeleton that occur in 10% of patients who present with focal lesions [30].

PET/CT is a very useful albeit expensive imaging technique for assessing MM bone disease. PET detects the hypermetabolic activity of MM cells in both intraosseous and extramedullary sites, while CT detects bone-destructive lesions. PET/CT has a similar sensitivity to that of MRI, and is better than MRI at detecting bony lesions. More importantly, PET/CT can be used to assess response to therapy [31]. Further, the presence of extramedullary lesions or an SUV Max greater than 4.21 on a PET/CT performed at diagnosis, persistence of FDG uptake following autologous stem cell transplantation for MM, or detection of extramedullary disease are all associated with a poor prognosis for patients. However, it is unclear if PET/CT or MRI is better for determining if patients with solitary plasmacytoma have disease restricted to one site or multiple sites. PET/CT is also useful for following patients with non-secretory MM [32]. However, PET/CT may also detect false-positive findings in patients following radiotherapy or infections.

Treatment of MM Bone Disease

The landmark studies of Berenson and coworkers in 1996 demonstrated that the nitrogen- containing bisphosphonate, pamidronate, decreased skeletal related events (surgery to bone, fractures, radiation to bone, and spinal cord compression) and bone pain in patients with MM bone disease [33]. Pamidronate and zoledronic acid are the cornerstone of treatment for MM bone disease. Bisphosphonates are non-hydrolyzable pyrophosphate analogues that block osteoclastic bone resorption and inhibit osteoclast formation through their capacity to inhibit protein prenylation by inhibiting farnesyl diphosphate synthase required for normal osteoclast activity [34]. Pamidronate is usually administered as a 90 mg intravenous infusion over 2 h, while its more potent analogue, zoledronic acid, is administered as 4 mg intravenously over 15 min. Both bisphosphonates have similar efficacy for treating MM bone disease and are routinely given every 3–4 weeks. Bisphosphonates are very safe drugs and their major toxicity is their potential deleterious effects on renal function. Therefore, serum creatinine levels must be measured prior to infusion. If creatinine levels in patients receiving these agents increase more than 10% from their baseline values, pamidronate or zoledronic acid should be withheld until the serum creatinine returns to within 10% of the previous baseline value. In patients who present with impaired renal function, the infusion time for pamidronate can be increased or the dose of zoledronate can be reduced, since renal toxicity of bisphosphonates is related to peak dose [35]. In patients who present with severe renal failure, initial therapy with bortezomib-based regimens should be started prior to initiation of bisphosphonate therapy (see below).

Multiple organizations have developed guidelines for use of bisphosphonates in MM. Each of these guidelines state that bisphosphonates can be given intravenously every 3–4 weeks for patients with MM bone disease that is identified by plain radiographs or MRI. More recent IMWG recommendations for treatment of MM-related bone disease state that bisphosphonate therapy should be considered for all patients with MM, regardless of the presence of osteolytic bone disease by conventional radiography [20]. These recommendations are based on the results of the MM IX trial that compared clodronate to zoledronic acid therapy in more than 1000 newly diagnosed patients receiving treatment for MM (see above). This study found that patients receiving zoledronate achieved a 5-month survival benefit compared to patients receiving clodronate [19]. This survival advantage occurred regardless if the patient had demonstrable bone disease at diagnosis. A subsequent secondary analysis of this study showed that the major impact on survival occurred in patients with bone disease [36]. However, it's unclear how long patients should continue to receive bisphosphonate therapy. This question became a major concern with the recognition that some MM patients receiving bisphosphonates develop bisphosphonate-associated osteonecrosis of the jaw (BRONJ). This complication of bisphosphonate therapy was first recognized by Marx et al. [37]. The occurrence of

BRONJ is usually dependent on the duration and dose of bisphosphonate therapy, undergoing invasive dental procedures, age of the patient, and treatment with glucocorticoids. BRONJ occurs more frequently in patients receiving zoledronate than pamidronate [37]. Because of concern for development of BRONJ, most guidelines recommend treatment with bisphosphonates for approximately 2 years, unless active MM persists, and then stopping or increasing the interval between administration of bisphosphonates should be considered. However, with the regular institution of close dental monitoring, dental prophylaxis, and performing most dental procedures prior to initiating bisphosphonate therapy, the incidence of BRONJ has markedly decreased.

Another question that often occurs is should bisphosphonate therapy should be stopped prior to invasive dental procedures. The American Dental Association recently recommended not stopping bisphosphonates or other bone-targeted agents when patients undergo dental procedures, and states that the decision to withhold bisphosphonate therapy should be based primarily on the patient's risk of developing a skeletal related event [38]. In contrast, the IMWG recommends stopping bisphosphonates for 90 days before and after invasive dental procedures, such as tooth extraction, dental implants, and surgery to the jaw [20].

Several studies assessed if bone resorption markers are useful for determining the interval between bisphosphonate administration in patients with MM bone disease. Patel and coworkers found in patients who had received bisphosphonate therapy for at least a year and had stable disease that the level of bone resorption markers could be used to determine when to administer bisphosphonate therapy [39]. However, other studies show that bone resorption markers are not sufficiently sensitive to guide bisphosphonate therapy [40]. Importantly, the MM IX trial demonstrated that extending bisphosphonate treatment beyond 2 years continued to have beneficial effects on skeletal related events [36]. However, only small numbers of patients received long-term bisphosphonate therapy in that study. Another consideration with bisphosphonate therapy is whether bisphosphonate therapy can be restarted in patients who developed BRONJ. A retrospective analysis of over 100 MM patients demonstrated that about 50% of patients who developed BRONJ healed their lesions and 50% of those who restarted bisphosphonates did not develop new lesions [41]. These results suggest that patients who have active MM and have healed their osteonecrosis of the jaw can receive bisphosphonate therapy but should be monitored closely for a reoccurrence of BRONJ.

In addition to bisphosphonates, denosumab, a human monoclonal antibody that targets Rank ligand, has been developed, and potently inhibits osteoclast formation and bone resorption. Multiple large phase 3 studies of denosumab versus zoledronate treatment for patients with bone metastasis found that denosumab has either a non-inferior or a superior effect on skeletal related events compared with zoledronate, and patients treated with denosumab who had breast cancer bone metastasis had a survival advantage [42]. A large phase 3 study compared denosumab to zoledronic acid treatment in patients with bone metastasis that did not have prostate cancer or breast cancer, and also included 200 MM patients. This study found a similar decrease in skeletal related events in the MM patients with either treatment, but a post hoc analysis found a decreased survival for MM patients receiving denosumab [43]. Further analysis of this trial found that the baseline characteristics of the MM patients receiving zoledronic acid or denosumab were not balanced, and that the patients receiving zoledronic acid treatment had more early withdrawals from the study compared to those treated with denosumab [43]. A large phase 3 study comparing denosumab to zoledronic acid treatment in newly diagnosed patients with MM bone disease has just been completed, and the results of this trial should be reported soon. It is important to note that the incidence of ONJ is similar in patients receiving denosumab or zoledronic acid so that similar dental screening, routine dental prophylaxis, and follow-up are also required for patients receiving denosumab. Finally, neither denosumab nor zoledronic acid increases bone formation in patients with MM, so there is still a great need for bone anabolic agents that can increase bone formation and are safe for MM patients.

Recently, several agents have been developed to enhance bone formation in patients with MM. These include an antibody to DKK1, BHQ880, and sotatercept, an activin receptor antagonist [22]. A phase 1B clinical trial of anti-DKK1 in patients with MM did not show any benefit for MM bone disease [44], although the anti-DKK1 did show some bone anabolic effects in a phase 2 trial of patients with smoldering MM. No anti-MM activity was found in MM patients or smoldering MM patients receiving anti-DKK1 therapy. Sotatercept is in clinical trial for MM but can also increase hemoglobin levels significantly [45]. Thus, its utility as a bone anabolic agent of MM is still unclear. Most recently an anti-sclerostin antibody has been developed and is in clinical trial for patients with osteoporosis [46]. Anti-sclerostin antibody had potent bone anabolic effects and was well tolerated by the patients. Preclinical studies demonstrated that anti-sclerostin antibody treatment of murine models of MM can increase bone formation and may affect tumor burden. Several agents used to treat MM also have effects on bone. Bortezomib has been reported to have bone anabolic effects in patients with MM whose MM responded to bortezomib therapy [47], and transient increases in alkaline phosphatase activity have been shown in patients receiving bortezomib therapy. In addition there have been anecdotal reports of bone healing in patients receiving bortezomib-based therapies [48]. Furthermore, in preclinical studies, immunomodulatory agents such as pomalidomide can block osteoclast

differentiation [47]. Finally, the role of parathyroid hormone as an anabolic agent for MM bone disease remains unclear. Several groups reported the presence of the PTH receptor 1 on MM cells and found that parathyroid hormone-related protein, which activates the PTH receptor, can increase MM cell growth [49]. Other investigators failed to demonstrate PTH receptors on MM cells and preclinical studies have shown an anabolic effect of PTH in SCID-hu mouse model of MM [50].

Radiation Therapy and Surgery for Myeloma Bone Disease

Radiation therapy is frequently used to treat painful bone lesions in myeloma. However, it must be used sparingly because of its myelosuppressive effects. Thus, radiation therapy is used primarily to treat painful lesions, impending fracture and spinal cord compression [20]. Similarly, vertebroplasty and kyphoplasty are used to treat painful vertebral fractures in patients with myeloma [51]. In a randomized study for painful vertebral fractures in patients with myeloma, kyphoplasty was shown to be superior to conservative management, so that kyphoplasty is currently recommended by the IMWG guidelines.

Thromboprophylaxis for Myeloma Patients

Patients with MM have an increased risk of a thrombotic event during the course of their disease. In the original clinical trial of thalidomide for treatment of patients with MM, a 30% incidence of DVT was reported in patients receiving thalidomide [52]. Subsequent studies using combination chemotherapy regimens containing thalidomide also found a high rate of deep venous thrombosis (DVT) in these patients. Lenalidomide and pomalidomide are also associated with increased risk of DVT [52]. These results led to the development of thromboprophylaxis guidelines for patients receiving immunomodulatory agents [6]. These guidelines suggest that patients should receive thromboprophylaxis for at least the first four cycles of immunomodulatory agent-based therapy because the risk of DVT or pulmonary embolism (PE) is greatly increased during that time. The type of DVT prophylaxis is based on individual risk factors (e.g., age, obesity immobilization, history of DVT). Patients who have no or only one risk factor should receive prophylaxis with low-dose or standard-dose aspirin (81–325 mg per day) and patients with two or more risk factors should receive low-molecular-weight heparin or the equivalent or full-dose warfarin therapy to maintain the INR at 2–3. A recent abstract at the American society of clinical oncology found that the risk of VTE persistently changes throughout the disease process [53]. Lipe and coworkers found that VTE can occur in MM patients at a median time from diagnosis of 952 days, much longer than the IMWG guidelines recommend for thromboprophylaxis. Importantly, Lipe et al. found that of 60% of patients at high risk for thrombosis, only 16% ever received the recommended prophylactic therapy. These results suggest that VTE may occur later in MM than was previously thought, and that guidelines for thromboprophylaxis in MM may need to be adjusted. Finally, the use of erythropoiesis-stimulating agents (ESAs) also increases the risk of thrombosis in patients with MM. Katodritou and coworkers reported that ESAs reduced survival in MM patients compared to patients not receiving ESAs (and increased the risk of thrombosis in patients with MM) [54]. Thus, ESAs should be used with caution in patients with MM.

Neuropathy in Myeloma

Neurological complications in MM range from peripheral neuropathy to compression of the nerve roots or spinal cord. Compression of the nerve roots and spinal cord is an oncological emergency and can result from compression by vertebral and extramedullary plasmacytomas, respectively. Early recognition and treatment of spinal cord or nerve root compression are more important than the type of treatment in improving outcomes.

Radiculopathy

Compression of the nerve root by vertebral plasmacytomas, neuroforaminal stenosis, or vertebral fracture usually presents with back pain and a unilateral radiculopathy that may progress to sensory loss and weakness. At least 5% of MM patients suffer from spinal cord or cauda equina compression, and MM is responsible for 15% of hospitalization for malignant spinal cord compression [55]. Spinal cord compression often presents with progressively worsening back pain and may have a symmetric radiculopathy. The thoracic cord is most commonly affected and is associated with a sensory-level deficit. Bowel and bladder dysfunction is a late complication of spinal cord compression and is often preceded by symmetric pain and weakness. Unilateral complaints are rare but may be seen with lateralized cord compression. Complete spinal MRI with contrast is the preferred method of evaluating spinal cord compression, as CT does not clearly demonstrate the spinal cord or epidural space. Immediate treatment with corticosteroids, followed by radiation therapy, is the mainstay of treatment. MRI screening of MM patients for cord compression has not been found to be beneficial for detecting spinal cord compression [56].

Clinically detectable peripheral neuropathy is uncommon in MM at diagnosis and presents as a mild and slowly progressive symmetric neuropathy. Occurrence rates vary from 2% [5] to approximately 50% [57] of patients. Peripheral neuropathy in MM is often caused by accompanying amyloidosis or chemotherapy, and is a major presenting feature of POEMS syndrome. Cranial nerve involvement is rare and is usually a sign of progressive disease. Chemotherapy-induced peripheral neuropathy is a serious and potentially reversible side effect of treatment. The dose and duration of treatment are commonly affected by the neurotoxic profiles of these medications, which in severe cases may result in discontinuation of treatment. The clinical history and neurological examination are crucial for distinguishing CIPN from neuropathic involvement from direct nerve compression by MM. Neuropathy is a frequent complication of thalidomide- and bortezomib-based therapies.

Thalidomide is a potent antiangiogenic therapy that has been used for MM since 1998. Severe peripheral neuropathy occurs in approximately 30% of patients who were treated with doses of thalidomide greater than 200 mg/day [58]. Thalidomide-induced peripheral neuropathy presents as a symmetric distal loss of light touch and temperature that is painful. The neurotoxic effects of thalidomide are cumulative and dose dependent. In approximately 60% of patients, neuropathy results in lowering the dose or discontinuation of treatment [59]. Reduced starting doses of thalidomide of 100 mg/day for patients greater than 75 years old, and 200 mg/day for patients less than 75 years old, have reduced the incidence of severe peripheral neuropathy to less than 10%. However, there has been an overall increase in the incidence of mild-to-moderate peripheral neuropathy at these thalidomide doses. Although peripheral neuropathy is partially reversible with discontinuation of thalidomide, the long-term reversibility of neuropathy with discontinuation of thalidomide requires further long-term studies [60, 61]. The pathogenesis of thalidomide-induced peripheral neuropathy is poorly understood but antiangiogenic and inflammatory insults to the dorsal root ganglia may be the cause. This may explain the reduced sensory nerve action potentials with relative sparing of compound motor action potentials found in thalidomide-treated patients [62]. Other neurotoxic side effects of thalidomide include tremor (in up to 30%) and somnolence.

Bortezomib-associated peripheral neuropathy was recognized as an early side effect in the initial phase I trials. The incidence of bortezomib-induced peripheral neuropathy (BIPN) in phase II and phase III trials was 30–64%, and occurred in up to 46% of patients treated for newly diagnosed MM [62, 63]. BIPN is a subacute predominately sensory neuropathy of the feet and hands that is often painful. Small unmyelinated fibers are affected, causing prominent neuropathic pain in 25–80% of cases [64]. BIPN occurs in 21% and 37% of patients at the onset of treatment at doses of 1.0 mg/m^2, and 1.3 mg/m^2, respectively. The severity typically plateaus by the fifth cycle, with an approximate cumulative dose of 30 mg/m^2 [65]. The pathogenesis of BIPN remains unclear. The involvement of satellite and Schwann cells in BIPN in animal models supports the involvement of the dorsal root ganglia in the pathogenesis of the pain. Although the autonomic nervous system is also innervated by unmyelinated fibers, it is very rarely affected. The clinical presentation of a symmetric distal peripheral neuropathy with a temporal correlation to recent bortezomib treatment is suggestive of BIPN. Electrodiagnostic studies can provide objective evidence to aid in the diagnosis. However, the diagnosis can usually be made clinically. The neurologic examination is very important for distinguishing the cause of peripheral neuropathy. If signs of motor weakness are present, nerve root compression is more likely, since BIPN is primarily a sensory neuropathy. In patients with BIPN, nerve conduction studies show reduced sensory and motor action potentials, with mild slowing of the distal sensory and motor nerve velocities with increased distal motor latencies.

Bortezomib neurotoxicity is a potentially reversible complication that must be recognized early. Currently, there is no accepted proven treatment for BIPN. The mainstay of treatment remains bortezomib dose modification or discontinuation and neuropathic pain medication. Subcutaneous administration of bortezomib has dramatically reduced the incidence of neuropathy, and newer proteasome antagonists (carfilzomib and ixazomib) are less neurotoxic and better tolerated. Severe peripheral neuropathy was reported in less than 1% of patients in phase II trials of carfilzomib who were treated previously with bortezomib [66, 67]. There is a lack of evidence to support prevention of BIPN with neuroprotective agents [65].

Neurologic involvement is a hallmark of POEMS syndrome, a rare osteoscerotic form of MM, and is a major criterion for diagnosis. Approximately 50% of patients present with a distal symmetric neuropathy that ascends proximally. Eventually the vast majority of POEMS patients suffer from prominent sensorimotor neuropathy. Severe neuropathy has been reported in up to 76% of patients [68, 69]. Ocular involvement is common in approximately 2/3 of patients. Papilledema occurs in approximately half of those patients, and patients with papilledema have a worse prognosis [70]. There is also an increased risk of thromboembolic disease and cerebral infarction in POEMS patients. In a retrospective cohort study of 208 POEMS patients 19 (9%) developed cerebral infarction at a relatively young age [71]. The risk of cerebral infarction increased with the degree of thrombocytosis, and of plasma cell proliferation in the BM was also associated with increased stroke risk [71]. Electrodiagnostic studies are important to distinguish neuropathy due to POEMS from CIDP; in contrast to CIDP, prominent axonal

loss in the lower limbs rather than slow conduction of the distal nerve segments with conduction block occurs with POEMS. Polyneuropathy is commonly the initial presenting symptom of POEMS with up to 60% of patients with POEMS initially misdiagnosed with CIDP. Thus, distinguishing between CIDP and POEMS is critically important for treatment and prognosis. Nerve conduction studies in POEMS show predominate slowing of the nerve trunk when compared to distal nerve involvement.

Renal Dysfunction in Multiple Myeloma

The characteristic M paraprotein in MM, specifically the light-chain component, is nephrotoxic to the kidney, and frequently the kidney is the major target organ in MM. Up to 50% of patients have evidence of renal impairment at the time of diagnosis and about 10–15% of patients require renal replacement therapy [72]. Multiple studies found that renal impairment alone is a strong negative predictor of overall survival (OS) [4, 73]. In one study, the difference in median OS between patients with and without renal impairment was as high as 8.6 vs. 34.5 months ($P < 0.001$) The same study also showed markedly improved OS if renal impairment was reversible [4]. The Nordic MM study group also found that severity of renal impairment was a determinant of OS MM [73]. Hypercalcemia, lower proteinuria (<1 g/day), and low serum creatinine were positive prognostic factors. Thus, early detection of MM-induced kidney disease is extremely important.

The IMWG defines renal injury as either an elevation of serum creatinine >2 mg/dL or a reduced creatinine clearance (CrCl) of <40 mL/min/1.73m^2, due to MM [74]. CrCl should be assessed using the Modification of Diet in Renal Disease (MDRD) formula or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation as these most accurately predict the clearance obtained from inulin-based glomerular filtration rate (GFR) estimation [75, 76]. The CKD-EPI group further suggests that an equation based on creatinine and cystatin C, which also reflects tumor burden, is more accurate, but this remains to be validated in larger studies [75]. The use of eGFR should be restricted to stable patients and not for those presenting with an acute kidney injury (AKI). RIFLE (Risk, Injury, Failure, Loss and End-Stage Kidney Disease) criteria and Acute Kidney Injury Network classification should be used for assessing the severity of AKI [77].

Initial Diagnostic Workup of Renal Injury in Myeloma

All patients with symptomatic MM should have an initial laboratory panel that includes serum creatinine, GFR estimation, electrolytes, serum free light chains (SFLC), and 24-h urine collection for proteinuria and urine electrophoresis. The presence of selective proteinuria composed almost entirely of light chains can be attributed to myeloma cast nephropathy (MCN), whereas the presence of significant albuminuria suggests alternative diagnoses that require further investigation [78]. A renal biopsy should be considered to exclude monoclonal immunoglobulin deposition disease, amyloidosis, or other underlying causes of renal impairment in the presence of nonselective proteinuria [78–80]. If amyloidosis is strongly suspected, a fat pad aspirate should be done prior to kidney biopsy, since a diagnosis of amyloidosis can be obtained in about 70% of cases with the less invasive procedure [80].

Pathogenesis of Myeloma Kidney Disease

Free light chains circulating as monomers (predominantly K, 25KD) or dimers (predominantly λ, 50KD) are freely filtered by the glomerulus. In the proximal tubule cells (PTC) they are reabsorbed by receptor-mediated endocytosis [81]. This glycoprotein receptor cubilin-mediated endocytosis incites a proinflammatory response that induces release of IL-6, IL-8, and monocyte chemoattractant protein 1 (MCP-1) via activation of nuclear factor kappa light-chain enhancer of activated B-cells (NF-kB) in the PTC [82]. Similar to other proteinuric diseases, excess light chains induce factors that promote interstitial injury and fibrosis, as well as direct DNA injury and induction of apoptosis [83].

Once the PTC is injured, LCs overflow into the distal lumen and interact with the Tamm-Horsfall protein (THP) secreted by the thick ascending limb (TAL). This leads to formation of the MM cast that is responsible for the presentation of MCN. The variability in cast formation by this interaction can be explained by the variation in the complementarity-determining region 3 (CDR3) of different LCs [84]. While urinary light chains are required for the formation of casts, the type or quantity of LC does not correlate with the severity of cast formation. Urinary LC quantity, however, is predictive of response to therapy and risk for renal failure. Tubular solute composition and flow rates are other factors that also influence cast formation. Obstructed tubules in turn induce an intense inflammatory response probably related to urine leak into the interstitium [85].

Common Patterns of Renal Insufficiency in Myeloma

Myeloma cast nephropathy (MCN) is the most common histologic finding with autopsy studies reporting rates between 30 and 50% of all MM patients with renal failure [86–88]. MCN almost always occurs in the presence of high free LC

burden and typically when serum FLC levels are >100 mg/dL [74, 89]. Almost all MM patients with significant renal impairment will also have high urine FLC levels [90]. The serum and urine FLC levels can be prognostic indicators in MCN [91, 92]. The hallmark of MCN is tubular obstruction due to formation of LC casts, as described previously, from the interaction of Tamm-Horsfall protein (THP) and monoclonal LCs. Factors that can influence formation of casts include urinary concentration of THP, sodium, calcium, pH, urine flow rate, and diuretic use [85].

MCN typically presents with acute renal failure; however, oliguric AKI is a feature in about half of the cases even with very high levels of serum creatinine [93]. The progression of AKI is rapid [94], with volume depletion and hypercalcemia being the most common precipitating factors. Other common risk factors for AKI MM include use of IV contrast media, presence of infection, and nonsteroidal anti-inflammatory drugs (NSAIDs) used for bone pain. One of the initial indicators for MCN is the presence of heavy proteinuria that is disproportionate to the albuminuria detected on a urine dipstick. The median amount of proteinuria is about 2 g/24 h and is almost exclusively Bence Jones protein with albuminuria contributing <10%.

Early identification of MCN is essential for the treatment of MCN since delay in decreasing light-chain burden is associated with lower kidney recovery rates [92]. Treatment is focused on elimination of the precipitating agent and rapid reduction of the paraprotein. This can be achieved with chemotherapy or extracorporeal removal via therapeutic plasma exchange (TPE). While renal replacement therapy (RRT) may be required in certain cases, the indication for initiation of RRT is similar to other AKI states. Role of TPE in the management of MCN and reduction of FLC burden remains controversial. Three randomized controlled trials have published conflicting results [95–97]. The largest trial showed no benefit but was limited by the absence of histologic diagnosis of MCN. A meta-analysis of the three trials showed higher rates of dialysis independence at 6 months for patients when TPE was combined with chemotherapy but no change in overall survival with use of TPE [98]. Arguments against using TPE include the absence of FLC monitoring in previous randomized trials and introduction of newer chemotherapeutic agents with high response rates that did not significantly improve with addition of TPE [99, 100].

The role of high-cutoff hemodialysis (HCO-HD) in treatment of patients with renal insufficiency is being evaluated in two large randomized controlled trials: EuLITE study (European Trial of Free Light Chain Removal by Extended Hemodialysis in Cast Nephropathy; NCT00700531) and the French MYRE study (Studies in Patients with MM and Renal Failure Due To MM Cast Nephropathy; NCT01208818). Both these trials include patients on a bortezomib-based regimen. A prior study examining the use of HCO-HD in combination with chemotherapy in 67 MM patients showed encouraging results, with a sustained reduction in FLCs by day 12 in 67% of patients and dialysis independency in 63% [101]. However, sustained reduction in FLC requires effective chemotherapy. The choice of regimen is oftentimes guided by the presence of renal failure and nonrenally cleared drugs like bortezomib and thalidomide are preferred.

General Principles of Treatment Renal Insufficiency in Myeloma

Initial treatment should include administration of intravenous fluids to achieve high urine, reduction of calcium levels in patients with hypercalcemia, treatment of infection, and avoidance of nephrotoxic agents. However, there is no established role for urine alkalization in treatment of RI [102]. Bisphosphonates can be used for hypercalcemia; however, pamidronate and zoledronic acid should be avoided in patients with CrCl <30 mL/min. Pamidronate has been associated with development of collapsing variant of focal and segmental glomerulosclerosis [103], whereas zoledronic acid is associated with development of ATN [104]. Denosumab may be helpful in this subgroup with close monitoring of serum calcium levels. The role of mechanical treatments, which include therapeutic plasma exchange (TPE) or high-cutoff hemodialysis (HCO-HD), in treatment of MM is limited to MM cast nephropathy (MCN) (see above).

Systemic chemotherapy should be started immediately to reduce FLC burden and provides the best chance of renal recovery, with bortezomib in combination with dexamethasone usually employed [72]. Bortezomib-based therapy has significantly higher rates of renal recovery (≥partial renal response) compared to thalidomide- or lenalidomide-based regimens (77% vs. 55% vs. 43%, respectively) in a large retrospective analysis of 133 patients [105]. Carfilzomib, a second-generation proteasome inhibitor, has shown good safety and efficacy when used in patients with RI, and progression-free survival was better with carfilzomib when compared to bortezomib [106]. High-dose corticosteroids (equivalent to dexamethasone 160 mg or greater over 4 days) can be effective for rapid recovery of renal function regardless of the initial chemotherapy regimen [105]. High-dose steroids should be used in the initial month of therapy for MM. Thalidomide can be used in renal insufficiency without dose adjustment; however there have been reports of hyperkalemia in patients receiving dialysis [107, 108]. The renal recovery rates with use of thalidomide have been as high as 75% in newly diagnosed MM and up to 60% in patients with relapse/refractory disease [105, 107, 109].

Lenalidomide requires dose adjustment in renal insufficiency and response to treatment is not as robust. Autologous stem cell transplant (ASCT) can be used in MM even in presence of severe RI requiring dialysis but requires dose adjustment of the high-dose melphalan [110]. RI at the time of transplantation, however, is associated with higher risk of transplant-related mortality (4% vs. <1%) [110, 111].

AL Amyloidosis

Amyloidosis represents the most common glomerular lesion in MM. AL amyloidosis is a systemic disease with deposition of congophilic fibrils in soft tissue. The fibrils are composed of light chains (AL), heavy chains (AH), or intact immunoglobulins (ALH) [112]. AL amyloidosis is the most common subtype accounting for >95% of cases. Autopsy studies report rates of 5–15% for AL amyloidosis [86–88]. MM is diagnosed in <10% of cases of AL amyloidosis. About 50% of patients present with renal failure. Proteinuria is present in >70% of the cases while about a fourth of the cases present with nephrotic syndrome [113]. As opposed to MCN, the proteinuria is predominantly albumin [78]. Rarely, amyloidosis will present with renal dysfunction in the absence of proteinuria as in vascular limited amyloidosis or diabetes insipidus. Kidney involvement can at times be the only presentation of amyloidosis. A fat pad biopsy can provide a diagnosis in about 70% of cases, whereas the remaining will require kidney biopsy [78]. Kidney response in amyloidosis is predictive of OS [114, 115]. Kidney transplantation can be considered in combination with chemotherapy and ASCT as one of the therapeutic options in patients with AL amyloidosis [116].

Kidney Transplantation in Myeloma

Kidney transplantation is challenging in patients with MM since the transplantation and ensuing use of immunosuppressive medications are thought to portend a high risk for disease recurrence and infections. Most centers require a treatment-free remission period of 3–5 years. The initial lesion can be predictive of graft survival and recurrence. Patients with MCN have a lower risk of graft recurrence if MM stays in remission [117]. In patients with AL amyloidosis, specifically those without significant cardiac involvement, kidney transplantation in combination with chemotherapy and ASCT has shown favorable outcomes [116]. Renal transplantation in patients with MIDD is not recommended unless complete response is noted, as recurrence rates are about 80% in patients who do not have a complete response to treatment [118].

Conclusion

Thus, supportive care for MM patients becomes increasingly important, if MM patients are to enjoy a higher quality of life. MM patients are living longer, receiving more intensive therapy, and are potentially curable.

32 POEMS Syndrome

Angela Dispenzieri

Introduction

POEMS syndrome is a rare paraneoplastic syndrome due to an underlying plasma cell disorder. The acronym, which was coined by Bardwick in 1980 [1], refers to several, but not all, of the features of the syndrome: polyradiculoneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder, and skin changes. Other important features not included in the POEMS acronym include papilledema, extravascular volume overload, sclerotic bone lesions, thrombocytosis/ erythrocytosis (P.E.S.T.), elevated vascular endothelial growth factor (VEGF) levels, a predisposition towards thrombosis, and abnormal pulmonary function tests. There is a Castleman disease variant of POEMS syndrome that may be associated with a clonal plasma cell disorder. Other names of the POEMS syndrome that are less frequently used are osteosclerotic myeloma, Takatsuki syndrome, Crow-Fukase syndrome, and PEP syndrome [2, 3]. A national survey conducted in Japan in 2003 showed a prevalence of approximately 0.3 per 100,000 [4].

The pathogenesis of the syndrome is not understood. Distinctive presenting characteristics of the syndrome that differentiate POEMS syndrome from standard multiple myeloma (MM) include the following: (1) dominant symptoms have little to nothing to do with bone pain, extremes of bone marrow infiltration by plasma cells, or renal failure; (2) dominant symptoms are typically neuropathy, endocrine dysfunction, and volume overload; (3) VEGF levels are high; (4) sclerotic bone lesions are present in the majority of cases; (5) overall survival is typically superior; and (6) lambda clones predominate [5]. VEGF is the cytokine that correlates best with disease activity, although it is likely not the driving force of the disease based on the mixed results seen with anti-VEGF therapy [6]. Little is known about the plasma cells in POEMS syndrome except that more than 95% of the time they are lambda light chain restricted with restricted immunoglobulin light-chain variable gene usage (*IGLV1*) [7, 8].

Diagnosis of POEMS Syndrome

The diagnosis is made based on a composite of clinical and laboratory features. The most notable symptoms include the constellation of neuropathy and any of the following: monoclonal protein (especially lambda light chain); thrombocytosis; anasarca; or papilledema. All the features of the acronym are not required to make the diagnosis (Table 32.1). A good history and physical examination followed by appropriate testing—most notably radiographic assessment of bones [9], measurement of VEGF [10–14], and careful analysis of a bone marrow biopsy [15]—can differentiate this syndrome from other conditions like chronic inflammatory polyradiculoneuropathy (CIDP), monoclonal gammopathy of undetermined significance (MGUS) neuropathy, and immunoglobulin light-chain amyloid neuropathy. Figure 32.1 demonstrates several classic findings among patients with POEMS syndrome.

Table 32.1 Criteria for the diagnosis of POEMS syndrome[a]

		% Affected[b]
Mandatory major criteria (both required)	1. Polyradiculoneuropathy (typically demyelinating)	100
	2. Monoclonal plasma cell disorder (almost always λ)	100[c]
Other major criteria (one required)	3. Castleman disease[d]	11–25
	4. Sclerotic bone lesions	27–97
	5. Vascular endothelial growth factor elevation[e]	
Minor criteria (one required)	6. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)	45–85
	7. Extravascular volume overload (edema, pleural effusion, or ascites)	29–87
	8. Endocrinopathy (adrenal, thyroid,[f] pituitary, gonadal, parathyroid, pancreatic[f])	67–84
	9. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails)	68–89
	10. Papilledema	29–64
	11. Thrombocytosis/polycythemia[g]	54–88
Other symptoms and signs	Clubbing, weight loss, hyperhidrosis, pulmonary hypertension/restrictive lung disease, thrombotic diatheses, diarrhea, low vitamin B_{12} values	

POEMS polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes
[a]The diagnosis of POEMS syndrome is confirmed when both of the mandatory major criteria, one of the three other major criteria, and one of the six minor criteria are present
[b]Summary of frequencies of POEMS syndrome features based on largest retrospective series [2, 3, 16–18, 27]
[c]Takasuki and Nakanishi series are included even though only 75% of patients had a documented plasma cell disorder.
[d]There is a Castleman disease variant of POEMS syndrome that occurs *without* evidence of a clonal plasma cell disorder that is not accounted for in this table. This entity should be considered separately
[e]A plasma VEGF level of 200 pg/mL is 95% specific and 68% sensitive for a POEMS syndrome [14]
[f]Because of the high prevalence of diabetes mellitus and thyroid abnormalities, this diagnosis alone is not sufficient to meet this minor criterion
[g]Approximately 50% of patients will have bone marrow changes that distinguish it from a typical MGUS or myeloma bone marrow

Clinical and Laboratory Presentation

The peripheral neuropathy is the dominant characteristic [2, 3, 16–18], and it is ascending, symmetrical, and affecting both sensation and motor function [19]. In our experience, pain may be a dominant feature in about 10–15% of patients, and in one report as many as 76% of patients had painful neuropathy [4, 20]. Nerve conduction studies in patients with POEMS syndrome show slowing of nerve conduction that is more predominant in the intermediate than distal nerve segments as compared to CIDP, and there is more severe attenuation of compound muscle action potentials in the lower than upper limbs [4, 21, 22]. In contrast to CIDP, conduction block is rare [4, 22]. The conduction findings suggest that demyelination is predominant in the nerve trunk rather than the distal nerve terminals, and axonal loss is predominant in the lower limb nerves [4]. Axonal loss is greater in POEMS syndrome than it is in CIDP [22]. The nerve biopsy is not specific, but uncompacted myelin lamellae, endothelial cytoplasmic enlargement, opening of the tight junctions between endothelial cells and presence of many pinocytic vesicles adjacent to the cell membranes, and absence of macrophage-associated demyelination have been described [23, 24]. As compared to CIDP, POEMS syndrome demonstrates more axonal degeneration and epineurial neovascularization but less endoneurial inflammation and onion-bulb formation [25].

Depending on the series, 45–85% of patients will have any combination of splenomegaly, hepatomegaly, and/or lymphadenopathy. Lymph nodes may appear reactive or reveal frank Castleman disease or merely “Castleman’s disease-like” changes. Between 11 and 30% of POEMS patients with documented clonal plasma cell disorder also have documented Castleman disease or Castleman-like histology [6]. Among individuals with POEMS who undergo lymph node biopsy, about 50% show angiofollicular hyperplasia typical of Castleman disease [3, 18], and 84% are of these are hyaline vascular type [18]. Only those with peripheral neuropathy AND a plasma cell clone should be classified as standard POEMS syndrome; without both, patients can be classified as Castleman disease variant of POEMS if they have other POEMS features [26].

Endocrinopathy is a central but poorly understood feature of POEMS. In one series [27], approximately 84% of patients had a recognized endocrinopathy, with hypogonadism as the most common endocrine abnormality, followed by thyroid

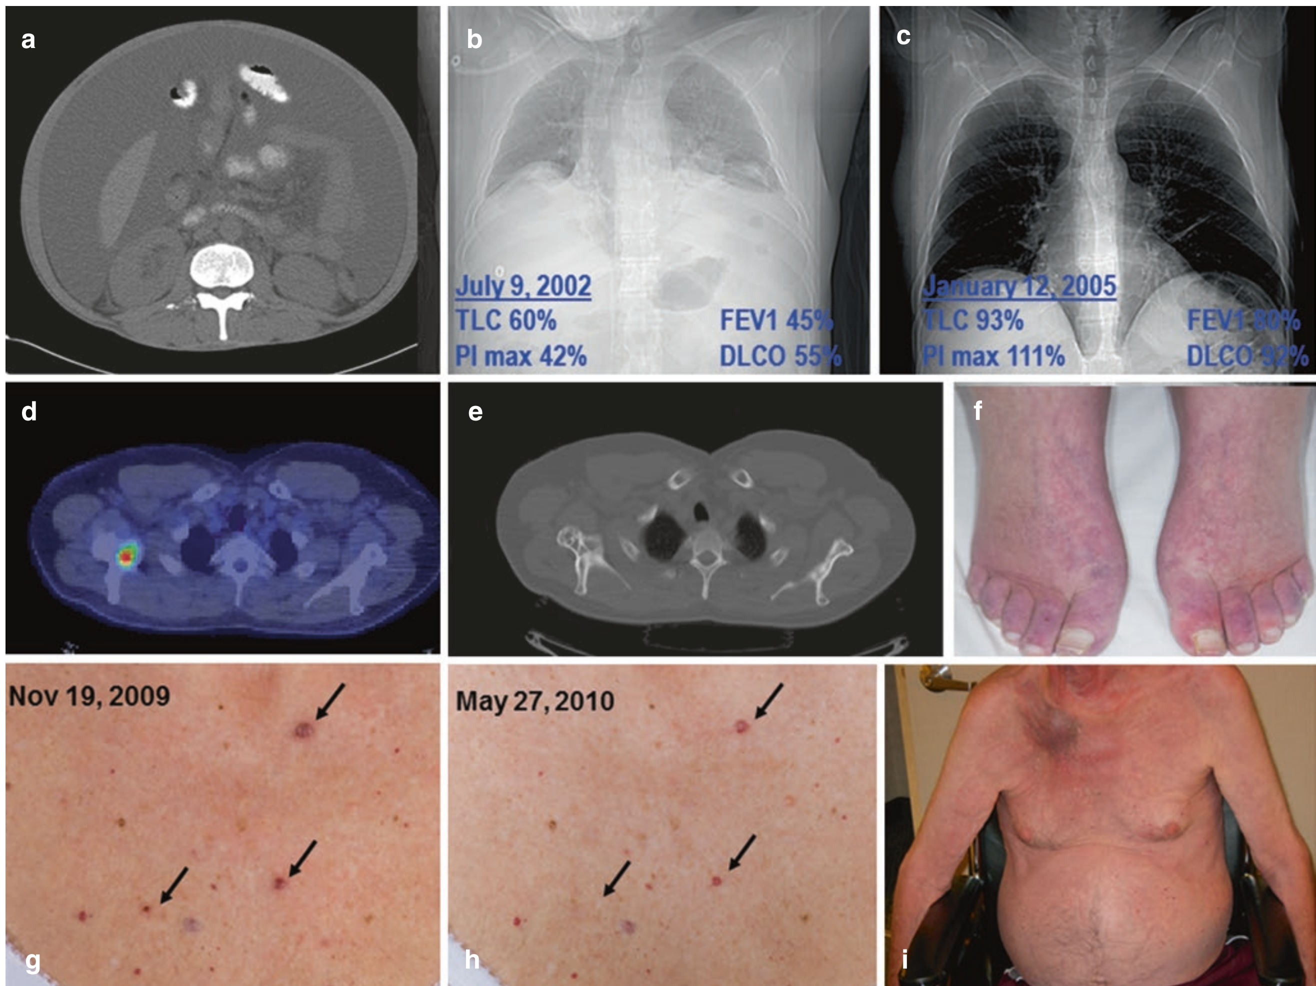

Fig. 32.1 Classic findings of POEMS syndromes. *Reproduced with permission from Dispenzieri, A., How I treat POEMS syndrome. Blood, 2012.* ***119****(24): p. 5650–8.* (**a**) Massive ascites and lipodystrophy. (**b**) Chest radiograph and pulmonary function test results demonstrating reduced lung volumes due to neuromuscular weakness, small effusions, and reduced diffusing capacity of carbon monoxide. (**c**) Improved chest radiograph and pulmonary function tests 2.5 years after ASCT (same patient as **h**). (**d**) Fusion CT PET of mixed lytic/sclerotic lesion in right scapula. (**e**) Bone windows of CT of mixed lytic/sclerotic lesion in right scapula. (**f**) Hyperemia of extremities and white nails. (**g**) Outcropping of cherry angiomata at diagnosis. (**h**) Shrinkage and disappearance of cherry angiomata after radiation to solitary osteosclerotic lesion right femur. (**i**) Plasmacytoma right scapula with overlying erythema as well as gynecomastia, muscle wasting, and ascites. Also present but unrelated is florid tinea corporis due to chronic steroid used for the incorrect diagnosis of CIDP

abnormalities, glucose metabolism abnormalities, and lastly adrenal insufficiency. The majority of patients have evidence of multiple endocrinopathies in the four major endocrine axes (gonadal, thyroid, glucose, and adrenal). Gynecomastia may be present on physical examination.

The characteristic skin changes include hyperpigmentation, a recent outcropping of hemangioma, hypertrichosis, dependent rubor and acrocyanosis, white nails, sclerodermoid changes, facial lipodystrophy, flushing, or clubbing [6]. Rarely calciphylaxis is also seen.

Papilledema is present in at least one-third of patients [28]; the majority of these patients do not have specific symptoms relating to this finding but a minority will report blurred vision, diplopia, or ocular pain. Peripheral edema, ascites, and effusions are the symptoms and signs that cause the next most morbidity after the peripheral neuropathy. The manifestations of extravascular overload occur in 29–87% of patients with POEMS syndrome and are not typically associated with severe hypoalbuminemia. Severe third spacing can lead to worsening renal function. Serum creatinine levels are normal in most cases, but serum cystatin C, which is a surrogate marker for renal function, is high in 71% of patients [29]. In a series from China, 22% of patients had a creatinine clearance (CrCl) of less than 60 mL/min including 8% with a CrCl of less than 30 mL/min; 10% had microhematuria [30]. The renal histologic findings are diverse with membranoproliferative features and evidence of endothelial injury being most common [31].

Finding the monoclonal plasma cell disorder can sometimes be a challenge. In one series, only 53% of patients had a positive protein electrophoresis, with another 31% being immunoelectrophoresis positively only, and 16% had their clone discovered only by either bone marrow biopsy or biopsy of a plasmacytoma, i.e., bone lesion [17]. The CBC is notable for an absence of cytopenias. Nearly half of patients will have thrombocytosis or erythrocytosis [17]. In a series from China, 26% of patients had anemia, which the authors attributed to impaired renal function [18]. Their series was enriched with Castleman disease cases (25%), which may have also contributed to this unprecedentedly high rate of anemia.

The bone marrow biopsy reveals megakaryocyte hyperplasia and megakaryocyte clustering in 54% and 93% of cases, respectively [15]. These megakaryocyte findings are reminiscent of a myeloproliferative disorder, but *JAK2* V617F mutation is uniformly absent. One-third of patients do not have clonal plasma cells on their iliac crest biopsy. These are the patients who present with a solitary or "multiple solitary plasmacytomas." The median percent of plasma cells observed is less than 5%. Immunohistochemical staining is more sensitive than is six-color flow since the former provides information on bone marrow architecture, which is key in making the diagnosis in nearly half of cases. In our study of 67 pretreatment bone marrow biopsies from patients with POEMS syndrome, lymphoid aggregates were found in 49% of cases. Of these, there was plasma cell rimming in all but one; and of these 32 cases, 31 were clonal lambda and 1 was kappa. This finding was not seen in bone marrows from normal controls or from patients with MGUS, multiple myeloma, or amyloidosis. Overall, only 8/67 (12%) of POEMS cases had normal iliac crest bone marrow biopsies, i.e., no detectable clonal plasma cells, no plasma cell-rimmed lymphoid aggregates, and no megakaryocyte hyperplasia.

Osteosclerotic lesions occur in approximately 95% of patients, and can be confused with benign bone islands, aneurysmal bone cysts, non-ossifying fibromas, and fibrous dysplasia [3, 17]. Some lesions are densely sclerotic, while others are lytic with a sclerotic rim, while still others have a mixed soap-bubble appearance. Occasionally patients have a lytic lesion without any evident sclerosis. Bone windows of CT body images are often very informative [32], often even more so than FDG uptake, which can be variable and most useful when there is an obvious lytic component to the bone lesion.

Plasma and serum levels of VEGF are markedly elevated in patients with POEMS [14, 33, 34] and correlate with the activity of the disease [10, 11, 14, 34]. The principal isoform of VEGF expressed is VEGF165 [10]. VEGF levels are independent of M-protein size [10]. IL-1β, TNF-α, IL-6, and IL-12 levels are often also increased [35]. Serum VEGF levels are 10–50 times higher plasma levels of VEGF [36]. Our group has demonstrated that a plasma VEGF level of 200 pg/mL had a specificity of 95% with a sensitivity of 68% in support of a diagnosis of POEMS syndrome.

Respiratory complaints are usually limited given patients' neurologic status impairing their ability to induce cardiovascular challenges [37]. The pulmonary manifestations are protean, including pulmonary hypertension, restrictive lung disease, impaired neuromuscular respiratory function, and impaired diffusion capacity of carbon monoxide, but improve with effective therapy [18, 37, 38]. Pulmonary hypertension has been reported to occur in 27% of unselected patients with POEMS syndrome [39]. Nail clubbing is seen in about 4–49% of cases [3, 37].

Patients are at increased risk for arterial and/or venous thromboses during their course, with nearly 20% of patients experiencing one of these complications [5, 40]. Ten percent of patients present with a cerebrovascular event, most commonly embolic or vessel dissection and stenosis [41]. Thrombocytosis and increased bone marrow infiltration are associated with risk for cerebrovascular accidents [41]. Aberrations in the coagulation cascade have been implicated in POEMS syndrome, but are not usually clinically apparent [24].

Treatment of Poems Syndrome

Despite the relationship between disease response and dropping levels of VEGF, the most experience with successful outcomes has been associated with directing therapy at the underlying clonal plasma cell disorder rather than solely targeting VEGF with anti-VEGF antibodies. The treatment algorithm is based on the extent of the plasma cell infiltration (Fig. 32.2). The approach to therapy differs based on whether there is bone marrow involvement as determined by blind iliac crest sampling [42].

The course of POEMS syndrome is usually chronic with an estimated 10-year survivorship rate of 77–79% [43, 44] and of more than 90% for those who undergo ASCT [17, 37, 44]. The number of POEMS features does not affect survival [5, 16]. Baseline risk factors for inferior survival have included fingernail clubbing, extravascular volume overload—i.e., effusions, edema, and ascites [17]—low serum albumin [44], coexistent Castleman disease [18], and respiratory symptoms [37]. In a recent publication from China of 362 patients, factors associated with inferior survival were age (40% of patients HR 4.1 [95%CI 1.4, 11.8]), pulmonary hypertension (20%, HR 4.0 [95%CI 1.4, 11,0]), pleural effusion (40%; HR 3.8 [95%CI 1.2, 11.8]), and eGFR <30 mL/min/1.73 m^2 (6%; HR 8.2 [95%CI 2.2, 31.2]).

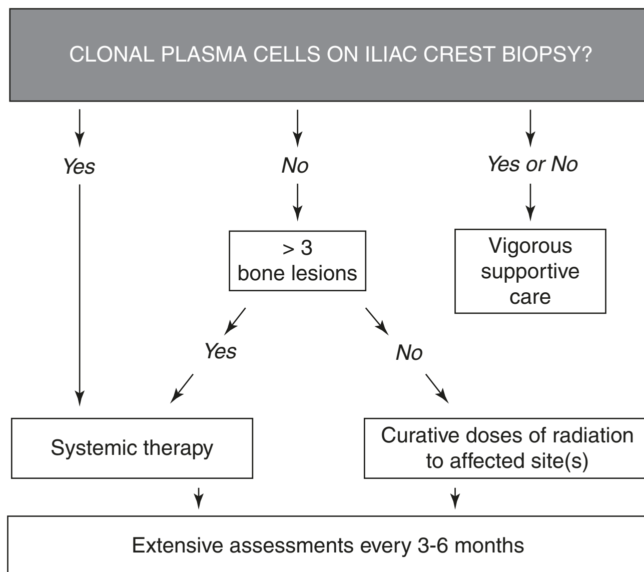

Fig. 32.2 Algorithm for the treatment of POEMS syndrome. *Reproduced with permission from Dispenzieri, A., How I treat POEMS syndrome. Blood, 2012.* ***119****(24): p. 5650–8*

Management of POEMS Syndrome Without Disseminated Bone Marrow Involvement

In the case of patients with an isolated bone lesion without clonal plasma cells found on iliac crest biopsy, radiation is the recommended therapy as it is in the case of a more straightforward solitary plasmacytoma of bone. Not only does radiation to an isolated (or even two or three isolated) lesion(s) improve the symptoms of POEMS syndrome over the course of 3–36 months, but it can also be curative.

Management of POEMS Syndrome with Disseminated Bone Marrow Involvement

Typically, once there is disseminated disease identified, systemic therapy is recommended with the caveat that large bony lesions with a significant lytic component may require adjuvant radiation therapy [42]. Decisions about adjuvant radiation should be made on a case-by-case basis, and typically not until a minimal of 6 months after completing chemotherapy. There is a lag between completion of successful therapy and neurologic response, often with no discernible improvement until 6 months after completion of therapy. Maximal response is not seen until 2–3 years hence. Other features like anasarca, papilledema, and even skin changes typically improve sooner. Optimal FDG-PET response may also lag by 6–12 months.

Table 32.2 Activity of therapy for the treatment of POEMS syndrome

Regimen	Outcome
Radiation	50–70% of patients have significant clinical improvement
Melphalan-dexamethasone	81% hematologic response rate; 100% with some neurologic improvement
Corticosteroids	50% of patients have significant clinical improvement
Cyclophosphamide-dexamethasone	At least 50% of patients have significant improvement
ASCT	100% of surviving patients have significant clinical improvement
Thalidomide-dexamethasone	Reported responses in 12 patients, but not recommended as first line due to risk of neuropathy. Additional 25 patients treated in randomized trial with crossover revealed improved VEGF and motor function [49]
Lenalidomide-dexamethasone	Reported responses in majority of patients (more than 60 patients reported)
Bortezomib	Used as single agent ($n = 1$), with dexamethasone ($n = 2$), with cyclophosphamide and dexamethasone ($n = 1$), and with doxorubicin and dexamethasone ($n = 1$). Reported responses in all
Bevacizumab	Two out of three using it as single agent died within weeks; one improved. Two other patients using it as “salvage” improved, but relapsed and died despite continued therapy, normal VEGF at 3.5 and 5.5 years. Six other cases of use with or after other alkylator-based therapy yielded one death and four patients with improvement

Modified from Dispenzieri [6]

Since there is a paucity of clinical trials among patients with POEMS syndrome [6], treatment recommendations are largely based on case series and anecdote. The treatment armamentarium is borrowed from other plasma cell disorders. Table 32.2 summarizes regimens and observed outcomes. Corticosteroids may provide symptomatic improvement, but response duration is limited. The most experience has been with alkylator-based therapy, either low dose or high dose with peripheral blood stem cell transplant. The first prospective clinical trial to treat POEMS syndrome was reported from China [45]. Thirty-one patients were treated with 12 cycles of melphalan and dexamethasone and 81% of patients achieved hematologic response, 100% had VEGF response, and 100% had at least some improvement in neurologic status. At 21 months, 100% were progression free and alive. Personal experience and retrospective reports of the use of cyclophosphamide-based therapy is effective [42].

High-dose alkylator with peripheral blood stem cell transplant is also quite effective, but selection basis may confound these reports [6]. Case series suggest that 100% of patients achieve at least some neurologic improvement. Doses of melphalan ranging from 140 to 200 mg/m^2 have been used, with the lower doses used for sicker patients. Of the 59 patients with POEMS syndrome treated at the Mayo Clinic Rochester, progression-free survival was 98%, 94%, and 75% at 1, 2, and 5 years, respectively [46]. Symptomatic progressions were rare, whereas radiographic and VEGF progressions were most common. Treatment-related morbidity and mortality can be minimized by recognizing and treating an engraftment-type syndrome characterized by fevers, rash, diarrhea, weight gain, and respiratory symptoms and signs that occur anytime between days 7 and 15 post-stem cell infusion [47]. In a recent EBMT series, engraftment syndrome was reported in 23% of patients. Survival figures were comparable to that seen in the Mayo series [48].

There is one randomized trial for patients with POEMS syndrome. Misawa and colleagues conducted a randomized, double-blind, placebo-controlled phase 2/3 trial for patients with POEMS syndrome who were not candidates for ASCT [49]. Twenty-five patients were randomized to either daily thalidomide plus 4 days of dexamethasone every 4 weeks or placebo and 4 days of dexamethasone for 24 weeks; thereafter all patients received open-label, single-agent thalidomide for 48 weeks. Patients treated with thalidomide had higher rates of VEGF reduction, greater change in summated muscle test scores, and smaller changes in SF-36 QoL physical function and physical scores. Not surprisingly, side effects including sinus bradycardia, constipation, and mild sensory neuropathy were more frequent in patients treated with thalidomide.

Lenalidomide has also yielded favorable results, seemingly with fewer side effects. The French have reported in abstract form their results of a Phase 2 study of lenalidomide and dexamethasone for 2 cycles as neoadjuvant therapy preceding radiation or high-dose therapy or as primary therapy as 9 cycles followed by 12 cycles of single-agent lenalidomide [50]. They treated 27 patients: 10 pre-radiation therapy; 8 pre-ASCT; and 9 primary therapy. Although follow-up is short, the authors report that several patients had rapid neurological response, no patient had died, and one patient had progressed. These results are similar to case reports and case series [51–53]. In the largest case series of 20 patients [53], all patients responded, but 4 patients relapsed 3–10 months after the end of treatment. Another retrospective case series of 12 patients with relapsed or refractory POEMS syndrome treated with lenalidomide and dexamethasone reported a 2-year PFS and OS of 92% [54]. A systematic review of lenalidomide use in patients with POEMS has been published [55], which estimates a 1- and 2-year PFS of 92 and 42% using lenalidomide. Given the intrinsic risk patients with POEMS syndrome have for thrombosis, it is imperative that at least an aspirin be used for prophylaxis. The use of low-molecular-weight heparin or warfarin should be balanced against fall risk.

Like thalidomide and lenalidomide, bortezomib can have anti-VEGF and anti-TNF effects. Enthusiasm for thalidomide and bortezomib should be tempered by the high rate of peripheral neuropathy induced by these drugs. Bortezomib use has been reported in a handful of patients, with favorable results, especially those with severe ascites [6]. Although an anti-VEGF strategy is appealing, the results with bevacizumab have been mixed. Most of these reports include patients who had also received either radiation or alkylator during and/or predating the bevacizumab had benefit [42].

Both our experience and the literature would support that single-agent IV IG or plasmapheresis is not helpful. Other treatments like interferon-alpha, tamoxifen, trans-retinoic acid, ticlopidine, argatroban, and strontium-89 have been reported as having activity mostly as single-case reports.

Managing Symptoms of Disease

Attention to supportive care is imperative. Orthotics, physical therapy, and CPAP all play an important role in patients' recovery. Ankle foot orthotics can increase mobility and reduce falls. Physical therapy reduces the risk for permanent contractures and leads to improved function both in the long and short terms. For those with severe neuromuscular weakness, CPAP and/or biBAP provides better oxygenation and potentially reduces the risk complications associated with hypoventilation like pulmonary infection and pulmonary hypertension.

Monitoring Response

Patients must be followed carefully on a quarterly basis tracking the status of deficits comparing these to baseline [46]. VEGF responses may occur as soon as 3 months [56], but they can be delayed. VEGF is an imperfect marker since discordance between disease activity and response has been reported [57], so trends rather than absolute values should direct therapeutic decisions. Serum M-protein responses by protein electrophoresis, immunofixation electrophoresis, or serum immunoglobulin free light chains also pose a challenge. The size of the M-protein is typically small making standard multiple myeloma response criteria inapplicable in most cases. In addition, patients can derive very significant clinical benefit in the absence of an M-protein response [45, 47]. Finally, despite the fact that the immunoglobulin free light chains are elevated in 90% of POEMS patients, the ratio is normal in all but 18% [29], making the test of limited value for patients with POEMS syndrome.

Conclusion

POEMS syndrome is a rare disorder. There is much to be learned about the pathogenesis of the disease. From a practical standpoint, however, one of the biggest challenges is that diagnosis is often delayed, which results in increased morbidity. Hematologic, clinical, VEGF, and PET scan responses can be achieved with a multitude of therapies, but there are no randomized data to determine which therapies are best in terms of rapid, deepest, and most durable responses. If the diagnosis is made too late, patients may be left with some extent of irreversible nerve damage, so neurologists and hematologists should be vigilant of POEMS in their differential diagnosis of patients with lambda-restricted plasma cell disorder, peripheral neuropathy, and other POEMS syndrome features.

Waldenstrom's Macroglobulinemia

33

Steven P. Treon, Giampaolo Merlini,
and Meletios Dimopoulos

Background

Waldenstrom's macroglobulinemia (WM) is a lymphoid neoplasm resulting from the accumulation, predominantly in the marrow, of a clonal population of lymphocytes, lymphoplasmacytic cells, and plasma cells, which secrete a monoclonal immunoglobulin (Ig) M [1]. WM corresponds to lymphoplasmacytic lymphoma (LPL) as defined in the Revised European-American Lymphoma (REAL) and World Health Organization classification systems [2, 3]. Most cases of LPL are WM; less than 5% of cases are IgA-secreting, IgG-secreting, or nonsecreting LPL.

Epidemiology

The age-adjusted incidence rate of WM is 3.4 per 1 million among males and 1.7 per 1 million among females in the United States. It increases in incidence geometrically with age [4, 5]. The incidence rate is higher among Americans of European descent. African-American descendants represent approximately 5% of all patients.

Genetic factors play a role in the pathogenesis of WM. Approximately 20% of WM patients are of Ashkenazi-Jewish ethnic background [6]. Familial disease has been reported commonly, including multigenerational clustering of WM and other B-cell lymphoproliferative diseases [6–9]. Approximately 28% of 924 sequential patients with WM presenting to a tertiary referral center had a first- or second-degree relative with either WM or another B-cell disorder [6]. Familial clustering of WM with other immunologic disorders, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody production (particularly to the thyroid), and manifestation of hyperactive B cells, has also been reported in relatives without WM [6, 9]. Increased expression of the *BCL-2* gene with enhanced survival has been observed in B cells from familial patients and their family members [9].

The role of environmental factors is uncertain, but chronic antigenic stimulation from infections and certain drug or chemical exposures have been considered but have not reached a level of scientific certainty. Hepatitis C virus (HCV) infection was implicated in WM causality in some series, but in a study of 100 consecutive WM patients in whom serologic and molecular diagnostic studies for HCV infection were performed no association was found [10–12].

Pathogenesis

Nature of the WM Clone

Examination of the B-cell clone(s) found in the bone marrow of WM patients reveals a range of differentiation from small lymphocytes with large focal deposits of surface immunoglobulins to lymphoplasmacytic cells and to mature plasma cells that contain intracytoplasmic IgM (Fig. 33.1) [13]. Circulating clonal B cells are often detectable in patients with WM, though lymphocytosis is uncommon [14, 15]. WM cells express the monoclonal IgM, and some clonal cells also express surface IgD [16]. The characteristic immunophenotypic profile of WM lymphoplasmacytic cells includes the expression of the pan B-cell markers CD19, CD20 (including FMC7), CD22, and CD79 [16, 17]. Expression of CD5, CD10, and CD23 can be present in 10–20% of cases, and their presence does not exclude the diagnosis of WM [18]. In addition, multiparameter flow

cytometric analysis has also identified CD25 and CD27 as being characteristic of the WM clone, and that a CD22^{dim}/CD25^{+}/CD27^{+}/IgM^{+} population can be observed among clonal B lymphocytes in IgM MGUS patients who ultimately progressed to WM [19].

Somatic mutations in immunoglobulin genes are present with increased frequency of nonsynonymous versus silent mutations in complement-determining regions along with somatic hypermutation, thereby supporting a post-germinal center derivation for the WM B-cell clone in most patients [20, 21]. A strong preferential usage of VH3/JH4 gene families without intraclonal variation, and without evidence for any isotype-switched transcripts, has also been shown [22, 23]. Taken together, these data support an IgM^{+} and/or IgM^{+}IgD^{+} memory B-cell origin for most cases of WM.

In contrast to myeloma plasma cells, no recurrent translocations have been described in WM, which can help to distinguish IgM myeloma cases that often exhibit t11;14 translocations from WM [24, 25]. Despite the absence of IgH translocations, recurrent chromosomal abnormalities are present in WM cells. These include deletions in chromosome 6q21–23 in 40–60% of WM patients, with concordant gains in 6p in 41% of 6q-deleted patients [26–29]. In a series of 174 untreated WM patients, 6q deletions, followed by trisomy 18, 13q deletions, 17p deletions, trisomy 4, and 11q deletions, were observed [29]. Deletion of 6q and trisomy 4 were associated with adverse prognostic markers in this series. As 6q deletions represent the most recurrent cytogenetic finding in WM cases, there has been great interest in identifying the region of minimal deletion and possible target genes within this region. Two putative gene candidates within this region include TNFAIP3, a negative regulator of nuclear factor kappa B signaling (NFκB), and PRDM1, a master regulator of B-cell differentiation [28, 30]. The removal of an NFκB-negative regulator is of particular interest as the phosphorylation and translocation of NFκB into the nucleus are crucial events for WM cell survival [31]. The success of proteasome inhibitor therapy in WM has been postulated to occur because the degradation of negative regulators of NFκB such as the inhibitor of kappa B (IκB) is blocked [32, 33].

Mutation in MYD88

A highly recurrent somatic mutation (MYD88^{L265P}) was first identified in WM patients by whole-genome sequencing (WGS), and confirmed by multiple studies through Sanger sequencing and/or allele-specific polymerase chain reaction assays [34–39]. MYD88^{L265P} is expressed in 90–95% of WM cases when more sensitive allele-specific PCR has been employed using both CD19-sorted and unsorted bone marrow (BM) cells [35–39]. By comparison, MYD88^{L265P} was absent in myeloma samples, including IgM myeloma, and was expressed in a small subset (6–10%) of MZL patients, who surprisingly have WM-related features [35–37, 40]. By polymerase chain reaction assays, 50–80% of IgM MGUS patients also express MYD88^{L265P}, and expression of this mutation was associated with increased risk for malignant progression [35–37, 41]. The presence of MYD88^{L265P} in IgM MGUS patient suggests a role for this mutation as an early oncogenic driver, and other mutations and/or copy number alterations leading to abnormal gene expression are likely to promote disease progression [28].

The impact of MYD88^{L265P} to growth and survival signaling in WM cells has been addressed in several studies (Fig. 33.2). Knockdown of MYD88 decreased survival of MYD88^{L265P}-expressing WM cells, whereas survival was enhanced by knock-in of MYD88^{L265P} versus wild-type MYD88 [42]. The discovery of a mutation in MYD88 is of significance given its role as an adaptor molecule in Toll-like receptor (TLR) and interleukin-1 receptor (IL-1R) signaling [43]. All TLRs except for TLR3 use MYD88 to facilitate their signaling. Following TLR or IL-1R stimulation, MYD88 is recruited to the activated receptor complex as a homodimer which then complexes with IRAK4 and activates IRAK1 and IRAK2 [44–46]. Tumor necrosis factor receptor-associated factor 6 is then activated by IRAK1 leading to NF-κB activation via IκBα phosphorylation [47]. Use of inhibitors of MYD88 pathway led to decreased IRAK1 and IκBα phosphorylation, as well as survival of MYD88^{L265P}-expressing WM cells. These observations are of particular relevance to WM since NF-κB signaling is important for WM growth and survival [31]. Bruton's tyrosine kinase (BTK) is also activated by MYD88^{L265P} [42]. Activated BTK co-immunoprecipitates with MYD88 that could be abrogated by use of a BTK kinase inhibitor, and overexpression of MYD88^{L265P} but

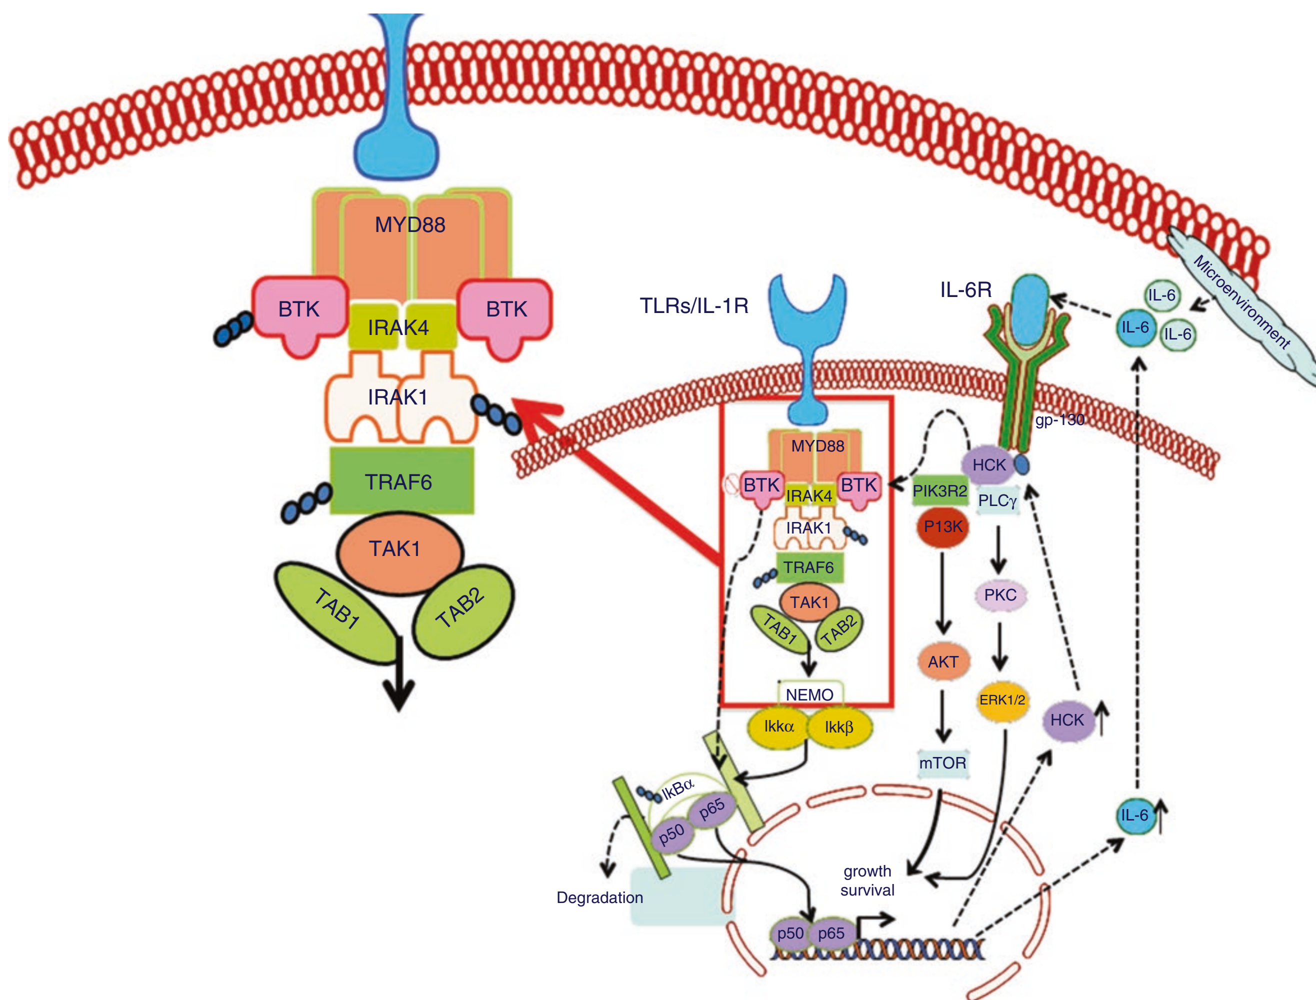

Fig. 33.2 MYD88-activating mutations are highly prevalent in patients with Waldenstrom's macroglobulinemia and trigger multiple growth and survival pathways. Activated MYD88 triggers NF-kB through BTK and IRAK1/IRAK4, as well as HCK that activates BTK, AKT, and ERK

not wild-type (WT) MYD88 triggers BTK activation. Knockdown of MYD88 by lentiviral transfection or use of a MYD88 homodimerization inhibitor also abrogated BTK activation in MYD88^{L265P}-mutated WM cells. MYD88 also triggers HCK, a SRC family member that regulates AKT and ERK survival signaling, and also activates BTK itself [48]. Rarely, non-L265P-activating mutations in WM may also occur, and Sanger sequencing of the entire MYD88 gene should be considered in patients suspected of having WM in whom PCR testing for MYD88^{L265P} is negative [49].

CXCR4 WHIM Mutations

The second most common somatic mutation after MYD88^{L265P} revealed by whole-genome sequencing was found in the C-terminus of the CXCR4 receptor. These mutations are present in 30–35% of WM patients, and impact serine phosphorylation sites that regulate CXCR4 signaling by its only known ligand SDF-1a (CXCL12) [28, 50–52]. The location of somatic mutations found in the C-terminus of CXCR4 in WM is similar to that observed in the germline of patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome, a congenital immunodeficiency disorder characterized by chronic noncyclic neutropenia [53]. Patients with WHIM syndrome exhibit impaired CXCR4 receptor internalization following SDF-1a stimulation, which results in persistent CXCR4 activation and myelokathexis [54].

In WM patients, two classes of CXCR4 mutations occur in the C-terminus. These include non-sense (CXCR4$^{WHIM/NS}$) mutations that truncate the distal 15–20 amino acid region, and frameshift (CXCR4$^{WHIM/FS}$) mutations that compromise a region of up to 40 amino acids in the C- terminal domain [28, 50]. Non-sense and frameshift mutations are almost equally divided among WM patients with CXCR4 somatic mutations, and over 30 different types of CXCR4^{WHIM} mutations have been identified in WM patients [28, 50]. In some

patients multiple $CXCR^{WHIM}$ mutations may be detected. $CXCR4^{WHIM}$ mutations are usually subclonal to MYD88, with highly variable clonal distribution [55]. The subclonal nature of these mutations suggests that CXCR4 mutations were likely acquired after MYD88 mutations.

Preclinical studies with WM cells engineered to express nonsense and frameshift $CXCR4^{WHIM}$-mutated receptors have shown enhanced and sustained AKT and ERK signaling following SDF-1a relative to $CXCR4^{WT}$, as well as increased cell migration, adhesion, growth and survival, and drug resistance (including ibrutinib) in WM cells [56, 57].

Other Somatic Events

Many copy number alterations have been revealed in WM patients that impact growth and survival pathways. Frequent loss of HIVEP2 (80%) and TNAIP3 (50%) genes that are negative regulators of NFkB expression, as well as LYN (70%) and IBTK (40%) that modulate BCR signaling, has been revealed by WGS [28]. WGS has also revealed common defects in chromatin remodeling with somatic mutations in ARID1A present in 17%, and loss of ARID1B in 70% of WM patients. Both ARID1A and ARID1B are members of the SWI/SNF family of proteins, and are thought to exert their effects via p53 and CDKN1A regulation. TP53 is mutated in 7% of sequenced WM genomes, while PRDM2 and TOP1 that participate in TP53-related signaling are deleted in 80% and 60% of WM patients, respectively [28]. Taken together, somatic events that contribute to impaired DNA damage response are also common in WM.

Impact of WM Genomics on Clinical Presentation

The importance of MYD88 and CXCR4 mutations in the clinical presentation of WM patients was recently reported. Significantly higher BM disease involvement, serum IgM levels, and symptomatic disease requiring therapy, including hyperviscosity syndrome, were observed in those patients with $MYD88^{L265P}CXCR4^{WHIM/NS}$ mutations [50]. Patients with $MYD88^{L265P}CXCR4^{WHIM/FS}$ or $MYD88^{L265P}CXCR4^{WT}$ had intermediate BM and serum IgM levels; those with $MYD88^{WT}CXCR4^{WT}$ showed the lowest BM disease burden. Fewer patients with $MYD88^{L265P}$ and $CXCR4^{WHIM/FS\ or\ NS}$ compared to $MYD88^{L265P}CXCR4^{WT}$ presented with adenopathy, further delineating differences in disease tropism based on CXCR4 status. Despite the more aggressive presentation associated with $CXCR4^{WHIM/NS}$ genotype, risk of death was not impacted by CXCR4 mutation status. Risk of death was found to be tenfold higher in patients with $MYD88^{WT}$ versus $MYD88^{L265P}$ genotype [50].

Marrow Microenvironment

Increased numbers of mast cells are found in the bone marrow of WM patients, wherein they are usually admixed with tumor cell aggregates (Fig. 33.3) [13, 17, 55]. The role of mast cells in WM has been investigated in one study wherein coculture of primary autologous or mast cell lines with WM LPC resulted in dose-dependent WM cell proliferation and/or tumor colony formation, through CD40 ligand (CD40L) signaling [58]. WM cells release soluble CD27 (sCD27) which may be triggered by cleavage of membrane-bound CD27 by matrix metalloproteinase 8 (MMP8) [59]. sCD27 levels are elevated in the serum of WM patients, and follow disease burden in mice engrafted with WM cells, as well as in WM patients [61]. sCD27 triggers the upregulation of CD40L as well as a proliferation-inducing ligand (APRIL) on mast cells derived from WM patients, as well as mast cell lines through its receptor CD70. Modeling in mice engrafted with a CD70-blocking antibody shows inhibition of tumor cell growth suggesting that WM cells require a microenvironmental support system for their growth and survival [60]. High levels of CXCR4 and very late antigen-4 (VLA-4) have also been observed in WM cells [61]. In blocking experiments studies, CXCR4 was shown to support migration of WM cells, while VLA-4 contributed to adhesion of WM cells to bone marrow stromal cells [61].

The white material at the edge of the veins may be cryoglobulin (*used with permission from Marvin J. Stone, MD*)

Clinical Features

Table 33.1 presents the clinical and laboratory findings at the time of diagnosis of WM in one large institutional study [15]. Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are uncommon (≤15%). Purpura is frequently associated with cryoglobulinemia and in rare circumstances with light-chain (AL) amyloidosis. Hemorrhagic and neuropathic manifestations are multifactorial (see "IgM-Related Neuropathy" below). The morbidity associated with WM is caused by the concurrence of two main components: tissue infiltration by neoplastic cells and, importantly, the physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 33.2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues [62–64].

Morbidity Mediated by the Effects of IGM

Hyperviscosity Syndrome

The increased plasma IgM levels lead to blood hyperviscosity and its complications [65]. The mechanisms behind the marked increase in the resistance to blood flow and the resulting impaired transit through the microcirculatory system are complex [65–68]. The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component, and (2) their interaction with blood cells. Monoclonal IgM increases red cell aggregation (rouleaux formation) and red cell internal viscosity

Table 33.1. Clinical and laboratory findings for 356 consecutive newly diagnosed patients with Waldenstrom's macroglobulinemia [14]

	Median	Range	Normal reference range
Age (years)	58	32–91	NA
Gender (male/female)	215/141		NA

Table 33.2 Physicochemical and immunological properties of the monoclonal IGM protein in Waldenstrom's macroglobulinemia [62–64]

Properties of IgM monoclonal protein	Diagnostic condition	Clinical manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to myelin-associated glycoprotein, ganglioside M_1, sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (type II)	Purpura, arthralgia, renal failure, sensorimotor neuropathies
Autoantibody activity to red blood cell antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: Bullous skin disease, papules, Schnitzler syndrome
		Gastrointestinal: Diarrhea, malabsorption, bleeding
		Kidney: Proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, hepatomegaly, macroglossia, organ dysfunction of involved organs (heart, kidney, liver, peripheral sensory, and autonomic nerves)

while reducing red cell deformability. The presence of cryoglobulins contributes to increasing blood viscosity, as well as to the tendency to induce erythrocyte aggregation. Serum viscosity is proportional to IgM concentration up to 30 g/L, and then increases sharply at higher levels. Increased plasma viscosity may also contribute to inappropriately low erythropoietin production, which is the major reason for anemia in these patients [68]. Renal synthesis of erythropoietin is inversely correlated with plasma viscosity. Clinical manifestations are related to circulatory disturbances that can be best appreciated by ophthalmoscopy, which shows distended and tortuous retinal veins, hemorrhages, and papilledema (Fig. 33.4) [69]. Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum viscosity is >4.0 centipoises (cp), but there is individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp [65]. The most common symptoms are oronasal mucosal bleeding, visual disturbances because of retinal bleeding, and dizziness that rarely may lead to stupor or coma. Heart failure can be aggravated, particularly in the elderly, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate red cell transfusion can exacerbate hyperviscosity and may precipitate cardiac failure.

Cryoglobulinemia

The monoclonal IgM can behave as a cryoglobulin in up to 20% of patients, and is usually type I and asymptomatic in most cases [15, 65, 70]. Cryoprecipitation is mainly dependent on the concentration of monoclonal IgM; for this reason plasmapheresis or plasma exchange is commonly effective in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud phenomenon, acrocyanosis, and necrosis of the regions most exposed to cold, such as the tip of the nose, ears, fingers, and toes (Fig. 33.5); malleolar ulcers; purpura; and cold urticaria. Renal manifestations are infrequent. Mixed cryoglobulins (type II) consisting of IgM-IgG complexes may be associated with hepatitis C infections [70].

Autoantibody Activity

Monoclonal IgM may exert its pathogenic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and red blood cell antigens.

IgM-Related Neuropathy

IgM-related peripheral neuropathy is common in WM patients, with estimated prevalence rates of 5–40% [71–73]. Approximately 8% of idiopathic neuropathies are associated with a monoclonal gammopathy, with a preponderance of IgM (60%) followed by IgG (30%) and IgA (10%) [74, 75]. The nerve damage is mediated by diverse pathogenetic mechanisms: (1) IgM antibody activity toward nerve constituents causing demyelinating polyneuropathies; (2) endoneurial granulofibrillar deposits of IgM without antibody activity, associated with axonal polyneuropathy; (3) occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin; and, rarely, (4) by amyloid deposits or by neoplastic cell infiltration of nerve structures [73, 76].

Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100-kDa glycoprotein component of nerve known as the myelin-associated glycoprotein (MAG). Anti-MAG antibodies are generally monoclonal IgMκ, and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG [77–79]. The anti–MAG-related neuropathy is typically distal and symmetrical,

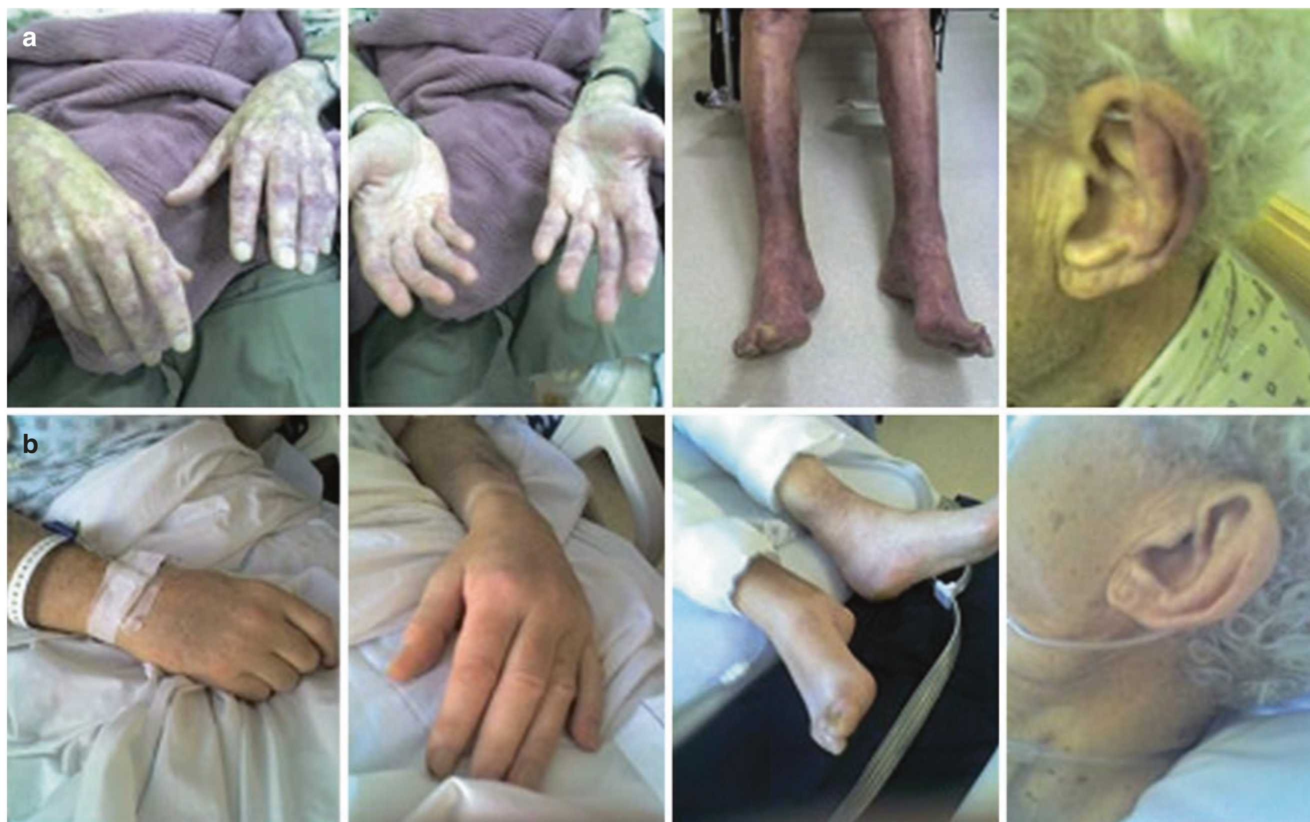

Fig. 33.5 Marrow clot section. (**a**) Tryptase-staining mast cells surrounding a nodule of lymphoplasmacytic cells in a patient with Waldenstrom's macroglobulinemia. (**b**) Mast cells in the same section exhibit strong CD40 ligand signaling, which has been shown to support (at least in part) the growth and survival of lymphoplasmacytic cells

affecting both motor and sensory functions; it is slowly progressive with a long period of stability [72, 80]. Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains), imbalance, and gait ataxia, owing to lack of proprioception and leg muscle atrophy in advanced stage. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b have also been reported [81, 82]. Anti-GD1b and anti-GQ1b antibodies were associated with sensory ataxic neuropathy. These antiganglioside monoclonal IgMs present core clinical features of chronic ataxic neuropathy sometimes with ophthalmoplegia and/or red blood cell cold-agglutinating activity. The disialosyl epitope is also present on red blood cell glycophorins, thereby accounting for the red cell cold agglutinin activity of anti-Pr2 specificity [83, 84]. Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including ganglioside M_2 (GM_2) and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia, unresponsive to glucocorticoids [85]. Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni*, whose infection is known to precipitate the Miller-Fisher syndrome, a variant of the Guillain-Barré syndrome [86]. Thus, molecular mimicry may play a role in this condition. Antisulfatide monoclonal IgM proteins, associated with sensory-sensorimotor neuropathy, have been detected in 5% of patients with IgM monoclonal gammopathy and neuropathy [87]. Motor neuron disease has been reported in patients with WM and monoclonal IgM with anti-GM_1 and sulfoglucuronyl paragloboside activity [88]. Polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes (the POEMS syndrome) are rare in patients with WM [89].

Cold Agglutinin Hemolytic Anemia

Monoclonal IgM may have cold agglutinin activity; that is, it can recognize specific red cell antigens at temperatures below 37 °C, producing chronic hemolytic anemia. This disorder occurs in <10% of WM patients and is associated with cold agglutinin titers greater than 1:1000 in most cases [90]. The monoclonal component is usually an IgMκ and reacts most commonly with red cell I/i antigens, resulting in complement fixation and activation [91, 92]. Mild-to-moderate

chronic hemolytic anemia can be exacerbated after cold exposure. Hemoglobin usually remains above 70 g/L. The hemolysis is usually extravascular, mediated by removal of C3b-opsonized red cells by the mononuclear phagocyte system, primarily in the liver. Intravascular hemolysis from complement destruction of red blood cell membrane is infrequent. The agglutination of red cells in the skin circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr specificity can occur. These properties may have as a common basis the binding of the sialic acid-containing carbohydrate present on red blood cell glycophorins and on Ig molecules. Several other macroglobulins with antibody activity toward autologous antigens (i.e., phospholipids, tissue and plasma proteins) and foreign ligands have also been described.

IgM Tissue Deposition

The monoclonal protein can deposit in several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease [93]. Amorphous IgM deposits in the dermis result in IgM storage papules on the extensor surface of the extremities, referred to as macroglobulinemia cutis [94]. Deposition of monoclonal IgM in the lamina propria and/or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding [95, 96]. Kidney involvement is less common and less severe in WM than in myeloma, probably because the amount of light chain excreted in the urine is generally lower in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia. Urinary cast nephropathy, however, has occurred in WM [97]. On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries [98]. Mild and reversible proteinuria may result and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) is uncommon in patients with WM [99]. Clinical expression and prognosis are similar to those of other AL amyloidosis patients with involvement of heart (44%), kidneys (32%), liver (14%), lungs (10%), peripheral or autonomic nerves (38%), and soft tissues (18%). The incidence of cardiac and pulmonary involvement is higher in patients with monoclonal IgM than with other immunoglobulin isotypes. The association of WM with reactive amyloidosis has been documented rarely [100, 101]. Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide noncongophilic fibrils and amyloid deposits, has been described [102].

Manifestations Related to Tissue Infiltration by Neoplastic Cells

Tissue infiltration by neoplastic cells is uncommon but can involve various organs and tissues, including the liver, spleen, lymph nodes, lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system.

Lung

Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is uncommon; the overall incidence of pulmonary and pleural findings is approximately 4% [103–105]. Cough is the most common presenting symptom, followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions.

Gastrointestinal Tract

Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine [106–109].

Renal System

In contrast to myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cell can occur in WM, and renal or perirenal masses are not uncommon [110, 111].

Skin

The skin can be the site of dense lymphoplasmacytic infiltrates, similar to those seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules [112]. Chronic urticaria and IgM gammopathy are the two cardinal features of the Schnitzler syndrome, which is not usually associated initially with clinical features of WM, although evolution to WM is not uncommon [113]. Thus, close follow-up of these patients is important.

Joints

Invasion of articular and periarticular structures by WM malignant cells is rarely reported [114].

Eye

The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retro-orbital lymphoid tissues, resulting in ocular nerve palsies [115, 116].

Central Nervous System

Direct infiltration of the central nervous system by monoclonal lymphoplasmacytic cells as infiltrates or as tumors constitutes the rarely observed Bing-Neel syndrome, characterized clinically by confusion, memory loss, disorientation, and motor dysfunction. The diagnosis and management of Bing-Neel syndrome are reviewed in 117.

Laboratory Findings

Blood Abnormalities

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors: decrease in red cell survival, impaired erythropoiesis, moderate plasma volume expansion, hepcidin production leading to iron reutilization defect, and blood loss from the gastrointestinal tract [15, 118, 119]. Blood films are usually normocytic and normochromic, and rouleaux formation is often pronounced. Mean red cell volume may be elevated spuriously owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate, that is, falsely high, because of interaction between the monoclonal protein and the diluent used in some automated analyzers [120]. Leukocyte and platelet counts are usually within the reference range at presentation, although patients may occasionally present with severe thrombocytopenia. Monoclonal B-lymphocytes expressing surface IgM and late-differentiation B-cell markers are uncommonly detected in blood by flow cytometry. A raised erythrocyte sedimentation rate is almost always present and may be the first clue to the presence of the macroglobulinemia. The clotting abnormality detected most frequently is prolongation of thrombin time. AL amyloidosis should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red.

Marrow Findings

Central to the diagnosis of WM is the demonstration, by trephine biopsy, of marrow infiltration by a lymphoplasmacytic cell population characterized by small lymphocytes with evidence of plasmacytoid and plasma cell maturation (Fig. 33.1) [1, 13]. The pattern of marrow infiltration may be diffuse, interstitial, or nodular, usually with an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of follicular lymphoma [1]. The marrow cell immunophenotype should be confirmed by flow cytometry and/or immunohistochemistry. The cell immunoprofile sIgM^{+}CD19^{+}CD20^{+}CD22^{+}CD79^{+} is characteristic of WM [13, 120, 121]. Up to 20% of cases may express either CD5, CD10, or CD23 [18]. In these cases, chronic lymphocytic leukemia and mantle cell lymphoma should be excluded. "Intranuclear" periodic acid-Schiff–positive inclusions (Dutcher-Fahey bodies) [122] consisting of IgM deposits in the perinuclear space, and sometimes in intranuclear vacuoles, may be seen occasionally in lymphoid cells. An increased number of mast cells, usually in association with the lymphoid aggregates, is commonly found, and their presence may help in differentiating WM from other B-cell lymphomas (see Fig. 33.3) [13]. MYD88^{L265P} testing of bone marrow samples has been incorporated into many clinical laboratories, and may help in clarifying the diagnosis of WM from other IgM-secreting entities [34–38]. The use of peripheral blood B cells may also permit determination of MYD88^{L265P} status by allele-specific polymerase chain reaction assays, particularly in untreated WM patients. CXCR4 mutation testing may also be useful in patients being considered for ibrutinib therapy (discussed below).

Immunologic Abnormalities

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75–80% of patients. More than one M-component may be present. The concentration of the serum monoclonal protein is very variable but in most cases lies within the range of 15–45 g/L. Densitometry should be adopted to determine IgM levels for serial evaluations because nephelometry is unreliable and shows large laboratory variation. The presence of cold agglutinins or cryoglobulins may affect determination of IgM levels and, therefore, testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed at 37 °C for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 h in only 3% of cases. Whereas IgM levels are elevated in WM patients, IgA and IgG levels are most often depressed and do not recover after successful treatment [123].

Serum Viscosity

Because of its large size (almost 1,000,000 daltons), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity [65]. Serum viscosity can be measured if the patient has signs or symptoms of hyperviscosity syndrome, though levels often slow to be resulted and erratic due to a lack of standardization in many clinical laboratories [15]. As such, serum IgM levels may be more expedient and relied upon. Patients typically become symptomatic at serum viscosity levels of 4.0 centipoise and above that relates to serum IgM levels above 6000 mg/dL [124, 125]. Patients may be symptomatic at lower serum viscosity and IgM levels, and in these patients cryoglobulins may be present. Recurring nosebleeds, headaches, and visual disturbances are common symptoms in patients with symptomatic hyperviscosity [15]. Funduscopy is an important indicator of clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity are the appearance of peripheral and midperipheral dot- and blot-like hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and scleral depression [69]. In more severe cases of hyperviscosity, dot-, blot-, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions resulting in "venous sausaging," as well as papilledema (Fig. 33.4).

Imaging

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis is useful in evaluating the disease status [126]. Marrow involvement can be documented by MRI studies of the spine in more than 90% of patients; CT of the abdomen and pelvis demonstrates enlarged nodes in approximately 20% of WM patients at diagnosis but may be higher at relapse [126].

Lymph Node Biopsy

Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns. Testing for MYD88 mutations may help.

Treatment

Initiating Treatment

As part of the Second International Workshop on Waldenstrom's macroglobulinemia, a consensus panel was organized to recommend criteria for the initiation of therapy in patients with WM [127]. The panel recommended that initiation of therapy should not be based on the IgM level per se, as this may not correlate with the clinical manifestations of WM. The consensus panel did, however, agree that initiation of therapy is appropriate for patients with constitutional symptoms, such as recurrent fever, night sweats, fatigue as a consequence of anemia, or weight loss. Progressive symptomatic lymphadenopathy and/or splenomegaly provide additional reasons to begin therapy. Anemia with a hemoglobin value of ≤10 g/dL or a platelet count of ≤100 × 10^9/L owing to marrow infiltration also justifies treatment. Certain complications, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, may also be indications for therapy [15, 127].

Initial Therapy

The International Workshops on Waldenström's Macroglobulinemia have also formulated consensus recommendations for both initial therapy and therapy for refractory disease based on the best available evidence. The most recent recommendations emerged from the Eighth International Workshop on WM [128]. Individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice of the drugs to use. For patients who are candidates for autologous stem cell transplantation, which typically is reserved for those patients younger than 70 years of age, the panel recommended that exposure to alkylating agents or nucleoside analogues should be limited. The use of nucleoside analogues should be approached cautiously in WM patients as there appears to be an increased risk for the development of disease transformation as well as myelodysplasia and acute myelogenous leukemia.

Oral Alkylating Agents

Oral alkylating drugs, alone and in combination therapy with glucocorticoids, have been extensively evaluated in the treatment of WM. Chlorambucil has been administered on both a continuous (i.e., daily-dose schedule) and an intermittent schedule. Patients receiving chlorambucil on a continuous schedule typically receive 0.1 mg/kg per day, whereas on the intermittent schedule patients typically receive 0.3 mg/kg for 7 days, every 6 weeks. In a prospective randomized study, no significant difference in the overall response rate between these schedules was observed [129], although the median response duration was greater for patients receiving intermittent- versus continuous-dose chlorambucil (46 versus 26 months). Despite the favorable median response duration in this study for use of the

intermittent schedule, no difference in the median overall survival was observed. Moreover, an increased incidence for development of myelodysplasia and acute myelogenous leukemia with the intermittent (3 of 22 patients) versus the continuous (0 of 24 patients) chlorambucil schedule prompted the preference for use of continuous chlorambucil dosing. The use of glucocorticoids in combination with alkylating agent therapy has also been explored. Chlorambucil (8 mg/m^2) plus prednisone (40 mg/m^2) given orally for 10 days, every 6 weeks, resulted in a major response (i.e., reduction of IgM by more than 50%) in 72% of patients [130]. Alkylating agent regimens employing melphalan and cyclophosphamide in combination with glucocorticoids have also been examined [131, 132]. This approach produced slightly higher overall response rates and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Pretreatment factors associated with shorter survival in the entire population of patients receiving single-agent chlorambucil were age older than 60 years, male sex, hemoglobin less than 10 g/dL, leukocytes less than 4×10^9/L, and platelets less than 150×10^9/L. Organomegaly, signs of hyperviscosity, renal failure, monoclonal IgM level, blood lymphocytosis, and percentage of marrow lymphoid cells were not significantly correlated with survival [133]. Additional factors to be taken into account in considering alkylating agent therapy for patients with WM include necessity for more rapid disease control given the slow response, as well as consideration for preserving stem cells in patients who are candidates for autologous stem cell transplantation therapy. A large randomized study showed an inferior response rate and time to progression in WM patients receiving chlorambucil versus fludarabine, as well as a higher incidence of secondary malignancies in the former. Neutropenia was however more pronounced in those patients on fludarabine [134].

Nucleoside Analogue Therapy

Cladribine administered as a single agent by continuous intravenous infusion, by 2-h daily infusion, or by subcutaneous bolus injections for 5–7 days has resulted in major responses in 40–90% of patients who received primary therapy, whereas in the previously treated patients, responses have ranged from 38 to 54% [135–141]. Median time to achievement of response in responding patients following cladribine ranged from 1.2 to 5 months. The overall response rate with daily infusion of fludarabine, administered mainly on 5-day schedules, in previously untreated and treated patients ranged from 38 to 100% and 30 to 40%, respectively [142–147], similar to the responses to cladribine. Median time to achievement of response for fludarabine (3–6 months) was also similar to cladribine. In general, response rates and durations of responses have been greater for patients receiving nucleoside analogues as initial therapy, although in several studies in which both untreated and previously treated patients were enrolled, no difference in the overall response rate was reported.

Myelosuppression commonly occurs following prolonged exposure to either of the nucleoside analogues. A sustained decrease in both CD4+ and CD8+ T lymphocytes, measured 1 year following initiation of therapy, is notable [135–137]. Treatment-related mortality as a consequence of myelosuppression and/or opportunistic infections attributable to immunosuppression occurred in up to 5% of all treated patients in some series with nucleoside analogues.

Factors predicting for a better response to nucleoside analogues include younger age at start of treatment (<70 years), higher pretreatment hemoglobin (>95 g/L), higher platelet count ($>75 \times 10^9$/L), disease relapsing off therapy, and a long interval between first-line therapy and initiation of a nucleoside analogue in relapsing patients [135, 140, 146]. There are limited data on the use of an alternate nucleoside analogue in previously treated patients among whom disease relapsed or who had resistance when not on cladribine or fludarabine therapy [148, 149]. Three of four (75%) patients responded to cladribine after progression following an unmaintained remission to fludarabine, whereas only one of ten (10%) with disease resistant to fludarabine responded to cladribine [148]. A response in two of six patients (33%) and disease stabilization in the remaining patients to fludarabine, in spite of an inadequate response or progressive disease, following cladribine therapy has been reported [149].

Harvesting autologous blood stem cells succeeded on the first attempt in 14 of 15 patients who did not receive nucleoside analogue therapy as compared to 2 of 6 patients who received a nucleoside analogue [150]. A sevenfold increase in transformation to an aggressive lymphoma and a threefold increase in the development of myelodysplasia or acute myelogenous leukemia were observed among patients who received a nucleoside analogue versus other therapies for their WM [151]. A meta-analysis of several trials in which patients were treated with nucleoside analogues in WM patients, included patients who had previously received an alkylating agent, and showed a crude incidence of approximately 8% for development of disease transformation and of approximately 5% for development of myelodysplasia or acute myelogenous leukemia [152]. None of the risk factors—that is, gender, age, family history of WM, or B-cell malignancies, typical markers of tumor burden and prognosis, type of nucleoside analogue therapy (cladribine versus fludarabine), time from diagnosis to nucleoside analogue use, nucleoside analogue treatment as primary or salvage therapy, or treatment with an oral alkylator (i.e., chlorambucil)—predicted for the occurrence of transformation or development of myelodysplasia or acute myelogenous leukemia in patients treated with a nucleoside analogue [152].

CD20-Directed Antibody Therapy

Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM [153]. Several retrospective and prospective studies have indicated that rituximab, when used at standard doses (i.e., 4-weekly infusions of 375 mg/m^2), induced major responses in approximately 30% of previously treated and untreated patients [154, 155]. Even patients who achieved minor responses benefited from rituximab by improved hemoglobin and platelet counts, and reduction of lymphadenopathy and/or splenomegaly [154]. The median time to treatment failure in these studies was found to range from 8 to 27+ months. Patients on an extended rituximab schedule consisting of 4-weekly courses at 375 mg/m^2 per week, repeated 3 months later by another 4-week course, have demonstrated major response rates of approximately 45%, with time to progression estimates of 16+ to 29+ months [156, 157].

In many WM patients, a transient increase or flare of the serum IgM may occur immediately following initiation of rituximab treatment [156, 158, 159]. Such an increase does not herald treatment failure and most patients will return to their baseline serum IgM level by 12 weeks. Some patients continue to show a prolonged increase in IgM despite an apparent reduction in their marrow tumor cells. However, patients with baseline serum IgM levels of >50 g/dL or serum viscosity of >3.5 cp may be particularly at risk for a hyperviscosity-related event and plasmapheresis should be considered in these patients in advance of rituximab therapy [158]. Because of the decreased likelihood of response in patients with higher IgM levels, as well as the possibility that serum IgM and blood viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity symptoms [128, 156, 157].

Time to response after rituximab is slow and exceeds 3 months on the average. The time to best response in one study was 18 months [157]. Patients with baseline serum IgM levels of <60 g/dL are more likely to respond, regardless of the underlying marrow involvement by tumor cells [156, 157]. An analysis of 52 patients who were treated with single-agent rituximab found that the objective response rate was significantly lower in patients who had either low serum albumin (<35 g/L) or a serum monoclonal protein greater than 40 g/L. [160] The presence of both adverse prognostic factors was associated with a short time to progression (3.6 months). Patients who had normal serum albumin and relatively low serum monoclonal protein levels derived a substantial benefit from rituximab with a time to progression exceeding 40 months.

A correlation between polymorphisms at position 158 in the FcγRIIIa receptor (CD16), an activating Fc receptor on important effector cells that mediate antibody-dependent cell-mediated cytotoxicity, and rituximab response was observed in WM patients [161]. Individuals may encode either the amino acid valine or phenylalanine at position 158 in the FcγRIIIa receptor. WM patients who carried the valine amino acid (either in a homozygous or in a heterozygous pattern) had a fourfold higher major response rate (i.e., 50% decline in serum IgM levels) to rituximab versus those patients who expressed phenylalanine in a homozygous pattern.

Proteasome Inhibitors

Both bortezomib and carfilzomib have been evaluated in prospective studies in patients with WM, though the latter only in combination therapy (discussed below). In a retrospective study, ten patients with refractory or relapsed WM were treated with bortezomib administered intravenously at a dose of 1.3 mg/m^2 on days 1, 4, 8, and 11 in a 21-day cycle for a total of four cycles. Most patients had been exposed to all active agents for WM and eight patients had received three or more regimens. Six of these patients achieved a partial response which occurred at a median of 1 month. The median time to progression in the responding patients is expected to exceed 11 months. Peripheral neuropathy occurred in three patients and one patient developed severe paralytic ileus in this series [162]. In a prospective study among 27 relapsed or refractory patients who received up to eight cycles of bortezomib at 1.3 mg/m^2 on days 1, 4, 8, and 11, median serum IgM levels declined significantly from 4.7 g/dL to 2.1 g/dL [32]. The overall response rate was 85%, with 10 and 13 patients achieving a minor (<25%) and major (<50%) decrease in IgM level. Responses occurred at a median of 1.4 months. The median time to progression for all responding patients in this study was 7.9 (range: 3–21.4+) months, and the most common grade III/IV toxicities were sensory neuropathies (22.2%), leukopenia (18.5%), neutropenia (14.8%), dizziness (11.1%), and thrombocytopenia (7.4%). Sensory neuropathies resolved or improved in nearly all patients following cessation of therapy. Twenty-seven patients with both untreated (44%) and previously treated (56%) disease received bortezomib, utilizing the standard schedule until they either demonstrated progressive disease or two cycles beyond a complete response or stable disease [163]. The overall response rate was 78%, with major responses observed in 44% of patients. Sensory neuropathy occurred in 20 patients following 2–4 cycles of therapy. Among the 20 patients developing a neuropathy, 14 showed resolution or improvement 2–13 months after therapy.

Combination Therapies

Because rituximab is not myelosuppressive, its combination with chemotherapy has been explored. A regimen of rituximab, cladribine, and cyclophosphamide used in 17 previously untreated patients resulted in a partial response in 94% of WM patients, including a complete response in 18% [161]. No patient had relapsed with a median follow-up of

21 months. The combination of rituximab and fludarabine used in 43 patients of whom 32 (75%) were previously untreated led to an overall response rate of 95.3%, with 83% of patients achieving a major response (i.e., 50% reduction in disease burden) [165]. The median time to progression was 51.2 months in this series, and was longer for those patients who were previously untreated and for those achieving a very good partial remission (i.e., 90% reduction in disease) or better. Hematologic toxicity was common: grade 3 neutropenia and thrombocytopenia observed in 27 and 4 patients, respectively. Two deaths occurred in this study from pneumonia. Secondary malignancies including transformation to aggressive lymphoma and development of myelodysplasia or acute myelogenous leukemia were observed in six patients in this series. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in previously treated patients, of whom four of five patients had a response [166]. In another combination study, rituximab along with pentostatin and cyclophosphamide given to 13 patients with untreated and previously treated WM or lymphoplasmacytic lymphoma resulted in a major response in 77% of patients [167]. The combination of rituximab, dexamethasone, and cyclophosphamide was used as primary therapy to treat 72 patients with WM in whom a major response was observed in 74% of patients in this study, and the 2-year progression-free survival was 67% [168]. Therapy was well tolerated, although one patient died of interstitial pneumonia.

Two studies have examined cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) in combination with rituximab (R-CHOP). In a randomized trial involving 69 patients, most of whom had WM, the addition of rituximab to CHOP resulted in a higher overall response rate (94% versus 67%) and median time to progression (63 versus 22 months) in comparison to patients treated with CHOP alone [169]. R-CHOP was also used in 13 WM patients, 10 of whom had relapsed or refractory disease [170]. Among 13 evaluable patients, 10 patients achieved a major response (77%), including 3 complete and 7 partial remissions. Two other patients achieved a minor response. In a retrospective study of symptomatic WM patients who received either R-CHOP; rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP) or cyclophosphamide, prednisone, and rituximab (R-CP) and were similar in most pretreatment variables, the overall response rates to therapy were comparable among all three treatment groups—R-CHOP (96%), R-CVP (88%), and R-CP (95%)—although there was a trend for more complete remissions among patients treated with R-CVP and R-CHOP [171]. Adverse events attributed to therapy showed a higher incidence for neutropenic fever and treatment-related neuropathy for R-CHOP and R-CVP versus R-CP. The results of this study suggest that in WM, the use of R-CP may provide analogous treatment responses to more intense cyclophosphamide-based regimens while minimizing treatment-related complications. The extended alkylator bendamustine has also been evaluated in combination with rituximab in both untreated and previously treated WM patients. A randomized study by the German STiL Group examined bendamustine plus rituximab (Benda-R) versus R-CHOP in patients with untreated, indolent B-cell lymphomas including WM [172]. Patients with WM in this study showed similar overall responses (96% versus 94%), though progression-free survival was significantly longer (69 versus 29 months) in patients who received Benda-R versus R-CHOP. Treatment was also better tolerated in patients receiving Benda-R. In the relapsed or refractory setting, an overall response rate of 83% was observed with bendamustine in combination with a CD20 monoclonal antibody [173]. The median time to progression was 13 months in this study. Prolonged myelosuppression was more common in patients who received prior nucleoside analogues.

The use of two cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM led to a partial response in 84% of patients and the median duration of response was 36 months [164]. Fludarabine in combination with intravenous cyclophosphamide resulted in partial responses in 6 of 11 (55%) WM patients with either primary refractory disease or who had relapsed on treatment [174]. The combination of fludarabine plus cyclophosphamide was also evaluated in 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients achieved a response, and the median time to treatment failure was 27 months [175]. Hematological toxicity was frequent, and three patients died of treatment-related toxicities. Two important findings in this study were the development of acute leukemia in two patients, histologic transformation to diffuse large B-cell lymphoma in one patient, and two cases of solid malignancies (prostate and melanoma), as well as failure to mobilize stem cells in four of six patients.

The combination of bortezomib, dexamethasone, and rituximab (BDR) as primary therapy in 23 patients with WM resulted in an overall response rate of 96%, and a major response rate of 83% [176]. Maintenance therapy with BDR was used in this study. The incidence of grade 3 neuropathy was approximately 30%, and led to discontinuance of bortezomib in 60% of patients on BDR. An increased incidence of herpes zoster was also observed prompting the prophylactic use of antiviral therapy. The median progression-free survival in this study was 66 months, and resolution of treatment-related neuropathy to at least grade 1 or less was observed in most (13/16; 81%) of the patients with prolonged follow-up [177].

Alternative schedules for administration of bortezomib (i.e., once weekly at higher doses) in combination with rituximab in patients with WM have achieved overall response rates of 80–90% [178, 179]. The European Myeloma Network (EMN) recently showed that transitioning bortezomib from twice-weekly intravenous dosing during the first

cycle to weekly administration thereafter reduced grade 3 neuropathy to under 10% in patients treated with BDR [180]. Overall, treatment was well tolerated and the overall response rate was 85% that included 68% major responders. The median PFS in this study was 43 months [181]. While subcutaneous bortezomib is also used to decrease the risk of treatment-related neuropathy with bortezomib, no formal studies addressing the safety and efficacy of subcutaneous bortezomib use in WM have been reported.

Carfilzomib is a proteasome inhibitor that is associated with a low risk of treatment-related peripheral neuropathy. The combination of carfilzomib with rituximab and dexamethasone (CaRD) was evaluated in WM patients [33]. Carfilzomib was administered intravenously at 20 mg/m^2 (cycle 1), and then 36 mg/m^2 (cycles 2–6), together with dexamethasone (20 mg) on days 1, 2, 8, and 9 as part of a 21-day cycle. As part of this regimen, rituximab 375 mg/m^2 was given on days 2 and 9 every 21 days. Maintenance therapy was given 8 weeks following induction therapy with intravenous carfilzomib (36 mg/m^2) and dexamethasone (20 mg) administered on days 1 and 2 and rituximab 375 mg/m^2 on day 2 every 8 weeks for up to eight cycles. Overall response rate with this regimen was 87% with major responses observed in 68% of patients, and was not impacted by MYD88^{L265P} or CXCR4^{WHIM} mutation status. With a median follow-up of 15.4 months, 20 patients remained progression free. Grade ≥2 toxicities included asymptomatic hyperlipasemia (41.9%), reversible neutropenia (12.9%), and cardiomyopathy in one patient (3.2%) with multiple risk factors. Treatment-related neuropathy occurred in one patient (3.2%) that was grade 2. Declines in serum IgA and IgG were common, and some patients required intravenous gamma globulin therapy for recurring sinus and bronchial infections.

Novel Therapeutics

The use of ibrutinib was recently approved by the United States Food and Drug Administration and the European Medicines Agency for the treatment of symptomatic patients with WM. Ibrutinib targets BTK and HCK, both targets of ibrutinib that are transactivated by MYD88^{L265P} [42, 48]. In a multicenter study that examined the role of ibrutinib in previously treated (median two prior therapies, 40% refractory) WM patients, the overall response rate was 91% [182]. Patients on this study received 420 mg a day of ibrutinib by mouth. Post-therapy, median serum IgM levels declined from 3610 to 880 mg/dL; hemoglobin rose from 10.5 to 13.8 g/dL, and bone marrow involvement declined from 60 to 25%. Decreased or resolved adenopathy was observed in 60% of patients with extramedullary disease, and five of nine patients with IgM-related PN had symptomatic improvement. At a median of 37 months of follow-up, the median progression-free and overall survival was 68% and 90%, respectively. Major responses were absent in patients with wild-type MYD88, and slower response kinetics were observed in those patients who were both MYD88 and CXCR4 mutated. Major response rates were also lower in those patients with CXCR4 mutations (62%) versus those with wild-type CXCR4 (92%). Grade ≥2 treatment-related toxicities included neutropenia (25%) and thrombocytopenia (14%) that were more common in heavily pretreated patients; atrial fibrillation associated with a prior history of arrhythmia (5%); and bleeding associated with procedures and marine oil supplements (3%). Serum IgA and IgG levels were unchanged following treatment with ibrutinib, and treatment-related infections were infrequent. A multicenter trial also examined the activity of ibrutinib in rituximab-refractory WM patients who had a median of four prior therapies. The overall response rate in this study was 90%, with major responses observed in 71% of patients. With a median follow-up of 18 months, the median progression-free and overall survival was 86 and 97% [183]. Delays in serum IgM and hemoglobin responses were observed among MYD88-mutated patients with CXCR4 mutations, versus those who were wild-type for CXCR4. One patient with wild-type MYD88 did not respond. A clinical study of the CXCR4 antagonist ulocuplumab with ibrutinib is being initiated in symptomatic WM patients with CXCR4 mutations.

Everolimus is an oral inhibitor of the mTOR pathway that is active in WM. A multicenter study examined everolimus in 60 previously treated patients that showed an ORR of 73%, with 50% of patients attaining a major response [184]. The median progression-free survival in this study was 21 months. Grade 3 or higher related toxicities were observed in 67% of patients with cytopenias constituting the most common toxicity. Pulmonary toxicity occurred in 5% of patients, and dose reductions due to toxicity occurred in 52% of patients. A clinical trial examining the activity of everolimus in 33 previously untreated patients with WM has also been reported that included serial bone marrow biopsies in response assessment [185]. The ORR in this study was 72%, including partial or better responses in 60% of patients. Among genotyped patients, nonresponders associated with wild-type MYD88 and mutated CXCR4 status. Median time to response was 4 weeks. Discordance between serum IgM levels and bone marrow disease burden was remarkable. The median time to progression was 21 months for all patients, and 33 months for major responders. Discontinuation of everolimus led to rapid serum IgM rebound in seven patients and symptomatic hyperviscosity in two patients. Toxicity led to treatment discontinuation in 27% of patients, including 18% for pneumonitis which appeared more pronounced versus previously treated WM patients.

Maintenance Therapy

The outcome of rituximab-naïve patients who were either observed or received maintenance rituximab categorical responses was examined in a large retrospective study [186]. Categorical responses improved after induction therapy in 42% of patients who received maintenance rituximab versus 10% in patients on observation. Additionally, both progression-free (56.3 versus. 28.6 months) and overall survival (>120 versus 116 months) were longer in patients who

received maintenance rituximab. Improved progression-free survival was evident despite previous treatment status, induction with rituximab alone or in combination therapy. Best serum IgM response was also lower, and hematocrit higher in those patients who received maintenance rituximab. Among patients who received maintenance rituximab therapy, an increased number of infectious events, predominantly grade 1 or 2 sinusitis and bronchitis, were observed, along with lower serum IgA and IgG levels. A prospective study examining the role of maintenance rituximab has also been initiated by the German STiL group [187]. In this study, patients received up to six cycles of bendamustine and rituximab, and responders randomized to either observation or maintenance rituximab every 2 months for 2 years. Enrollment for this study is complete, and response outcome for maintenance rituximab therapy is awaited.

High-Dose Therapy and Stem Cell Transplantation

The European Bone Marrow Transplant Registry reported the largest experience for both autologous and allogeneic SCT in WM [188, 189]. Among 158 WM patients receiving an autologous SCT, which included primarily relapsed or refractory patients, the 5-year progression-free and overall survival rate was 39.7% and 68.5%, respectively [188]. Non-relapse mortality at 1 year was 3.8%. Chemorefractory disease and the number of prior lines of therapy at time of the autologous SCT were the most important prognostic factors for progression-free and overall survival. In the allogeneic SCT experience from the EBMT, the long-term outcome of 86 WM patients was reported [189]. A total of 86 patients received allograft by either myeloablative or reduced-intensity conditioning. The median age of patients in this series was 49 years, and 47 patients had three or more previous lines of therapy. Eight patients failed prior to autologous SCT. Fifty-nine patients (68.6%) had chemotherapy-sensitive disease at the time of allogeneic SCT. Non-relapse mortality at 3 years was 33% for patients receiving a myeloablative transplant, and 23% for those who received reduced-intensity conditioning. The overall response rate was 75.6%. The relapse rates at 3 years were 11% for myeloablative, and 25% for reduced-intensity conditioning recipients. Five-year progression-free and overall survival for WM patients who received a myeloablative allogeneic SCT were 56% and 62%, and for patients who received reduced-intensity conditioning were 49% and 64%, respectively. The occurrence of chronic graft-versus-host disease was associated with improved progression-free survival, and suggested the existence of a clinically relevant graft-versus-WM effect in this study.

Response Criteria in Waldenstrom's Macroglobulinemia

Table 33.3 summarizes the response categories and criteria for progressive disease in WM based on the most recent consensus recommendations [190]. The term "overall response" is used to characterize all responses, including minor

Table 33.3 Summary of consensus response criteria for Waldenstrom's macroglobulinemia [190]

Complete response	CR	Absence of serum monoclonal IgM protein by immunofixation
		Normal serum IgM level
		Complete resolution of extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline
		Morphologically normal bone marrow aspirate and trephine biopsy
Very Good Partial Response	VGPR	Monoclonal IgM protein is detectable
		90% reduction in serum IgM level from baseline, or normalization of serum IgM level
		Complete resolution of extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline
		No new signs or symptoms of active disease
Partial Response	PR	Monoclonal IgM protein is detectable
		≥50% but <90% reduction in serum IgM level from baseline
		Reduction in extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline
		No new signs or symptoms of active disease
Minor response	MR	Monoclonal IgM protein is detectable
		≥25% but <50% reduction in serum IgM level from baseline
		No new signs or symptoms of active disease
Stable disease	SD	Monoclonal IgM protein is detectable
		<25% reduction and <25% increase in serum IgM level from baseline
		No progression in extramedullary disease, i.e., lymphadenopathy/splenomegaly
		No new signs or symptoms of active disease
Progressive disease	PD	>25% increase in serum IgM level from lowest nadir (requires confirmation) and/or progression in clinical features attributable the disease

responses. "Major responses" only include partial, very good partial, and complete responses. The attainment of very good partial or complete responses is associated with improved progression-free survival [165, 176, 180, 188, 191]. Response assessments in WM rely primarily on serum IgM or IgM paraprotein levels, though complete responses require disappearance of the IgM monoclonal protein, and resolution of bone marrow and/or extramedullary WM disease [190]. An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate, independent of tumor cell killing with some agents. By way of example, rituximab can induce a flare in serum IgM levels, whereas everolimus, bortezomib, and ibrutinib can suppress IgM levels independent of tumor cell killing in some patients, a finding referred to as IgM discordance [32, 156, 158, 159, 182, 185, 192]. Moreover, with selective B-cell-depleting agents such as rituximab and alemtuzumab, residual IgM-producing plasma cells are spared and continue to persist, thus potentially skewing the relative response and assessment to treatment [193]. Soluble CD27 levels have been investigated as an alternative surrogate marker in WM given their correlation with WM disease burden, and may remain a faithful marker of disease in patients experiencing a rituximab-related IgM flare, as well as after plasmapheresis [194]. The use of quantitative allele-specific polymerase chain reaction assays to assess serial MYD88^{L265P} burden in WM patients is also under investigation [35, 37, 195].

Course and Prognosis

WM typically presents as an indolent disease. The presence of 6q deletions may have prognostic significance, but does not appear to impact overall survival [29, 196, 197]. Age is an important prognostic factor (>65 years) [198–200], but is influenced by comorbidities. Anemia that reflects both marrow involvement and serum level of the IgM monoclonal protein (because of the impact of IgM on intravascular fluid retention) has emerged as a strong adverse prognostic factor with hemoglobin levels of <9 to 12 g/dL associated with decreased survival in several series [145, 198–200]. Other cytopenias also may be significant predictors of survival, and the number of cytopenias in a given patient has been proposed as a prognostic factor [199]. Serum albumin levels have also correlated with survival in some studies in WM patients [199, 200]. Elevated serum β_2-microglobulin levels (>3–3.5 g/dL) have also shown strong prognostic correlation in WM [145, 200, 201]. Several scoring systems have been proposed based on these analyses (Table 33.4), including the WM International Prognostic Scoring System (WM IPSS) which incorporates five adverse covariates: advanced age (>65 years), hemoglobin less than or equal to 11.5 g/dL, platelet count less than or equal to 100 × 10^9/L, beta2-microglobulin more than 3 mg/L, and serum monoclonal protein concentration more than 7.0 g/dL [202]. Among

Table 33.4 Prognostic scoring systems in Waldenstrom's macroglobulinemia

Study	Adverse prognostic factors	Number of groups	Survival
Gobbi et al. [198]	Hgb <9 g/dL	0–1 prognostic factors	Median: 48 months
	Age > 70 years	2–4 prognostic factors	Median: 80 months
	Weight loss		
	Cryoglobulinemia		
Morel et al. [199]	Age ≥ 65 years	0–1 prognostic factors	5 years: 87% of patients
	Albumin <4 g/dL	2 prognostic factors	5 years: 62%
	Number of cytopenias:	3–4 prognostic factors	5 years: 25%
	Hgb <12 g/dL		
	Platelets <150 × 10^9/L		
	WBC <4 × 10^9/L		
Dhodapkar et al. [147]	β_2M ≥ 3 g/dL	β_2M < 3 mg/dL + Hgb ≥12 g/dL	5 years: 87% of patients
	Hgb <12 g/dL	β_2M < 3 mg/dL + Hgb <12 g/dL	5 years: 63%
	IgM <4 g/dL	β_2M ≥ 3 mg/dL + IgM ≥4 g/dL	5 years: 53%
		β_2M ≥ 3 mg/dL + IgM <4 g/dL	5 years: 21%
Application of international staging system criteria for myeloma to WM Dimopoulos et al. [200]	Albumin ≤3.5 g/dL	Albumin ≥3.5 g/dL + β_2M < 3.5 mg/dL	Median: NR
	β_2M ≥ 3.5 mg/L	Albumin ≤3.5 g/dL + β_2M < 3.5 or	Median: 116 months
		β_2M 3.5–5.5 mg/dL	Median: 54 months
		β_2M > 5.5 mg/dL	
International Prognostic Scoring System for WM Morel et al. [202]	Age > 65 year	0–1 prognostic factors (excluding age)	5 years: 87% of patients
	Hgb <11.5 g/dL	2 prognostic factors (or age > 65 years)	5 years: 68%
	Platelets <100 × 10^9/L	3–5 prognostic factors	5 years: 36%
	β_2M > 3 mg/L		
	IgM >7 g/dL		

β_2M β_2-microbloulin, *Hgb* hemoglobulin, *NR* not reported, *WBC* white blood cell count

537 WM patients evaluated in the development of WM IPSS, low-risk patients (27%) presented with no or one of the adverse characteristics and advanced age, intermediate-risk patients (38%) with two adverse characteristics or only advanced age, and high-risk patients (35%) with more than two adverse characteristics. Five-year survival rates for these patients were 87%, 68%, and 36%, respectively. Importantly, the WM IPSS retained its prognostic significance in subgroups defined by age, treatment with alkylating agent, and nucleoside analogues. Recent data from the Surveillance, Epidemiology, and End Results (SEER) database involving 7744 WM patients showed that the relative survival of WM patients has improved over time [203]. Patients diagnosed during 2001–2010 had higher 5-year (78% versus 67%) and 10-year (66% versus 49%) relative survival rates versus patients diagnosed during 1980–2000. A Greek study that included 345 patients with WM failed to show any overall or cause-specific survival improvement in recent years, though the study might have been underpowered to detect any expected benefit [204]. However, a Swedish study of 1555 patients diagnosed with WM between 1980 and 2005 showed that the 5-year relative survival rate improved from 57% in 1980–1985 to 78% in 2001–2005 [205].

34 Plasma Cell Leukemia

Nisha S. Joseph and Sagar Lonial

Introduction

Plasma cell leukemia (PCL) is a rare and aggressive variant of multiple myeloma that comprises roughly 1% of all myeloma cases [1]. This unique plasma cell dyscrasia is characterized by an increased number of circulating plasma cells in the peripheral blood. It can either arise de novo, as is the case in primary plasma cell leukemia (pPCL), or alternatively as a transformed leukemic phase in an end-stage previously diagnosed case of myeloma.

PCL was first described in 1906 by Professor Gluzinski and Dr. Reichenstein at the University Hospital of Lemberg, now located in present-day western Ukraine [2]. The authors reported a case of a 47-year-old male presenting with bone pain, a palpable chest wall mass, anemia, and splenomegaly. Diagnostic workup revealed elevated urine protein and immature plasma cells on the peripheral blood smear. Plasma cells were elevated at 91% in the blood, and the patient was subsequently diagnosed with multiple myeloma and "leucaemia lymphatica plasmocellularis." He was treated with arsenic-based compounds with an initial reprieve in symptoms; however the patient eventually succumbed to his disease and passed away within 6 months. Unfortunately, despite the significant progress we have seen in multiple myeloma, the prognosis of PCL has not changed much since its initial discovery.

Though the myeloma community has experienced significant advancements and progress in outcomes with the advent of novel therapeutic agents such as bortezomib and lenalidomide, followed by high-dose therapy (HDT) and autologous stem cell transplantation (ASCT), unfortunately the same success has not yet been achieved in PCL. Historically, the use of conventional chemotherapeutics such as alkylating agents, anthracyclines, and steroids in PCL has proven ineffective. The prognosis remains poor, with even worse outcomes observed in patients with sPCL. Utilization of HSCT has improved survival, but still has not achieved lasting results. With such significant success of novel agents in MM, this area warrants further exploration in PCL. The literature in this subject area is limited and our knowledge base is mainly restricted to findings from small retrospective studies and case reports. Furthermore, these studies often do not differentiate between pPCL and sPCL or between younger and older patients, making extrapolation of data to the clinical setting difficult. In this chapter, we review the clinical presentation and diagnostic evaluation of plasma cell leukemia, review the data available to date about optimal treatment options for PCL, as well as discuss future directions in research for this challenging disease.

Epidemiology

The epidemiology of PCL is very similar to that of multiple myeloma. The median age of diagnosis is 67. Primary PCL (pPCL) is more common than secondary PCL (sPCL), accounting for 60–70% of cases. Per the SEER database that surveyed patients between the years of 1973 and 2004, 291 patients with PCL were identified out of the 49,000 multiple myeloma patient in sum making the incidence of PCL 0.6%. There were no significant differences between gender, age, or race as compared with myeloma patients. Of note, this database did not distinguish between primary and secondary PCL [3].

Clinical Presentation

The clinical presentation of PCL is also very similar to that seen in patients with myeloma and leukemia. As in myeloma, many patients present with renal insufficiency, anemia, hypercalcemia, and bone pain associated with lytic lesions;

similarly, as seen in patients with leukemia, PCL patients often present with coagulopathy, cytopenias, and hepatosplenomegaly. Other physical exam findings can include lymphadenopathy, pleural effusions, and neurologic symptoms secondary to CNS involvement. Compared with multiple myeloma, patients presenting with pPCL are more likely to have an aggressive presentation including increased tumor burden, extramedullary disease, renal involvement, and cytopenias [3].

Diagnosis

The diagnostic criteria for PCL are not clearly defined or universally agreed upon, but the diagnostic workup for a suspected case of PCL is essentially the same for that of multiple myeloma and would include peripheral blood smear, a bone marrow aspirate and biopsy, serum and urine protein electrophoresis, free light chain assay, skeletal survey, as well as chemistry panel, complete blood count with differential, and β2-microglobulin. Additional imaging and diagnostic tests such as lumbar puncture, cross-sectional imaging, or PET-CT may also be needed depending on symptoms and potential concern for extramedullary involvement. On physical examination, particular attention should be paid to bone pain, neurologic symptoms, and pleural effusions (Table 34.1).

The diagnosis of PCL must include an absolute plasma cell count >2 × 10^9/L in addition to greater than 20% circulating plasma cells of the white blood cell differential in the peripheral blood. On review of a peripheral blood smear, detection of circulating plasma cells can often be difficult morphologically as the appearance of the plasma cell can vary depending on the stage of maturity. Commonly, flow cytometry is used to confirm the diagnosis and identify the malignant clone of plasma cells. As with myeloma cells, CD138 and CD38 are often expressed whereas CD19 and CD20 are absent, and unlike myeloma, CD56 is often not expressed [4, 5].

Table 34.1 Initial diagnostic workup for plasma cell leukemia

Lumbar puncture (CNS symptoms)
Imaging (As indicated)
MRI
CT scan
PET-CT

Bone marrow aspiration with biopsy is part of the diagnostic workup for pPCL for morphology and cytogenetic analysis by FISH. In PCL, pathologic review often shows an elevated number of monoclonal plasma cells with extensive infiltration of the marrow and high proliferation index. Of note, the median plasma cell percentage is higher in pPCL than in myeloma [6]. Additionally, biologic differences are seen between the myeloma plasma cell and the plasma cell seen in PCL. In PCL, malignant cells proliferate in the bone marrow as in myeloma; however these cells have an increased capacity for release into the peripheral circulation due to different expression of adhesion markers, namely NCAM (neural cell adhesion molecule/CD56) and LFA-1 (leukocyte function-associated antigen-1). Additionally, there is different expression of chemokine receptors and other genetic abnormalities that allow even more pronounced independent growth, evasion of immune detection, and prevention of apoptosis [6]. These genetic abnormalities are also seen in myeloma cells, though they tend to accumulate throughout the progression from MGUS to symptomatic myeloma, whereas in PCL, they are present at the onset. These differences may explain the extramedullary disease seen in PCL and superior evasion from immune surveillance.

Cytogenetic testing is routinely done in plasma cell dyscrasias as part of risk stratification and more recently for staging purposes. Analysis is focused on high-risk mutations such as del(17p13), del(13q), del(1p21), and amp(1q21) as well as translocations t(11;14), t(14;16), t(4;14), and t(14;20). Heavy gene translocations and hyperdiploidy are both significant oncogenic events key in the transformation to a malignant plasma cell and are seen in PCL as well. There are no distinguishable genetic features seen in PCL as compared to myeloma, but the same high-risk mutations seen in myeloma tend to occur at higher rates. Hyperdiploidy, conversely, is only found in up to 8.8% of pPCL cases whereas it is seen in ~50% of myeloma cases. This same trend is seen in sPCL, although hyperdiploidy is seen at an even higher rate (~17%) [6–9]. IgH translocations occur at a significantly higher rate in pPCL. The most commonly seen translocation in PCL is t(11;14) which used to be thought of as a favorable prognosticator in myeloma and is now more likely to be a neutral finding; however in PCL, t(11;14) is associated with

an unfavorable prognosis. The translocations t(4;14) and t(14;16) associated with poor risk in myeloma are seen in both primary and secondary PCL but at higher frequencies [3]. In PCL, an increased incidence of monosomy 13 (86% versus 26%) and a decreased incidence of trisomy 6 and monosomy 9 are seen. Additionally, it is more common to have a complex karyotype.

The differential diagnosis should include diagnoses that would also be defined by abnormal circulating cells like leukemias/lymphomas, though this can easily be distinguished with flow cytometry. It is also imperative to exclude a reactive polyclonal plasmacytosis that can be seen with bacterial or viral infections, autoimmune disorders, and serum sickness. A polyclonal plasmacytosis can be ruled out by confirming light-chain restriction on immunofixation.

Treatment

There have only been two prospective randomized trials conducted to date and these were conducted quite recently. Most of our information regarding optimal treatment in PCL is drawn from small retrospective studies and case reports; thus we have limited evidence-based data on which to base treatment decisions. For initial cytoreduction, in younger fit patients, historically aggressive chemotherapeutic regimens such as VAD and VDT-PACE were favored followed by ASCT versus chemotherapy alone in transplant-ineligible patients [10]. In the era of novel therapeutics, efforts have focused on utilization of these agents, namely lenalidomide and bortezomib (Table 34.2). These agents have shown to provide benefit but not as pronounced as in myeloma. Nevertheless, utilization of immunomodulatory agents and proteasome inhibitors has become standard of care in PCL.

Lenalidomide

The first prospective trial evaluating the optimal initial treatment in pPCL was conducted by Musto et al. and specifically studied the efficacy of lenalidomide in combination with low-dose dexamethasone in newly diagnosed pPCL. The study selected newly diagnosed pPCL patients with a performance status of 0–2, who then received lenalidomide 25 mg daily for 21 days with oral dexamethasone 40 mg given on days 1, 8, 15, and 22 on a 28-day cycle. After completion of four cycles, transplant-ineligible patients continued on with four additional cycles followed by maintenance lenalidomide at 10 mg daily on days 1–21 of a 28-day cycle until evidence of relapsed disease. Transplant-eligible patients proceeded to ASCT following four cycles of lenalidomide and dexamethasone. Patients who did not respond or progressed on initial treatment were taken off study. On intention-to-treat analysis, the overall response rate was 73.9%, and at a median follow-up of 34 months, median PFS and median overall survival were 14 and 28 months, respectively. Additionally, in evaluating the role of ASCT in treatment, PFS and OS were 27 months and not reached, respectively, in the cohort who underwent ASCT in comparison to PFS and OS of 2 and 12 months, respectively, for those patients who were transplant ineligible. Important conclusions from this study include demonstration of lenalidomide and dexamethasone as a valid frontline therapy in pPCL, as well as the important role consolidative ASCT may play as part of the larger treatment plan [11].

Bortezomib

There have been several studies that supported bortezomib-containing regimens followed by auto-SCT. Bortezomib has been shown to quickly reduce tumor volume and reverse

Table 34.2 Induction regimens for plasma cell leukemia

Author, year	*N*	Regimen	Median f/u	Best response			PFS (m)	OS (m)	ORR

end-organ damage, namely renal dysfunction. It has also been shown to overcome the negative implication of high-risk mutations such as del17p and t(4;14) [6].

The first prospective trial to date investigating the utilization of bortezomib-based regimens (BBR) in PCL was a prospective phase two clinical trial conducted by the IFM in 2016. The aim of the study was to evaluate the efficacy of induction regimens combining both standard chemotherapy with bortezomib in conjunction with HDT and autologous stem cell transplant followed by immunomodulatory agent and/or proteasome inhibitor maintenance versus a second allogeneic transplant [12]. Forty patients were enrolled and age 70 or younger and were treated with four alternating cycles of VAD and VCD followed by ASCT. Younger, fit patients then underwent a consolidative reduced-intensity allogeneic transplant, and the remainder of patients underwent a second ASCT followed by maintenance with RVD (lenalidomide, bortezomib, and dexamethasone) for 1 year. At a median follow-up of 28.7 months, the median PFS was 15.1 months and median overall survival was 36.3 months. The overall response rate to bortezomib-containing induction was 69%. This was the first prospective trial in PCL that demonstrated that bortezomib-containing induction regimens followed by transplant led to better response rates and improved PFS.

There have been several retrospective analyses published regarding use and efficacy of bortezomib-based regimens in PCL. The largest multicenter retrospective study comes from the Italian GIMEMA working group that focused on 29 patients with pPCL who received bortezomib in varying combination regimens with other therapeutics such as dexamethasone, thalidomide, doxorubicin, melphalan, prednisone, vincristine, or cyclophosphamide. The overall response rate was ORR 79%, with 38% of subjects achieving a VGPR or better. At a median follow-up time of 24 months, 55% of these patients were living and three-quarters of these patients were in remission. The most lasting results were seen in those who had undergone HSCT following induction. Additionally, improvement in renal function was seen in 10 of the 11 patients who had presented initially with renal failure, highlighting the benefit of bortezomib particularly in those with renal dysfunction at diagnosis [13].

Another multicenter retrospective study analyzed 128 patients with plasma cell leukemia, 73 of which were classified as primary plasma cell leukemia, from January 2000 to December 2008. In this group of patients who were treated with either alkylators, anthracycline-based regimens, or bortezomib/thalidomide used as additional or single agents, it was concluded that those patients receiving thalidomide or bortezomib as first-line therapy experienced and increased duration of response by 79% [14].

Katodritou and colleagues conducted another retrospective study with the purpose of examining the efficacy of bortezomib-based regimens in 42 PCL patients, 25 with pPCL, and 17 with sPCL. BBR were given to 29 of the patients, and 6 of the 25 patients with pPCL underwent ASCT. Response rates, being defined as a PR or better, were higher in patients treated with BBR (69% versus 30.8% in those that were treated with other regimens). The ORR of pPCL treated with BBR was 88.9%, which was the highest ORR seen in the varying cohorts. With a median follow-up of 51 months, median overall survival of the BBR group was 13 versus 2 months. Between the pPCL and sPCL, median overall survival differed by 18 and 7 months. Of note, improved response rates were seen regardless of ASCT and showed treatment of PCL with BBR induces better response rates [15].

Finally, another retrospective study done by the Italian group examined patients with either primary or secondary PCL who were treated with BBR either alone or in combination with other therapies. Twelve patients were included, three of whom received bortezomib as frontline treatment, and the remaining nine patients received bortezomib after 1–4 prior lines of treatment. Important findings included an overall response rate of 92% with 50% of patients achieving VGPR or better. The median PFS and median overall survival after bortezomib were 8 and 12 months, respectively [16].

The role of immunomodulatory agents and proteasome inhibitors in PCL is promising and needs to be further explored. Additionally, combinations of these agents, which have only been studied in small patient samples, have potential and call for further study as well.

Role of Transplant

In 1983, Dr. Mcelwain and Dr. Powell in the United Kingdom first described the use of melphalan 140 mg/m^2 in a patient with pPCL, and impressively, the patient lived for 30 months after therapy [17]. HDT followed by ASCT has become the standard of care in multiple myeloma, but its role is not as well defined in PCL. Prospective randomized trials to date of HCT have excluded PCL patients. There are some case reports that have noted improved outcomes and long-term responses with ASCT/allo-SCT. The following are some of the more significant studies published regarding the role of HCT in PCL, which suggest that HCT have a role in PCL treatment; however it becomes difficult to draw definitive conclusions given the lack of randomization and no comparison of allogeneic versus autologous transplantation.

The largest retrospective study to date reviewing the role of HCT in PCL was conducted by the European Group for

Blood and Marrow Transplantation. The study identified 272 pPCL patients and compared outcomes following autologous stem cell transplant with over 20,000 myeloma patients between the years of 1980 and 2006 [18]. The median PFS following transplant of PCL versus myeloma patients was 14.3 months versus 27.4 months, and the medial overall survival was 25.7 months versus 62.3 months, respectively. Significantly improved outcomes were seen in myeloma patients, and there was higher transplant-related mortality seen in the pPCL group as well.

The Center for International Blood and Marrow Transplant Research (CIBMTR) led another large retrospective study published in 2012. Of 147 patients with pPCL, 97 underwent autologous transplant and 50 underwent allogeneic HCT. Significant findings include the following: a median PFS of 34%, median overall survival at 3 years was 64% versus 39%, and relapse rate at 3 years was 61% versus 38% in the autologous group versus allogeneic group, respectively. Though the relapse rate was significantly lower with allogeneic transplant, transplant-related mortality was significantly higher (41% versus 5% in the autologous transplant cohort). Given better OS with autologous transplant in light of increased mortality associated with allogeneic transplant, this study supported use of ASCT with improved outcomes and decreased toxicities [19].

Another multicenter retrospective analysis performed by Pagano et al. looked at 73 patients with pPCL. In those patients who had undergone HSCT, they experienced longer overall survival and duration of response at 83.1 and 25.8 months, respectively, in contrast to 9.1 and 7.3 months seen in non-transplanted patients. Impressively, this analysis revealed an increase in mean overall survival by 69% and duration of response by 88%; however though this study supported use of HSCT, it unfortunately did not differ between autologous and allogeneic transplantation.

Prognosis

In general, the prognosis for PCL remains poor. These dismal outcomes are likely attributable to the increased incidence of the same high-risk mutations seen in myeloma, namely del17p, t(14;16), and t(4;14). As in myeloma, these mutations are noted to be of high risk due to the more aggressive nature and higher proliferative rate of these malignant cells. Mean overall survival is less than 1 year, and even worse in those patients with secondary PCL in the context of relapsed/refractory multiple myeloma. There has been modest improvement in outcomes with incorporation of ASCT in conjunction with novel agents. This is best demonstrated by a registry study including 445 patients which shows improved median survival from decade to decade, particularly when entering the early 2000s which encompasses the time period when novel agents were introduced in myeloma. Median survival through the decades trended as follows: from 1973 to 1995 median overall survival was 5 months, from 1996 to 2000 median overall survival was 6 months, from 2001 to 2005 median overall survival was 4 months, and then notably from 2006 to 2009 median overall survival improved to 12 months [20]. The most significant improvement has been seen in older patients, with early mortality decreasing from rate of 26 to 15% since the 1970s. Additional prognostic value can be drawn from patient's response to treatment. In those whose disease does not respond to initial therapy, prognosis is generally only a few months. Response to induction is defined as at least 50% reduction in circulating plasma cells within the first 10 days of treatment or complete clearance within 1 month [21].

Future Directions

There continues to be significant advances and study of novel therapeutics for multiple myeloma, and this provides the opportunity for continued study in the PCL subset. There are numerous ongoing clinical trials, some of which include study of efficacy of newer proteasome inhibitors (carfilzomib and ixazomib), peptide vaccines, second-generation immunomodulatory agent pomalidomide in combination with ixazomib, and the kinesin spindle inhibitor ARRY-520, among several others (Table 34.3). Future areas for exploration also include investigating monoclonal antibodies elotuzumab and daratumumab and utility of CAR T-cells. Of note, a new phase two prospective trial for pPCL being conducted by the European Myeloma Network is currently under way. The study looks at the use of carfilzomib in combination with lenalidomide and dexamethasone (KRD), followed by autologous transplant, then a second autologous transplant versus a non-myeloablative allogeneic transplant, and finally maintenance therapy with carfilzomib and lenalidomide. The findings of this study are eagerly anticipated and will provide further insight into the efficacy of these newer agents.

Table 34.3 Future directions for therapy in PCL: current therapeutic options being actively studied in clinical trials for PCL as single-agent and/or combination regimens

Carfilzomib (second-generation proteasome inhibitor)
Ixazomib (third-generation proteasome inhibitor)
Pomalidomide (second-generation immunomodulatory agent)
Peptide vaccines
CAR T-Cells
Venetoclax (BCL-2 inhibitor)
ARRY-520 (kinesin spindle inhibitor)
Elotuzumab, daratumumab (monoclonal antibodies)

35 Prognosis of Myeloma/Genetics of Myeloma

Sébastien Robiou-Du-Pont, Jill Corre, and Hervé Avet-Loiseau

Multiple myeloma (MM) is a very heterogeneous disease. This heterogeneity is observed at all the levels: clinical, biological, and molecular. This heterogeneity translates in extremely variable length of survival, from a few weeks to more than 15 years, and even cure. MM is probably the cancer for which the highest number of prognostic parameters have been described. These prognostic factors can be divided in three parts: related to the patient's conditions, related to disease burden, and related to the tumor clone itself.

Prognostic Parameters

Patient's Conditions

The first parameter is age. As for many diseases, patients diagnosed at an earlier age display a better outcome. Several factors contribute to this survival variability. Older patients more frequently present comorbidities (cardiac, renal, pulmonary, hepatic) which could prevent the optimal delivery of therapy. Another major parameter is related to the treatment schema. It has been shown that high-dose melphalan, with autologous stem cell rescue, improved at least the progression free survival (PFS), and even overall survival (OS). However, this intensive approach is not feasible in the oldest population. Historically, the cutoff has been set at 65 years of age. With the improvement of patients' condition, it is now currently set at 70 years. All these parameters translate in a shorter OS in elderly patients, in the 5–6 years range.

Tumor Burden

As in many cancers, the clinical stage is associated with outcome. In MM, this fact has been shown by Durie and Salmon [1]. Their staging system correlated with the tumor burden, even if this system is currently abandoned for prognosis assessment. The tumor burden is reflected, at least partially, by the serum β2-microglobulin level [2]. This protein is expressed at the surface of the malignant plasma cells, and is shed by proteases, and released in the serum. The outcome is linearly correlated with the β2-microglobulin levels, the highest levels being associated with the shortest survivals. This serum level is also correlated with renal function, since the protein is eliminated via the kidney. Whether the level of β2-microglobulin is prognostic in case of renal failure is still a matter of debate. β2-Microglobulin level is the basis of the International Staging System (ISS), in association with the serum albumin level (Table 35.1) [3]. This system divides the patients in three groups, with very significant differences in both PFS and OS, independently of age and treatment approach. Other parameters have been linked to the tumor burden, and especially the bone marrow involvement. Even though the mechanisms of anemia and thrombocytopenia are probably very complex in MM, it has been clearly shown that both factors were associated with a shorter OS [4].

Table 35.1 International staging system

ISS 1	β2m < 3.5 mg/L and Albumin ≥35 g/L
ISS 2	All other cases
ISS 3	β2m > 5.5 mg/L

β2m = β2-microglobulin

Tumor Clone

Several characteristics of the tumor clone are associated with outcome. First, extra-medullary localizations are clearly associated with shorter survival. This is particularly obvious in the case of primary plasma cell leukemias, with a median OS of less than two years [5]. The causes of these extra-medullary developments are poorly understood, and might be related to the default of bone marrow homing factors expression. The second parameter is the tumor proliferation. It can be evaluated by the plasma cell labeling index (assessed by flow cytometry), or by conventional cytogenetics [6, 7]. High proliferation correlates with shorter survival. But the most important prognostic factor is certainly genetics, meaning the chromosomal/molecular abnormalities observed in the tumor plasma cells.

Genetics

Myeloma is characterized by many chromosomal changes [8]. Even though conventional karyotypes are often normal (because of the low proliferative index of the tumor plasma cells), analyses based on SNP array did show that the large majority of patients present chromosomal changes, with usually complex molecular karyotypes. Multiple myeloma can be divided in two groups based on ploidy, i.e., hyperdiploidy and non-hyperdiploidy. Hyperdiploidy is observed in at least 50% of the patients, with a nonrandom gain of specific chromosomes, i.e., chromosomes 3, 5, 7, 9, 11, 15, 19, and 21 [9]. The causes of these nonrandom gains are currently totally unknown. Non-hyperdiploidy is characterized by usual more complex karyotypes, displaying many structural abnormalities (partial gains and losses), with a specific enrichment of 14q32 translocations (60–70% of the cases). These 14q32 translocations systematically involve the *IGH* gene at 14q32, with several chromosomal partners. The most frequent partners are *CCND1* at 11q13 (15–20% of the patients) [10], *MMSET* and *FGFR3* at 4p16 (12–15% of the patients) [11], and *MAF* at 16q23 (3% of the patients) [12]. These specific translocations are due to errors during the physiological class switch and hypermutation processes. What is unknown so far is the specificity of the partners.

Many other chromosomal changes have been identified, including monosomy 13, gain of 1q, and losses of the 1p, 8p, 14q, 16q, and 17p regions. At the molecular level, frequent rearrangements of the *MYC* locus have been described. Recent exome sequencing studies revealed another level of heterogeneity [13–16]. No specific gene mutation has been observed. The most frequently mutated genes were *KRAS* (~20%), *NRAS* (~15%), *DIS3*, *TP53*, *BRAF*, and many others. Compared with other hematopoietic tumors, and especially with leukemias, MM present a high number of mutations. In contrast, if compared with solid tumors, the mutation load is low.

Prognostic Impact of Chromosomal Abnormalities

Many of the chromosomal changes observed in the tumor plasma cells are associated with specific outcomes (Table 35.2). Very few "good risk" abnormalities have been described, in contrast to "high-risk" changes. Most of these prognostic values have been described with old treatment strategies, and have to be reevaluated in the context of novel therapies.

High-Risk Features

The first chromosomal abnormality associated with a shorter PFS and OS has been del(13q14) [17]. Actually, this chromosomal loss is mainly due to chromosome 13 monosomies. Further studies did show that monosomy 13 does not present an intrinsic prognostic value [4]. The shorter PFS and OS observed in old studies were in fact related to the frequent association of monosomy 13 with the specific t(4;14) and del(17p) (80% of those cases).

The loss of part of the chromosome 17 short arm has been associated with very dismal outcome [18]. The minimal target region is currently unknown, even though all the studies did focus on the 17p13 region, and more specifically on the *TP53* gene. The *TP53* gene is a tumor suppressor gene, and per se, has to be mutated on the second allele to display its oncogenic properties. Several studies did address this issue, and none of them did show a systematic mutation on the remaining allele [14, 19], in contrast to what has been observed in chronic lymphoid leukemia or diffuse large B-cell lymphoma. In the 30–50% of the cases presenting a *TP53* mutation, *TP53* is probably the target gene. In the 50–70% remaining cases, other gene(s) are probably the cause of the prognostic impact of del(17p) losses. A recent study in a mouse model of leukemia/lymphoma did suggest that the loss of several genes in the *TP53* vicinity is associated with tumorigenesis [20]. This paradigm has to be dem-

Table 35.2 Prognostic value of cytogenetic abnormalities

t(4;14)	High Risk
Del(17p)	High Risk
1q gain	High Risk
Del(1p32)	High Risk
Trisomy 3	Good Risk
Trisomy 5	Good Risk
Trisomy 21	High Risk

onstrated in MM. However, all the cases of del(17p) (7–10% of the patients) are associated with a poor outcome, independently of *TP53* mutations. This poor outcome is not related to lower response to therapy, but to a shorter PFS. Recent clinical studies in relapse patients with novel proteasome inhibitors such as carfilzomib and ixazomib did show that this prognostic impact might be overcome, at least partially [21, 22]. This important finding has to be confirmed in the frontline setting, but may lead to a new paradigm in the therapeutic strategy for these specific patients. One hot topic is the relationship between the prognostic impact and the size of clone harboring the deletion. It has been suggested that the deletion is impacting the survival only if present in the major subclone [4]. This issue is currently evaluated.

The second important prognostic parameter is the translocation t(4;14). The target gene on chromosome 14 is *IGH*. This gene is targeted in many B-cell malignancies, but in contrast to the other translocations, the t(4;14) is peculiar since it disrupts two genes on chromosome 4: *FGFR3* and *MMSET* [11]. The *FGFR3* gene is displaced on chromosome 14, leading to its overexpression in a classical mechanism. In contrast, the *MMSET* gene remains on chromosome 4, and is upregulated through a novel fusion gene, *Eμ-MMSET*. The most important event is probably this latter one, for at least two reasons: (1) in 1/3 of the patients presenting the t(4;14), *FGFR3* is lost through an unbalanced translocation [23], and (2) the prognostic impact of the translocation is the same, independently of the translocation configuration [24]. The *MMSET* gene is a methyl-transferase, and its upregulation leads to a chromatin configuration modification, that may modify the expression of many target genes. Observed in 12–15% of the patients, the prognostic value of t(4;14) has been clearly shown in the context of old drugs [4]. Since the availability of proteasome inhibitors such as bortezomib, its prognostic impact is more questionable. Several studies did show that bortezomib may partially overcome this impact [25], and this fact has been recently confirmed in studies using second generation proteasome inhibitors such as carfilzomib and ixazomib [21, 22].

Other factors have been shown to negatively impact the prognosis. Extra-copies of the chromosome 1 long arm (1q gains) are observed in about 1/3 of the patients, and have been shown to be associated with a shorter survival [26]. However, the prognostic value of 1q gains seems to be lower than del(17p) or t(4;14). Since in the large majority of the cases the whole 1q is gained, it is difficult to find a single target gene which could drive the prognosis. The chromosome 1 does also drive the prognosis through deletions of the short arm (del(1p)). Several regions can be involved, but the most important seems to be the 1p32 region, targeting the *FAF1* and/or *CDKN2C* genes [27]. These del(1p32) are observed in 7–8% of the patients, and are associated with a dismal outcome.

Table 35.3 Revised-international staging system

R-ISS 1	ISS 1 *and* no high-risk cytogenetics *and* LDH = Normal
R-ISS 2	All other cases
R-ISS 3	ISS 3 *and* [high-risk cytogenetics *or* LDH > Normal]

High-risk cytogenetics = del(17p), or t(4;14), or t(14;16)

Good/Standard Risk Features

Some studies did suggest that hyperdiploidy may be associated with a better outcome. However, these studies were based on conventional cytogenetics, and so the results are restricted to patients presenting a proliferative disease. Two studies did address the issue of the impact of trisomies in the high-risk patients, with totally opposite results [28, 29]. A third study based on SNP array did show that only some specific trisomies (chromosome 3 and 5) improve the outcome of high-risk features. In contrast, another trisomy (chromosome 21) worsens the prognosis [30].

In conclusion, cytogenetics is probably the most important prognostic parameter in MM. But all the abnormalities should be analyzed more globally, some high-risk changes could become standard risk if combined with some trisomies. A first attempt has been proposed by IMWG with the R-ISS (Revised-International Staging System), which combines ISS with chromosomal abnormalities (Table 35.3) [31]. In the future, global analyses including ISS and multiparametric genetic analyses may contribute to define high risk more precisely, but also good and standard risk groups.

Prognostic Impact of Gene Expression Profiling

Besides the chromosomal changes, MM is also characterized by abnormalities in the gene expression profiles (GEP) . In 2006, the Arkansas group proposed a MM classification based on similarities of GEP [32]. This classification is mostly driven by the chromosomal changes, i.e., 14q32 translocations and hyperdiploidy. Two other subgroups, corresponding to “proliferation” and “bone disease” were identified. This molecular classification has been partially confirmed by a study by the HOVON group [33]. The “low bone disease” group was not confirmed. In contrast, three other groups were identified: one group enriched by “myeloid” genes (that could be related to plasma cell sorting problems), one group characterized by overexpression of cancer testis antigen genes, and finally a group defined by overexpression of positive regulators of the NFκB pathway. However, these classifications, based on gene expression, were not translated into prognostic subgroups. Different studies based on GEP did identify a high-risk group [33–35]. Of note, these different prognostic models, based on variable

number of genes, do not share any common gene. Whether these discrepancies are due to different algorithms to identify the high-risk signatures, or to differences in the treatments used in the training cohort is still unresolved.

Prognostic Impact of Next Generation Sequencing

Next generation sequencing (NGS) has been used to analyze the different mutations present in the tumor plasma cells. At least four studies based on exome sequencing have been published, with a total of more than 700 patients analyzed [13–15, 36]. So far, preliminary results are rather disappointing, without the identification of significant group of patients who would present a good or poor prognosis. All these studies describe subclonality, but none of them did show that this process can be useful in either prognostic assessment, or adaptation of treatment strategies. Whether the number of mutations per patient is prognostic is still unresolved.

Conclusions

The assessment of prognosis in patients with MM is mandatory at diagnosis. The most important variables are age, ISS, and cytogenetic changes, summarized in the R-ISS. In the future, the development of multiparametric systems will probably enable to improve this assessment.

Immunoglobulin Light Chain Amyloidosis (AL)

36

Morie A. Gertz, Francis K. Buadi, Taimur Sher, and Angela Dispenzieri

History

"The term 'lardaceous change' has … come more into use chiefly through the instrumentality of the Vienna School… The term 'lardaceous changes' … has but very little to do with these tumors, and rather refers to things, upon which the old writers … who are better connoisseurs in bacon than our friends in Vienna, would hardly have bestowed such a name [1]… The appearance of such organs … are said to look like bacon, bears … a much greater resemblance to wax and I have, therefore, now for a long time … made use of the term waxy change… These structures … are the simple action of iodine … assume just as blue a color as vegetable start…"

In this publication by Rudolph Virchow [2], he decides that amyloid must be made of starch. The iodine reaction turning amyloid deposits blue is a throwback to high school chemistry when iodine will stain the open face of a potato blue, documenting it as starch. At the same time, Prof. Virchow directly insults his chief competitor of the day, Rokitansky, who had previously written about lardaceous changes because of the greasy texture the liver of an amyloid patient would have and implies that the Viennese School is incapable of distinguishing amyloid from bacon, reflecting the intense competitive nature of two leaders during the age of medical discovery.

The term "amyloid" was first used in 1838 by Schleiden to describe a normal constituent of plants. Virchow, in 1858, gave a lecture entitled, "Amyloid Degeneration." Virchow's conclusion that amyloid substance was starch continues today, where amyloid means amyl-like or starch-like. In 1859, Friedreich, Nikolau, and Kekule indicated that the waxy spleen described by Virchow did not contain starch and that the deposits were derived from protein.

Budd analyzed the liver of a patient with amyloidosis and found it was not lardaceous. Wilks described a 52-year-old patient that had lardaceous change that was unrelated to any secondary cause and may have been the first description of AL. Schmiedeberg, in 1920, indicated that amyloid was composed of amino acids and strongly resembled the composition of serum globulin. In 1922, Bennhold first used Congo red as a specific stain. Five years later, Divry and Florkin reported green birefringence under polarized light when amyloid-laden brain from an Alzheimer's patient was stained with Congo red. In 1931, Magnus-Levy postulated that Bence-Jones proteins were a precursor of the amyloid substance and noted that there was a relationship between amyloid, Bence-Jones protein, and multiple myeloma. Cohen and Calkins published in 1959 that, under electron microscopy, all forms of amyloid were fibrils of indefinite length but a constant width of 9.5 nm [3]. Apitz claimed that amyloid in tissues was analogous to the excretion of light chain proteins by the kidneys and coined the term "paraprotein" to describe monoclonal immunoglobulins. Isobe and Osserman, in 1974, published that Bence-Jones proteins had a direct role in the pathogenesis of AL [4]. In 1968, Eanes and Glenner reported by X-ray diffraction [5] that amyloid proteins formed an alternate three-dimensional configuration of a beta-pleated sheet [6] unlike the normal alpha-helical configuration of proteins. Amyloid proteins are highly resistant to solvents, and the first amyloid extraction relied on this insolubility by repeated centrifugations in saline where the supernatant, containing all the soluble compounds, would be

discarded, and the residual pellet contained all the amyloid and could be suspended in distilled water. Amyloid was first purified in 1968 [7]. The first sequence of an immunoglobulin light chain amyloid was reported in 1970 as the N-terminal fragment of the immunoglobulin light chain.

Introduction

Amyloid is a vague term that describes a group of disorders that have only one thing in common, and that is the deposition of protein fibrils composed of protofibrils. The clinical presentation depends on the organ involved and the protein subunit structure of the amyloid protein. These heterogenous disorders are classed together because they share common tinctorial properties of an amorphous eosinophilic deposit when stained with hematoxylin and eosin, and distinct binding to the cotton-wool dye, Congo red, in the sine qua non of green birefringence when viewed under polarized light [8]. Congo red is an imperfect stain insofar as there is a measurable false-positive rate either due to trapping of dye in thick sections or the misinterpretation of white birefringence as green and points out the importance of having positive and negative controls whenever amyloid is diagnosed.

The immunoglobulin fragments that compose AL amyloidosis are thermodynamically unstable and will demonstrate misfolding into the β-pleated sheet configuration [9]. It is possible to synthetically create amyloid fibrils by pepsin digestion of monoclonal immunoglobulin light chains.

Injection into mice of purified immunoglobulin light chains from the urine of patients with multiple myeloma does not produce any pathologic deposits. However, when light chains extracted from the urine of patients with amyloidosis are injected into mice, amyloid deposits do develop, reflecting the importance of [10] the amino acid structure of the immunoglobulin light chain in predisposing to misfolding into an amyloid configuration. Amyloid associated with the λ6 subgroup of light chains is virtually always associated with amyloidosis, and nearly 60% of patients with light chain amyloidosis have a λ light chain compared to only one-third of patients that have multiple myeloma [11].

As part of the standard evaluation of light chain amyloidosis, a bone marrow is routinely performed. Patients that fulfill criteria for multiple myeloma with >10% plasma cells or have myeloma-associated CRAB criteria (hypercalcemia, cast nephropathy, anemia due to marrow infiltration or bone lesions) have a shortened survival when compared with patients with light chain amyloidosis and <10% plasma cells, and this has important therapeutic implications with regard to systemic chemotherapy [12]. Renal insufficiency in amyloidosis is not due to cast formation in the tubule but due to progressive destruction of the glomerular basement membrane and loss of glomeruli associated with long-standing proteinuria that results in tubular atrophy [13].

Amyloidosis does not appear to be neoplastic, although it is clonal. Monitoring of the bone marrow over time in a patient with amyloidosis does not show the proliferative characteristics that myeloma patients have where, left untreated, the bone marrow plasma cell percentage rises over time [14]. In light chain amyloidosis, the disorder is far more static. Moreover, although patients with light chain amyloidosis have a high frequency of t(11;14), high-risk features such as seen in multiple myeloma such as -17p, t(4;14), or t(14;16) are lacking [15]. If multiple myeloma is not present at the time of diagnosis, it will subsequently develop in <1% of patients. Even in those patients that have a high proportion of plasma cells in the bone marrow, the cause of death is generally amyloid-related organ failure and not the typical problems associated with end-stage myeloma such as pancytopenia and infection [16, 17].

Amyloidosis is thought to occur in approximately eight patients per million per year and is approximately one-fifth as common as multiple myeloma [18]. Although recent estimates are not available, since the current incidence of multiple myeloma in the United States is 24,000 new patients per year, it is reasonable to speculate that the number of new patients with light chain amyloidosis is approximately 5000 annually. Translocations of the immunoglobulin heavy chain locus located on chromosome 14, band 14q32, have been reported in 55% of patients with light chain amyloidosis. Cyclin D1 overexpression accounts for 76% of all IgH translocations [19].

Symptoms and Signs of Amyloidosis

The most common symptoms associated with amyloidosis are weight loss, fatigue, edema, dyspnea on exertion, and paresthesias [20]. Unfortunately, these common symptoms of AL are nonspecific and are generally not helpful in determining when the diagnosis should be suspected and when to launch an investigation. Extreme weight loss usually results in a futile search for metastatic malignancy [21]. Fatigue, which can be related to early cardiac or renal involvement, can be quite subtle since the restrictive cardiomyopathy is usually associated with a normal ejection fraction and a cardiac etiology may be overlooked. Reduced filling, seen in the heart during diastole, will result in a decline in systolic blood pressure, but it is often difficult to associate this with the presence of an infiltrative cardiomyopathy [22]. Typically, patients with cardiac amyloid have normal coronary arteries; and not infrequently, coronary angiography is performed, and the patient's symptoms are interpreted as being noncardiac in origin [23].

Lightheadedness and orthostatic syncope occurs in a significant proportion of patients [24]. Patients that have significant proteinuria and hypoalbuminemia lose oncotic effect, and serum will, therefore, transude from the intravascular space into the extravascular, extracellular space. This results in contraction in the intravascular volume and can lead to

orthostatic hypotension. Diuretics used to manage the edema that patients with hypoalbuminemia have will frequently result in further hypotension and reduced renal blood flow and resultant rise in serum creatinine level. When these patients undergo echocardiography, it is common to see thickening of the walls, which is often interpreted as hypertrophy, which is then considered a reflection of untreated hypertension or workload hypertrophy, since valvular insufficiency is often seen on echocardiography [25].

Occasional patients will have autonomic failure as the cause of their orthostatic hypotension. This is generally associated with peripheral neuropathy and other signs of autonomic dysfunction, such as upper intestinal dysmotility with pseudo-obstruction and vomiting or lower intestinal dysmotility with alternating obstipation and intractable diarrhea [26]. Since the symptoms associated with light chain amyloidosis are often vague, clinicians may rely on the signs of amyloidosis to lead to a diagnosis. Unfortunately, the signs, which are highly specific, are quite insensitive. The classic pinch or periorbital purpura (Fig. 36.1) seen with amyloidosis is seen in <20% of patients [27]. Clues are that the purpura tends to stop at the nipple line; can be periorbital or petechiae on the eyelids; and can be seen on the webbing of the neck, malar regions, and upper chest. These purpura have been misinterpreted as being senile purpura in an elderly population. Hepatomegaly is present in only 10% of patients and is rarely over 5 cm below the right costal margin. Splenomegaly and splenic rupture are rarely seen [28].

Macroglossia is the most specific finding of amyloidosis (Fig. 36.2). Patients can be misdiagnosed as tongue cancer, acromegaly, and hypothyroidism [29]. Tongue enlargement with submandibular indentations, due to pressure on the lower row of teeth, is quite specific for immunoglobulin light chain amyloidosis and, virtually, is never seen in AA or TTR amyloidosis. Tongue enlargement, however, is seen in only approximately 10% of patients and is very easy to overlook unless massive and interferes with the patient's ability to swallow or concomitant sleep apnea when supine. Tongue enlargement is associated with bilateral enlargement of the submandibular salivary glands. Dry mouth can be seen and can be misdiagnosed as Sjögren syndrome [30].

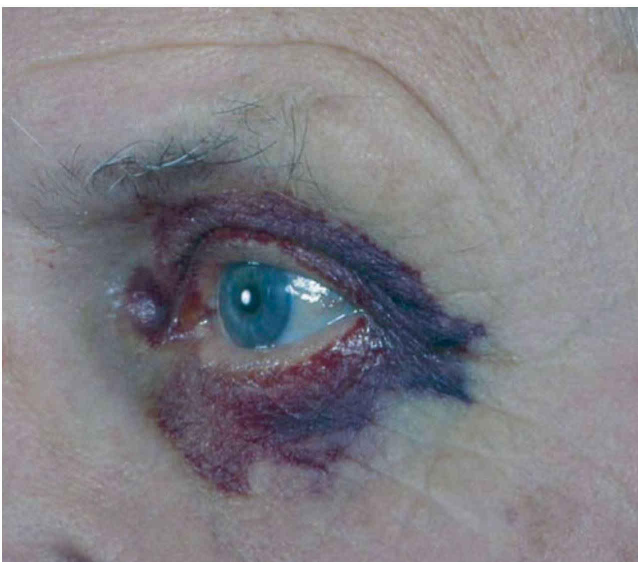

Fig. 36.1 Periorbital purpura in amyloidosis

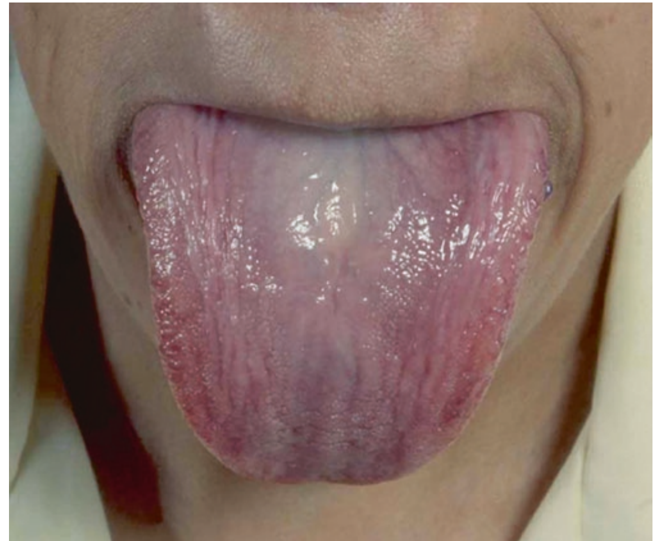

Fig. 36.2 Enlarged tongue in an AL amyloidosis patient

Occasional patients have diffuse small vessel amyloidosis that can cause calf, jaw [31], or buttock claudication with exertion and is difficult to distinguish from pseudoclaudication related to spinal stenosis. A rare patient will have coronary arteriolar amyloid deposits that will result in exertional angina [32]. A very rare finding is periarticular amyloid deposition leading to the shoulder-pad sign (Fig. 36.3), which represents pseudohypertrophy of the shoulder joint. As a consequence, if one waits for the signs of amyloidosis to develop, the majority of patients will be overlooked [33].

Diagnosis of Amyloidosis

The diagnosis of amyloidosis is best suspected when patients fulfill one of the five following criteria [34] (Fig. 36.4):

1. Diastolic heart failure, heart failure with preserved ejection fraction, or infiltrative cardiomyopathy
2. Nephrotic range proteinuria in a nondiabetic
3. Unexplained hepatomegaly with alkaline phosphatase elevation with no history of malignancy
4. A progressive demyelinating peripheral neuropathy with paresthesias that is generally painless
5. A patient presenting to the hematologist with "atypical" multiple myeloma where fatigue and edema are the

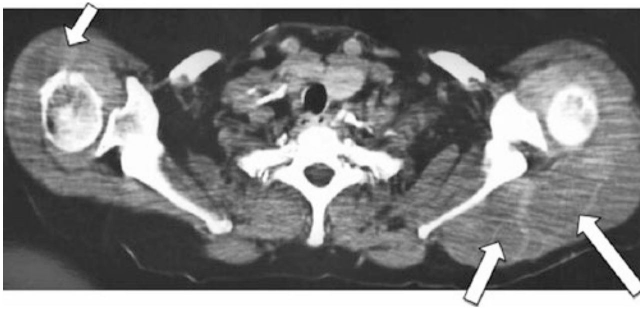

Fig. 36.3 CT scan of the shoulder showing periarticular infiltration (shoulder pad sign)

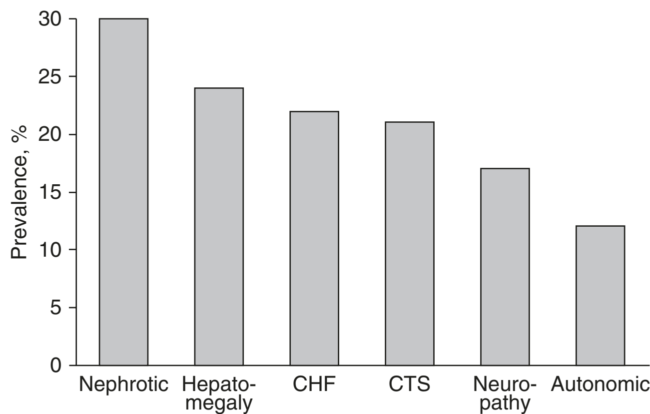

Fig. 36.4 Prevalence of clinical syndromes in AL

presenting symptoms rather than the classical CRAB criteria of anemia, renal insufficiency, or bone disease

In patients that present with any of these symptoms, the first screening should be immunofixation of the serum and an immunoglobulin free light chain assay [35]. Nearly all patients with immunoglobulin light chain amyloidosis will have an abnormal involved free light chain or the presence of a monoclonal protein on serum immunofixation. A positive result would be a powerful clue to the origin of the patient's symptoms and is quite sensitive with only 1% of amyloid patients failing to have a monoclonal protein [36]. The test is specific since only 3% of the adult population will have an incidental monoclonal gammopathy of undetermined significance. Using sensitive techniques, whether immunohistochemistry or flow cytometry of the bone marrow, a clonal population of plasma cells can be demonstrated [37]. All patients with a monoclonal gammopathy of undetermined significance that have any symptoms of dyspnea or fatigue should have the urine screened and should be screened with cardiac biomarkers to exclude the possibility of an infiltrative cardiomyopathy [38].

A clonal population of plasma cells is observed in virtually all patients with AL, even when the marrow percentage of plasma cells is 1–2% [39]. The amyloid deposits of light chain amyloidosis are derived, usually, from a fragment of the immunoglobulin light chain variable region. The source of this light chain (which averages approximately 12 kDa or half the molecular weight of a normal intact immunoglobulin light chain) is the clonal plasma cell population. An immunoglobulin free light chain assay is important for screening any patients with dyspnea, neuropathy, and proteinuria. Serum immunofixation will fail to detect a monoclonal light chain in nearly a quarter of patients. The light chain levels are low in AL, and a high percentage of the light chain passes through the glomerular basement membrane into the urine, and there is no discernible monoclonal peak in the serum [40]. The immunoglobulin free light chain assay is ten times more sensitive than serum immunofixation, capable of detecting levels as low as 2 mg/dL; where serum protein electrophoresis detects peaks of 200 mg/dL, and the estimated sensitivity of immunofixation is 20 mg/dL [41].

The plasma cells in patients with light chain amyloidosis are λ in nearly 70% of patients. If a patient with known amyloidosis does not have a monoclonal protein in the serum, polyclonal bone marrow plasma cells, and normal levels of immunoglobulin free light chain, the amyloidosis should be considered either localized or, if systemic, it should be considered an inherited or acquired form of non-AL until proven otherwise [42].

All forms of amyloid contain approximately 15% glycoprotein by weight, consisting of amyloid P component. Mass spectroscopic analysis identifies P component in all amyloid deposits [43]. The function of amyloid P component remains unknown, but no human has ever been described lacking amyloid P component, suggesting it performs a vital function. Outside of the United States, imaging with I123-labeled amyloid P component can be used to identify amyloid deposits in vivo [44]. Patients that have high amyloid burdens have shorter survival. P component is also a potential target of antibody therapy as will be described in the treatment section [45].

Serialized imaging with P component has been used to assess response and progression to therapeutic interventions [46]. P component scanning is incapable of distinguishing among the various forms of amyloid deposits. The heart cannot be imaged with the P component scan, and kidneys are not well seen. The correlation between imaging findings and the extent of organ dysfunction assessed biochemically is not good. However, the diagnostic sensitivity of SAP scintigraphy for AL amyloidosis is 90% [47].

Biopsy Proof of Amyloidosis

At the time of diagnosis, amyloidosis is widespread, and extensive involvement of microvessels is characteristic. As a consequence, it is possible to biopsy nearly any site to obtain a diagnosis. Although biopsy of an affected organ (such as heart, kidney, liver, and nerve) will yield a diagnosis, the widespread nature of the disorder allows one to establish a histologic diagnosis noninvasively. Biopsy of the skin [48], subcutaneous fat, bone marrow [49], and gingiva [50] are highly sensitive and easily accessible (Fig. 36.5). Fine needle aspiration of the fat will yield a diagnosis in 75% of patients [51], but a trial comparing subcutaneous fat aspiration with surgical biopsy demonstrated a higher yield with surgical biopsy [52]. Biopsy of these less-invasive sites reduces the risk of bleeding that has been reported with liver and kidney biopsies. Endoscopic biopsy of the stomach, jejunum, and colon will also yield a diagnosis in nearly 95% of patients, usually localized to submucosal blood vessels [53]. Endoscopy can be performed then as an outpatient, and the risk of GI hemorrhage is quite small. Labial salivary gland biopsy has been reported for its ability to diagnose amyloidosis noninvasively [54].

The specificity of a subcutaneous fat aspirate is 99%, and the false-positive rate is 1%. Concordance between pathologists is 95%, and the tissue is suitable for mass spectroscopic analysis of the amyloid deposits [55]. At our center, trained nurses perform both the subcutaneous fat aspiration and the bone marrow biopsy as a single procedure that allows two samples to be submitted for analysis and an overall sensitivity to detect amyloidosis of 85%. A bone marrow is required to estimate the percentage of plasma cells, and it is convenient to do both procedures at a single setting. Caution is required when interpreting the Congo red stain because of the risk of false-positives [56]. Rectal biopsy specimens [57] with amyloid have been misinterpreted as collagenous colitis. As a screening technique in our laboratories, the myocardial biopsies are stained with sulfated Alcian blue; and in our peripheral nerve laboratory, crystal violet screening is used subsequently confirmed with Congo red [58].

Identifying the Type of Amyloid

Once amyloid has been recognized by a pathologist on tissue section, classification of the type of amyloid is required. Immunohistochemical staining with commercial antisera has been promoted as a highly sensitive technique. There are major drawbacks with the use of antibody-mediated techniques to identify amyloid deposits [59] (Fig. 36.6). Since the immunoglobulin protein in light chain amyloidosis is only a fragment of the immunoglobulin light chain, constant portions may be deleted [60]. Most commercial antisera identify light chains by binding to the constant region, and with the deletion of constant immunoglobulin fragment the epitope cannot be recognized [61]. Moreover, one characteristic of the light chains in amyloid is misfolding of the light chain, which can result in suppression of the epitopes that commercial antisera recognize buried within the misfolded protein [62]. As a consequence, particularly for immunoglobulin light chain amyloidosis, immunohistochemistry lacks sensitivity. It has been repeatedly demonstrated that immunohistochemistry is an excellent technique for the recognition of both TTR and AA amyloidosis. Unfortunately, there are over a dozen recognized forms of amyloidosis, which include

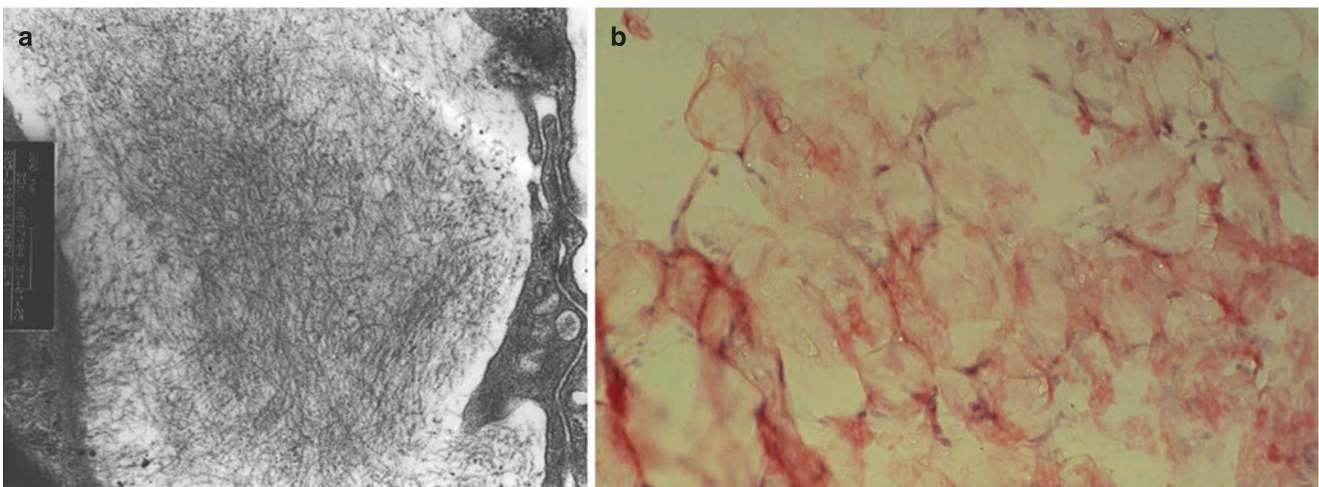

Fig. 36.5 (**a**) Electronic micrograph of amyloid fibrils (published from the prior book chapter). (**b**) Congo red stained fat aspiration

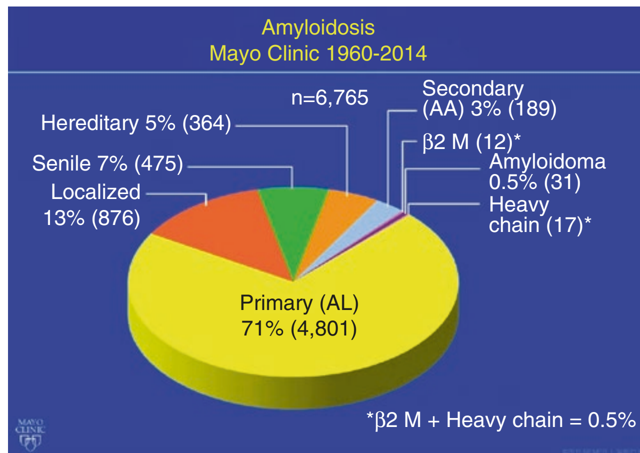

Fig. 36.6 Amyloid type seen at Mayo Clinic

Table 36.1 Types of amyloid identified in tissues

Amyloid subtype	Percentage
AL (light chain)	61.7
ATTR (familial or wild type)	24.5
AA (secondary)	3.7
ALECT-2 (renal)	3.6
A Ins (localized insulin)	1.1
Keratin (cutaneous)	0.9
A Apo 1 (inherited)	0.7
AH (heavy chain)	0.7
A Fib (hereditary renal)	0.6

apolipoprotein, lysozyme, insulin, gelsolin, etc. [63]. Most laboratories are not adequately configured to perform immunohistochemical studies for all forms of amyloidosis. Currently, the gold standard for the identification of amyloid deposits is laser capture microdissection mass spectroscopic analysis of the amyloid deposits [64]. Sequencing of the proteome and subsequent comparison with a library of protein sequences is virtually 100% sensitive in identifying the primary structure of the amyloid protein subunit [65] (Table 36.1). LCMS is also capable of identifying other proteins such as apolipoprotein E, serum amyloid P, and vitronectin, which are common in amyloid deposits and validate that the deposit is indeed amyloid [43]. Using this technique, we have demonstrated that 38% of amyloid deposits are not of immunoglobulin light chain origin, and an increasing number of new proteins have been identified, including Alect2, keratin, A-fibrinogen, and A-atrial natriuretic factor [66].

One of the great dangers in clinical practice reflects the high prevalence of monoclonal gammopathies in the serum of the elderly, ranging from 3% prevalence at age 70 years to 5% at age 90 years. This is the same population that has a high incidence of wild-type TTR cardiac amyloidosis. Therefore, the finding of classic amyloidosis in the heart of an elderly male that has a monoclonal protein does not necessarily indicate cardiac AL amyloidosis. A tissue specimen is required in order to exclude wild-type TTR amyloidosis, and mass spectroscopy is well suited to make this distinction [8, 67].

Distinguishing Localized and Systemic Amyloidosis

Even when mass spectroscopic analysis demonstrates immunoglobulin light chain as the primary protein subunit of the amyloid deposits, it does not prove that it is systemic. There are a number of localized forms of AL amyloidosis that can involve skin, bladder, larynx, and gastrointestinal tract and not be evidence of a systemic syndrome [68–70]. Supportive evidence in these instances is the absence of a monoclonal protein in serum and urine, a normal immunoglobulin free light chain assay, and failure to find a clonal population of plasma cells in the bone marrow. At Mayo Clinic, nearly 16% of patients seen with amyloidosis have localized disease. Amyloidosis involving the renal pelvis [71], ureter, bladder [72], and urethra can present with hematuria, unilateral renal obstruction, mimicking colic, or imaging findings that would be suggestive of ureteral and bladder carcinoma, respectively. Patients with tracheobronchial amyloidosis will present with hoarseness, poor vocal cord movement, and occasional stridor. Patients with genitourinary and tracheobronchial amyloid do not benefit from systemic therapy and need to be treated locally.

Pulmonary nodules that have all the characteristics of a solitary malignancy can represent localized nodular amyloidosis [73]. These deposits are AL in origin, are unassociated with a systemic light chain disorder, and do not require therapy.

Cutaneous deposits of amyloid are usually found to represent keratin [74] deposits and are 1% of all amyloid proteins analyzed at Mayo Clinic. These lesions cause pruritus but are not at risk of developing a systemic form of amyloidosis. Localized amyloidosis has also been described in the conjunctiva [75]. Management is by an oculoplastic surgeon. Conjunctival amyloid can often be confused with conjunctival lymphoma. Carpal tunnel syndrome is seen in 15% of patients with light chain amyloidosis, but there is a separate syndrome of localized carpal tunnel amyloidosis, which has been demonstrated to be composed of TTR [76]. Men who have wild-type TTR cardiac amyloidosis have a history of carpal tunnel syndrome in nearly 50% [58]. Trace amounts of amyloid can be found in the cartilage of the hip and the knee and represent incidental findings. There is also a form of localized atrial amyloidosis that is composed of atrial natriuretic factor and contributes to atrial arrhythmias but is not associated with systemic cardiac amyloidosis with ventricular dysfunction [77]. Whenever amyloidosis is detected, exclusion of localized amyloid that does not require chemotherapy is essential. Amyloid deposits found in the cardiac ventricle, kidney, and liver virtually always represent systemic AL amyloidosis even if only a single organ is involved.

Systemic Forms of Amyloidosis that Are Not Immunoglobulin Light Chain in Origin

The clinical presentation of systemic non-AL amyloidosis involving nerve, kidney, and heart are not distinguishable from light chain amyloidosis. Patients with renal amyloidosis can be composed of light chains, Alect2, fibrinogen-Aα, or be a manifestation of AA amyloid [78]. In all instances, there is proteinuria or renal insufficiency. Most patients with light chain, AA and fibrinogen amyloid present with nephrotic range proteinuria. Patients with Alect2 actually have modest degrees of amyloid deposition with significant elevations in serum creatinine, and histology shows preferential deposition in the tubular and interstitial regions of the kidney [79]. Apolipoprotein amyloid, also an inherited form of amyloid preferentially involving the kidney, presents with creatinine elevation and only modest degrees of proteinuria in the range of 1 g/24 h [63].

The differential diagnosis of systemic cardiac amyloid is AL amyloid; mutant TTR amyloid, formerly known as familial amyloid cardiomyopathy; and wild-type TTR cardiac amyloid, formerly known as senile cardiac amyloid or senile systemic amyloid [80]. Mutant TTR amyloidosis has echocardiographic features similar to AL amyloidosis but is 90% men, usually over the age of 60 years, with a high incidence of associated carpal tunnel syndrome [81]. The extent of amyloid infiltration seen on echocardiography is usually greater than that in AL, suggesting that the fibrils of TTR amyloid are less toxic to the myocardium [82]. It is not unusual to see an interventricular septal thickness of 20 mm in TTR amyloidosis, where this would be unusual in AL amyloidosis. Increased recognition has led to a surge in the diagnosis of wild-type TTR amyloidosis as the willingness of cardiologists to biopsy the heart in older individuals is increasing and as new investigational therapies become available. Wild-type TTR amyloidosis also has a much better prognosis than light chain amyloidosis [83], with survivals of 5–7 years, compared with AL amyloidosis of 1–2 years. Recently, it has been demonstrated that radionuclide scanning with either technetium pyrophosphate [84] or technetium DPD [85] is quite specific for TTR amyloidosis. The finding of a compatible echocardiogram with restrictive cardiomyopathy and poor filling with a positive technetium imaging scan (Fig. 36.7 PYP or DPD) is diagnostic of TTR amyloidosis and is a useful distinguishing feature.

Amyloidosis and the Heart

The heart is the most important organ to be involved with amyloidosis and drives the prognosis. Amyloid is deposited extracellularly and results in the thickened and noncompliant left ventricle that is seen on echocardiography and magnetic resonance imaging [86]. Because systolic function is pre-

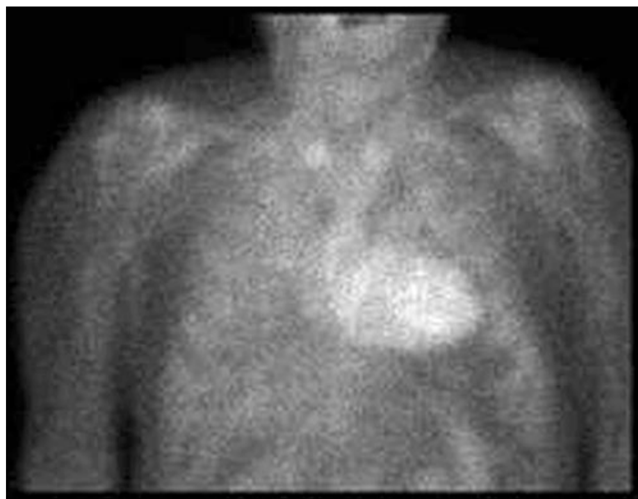

Fig. 36.7 PYP scan of TTR amyloidosis

served until late in the course and cardiomegaly is not seen on a chest radiograph, it is easy to misattribute the thickening to a more common systemic illness such as hypertension or valvular disease. Coronary angiography is typically normal. The median septal thickness for patients with immunoglobulin light chain amyloidosis is 14 mm (normal ≤11) [87]. Thickening of the septum has also been misattributed to asymmetric septal hypertrophy. The finding of a monoclonal protein in a patient with “hypertrophic cardiomyopathy” or “hypertensive cardiomyopathy” should lead to an evaluation for amyloidosis [88]. Doppler studies on echocardiography are quite useful in demonstrating the restriction to inflow and the rapid rise in diastolic filling pressures characteristic of the restrictive physiology of amyloidosis [22]. Wall thickness and fractional shortening are predictive of survival in this disease [89]. The recent introduction of strain echocardiography allows measurement of a rate at which the myocardial wall shortens; normal is −18% or less (−20% normal). Amyloid is characterized by rises (−15%, −12%, etc.) and is shown to predict survival in patients with amyloidosis [90]. Patients with amyloidosis of the heart can develop atrial thrombi, which can be a potential source of arterial embolization and stroke [91]. There is a high incidence of supraventricular rhythm disturbances that are resistant to ablation therapy [92]. There is a high incidence of sudden death [93], and nearly 30% of patients with cardiac amyloidosis die within the first 2 months of recognition [94]. There is a rare syndrome of intramural coronary arteriolar amyloidosis. These patients present with classic anginal symptoms with normal extramural coronary arteries seen after angiography [95].

A particular area of misdiagnosis is in elderly African-American men, 3% of whom carry a mutation for TTR V122I [96]. The finding of cardiac amyloidosis in an African-American male necessitates mass spectroscopic analysis of the deposits due to the high prevalence of this form of

inherited TTR amyloidosis. The echocardiographic features of these forms of amyloidosis are indistinguishable, and all are positive for Congo red, necessitating careful analysis of the amyloid protein subunit.

There is increasing recognition of wild-type TTR cardiac amyloidosis, formerly known as senile systemic amyloid and senile cardiac amyloid. These patients have the same echocardiographic features as other patients with cardiac amyloid but tend to be older, nearly 90% are men, nearly half have associated carpal tunnel syndrome, and renal involvement is conspicuously absent [97]. The severity of the heart failure is less for the extent of infiltration identified by echocardiography, and median survival is longer than that in cardiac AL. These patients do not benefit from systemic chemotherapy, and the mechanism by which a normal protein, such as TTR, preferentially deposits in the myocardium of elderly men remains unknown. In an observational study, patients with mutant TTR amyloid had a survival of 25.6 months inferior to those with wild-type TTR amyloidosis at 43 months. In a subsequent analysis of 272 patients with wild-type TTR, the mean age was 77; 89% were men and the median survival was 3.5 years. We have seen rare patients with wild-type TTR amyloid under the age of 60. So the overlap is quite substantial, and age alone cannot be used as a distinguishing feature. The clinical spectrum of wild-type TTR amyloidosis is quite broad. It is the obligation of the hematologist to ensure that these patients are not inappropriately administered cytotoxic chemotherapy [98].

The mechanism whereby immunoglobulin light chains and amyloid produce cardiac dysfunction is not well understood [99]. Light chains produce oxidative stress, cellular dysfunction, and apoptosis in adult cardiac myocytes through activation of p38 mitogen-activated protein kinase [100, 101]. The presentation of cardiac amyloidosis is heart failure with a preserved ejection fraction [58]. Again, hypertrophy, asymmetric septal hypertrophy, and hypertrophic cardiomyopathy have all been incorrectly diagnosed in patients with light chain cardiac amyloidosis. The electrocardiogram in light chain amyloidosis is neither sensitive nor specific. Low voltage is found in only 46%, a pseudo-infarct in 47%, and 16%, despite infiltration, had EKG findings that met criteria for LVH [102]. Since this is a diastolic disorder, ejection fraction remains normal until advanced disease onset. The standard for evaluating cardiac amyloidosis is the echocardiogram, showing increased wall thickness, left ventricular outflow obstruction, peak systolic tissue velocity, abnormal systolic strain, and abnormal systolic strain rate compared with patients without amyloidosis [103]. Doppler imaging is used to detect impaired left ventricular diastolic filling. In 249 consecutive patients, strain rate imaging predicted mortality and was independent of age and New York Heart Association class as well as cardiac biomarkers [104]. Not all patients with cardiac amyloid have thickening of the ventricular walls; 36% of patients in one trial had a left ventricular wall thickness of ≤12 mm with a median survival of 2 years [105].

Radionuclide imaging serum amyloid P component will bind to all forms of amyloid and will demonstrate deposits but not in the heart. Technetium 99 M derivatives, including pyrophosphate and DPD [106], are capable of binding to TTR cardiac amyloid and are a useful test to distinguish AL from ATTR amyloidosis. Technetium DPD is primarily used in Europe, and Technetium PYP [84] is primarily used in the United States. Carbon 11-PIB with PET scanning has been used to study amyloidosis affecting the heart after it was shown to be effective in diagnosing Alzheimer's plaques; this is ongoing [107].

Cardiac Magnetic Resonance Imaging

MRI is an effective technique when cardiac amyloidosis is suspected. It shows ventricular wall thickening, ventricular wall mass, and a characteristic late gadolinium enhancement [108, 109] (Fig. 36.8). The use of gadolinium in patients

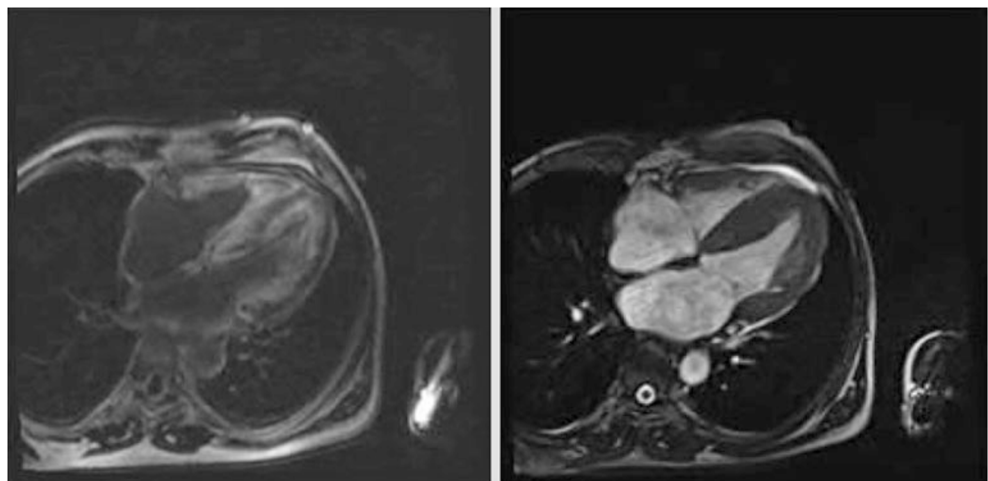

Fig. 36.8 MRI of heart showing amyloid

with renal amyloid is unwise because they are at risk of developing late systemic fibrosis [110]. Cardiac MRI can identify 91% of patients with restrictive filling patterns. Expansion of the extracellular space indicative of amyloid deposition in the heart results in circumferential late shortening of the endocardium and thickening of the myocardial wall. Diffuse transmural late gadolinium enhancement correlates with interstitial amyloid infiltration and correlates with other clinical indicators such as New York Heart Association class and left ventricular wall thickness.

Biomarkers

Although echocardiogram and cardiac magnetic resonance imaging has been a standard for diagnosis for nearly three decades, there are issues of interobserver variability and reproducibility so that serial changes of the echocardiogram over time have not been validated as being predictive of survival. Serum biomarkers that indicate myocyte injury (troponin) or left atrial stress (N-terminal propeptide of B natriuretic peptide (NT-proBNP)) are more reproducible and have been incorporated into systems designed both to stage and predict outcomes in patients with amyloidosis [16, 111].

The symptoms of cardiac amyloidosis are nonspecific. Poor diastolic filling, low left ventricular end-diastolic volume, and reduced cardiac output result in reduction in systolic blood pressure. Levels of troponin T and NT-proBNP can be used in conjunction with the immunoglobulin free light chain level to determine patient's stage and median survival and can be used to predict early [112] mortality with autologous stem cell transplantation [113]. The main cause of death in patients with all forms of light chain amyloidosis (whether hepatic, renal, or peripheral nerve) is cardiac involvement with subsequent heart failure or sudden death. In a multivariable model of over 800 patients with AL amyloidosis, the concentration of cardiac troponin T and NT-proBNP independently predicted overall survival. The cutoffs were NT-proBNP > or < 332 ng/mL and troponin T of 0.035 μg/L. By assigning one point for each, patients could have both normal, one abnormal, or both abnormal, resulting in three stages [114]. It has subsequently been demonstrated that the DFLC is prognostic as is the percentage of plasma cells in the bone marrow and whether the patient has multiple myeloma in the bone marrow or any CRAB criteria, all of which shorten the survival in patients with light chain amyloidosis [12].

The new system has four stages, where one point is assigned for a cardiac troponin T level > or < 0.025 μg/L, an NT-proBNP level ≥ 1800 ng/L, and a clonal free light chain burden >18 mg/dL. Investigators at University College London Amyloid Center have further refined stage 3 into stage 3A (BNP between 1800 and 8500) and stage 3B (all features of stage 3 with an NT-proBNP > 8500) [115]. This results in four (or five) stages. The median survival in the Mayo system for the four stages, respectively, is 94.1, 40.3, 14, and 5.6 months (Table 36.2).

Table 36.2 Amyloid staging system [112]

1 Point each for:
dFLC >18 mg/dL
cTnT >0.025 ng/mL
NT-proBNP >1800 pg/mL

Median survivals: 0 = 94.1; 1 = 40.3; 2 = 14; 3 = 5 months

Renal Amyloidosis

In a patient with nephrotic range proteinuria, measurement of immunoglobulin free light chains, if abnormal, will rapidly narrow the possibilities into myeloma cast nephropathy, Randall light chain deposition disease, light chain amyloidosis, and cryoglobulinemia [116]. In most instances, the finding of light chains in the serum and in the urine will obviate the need for renal biopsy since biopsy of the fat and bone marrow will usually demonstrate the presence of amyloid without having to proceed with the risks of renal biopsy. It is important that all patients with proteinuria have immunofixation performed of the serum, urine, and a free light chain assay. The kidneys are affected in nearly 40% of patients with AL amyloidosis; and for nondiabetic adults with nephrotic range proteinuria, amyloid is 12% of renal biopsy specimens. If one looks at all renal biopsy specimens that are performed, amyloid represents 2.8%. A recent system looking at the initial urinary protein and the serum creatinine at diagnosis is useful for predicting the risk of dialysis (see Table 36.3) [117]. The amount of urinary protein has no impact on overall survival, which is driven by the presence or absence of cardiac involvement.

Two-thirds of AL patients with immunoglobulin light chain amyloidosis have detectable light chains in the urine or in the serum. Monoclonal light chain proteins are more common when the urinary protein loss is high. Symptomatically, the massive proteinuria leads to hypoalbuminemia, and the decline in oncotic pressure results in progressive edema, requiring diuretics. However, diuretics often will further

Table 36.3 Renal staging system [117]

Proteinuria >5 g/24 h
eGFR <50 mL/min
Risk at dialysis at 3 years:
Both favorable: 0–4%
Both unfavorable: 60–85%
1 Unfavorable: 30%

decrease intravascular volume, which can result in significant hypotension and decline in renal vascular blood flow, with resultant rise in the serum creatinine level. Approximately one-third of our patients have an antecedent history of a marked change in the level of serum cholesterol, and the rapid rise in cholesterol is a manifestation of the evolving nephrotic syndrome. In our experience, the median time from diagnosis of nephrotic syndrome to dialysis was 14 months [118]. After initiation of dialysis, the median survival time was 8 months, with patients usually succumbing to cardiac involvement. There does not appear to be any reported differences between hemodialysis and peritoneal dialysis in terms of outcome [119]. Effective chemotherapy will reduce urinary protein loss and slow the progression to end-stage renal disease and ultimately improve survival [120]. Concomitant cardiac amyloidosis makes dialysis quite difficult to complete because of hypotension with each dialysis run. There is no correlation between the amount of amyloid in the glomerulus and the extent of urinary protein loss. The urinary sediment is rather benign with fat or fatty acid crystals, but the sediment is not inflammatory or nephritic. Occasionally, amyloid patients will present with adult Fanconi syndrome with crystalline deposits in the proximal tubules and resultant urinary loss of uric acid, phosphorus, amino acids, and potassium. Immunotactoid glomerulopathy can be confused with light chain amyloidosis, but the majority of patients with immunotactoid fibrils in the kidney do not have an associated plasma cell dyscrasia [43]. The fibrils seen by electron microscopy in immunotactoid glomerulopathy do not stain with Congo red. Randall light chain deposition disease is very hard to distinguish from light chain amyloidosis. However, light chain deposition disease rarely involves liver, heart, and nerves [121, 122].

Therapy

Supportive Care Treatment for Amyloidosis

For both cardiac and renal amyloidosis, the mainstay is diuretic therapy. Diuretic therapy can be complicated because so many patients have orthostatic hypotension and intravascular volume contraction due to their hypoalbuminemia. Diuretic therapy can raise the creatinine level and lower the systolic blood pressure. Our cardiologists appear to have a preference for torsemide over furosemide as having better bioavailability for patients; and for those patients in whom loop diuretics fail to control edema, the addition of Metolazone in doses from 2.5 mg QOD to 5 mg BID can be beneficial but can be complicated with relatively severe hypokalemia. Patients that develop orthostatic syncope are often treated with fludrocortisone or midodrine. The latter is complicated by severe supine hypertension.

Cardiac arrhythmias are a common problem in patients with amyloidosis; and clearly, if syncope can be documented to be related to severe bradycardia or supraventricular tachyarrhythmia that results in poor filling in between beats, a permanent pacemaker can be placed [123]. There is no evidence that afterload reduction with ACE or ARBS is of any benefit for patients with cardiac amyloidosis, and it has been our observation that patients tolerate these medications poorly and symptomatically feel worse. Moreover, because of poor diastolic filling, many of these patients require a rapid heart rate to maintain their stroke volume. As a result, artificially lowering a rapid heart rate with beta blockers can result in a decline in cardiac output and symptomatic deterioration in patients. Our cardiologists tend to avoid the use of beta blockers in amyloidosis patients [51].

There is data to suggest that an implantable defibrillator can be of benefit in patients for whom ventricular fibrillation has been diagnosed or those with recurrent syncope that cannot be attributed to orthostatic hypotension [93, 124] and is likely to be related to high-grade cardiac arrhythmias [125]. Digoxin is relatively contraindicated in the management of amyloid heart disease because there has been a previously reported high prevalence of sudden cardiac death. However, there are instances where it can be used to increase AV nodal blockade and reduce the heart rate in patients with rapid ventricular response. Calcium channel blockers have been reported to precipitate congestive heart failure and are best avoided in the management of these patients.

A small number of patients with cardiac amyloidosis have been reported with a left ventricular assist device as both destination therapy and as a bridge to transplantation. The numbers are too small to actually determine the appropriate role of a left ventricular assist device [126].

Cardiac transplantation has been used at multiple centers for amyloid, but major problems exist [127]. Systemic chemotherapy is clearly required. Without chemotherapy, one can expect recurrence of amyloid into the allografted heart [128]. Virtually all reported outcomes suggest that patients with heart transplant for amyloid do not do as well as patients with cardiomyopathy. As long as organ availability remains an issue, the question arises for every amyloid patient that gets a heart, which patient did not get a heart? Different centers have different philosophies about chemotherapy either before or after cardiac transplant. On one side, systemic chemotherapy is given before cardiac transplant in order to ensure chemotherapy sensitivity and the ability to control light chains. The downside of this is patients with advanced cardiac failure who are candidates for heart transplants do not tolerate significant amounts of systemic chemotherapy, and a real test of the ability to control the plasma cell dyscrasia cannot be accomplished. Unfortunately, delaying chemotherapy until after a heart transplant runs the risk that patients will be chemotherapy nonresponsive after they have received an allografted

heart, and this raises major challenges in trying to prevent recurrence. The Mayo Clinic standard has been to give patients an allografted heart followed by an autologous stem cell transplant [129]; and if there is persistent disease, use bortezomib-based chemotherapy as part of consolidation [130]. Cardiac transplantation does not bring up any major technical problems compared with patients receiving an allograft for cardiomyopathy, but outcomes will not be favorable without treatment of the underlying plasma cell dyscrasia [131]. Between May 1992 and November 2012, 178 adult patients referred for cardiac transplant for amyloidosis were evaluated; 78 did not complete evaluation, 94 completed evaluation, and 38 were considered ineligible primarily because of extracardiac amyloidosis, which we consider exclusion criteria for transplant; 56 were listed for transplant and 31 received transplant, 22 of whom had AL amyloidosis. The overall survival of the patients was a median of approximately 4 years with 20% alive at 10 years. Survival following heart transplant of amyloid patients was 81.6% and at 5 years, 48%. This compares with non-amyloid patients who have a 1- and 5-year survival of 93.4 and 83.6, respectively [132]. Chemotherapy and/or stem cell transplant following a heart transplant may significantly improve survival and needs ongoing study. The role of cardiac transplant in AL amyloidosis remains uncertain. Other groups have performed cardiac transplantation reported through the UNOS database, and 69 patients were reported in aggregate with 5 operative deaths and 29 late deaths and 9 deaths attributed to amyloid-related complications. The 5 patients had sequential cardiac and stem cell transplantation; 2 died of progressive amyloid 33 and 90 months after heart transplant; 1 patient actually had an allogeneic bone marrow transplant. In the United Kingdom, 24 patients with amyloid heart disease were reported with cardiac transplantation, 17AL [133]. One-, two-, and five-year survival rate was 86%, 86%, and 64%, respectively. Progression of amyloid systemically contributed to increased mortality.

Supportive care for renal amyloidosis includes hemodialysis for those patients who go onto end-stage renal disease, but their outcomes are inferior related to the high proportion of patients that have concomitant cardiac amyloidosis. Renal transplantation has also been performed for these patients [134]. The majority at Mayo Clinic receive a living related kidney because of the long wait for a cadaver donor [135]. These patients also require systemic chemotherapy because amyloid deposits in the transplanted kidney are well reported [136]. In a report of 45 patients who underwent kidney transplantation, the 3-year survival rate was 51%, with recurrent amyloid in the transplanted kidney detected in four. The estimated recurrence rate of amyloid at 1 year after transplant was 20%. No specific predictors of recurrence were identified. Sequential living donor renal transplant and autologous stem cell transplant is feasible. We have reported eight such patients with six long-term survivors.

Chemotherapy Treatment for Light Chain Amyloidosis

The primary therapy currently available for the treatment of light chain amyloidosis is plasma cell-directed therapy. Therapies are capable of destroying the underlying plasma cell clone responsible for the synthesis of the immunoglobulin light chains. These chains ultimately become resistant to catabolic breakdown and subsequently misfold into the amyloid configuration. Alkylator and steroid therapy remains one of the viable options for the treatment of amyloidosis, but none of the available regimens have been subjected to rigorous phase III randomized clinical trials [87]. The first use of alkylating agents dates back to 1972. The use of high-dose, alkylating-agent chemotherapy followed by autologous stem cell transplantation dates back over 20 years [137]. The ultimate goal of therapy is not reduction of the M component the way it is in multiple myeloma where response depth is a prediction of improved survival. In light chain amyloidosis, the goal of plasma cell-directed chemotherapy is to eventually invoke an organ response with improved cardiac, renal, or hepatic function. Because response to chemotherapy is time-dependent and there is a lag time between a hematologic response and an organ response, there are a number of patients that will succumb due to advanced organ failure before sufficient time elapses to allow for reducing the burden of toxic circulating light chains. The first alkylator combination was melphalan and prednisone, and two phase III trials have been performed using colchicine as the comparator arm that showed benefit [138]. Unfortunately, the majority of patients failed to achieve a hematologic response; and as in multiple myeloma, the doublet of melphalan and prednisone has been relegated to historical interest only. Early patients treated with melphalan and prednisone have clear-cut organ regression and improvement with SAP scintigraphy demonstration of a reduction in amyloid deposits.

The Mayo Clinic experience with melphalan and prednisone reported an objective hematologic response rate of 18%. Moreover, patients presenting with a serum creatinine >3 mg/dL were nonresponders and destined to go on to dialysis-dependent renal failure. The best responses were seen in renal amyloid nephrotic syndrome, but patients with amyloid cardiomyopathy can definitely respond; and melphalan and prednisone can be dose-adjusted so that it can be administered to virtually any patient of any age with any degree of cardiac or renal dysfunction [139]. Although only a few patients actually respond to melphalan, when they do, median survival is as long as 89 months. For melphalan-based therapy, it can be a challenge to know when to abandon the therapy since organ responses can be delayed. A trial of bortezomib-based chemotherapy and melphalan-dexamethasone failed to demonstrate a survival advantage

for the bortezomib arm [140]. Even in the era of melphalan and prednisone, 10-year survivors were regularly seen, almost all responders to alkylating-agent chemotherapy. Predictors of poor outcome, as in all trials of amyloid, include heart failure, age, serum creatinine, and percentage bone marrow plasma cells. When melphalan-prednisone was compared to colchicine, median survival in the melphalan-prednisone arm was 17 months compared to 8.5 months. These short survivals are a reflection both of the late diagnosis commonly seen with melphalan treatment of amyloidosis as well as the relatively low frequency with which response was achieved. Melphalan, particularly with prolonged exposure, has a significant risk of MDS or ANLL. In a series of 153 closely followed patients exposed only to melphalan, ten ultimately developed therapy-related MDS or ANLL [141]; eight of the ten showed classic cytogenetic features, which include hypodiploidy, deletion of chromosome 5, or deletion of chromosome 7. The actuarial risk for developing myelodysplasia at 42 months was 21%, reflecting the small proportion of long-term survivors. Today, melphalan is rarely given for longer than 12 months; and with the multiple alternatives available, reexposure to melphalan is uncommon, and rates of MDS that we are currently seeing are approximately 1%.

Approximately 10 years ago, melphalan-prednisone was supplanted with melphalan and high-dose dexamethasone [142]. Most patients were selected on the basis of stem cell transplant ineligibility. In an original trial of 46 patients, a hematologic response was seen in 67%, with an organ response in 33%, where hematologic response was the most powerful predictor of organ response [143]. This oral regimen had only a 4% all-cause mortality at day-100 and resulted in resolution of cardiac failure in 6 of 32 patients, with a median time to response of 4.5 months. In a follow-up trial of 93 patients, complete hematologic responses were seen in 24%, and improvement in amyloid-related organ failure was seen in 45%, with a 2-year event-free survival of 52%. In this trial, heart failure and β2 microglobulin levels predicted adverse outcome and durable reversal of amyloid-related organ dysfunction. Since patients on chemotherapy trials of amyloidosis are usually cared for at a trial center, there is inherent referral bias with regard to the outcomes, which is not reflective of the real-world experience.

Stem Cell Transplantation for the Management of Amyloidosis

Since the first report of five patients receiving high-dose therapy with stem cell transplant for the treatment of patients with amyloidosis, hundreds of articles have been published, demonstrating the benefits of stem cell transplantation in this disorder [144]. In multiple myeloma, patients tend to have unhealthy bone marrow but tend to have preserved vital organ function. Unfortunately, in patients with amyloidosis, comorbidities associated with cardiac failure, hypoalbuminemia, renal insufficiency, and chronic hepatic dysfunction lead to major complications after the administration of high-dose melphalan. The visceral organ dysfunction, which is always part of amyloidosis, has resulted in early mortality rates reported as high as 10% [145]. A mortality level this high was previously acceptable when the number of standard-dose chemotherapeutic alternatives was small but would not be considered an acceptable mortality rate in an era when multiple alternatives to transplantation exist. Most centers collect stem cells in amyloidosis without mobilizing chemotherapy. Although the majority of patients can be collected with growth factor alone, there has been an increasing tendency to give plerixafor [146] to enhance peripheral blood stem cell collection [147]. Patients with amyloid have a tendency to retain a good deal of fluid during filgrastim mobilization of peripheral blood stem cells [148, 149]. Although many centers incorporate plerixafor on a routine basis, our policy is to measure the peripheral blood CD34 on day-5; and if it is <10, we would begin plerixafor that evening and initiate collections the following morning. We dose plerixafor at 0.24 mg/kg when the creatinine clearance is >50; and for patients with a creatinine clearance <50, we reduce the dose to 0.16 mg/kg, and we never exceed a maximum dose of 24 mg. Even using this regimen, we find a high proportion of patients that still retain fluid; and in up to 20%, stem cell transplant would be delayed while we use diuretics to restore their weight to the pre-mobilization level.

We have successfully reduced the transplant-related mortality rate to 1.1% [150] and continue to see good outcomes, including patients with cardiac amyloidosis before the onset of advanced congestive heart failure. Our hematologic and cardiac response rates are now approaching 66% and 41%, and hematologic response is directly connected to survival. We have reported our 10-year results and survival in patients who have received transplants and it is 43% [151]. At Boston University Medical Center, 10-year survival has been reported to be 53%, with mortality rates of 4–7%.

Currently, we are excluding patients from stem cell transplant who have an NT-proBNP level > 8500 or a systolic blood pressure < 90, suggesting that the extent of cardiac failure makes high-dose chemotherapy excessively toxic. Overall, we find 20–25% of all patients eligible for transplant. We are now seeing complete posttransplant responses of 39%. The most important predictor of survival is Mayo stage. The most important predictor of outcome, however, is maximal hematologic response. Some patients improve long before it would be considered possible for amyloid to be removed from the organ. This is particularly the case with cardiac amyloid and does suggest that immunoglobulin light chains have a direct toxicity to the heart, and this has been verified in isolated mouse muscle studies and in a *C. elegans* model of contractility [152]. Occasional second courses of

high-dose chemotherapy can be administered in those patients that had a durable first response. Induction chemotherapy plays an important role in the treatment of amyloidosis. In a prospective randomized study recently published, albeit small, the use of induction chemotherapy followed by transplant resulted in a better overall survival than transplant alone. Unfortunately, this trial was not stratified for the percentage of plasma cells in the bone marrow at the time of diagnosis and randomization. A recent review of the ABMTR registry identified 1536 patients with AL transplanted at 134 centers. The overall survival and early mortality were analyzed in three time cohorts: 1995–2000, 2001–2006, and 2007–2012. When available, both hematologic and renal response data was included. This trial showed that all-cause mortality at day-100 declined from 20% to 5%, with a 5-year overall survival improvement from 55% to 77% [145]. In the cohort study from 2007 to 2012, hematologic response to transplantation improved, and the renal response rate was 32%. This trial reported that centers that performed more than four AL transplants per year had superior outcomes, suggesting experience matters, and familiarity with myeloma transplant is not a surrogate for amyloidosis experience. In a multivariable analysis, cardiac AL was associated with the highest mortality and worst progression-free and overall survival. Higher doses of melphalan were associated with a reduced risk of relapse, although patients who received lower doses of melphalan are generally older and have greater degrees of cardiac and renal insufficiency. A creatinine of 2 mg was associated with a poorer overall survival [145].

In an observational trial of GCSF and plerixafor, the combination produced a higher total CD34 yield and a greater proportion of CD34 cells collected on the first day of apheresis. Four patients were mobilization failures with G but none with G and plerixafor, and patients who received plerixafor actually had a lower weight gain of 0.5 kg vs. 3.2 kg. The number of apheresis sessions, the number of hospitalization days, and cardiac arrhythmias were similar. This trial suggests that the up-front use of plerixafor results in a superior stem cell mobilization compared with G alone [153].

The British Amyloidosis Center reported on 90 patients who had undergone autologous stem cell transplantation over a 9-year period (38% as part of initial therapy). The responses, as measured by complete and very good partial response rates, were thought to be superior to those reported with low-dose chemotherapy. Renal responses were noted in 33% and liver responses in 7%; and out of 17 patients evaluable for a cardiac response, a cardiac response was seen in 6 (35%). The median progression-free survival was approximately 4 years, supporting the use of stem cell transplantation and its ability to produce deep and durable responses [154].

Oregon Health Sciences University reported on 31 patients receiving autologous stem cell transplant, including patients who were pretreated and those who had received prior induction chemotherapy; 13 patients proceeded directly to transplant after diagnosis, 12 received a bortezomib-containing regimen before transplant, and 6 had other variable induction therapies prior to transplant. The all-cause, day-100 mortality was 9.6%, and the hematologic and organ response rates were 77% and 58%, respectively. The median time to hematologic response after transplant was shorter in the group that received bortezomib induction, 3 vs. 14 months. The overall cardiac response rate was 60% (100% in those pretreated with bortezomib and 43% in those without induction treatment). The 3-year progression-free and overall survival was 66% and 73%, and they concluded that bortezomib-based induction was well tolerated both in patients with and without cardiac involvement and could be considered as part of the initial therapy of amyloidosis [155].

The European HOVON German Cooperative Group for the treatment of amyloidosis conducted a phase II trial evaluating three courses of vincristine, doxorubicin, and dexamethasone, followed by an autologous transplant; and 69 patients were transplanted between November 2000 and January 2006. After long-term follow-up of 115 months, the median survival of all patients was 96 months from registration and, for the transplanted patients, 120 months from the date of transplant. Therapy-related mortality was 12%. Four patients died during vincristine, doxorubicin, and dexamethasone, and two additional patients of the remaining 57 (or approximately 4%) died following high-dose melphalan. A two-step approach consisting of less toxic induction therapy followed by high-dose melphalan may result in extended overall survival [156].

The Mayo Clinic Group has now completed stem cell transplantations on a total of 663 patients. The profound effect of NT-proBNP on outcome is given in the figure where survival is split at the level of NT-proBNP of 1800 pg/mL (Fig. 36.9).

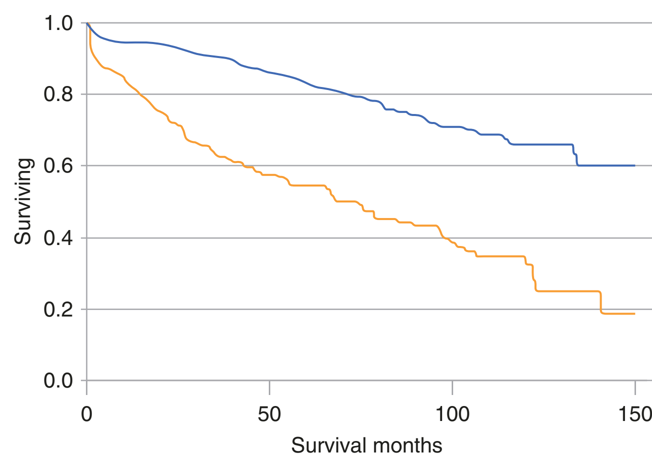

Fig. 36.9 Survival after stem cell transplantation stratified by NT-proBNP ≥ 1000 ng/mL. *Blue line*: NT-proBNP < 1000 ng/mL; *orange line*: NT-proBNP ≥ 1000 ng/mL

There is no reliable phase III data that demonstrates a survival advantage for stem cell transplantation. The only published phase III trial was plagued with poor patient selection and a very high therapy-related mortality [157]. Patients with AL, however, are highly selected for transplant. They are younger, have fewer organs involved, and will not have advanced heart failure. Therefore, concluding that stem cell transplantation is superior to conventional chemotherapy is not possible. The experience of most amyloid experts remains that if the patient is eligible for stem cell transplantation, they should be referred for therapy. Our current policy is to offer induction chemotherapy for those patients that have >10% plasma cells in the bone marrow. However, if the percentage of plasma cells is well below the threshold for multiple myeloma, then we are comfortable in going directly to stem cell transplantation and following the policy of Memorial Hospital in New York that uses bortezomib consolidation after transplant for those that have not, as yet, achieved a complete response [158].

Immunomodulatory Drugs

Thalidomide, lenalidomide, and, most recently, pomalidomide have been introduced for the treatment of immunoglobulin light chain amyloidosis, and all have shown significant activity. In the first thalidomide trial of amyloidosis, 16 patients had dose escalations to 300 mg/day. At this dose, treatment was poorly tolerated, and a high proportion had to abandon therapy before they had an opportunity to develop an organ response [159]. In a report of 12 patients with light chain amyloidosis treated with thalidomide, nine had severe drug-related toxicity and a median treatment exposure of only 72 days [160].

In Great Britain, thalidomide was combined with cyclophosphamide, thalidomide, and dexamethasone at only 100 mg/day, and 31% still had to discontinue therapy, although the hematologic response rate was 55%, and the treatment-related mortality was only 4%. Bradycardia can be seen in as many as 26% of patients. Therefore, care is required when this is administered to patients with cardiac amyloidosis [161]. A recent joint European study compared outcomes of bortezomib-based regimens with thalidomide-based regimens, and this retrospective multicenter review suggested that risk-adjusted bortezomib regimens were better than IMID-based regimens [162].

The second-generation immunomodulatory drug, lenalidomide, has a much better safety and toxicity profile in patients with amyloidosis [163]. It has been used with dexamethasone as well as with cyclophosphamide. The usual maximum-tolerated dose of lenalidomide is approximately 15 mg/day, but it can produce a response rate of 58%, 42 complete, with a 2-year overall survival of 81%. As with thalidomide, prophylaxis against venous thromboembolism is required. A combination of cyclophosphamide, lenalidomide, and dexamethasone is safe. No comparative trials exist to determine if it offers advantages to the doublet alone. Lenalidomide has been reported to increase the level of NT-proBNP and can actually aggravate heart failure; and the dose should not exceed 15 mg daily. The discontinuation rate of lenalidomide is high within the first three cycles. Skin rash, fatigue, and myelosuppression remain common. In a study of lenalidomide and dexamethasone in patients who failed melphalan and bortezomib, two (8%) died prior to first-response evaluation, 50% experienced grade 3 or greater toxicity, and the hematologic response rate overall was 41%. The median overall survival was 14 months. When cyclophosphamide was added in doses of 100 mg/day, the hematologic response rate was 55%. Lenalidomide was associated with fatigue and fluid retention. When amyloidosis, refractory to both melphalan and bortezomib, was treated with lenalidomide and dexamethasone, 24 patients were enrolled; 19 were refractory to thalidomide, two died before response evaluation, and the adverse event rate was 50%. Survival was shorter in patients with an elevated troponin and in those patients diagnosed <18 months before treatment initiation. Hematologic response rate was 41%, with a median overall survival of 14 months [164].

Melphalan and dexamethasone have been combined with lenalidomide; and in a phase I dose escalation, an MTD of 15 mg was achieved. Melphalan dose for amyloid patients was scaled back due to their frailty at 0.17 mg/kg/day for 4 days. In this trial, dexamethasone was given in a little-used schedule of 40 mg on days 1–4 every 28 days. All patients received low-molecular-weight heparin for DVT prophylaxis; 26 patients were evaluable, and 6 deaths were seen. The complete response rate was 42%, PR rate was 9 of 26, and an overall response rate was 58%, with 50% organ responses, a 54% event-free survival of 2 years, and an overall survival of 81% at 2 years [165].

When melphalan, dexamethasone, and lenalidomide was used in advanced cardiac amyloidosis, 25 patients were enrolled at a dose of 0.18 mg/kg/day for 4 days and dexamethasone 40 mg once weekly with lenalidomide 10 mg/day. Early cardiac deaths were seen in 42% of patients, arrhythmias in 33%, and the hematologic response rate was 58%. Overall survival at 1 year was 58%, but cardiac response rate was only 9%; and the median overall survival for patients with heart failure was 1.75 months [166].

Lenalidomide, dexamethasone, and cyclophosphamide were given to patients for 12 cycles, two-thirds of whom had no prior therapy. The MTD for lenalidomide was 15 mg, and

the MTD for cyclophosphamide was 100 mg/day. The PR rate was 55%, the CR was 8%, and four of five prior bortezomib patients responded. In 6-month survivors, the organ response rate was 40%, and the 2-year overall survival rate was 41%. A trial in newly diagnosed amyloidosis with cyclophosphamide, lenalidomide, and dexamethasone ended up enrolling a total of 41 patients. The ≥VGPR rate was 43%. Organ responses were seen in 23 heart, 23 kidney, and 4 liver patients. The overall and progression-free survival in those patients who achieved a PR or better was highly significant ($p < 0.001$).

Bortezomib-Based Chemotherapy for AL Amyloidosis

Eighteen patients, including seven who had relapsed or progressed, were treated with bortezomib and dexamethasone; 94% had a hematologic response, 44% complete, five patients (28%) had a response of at least one affected organ, first establishing activity of bortezomib in amyloid [167]. Our report on bortezomib in 20 patients with active clonal disease despite prior therapy, including thalidomide, was reported. Three (15%) achieved completed hematologic response, and a further 13 (65%) achieved a partial response, but 75% experienced toxicity, requiring discontinuation in 40% [168]. The first published study of weekly and twice-weekly bortezomib that was prospective reported hematologic responses in 50% of 30 evaluable patients, including 20% complete responses with a median time to response of 1.2 months with no difference between once-week and twice-weekly bortezomib [169]. A multicenter survey on the use of bortezomib across Europe reported on 94 patients from three centers. Previously untreated patients had a 47% complete response rate, and a 1-year survival was 76% with the NT-proBNP independently associated with survival [170]. In a series of 26 patients treated with bortezomib and dexamethasone, 69% received it as first-line therapy. The overall response rate was reported at 54%, with 31% hematologic complete responses. Median progression-free and overall survival was 5 and 18 months, respectively, but not reached in complete-response patients [171]. Bortezomib has also been used following autologous stem cell transplant as back-end consolidation for patients who do not achieve a complete response and was demonstrated to eradicate clonal disease at 12 months post stem cell transplantation. Consolidation with bortezomib achieves high stringent complete response rates [158]. An update of the original phase I-II trial conducted in Canada showed 1-year hematologic progression-free rates of 72.2 and 74.6 in patients receiving weekly and twice-weekly bortezomib. Organ responses included 29% renal and 13% cardiac [172].

The combination of cyclophosphamide, bortezomib, and dexamethasone was administered to 17 patients; a response was seen in 16 (94%), 71% achieving a complete hematologic response, and 24% a partial response. Three patients originally not eligible for stem cell transplantation became eligible, and this has become the standard of care at Mayo Clinic [173]. Bortezomib has also been combined with cyclophosphamide and dexamethasone, and the patients who received this at initial therapy had complete response rates of 65% with a 2-year progression-free survival of 66.5% and an overall survival at 2 years of 97.7% [174]. A confirmatory trial of cyclophosphamide, bortezomib, and dexamethasone as first-line treatment reported an overall response rate of 93% with 59% achieving a very good partial or complete response with no grade III-IV peripheral neuropathy [175]. Induction therapy with bortezomib and dexamethasone followed by autologous stem cell transplantation resulted in better outcomes than patients who went directly to stem cell transplantation without bortezomib therapy, achieving statistically significant improvement in overall survival at 24 months (95% vs. 69.4%) [176].

Bortezomib, cyclophosphamide, and dexamethasone have also been shown to be effective in high-risk cardiac amyloidosis (Mayo Clinic stage III). The overall response rate in this cohort was 68%. The estimated 1-year survival was 57%, 40% dying on therapy. Although unable to save the poorest-risk patients, bortezomib, cyclophosphamide, and dexamethasone achieved a high number of hematologic and cardiac responses [177]. Bortezomib has been combined with melphalan and prednisolone in the treatment of newly diagnosed AL amyloidosis. Among 19 patients enrolled in the trial, 16 (84%) had a hematologic response, including 37% complete responses with cardiac and renal responses in 44% and 33%, respectively [178]. In a matched-case control study of melphalan and dexamethasone with or without bortezomib, a higher rate of complete responses was observed with bortezomib (42% vs. 19%), but this did not result in a survival improvement for the overall population [140]. Induction bortezomib followed by high-dose melphalan and autologous stem cell transplantation was reported in 12 patients. The day-100 treatment-related mortality was 9.6%. Hematologic and organ response rates in the entire cohort were 77% and 58%, respectively. Overall cardiac response rate was 60%. The 3-year progression-free and overall survival rates were 66% and 73% [155]. A matched comparison of cyclophosphamide, bortezomib, dexamethasone with cyclophosphamide, thalidomide, and dexamethasone reported that the bortezomib-containing combination improved depth of response and resulted in a superior progression-free survival, supporting its use as opposed to a thalidomide-based therapy [161]. Translocation 11;14 is

associated with a poorer outcome in patients treated with bortezomib-based regimens. The reason for this negative impact of this translocation remains uncertain [15]. Bortezomib-based induction for transplant and eligible amyloidosis has resulted in a significant improvement to allow patients to undergo transplant; and in one trial, 8 of 24 initially transplant-ineligible patients became eligible, 7 of whom achieved sustained hematologic response 33 months posttransplant [179]. An update of long-term outcomes after bortezomib therapy of patients reported a median survival of 47 months in patients treated with bortezomib. Bortezomib was associated with improved 1-year survival compared to lenalidomide therapy (81% vs. 56%) [162]. A European collaborative report of cyclophosphamide, bortezomib, and dexamethasone reported 230 patients treated with front-line cyclophosphamide, bortezomib, and dexamethasone. Overall hematologic response rate was 60%, cardiac responses in 17%, and renal responses in 25% [180]. Induction therapy with bortezomib followed by bortezomib and melphalan conditioning for autologous stem cell transplantation was applied to 27 patients, and 100% hematologic responses were seen, 37 very good partial responses; and with a median follow-up of 36 months, median overall and progression-free survival had not been reached [181].

Seventy-three consecutive unselected patients were treated with first-line bortezomib-based induction. Hematologic responses were seen in 77%, including 33% very good partial responses. First-line bortezomib resulted in favorable response and survival [182]. In conclusion, it appears that bortezomib is the single most active agent available for the treatment of amyloidosis. A current randomized phase III trial looking at the oral proteasome inhibitor, ixazomib, is underway.

Antibodies

Anti-plasma-cell-directed chemotherapy does nothing to address established amyloid deposits. Three monoclonal antibodies are currently being tested for efficacy in the treatment of amyloidosis. The 11-1F antibody is currently undergoing clinical testing for efficacy. A second antibody against serum amyloid P component has been shown to improve the amount of amyloid in the liver and spleen and has resulted in improved ultrasound characteristics of the liver. Finally, the Neotope antibody has been given to 27 patients who no longer required anti-plasma-cell chemotherapy; and of 14 cardiac evaluable patients, 57% met the criteria for cardiac response; and of 15 renal evaluable patients, 60% met the criteria for renal response. This antibody, NEOD001, is now undergoing a global phase III trial [183].

Conclusion

Light chain amyloidosis needs to be considered in the differential diagnosis of patients with nondiabetic nephrotic range proteinuria, unexplained fatigue or heart failure with preserved ejection fraction, a progressive peripheral neuropathy associated with a monoclonal protein, or atypical multiple myeloma. Screening involves serum and urine immunofixation and an immunoglobulin free light chain assay. Most patients can have the diagnosis established via biopsy of the bone marrow and subcutaneous fat. Visceral organ biopsy is rarely needed. The prognosis is determined by the DFLC, the levels of cardiac biomarkers, troponin and BNP. Therapy includes high-dose chemotherapy; and for patients ineligible for high-dose chemotherapy, bortezomib appears to be the single most active agent (Fig. 36.10). Combinations of bortezomib and the inclusion of monoclonal antibodies are the subject of further studies.

Historical Landmarks in an Understanding of the Lymphomas

37

Marshall A. Lichtman

Ancient Oncology

Cancer, generically, has been an affliction of both simple and complex species, presumably since their evolution, and studied most exhaustively, although not exclusively, in mammals [1]. The presence of cancer in ancient times has been suggested by holes in bones found in ossuaries or in the remains of mummies, which in some cases have been thought to be lesions indicative of myeloma. Metastatic cancer was considered if the lesions had osteoblastic features and myeloma was thought probable if osteolysis alone was present [2, 3]. Differences in reproductive patterns, life expectancy, diet, tobacco and alcohol use, and exercise should lead to differences in cancer prevalence today, compared to the frequency in ancient societies. One study has concluded that, corrected for sex and age distributions of ancient populations, Upper Egyptian societies, circa 3200 to 500 B.C.E., Southern German populations, circa 1400 to 1800 C.E., and British populations, circa 1901 to 1905 C.E., may have had similar frequencies of cancer as in modern times [2]. The increase in the incidence of cancer in modern times was ascribed largely to longer life spans. Paleo-pathology, or, more specifically, paleo-oncology, is fraught with the challenge of artifacts, some of which occur postmortem and do not reflect antemortem disease; thus, the conclusion that lesions found in mummies in societies that preserved corpses (e.g., Egyptian, Incan, Papua New Guinean) represent the residue of cancers has been challenged [2–4]. Soft tissue cancers, such as lymphoma, would be very hard to discern after thousands of years of internment, but cancers have been described in Egyptian and Peruvian mummies. Our current understanding of the development of somatic mutations from errors in cellular DNA replication or repair, neoplastic clone formation, clonal selection, and clonal evolution to a progressive neoplasm underlies the knowledge that cancer is an invariable coincidence of the evolution of multicellular organisms from time immemorial [1, 5, 6].

Breast cancer is the best documented soft tissue cancer that afflicted ancient societies, in part because of its location. Cancer of the breast and its treatment by cauterization were described in the Edwin Smith (1822–1906) papyrus written circa 1600 B.C.E., the only surviving copy of part of an ancient Egyptian medical textbook and one of the world's earliest surviving examples of medical literature, held by the New York Academy of Medicine. It indicates a rather rational approach to problems for that era. The Kahun gynecological papyri, considered the oldest of the medical papyri, dated to circa 1800 B.C.E., deals exclusively with diseases of women, fertility, contraception, and pregnancy. Other disease descriptions are found in the Georg Moritz Ebers (1837–1898) papyrus of Thebes, dated to circa 1550 B.C.E. held in the library of the University of Leipzig. Similar medical descriptions have been found in recovered ancient Persian and Hindu literature. Ancient cultural views thought of cancer as the result of evil spirits, astrological events (e.g., the disharmonious movements of celestial bodies), violation of religious rules, and, generally, the anger of the gods. Thus, incantations and mystical approaches to disease are described, especially in the Ebers papyrus. However, arsenical ointments and other escharotics were used by the ancients for cancer therapy. Although there is no specific information available relevant to lymphoma, given our current understanding of de novo cancer development, as an inevitable

Note: Many of the English, Scottish, and Irish physicians or scientists discussed in this chapter received a knighthood and the appellation "Sir" could be used. Since they virtually all did their seminal work before they had been knighted, I have not identified them as "Sir" in the chapter.

consequence of errors in DNA replication and repair, malignancies of lymphocytes surely occurred in antiquity. Their frequency may have been much lower, since lymphoma incidence increases with age and lifespan was shorter. Also, the incidence of lymphoma increased significantly in the twentieth century. It has been postulated that modern methods of hygiene and antibiosis prevent postnatal modulation of the immune system, an evolutionary requirement to ensure normal function. The absence of modulation, induced by untreated, more frequent bacterial infections in childhood, may be a determinant of the increased frequency of lymphoid malignancies in First World countries in modern times.

It was over 1000 years after the Ebers papyrus was written that Hippocrates (460 to 370 B.C.E.) used the Greek term "carcinos" to describe tumors and "carcinoma" to describe ulcerating tumors. The root "carcino" is derived from the Greek for crab. The reason for this derivation is unknown, but it has been speculated that Hippocrates may have drawn an analogy between the limbs of a crab and the invasion by radial extensions of a cancer into tissues. Hippocrates also described cautery to remove skin cancers. Aulus Cornelius Celsus (circa 28 B.C.E. to 50 C.E.), a Roman, translated the Greek word "carcinos" into the Latin term "cancer." Celsus was a Roman encyclopedist and medical historian. His encyclopedia, *De artibus*, contained five books on agriculture, and other books on government, history, law, medicine, military techniques, philosophy, rhetoric, and science. Only *De medicina octo libri (The Eight Books of Medicine)*, the most comprehensive medical history and detailed description of medical and surgical procedures ever produced by a Roman writer, has survived. Celsus, for example, wrote about the appropriate surgical approach to mastectomy for breast cancer, a technique that spared the pectoralis muscles. Aelius (a.k.a. Claudius) Galenus (Galen) (131–203 C.E.) was born in the Greek city of Pergamum in Asia minor (current day Turkey). He introduced the term "onkos" from the Greek meaning mass or tumor, to refer to a malignant growth, and he espoused the concept of accumulation of black bile in tissues as the immediate cause of cancer. The latter concept was spawned by the Aristotelian division of the physical world into four elements: earth, air, fire, and liquid (water). Galen conducted anatomical studies on monkeys, did nerve ligation studies, had an interest in arteries and veins, and used the pulse rate as an indicator of disease. Some consider him the father of experimental medicine. Unfortunately, Galen had his imagination but few scientific tools to apply to his interests. He believed that food decomposed in the bowel was transported to the liver by the sucking ability of the vessels, and in the liver was converted to blood, which was transported to the heart by hepatic veins and from there only to the lungs for their sustenance. These concepts lead Galen to conclude that blood was the direct derivation of food and quantitatively related to the amount of food ingested. Galen theorized that four fluids, blood, phlegm (mucous), yellow bile, and black bile governed bodily processes and the balance or imbalance among them caused disease. He thought that black bile was formed in the spleen as a result of undigested food reaching it through a canal from the stomach. These concepts dominated medical thinking for the next 1200 years.

This inability to apply logic, anatomical dissection, and experimentation to medicine, in part, was the result of the prohibition by early cultures and, later, the Church to dissecting the human body or to study or use surgical procedures, leaving monks to translate and propagate the misconceptions of Galen and the application of alchemy, astrology, and magic to the causation of human disease. Even the opening of the universities in Paris and other principal European cities at the end of the first millennium C.E. did not significantly advance learning about human physiology or medicine because the Church at that time dictated the books that could be used in those institutions.

Theophrastus Phillippus Aureolus Bombastus von Hohenheim (a.k.a. Paracelsus) (1493–1541) was one of the first to challenge the Galenic theory of disease. Paracelsus was used as his pseudonym and meant "equal to or greater than Celsus." Paracelsus was a Swiss physician and chemist who derided Galen's views on disease causation and suggested sulfur or arsenic accumulated in the blood, especially in miners, masons, metal workers, and others exposed to potential toxins, which led to cancer. Ambroise Paré (1510–1590), the renowned French surgeon and expert on battlefield wounds, argued that an inappropriate diet resulting in feculent material accumulating in the blood was the immediate cause of cancer. Although both were considerably off the mark, one can see a shift from unhappy gods to more relevant precedents, such as exposure to environmental toxins or inadvisable ingestants. Paracelsus, in part because of his argumentative, adversarial, and zealous approach to controversy, incited the Galenists who beat him to death.

The development of the printing press and the environment for observation and discovery defining the Renaissance made possible the propagation of the remarkable anatomical studies of Andreas Vesalius (1514–1564) in his seven-volume masterpiece, *De Humani Corporis Fabrica Libri Septem* (*On the fabric of the human body in seven books*). The influence of René Descartes (1596–1650) who, in the eternal dispute between faith and reason, favored questioning everything until one reached the strength of fact, established the foundation of the scientific method, and the distrust of pontification. Descartes' publication *Discours De La Methode Pour bien conduire sa raison, & chercher la verité dans les sciences…* (*Discourse on the Method of Rightly Conducting the Reason and Seeking Truth in the Sciences…*) was, perhaps, the most influential publication of the seventeenth century, providing a framework for scientific reasoning.

Isaac Newton (1643–1727), the English mathematician, astronomer, and physicist, published *Philosophiæ Naturalis Principia Mathematica* (*Mathematical Principles of Natural Philosophy*), often referred to as *Principia*, in 1687. It was the basis for the field of mechanics, describing universal gravitation and the laws of motion and providing the scientific perspective of the physical universe for the next 300 years. Newton showed that the motions of objects on Earth and of celestial bodies are governed by the same set of natural laws by demonstrating the consistency between Johannes Kepler's (1571–1630) laws of planetary motion and Newton's theory of gravitation, thus confirming, indisputably, the concept of heliocentrism. Buoyed by these great achievements in the physical sciences, the studies of Malpighi, Morgagni, Harvey, and other great experimentalists of the day, in fields related to biology and medicine, encouraged scientists to challenge earlier misguided ideas about cancer and its causes and to pursue new avenues of inquiry using dissection, microscopy, clinical description, classification, and other techniques to which could be applied the developing ideas about the scientific method of inquiry (covered later in this chapter).

The Introduction of Microscopy and of Examination of Tissues

The invention of the microscope was essential for the furtherance of knowledge about the cellular pathology of cancer and was among the most significant inventions leading to our advanced understanding of the lymphomas. At the end of the sixteenth century, a Dutch spectacle maker, Sacharias (Zacharias) Jansen (Janssen) (c.1580–c.1638), discovered that nearby objects appeared greatly enlarged when examined through lenses in a tube. His simple and crude device, using an eyepiece lens and an objective lens, was the forerunner of the modern compound microscope. In 1609, Galileo Galilei (1564–1642), the Italian physicist, mathematician, astronomer, and philosopher, considered the father of modern science, learned of Jansen's experiments and, so stimulated, developed the principle of lenses and made an improved compound microscope that included a focusing device. Galileo's contemporary Giovanni Faber (or Johann Faber) (1574–1629) was a German botanist who moved to Rome in 1598. He was curator of the Vatican botanical garden, a member and the secretary of the Accademia dei Lincei ("Academy of the Lynx-Eyed"), anglicized as the Lincean Academy, in Rome. Faber coined the term "microscope" from the Greek words "micron" meaning "small," and "skopein" meaning "to look at." The Academy, founded in 1603, was one of the first academies of science to exist in Europe and was named after the lynx, an animal whose sharp vision symbolizes the observational skill required by scientists.

The Dutchman Antonj van Leeuwenhoek (1632–1723) was an apprentice in a linen-draper shop in Delft where he was being instructed in the use of magnifying glasses to count the threads in cloth. Later, he married and opened his own draper shop. His early experience resulted in his attempts to develop new methods for grinding and polishing lenses of a curvature that were capable of magnifications of nearly 300-fold. Using these monocular magnifying devices of his construction, he described the appearance of bacteria, the first description of spermatazoa, and other microscopic findings, and published his observations in several hundred letters to the Royal Society of England and the French Academy. Leeuwenhoek, the first to describe single cell organisms (i.e., bacteria), which he called "animalcules," was initially disbelieved, as there was no concept of living organisms of these dimensions. The Royal Society sent a group of men to Delft to verify these findings. When verified, the observations required the Society (and the world) to revisit its theory of living organisms. Robert Hooke (1635–1703), an Englishman, confirmed many of Leeuwenhoek's observations, lauded his pioneering work, and improved the design of the light microscope. Hooke wrote *Micrographia*, the first book published on the topic of microscopy in which he described his microscopical observations. He was the first to use the word "cell" to identify microscopic structures when studying the structure of cork.

By the mid-nineteenth century, European countries began to manufacture fine optical equipment including microscopes. Advances were made in the nineteenth century that removed disturbing artifacts (e.g., bright halos), which interfered with the visualization of objects. The development of the achromatic lens by the specific fusion of a convex and concave lens eliminated chromatic and spherical distortions. Other improvements were accomplished by determining preferred combinations of lenses and the distance between lenses that resulted in an optimal image. These advances were paralleled by improved methods of preserving, hardening, cutting, and staining tissue for examination. Among the finest microscopes of the day were those built by the American Charles A. Spencer (1813–1881) living in relative isolation in a small village in central New York State; they provided magnification of nearly 1000-fold and were deemed the equal of or better than the finest English or Continental models. Spencer, self-taught, was one of the finest opticians of his day. In Europe, Carl Zeiss (1816–1888) opened an optics workshop in Jena, Germany, in 1846. By 1861, Zeiss was considered to be among the best lens and scientific instrument makers in Europe. The lenses he was manufacturing in addition to advancing microscopy also propelled photography.

Even with these superb light microscopes, structures less than half the wavelength of light, 0.275 mm, were not resolvable. It required about 100 years to advance microscopy to

see smaller objects and structures. In the early 1930s a team in Germany had been able to bypass light and use a different form of illumination, an electron beam accelerated in a vacuum. In 1931, working closely with Max Knoll (1897–1969), Ernst Ruska (1906–1988) built the first electron lens, an electromagnet that could focus a beam of electrons as if it were a light source. His prototype of an electron microscope could magnify only 17-fold, but he had accomplished proof-of-principle. Within 2 years, Ruska's electron microscope, which he termed a "transmission microscope," was much improved. An image was generated by passing electrons through a thin specimen and then deflecting them to a photographic film emulsion or projecting them onto a fluorescent screen, generating an image at high magnification. This device was capable of magnifying specimens up to approximately 10,000-fold. Ruska temporarily joined the Siemens Company in Germany[1] as an electrical engineer in 1937 and the company released its first commercial electron microscope in 1939, based on Ruska's design. When Ruska received the Nobel Prize in Physics in 1986 for his work, the Nobel Committee described the electron microscope as one of the most important innovations of the twentieth century. By that time further improvements of the device had made it capable of magnifying an object up to one million times its size, making it possible to view viruses and molecules. The electron microscope made possible the discovery of the Epstein–Barr virus (see later discussion in this chapter) among innumerable other findings important to the advanced understanding of cancer in general and lymphoma in particular.

Early Views of the Lymphatic System and Cancer

The lymph nodes had been described by the last third of the seventeenth century by the pioneering physician, embryologist, and histologist Marcello Malpighi (1628–1694). Malpighi was an extraordinary observer and the earliest biological microscopist. Although the compound microscope was available since the late sixteenth century, Malpighi was the first to use it with such significant results.

His discoveries in human and animal biology and botany were such that he was made a member of the Royal Society of England, the first Italian to be so honored. Many of his findings were published as letters to the Royal Society. Although William Harvey (1578–1657) predicted the existence of capillaries when he announced his discovery of the pulmonary and systemic circulatory systems in 1616, fully described in his monumental treatise, *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (An Anatomical Exercise on the Motion of the Heart and Blood in Living Beings) published in 1628, Malpighi observed blood coursing through them, having the advantage of the application of microscopy to his work. In an undated letter from Malpighi to Prince Marcantonio Borghese (circa 1687), he gave his detailed description of the conglobate glands, which included the lymph nodes, into which lymphatic vessels flowed and exited. He refuted the idea that they were fibrous swellings, as had been suggested by others. He also described the white pulp of the spleen, the splenic lymph nodules, which were later named Malpighian corpuscles in recognition of his landmark studies of splenic structure [8]. He did not appreciate that they were lymphatic in nature, but identified them as separate, glandular structures. Malpighi also recognized diseases that led to gross enlargement of lymph nodes and spleen and he may have been the first to describe cases of lymphoma. Malpighi and Morgagni described the histopathology of cases that were felt by David Craigie (see later discussion in this chapter) to have been the earliest descriptions of Hodgkin's disease.

Giovanni Battista Morgagni (1682–1771) was an Italian anatomist, and the earliest of the anatomical pathologists. He had studied with Antonio Maria Valsalva (1666–1723), who had been a student of Malpighi. He became the professor of anatomy at Padua. In 1761, when he was 80 he published his great work, *De Sedibus, et causis morborum per anatomem indagatis libri quinque* (The seats and causes of disease, investigated by anatomy, in five books), which made pathological anatomy a science and enhanced the precision of medical practice. His treatise was based on the study of hundreds of case histories and autopsies performed at the University of Padua. His proposal that disease was caused by a malfunction in bodily organs provided a rational substitution for the ancient concept of ill humors, black bile, and other irrelevancies as a cause of disease, a revolution in the understanding of illness. His association of exaggerated fat accumulation at autopsy with several diseases established today as related to obesity is an example of his perceptive analyses. During the succeeding 10 years, his treatise was reprinted several times in Latin (its original language) and translated into French, English, and German. Although Andreas Vesalius, Gabriele Falloppio (1523–1562), Geronimo Fabrizio (a.k.a. Hieronymus Fabricius) (c1533–1619), and others in prior generations had described normal

[1]At this period, the Siemens company (and other German industries) had abetted the rise of the National Socialist Workers Party (commonly called the Nazi party) and supported the policies of Adolph Hitler (1889–1945). A few years later, Siemens built electronics factories in the close vicinity of concentration camps and used slave labor in its plants. The company was complicit in the worst aspects of the Third Reich's inhumane policies and its execution of the Holocaust. Siemens ran factories at Ravensbrück (a camp limited to women prisoners at which brutality and vile and grotesque medical experiments were the norm) and in the Auschwitz subcamp of Bobrek among others [7].

human anatomy carefully, indeed brilliantly, and, thereby, to debunk such concepts as Galen's canal connecting the stomach to the spleen, Morgagni was the first to make pathological anatomy a central approach to medicine.

The milky fluid of lacteals was described in the mid-seventeenth century. Jean Pecquet (1622–1674), a French physician, described the cisterna chyli, the thoracic duct, and observed that the thoracic duct entered into the large veins of the upper thorax in the dog. In Denmark, Thomas Bartholin (1616–1680) confirmed these findings in humans and observed that they formed a separate vascular system and named them "lymphatics" and their content "lymph" (from the Latin, *lympha*—meaning "clear spring water"). It had been speculated that they arose from arteries, but Bartholin provided evidence that there were three systems of vessels: arteries, veins, and lymphatics.

For nearly 175 years during the sixteenth and seventeenth centuries, some observers thought that lymph nodes were the coiled mass of lymphatic vessels. The afferent lymphatics were thought to enter the gland over its convex surface and become intertwined to make up the bulk of the gland and then exit as efferent lymphatics. William Hewson (1739–1774), the son of a country surgeon, was trained in medicine as an apprentice to a surgeon in Newcastle-on-Tyne [9]. After studies in Edinburgh and Paris, in 1759, he went to William Hunter's (1718–1783) preeminent school of anatomy in London; he also studied at St. Thomas's and Guy's hospitals. During 1768–1769, Hewson read three papers to the Royal Society on his exploration of the lymphatic system in the lower vertebrates (birds, amphibia, and fish), and made a more complete demonstration of the lymphatic system than his predecessors. He was elected a fellow of the Royal Society in 1770. He provided the first account of coagulation of the blood and showed that it was the result of changes in plasma rather than cellular constituents. The compound microscopes at that time produced distortions and the procedures for preparing tissue for examination were inadequate. Hewson relied on a single lens and devised a satisfactory means of mounting "wet" specimens. In 1771, he published "An Experimental Inquiry into the Properties of the Blood, and an Appendix Relating to the Discovery of the Lymphatic System" in the *Philosophical Transactions of the Royal Society*, London. He gave the first good description of the various types of granular and agranular leukocytes. He was the first to observe the lymphocytes in the thymus and spleen (recognizing for the first time that the splenic corpuscles of Malpighi were lymphatic in nature) and concluded that their production was the intrinsic function of the thymus, lymph nodes, and spleen. The lymphocyte was so named because it was the principal cell found in the thin fluid, the lymph. He wrote, "By the lymphatic system and its appendages we mean the lymphatic vessels, the lymphatic glands, the thymus and the spleen." He recognized that the thymus provided lymphocytes "in the fetus and the early part of life." He reported his observations on the red corpuscles in 1773, showing that they were "flat as a guinea," not spherical, as was believed because of prior observers mistaking the center of the disk for a nucleus, probably an artifact of the primitive lens systems in use. He died from the effects of an infected dissection wound in 1774.

During the sixteenth through eighteenth centuries, a series of hypotheses about the nature of cancer developed, in part, related to the lymph. Cancers were thought to be contagious, thought to arise from coagulated lymph, thought to result from lack of movement of tissues (atony), and thought to result from the abnormal fermentation of blood and lymph. Despite these primitive and fallacious concepts, there was a steady progression among leading physicians of the day toward a cellular theory of cancer and the concept that cancers developed, locally, in a tissue related to the particular type of cancer formed. For example, in 1775, Percivall Pott (1714–1788) reported an association between exposure to soot in chimney sweeps and the incidence of scrotal cancer (later determined to be squamous cell carcinoma). He was the first person to demonstrate that a malignancy could be caused by an environmental carcinogen. Pott also showed that the cancer could be cured by prompt excision. Pott was one of the most respected surgeons of his day and published many other groundbreaking papers including his piece on fractures and dislocations. In London, in 1777, Bernard Peyrilhe (1735–1804) published the first treatise on cancer in Latin (*Dissertatio academica de cancro*), which was translated into English (*Dissertation on Cancer*). The publication highlighted the increasing exploration of and attempt to better understand this disorder. Peyrilhe was convinced that a microbe caused cancer and that a tumor's growth simulated the growth of a hen's egg into a chicken by incubation, requiring heat, humidity, perhaps obstructed blood vessels, and other factors.

The progress in this age was particularly notable in the life and works of Johannes Peter Müller (1801–1858). Müller became professor of anatomy and physiology and director of the Museum of Comparative Anatomy at the University of Berlin. He built a school that became famous and his students, who included Hermann Ludwig Ferdinand von Helmholtz (1821–1894), Theodor Schwann (1810–1882), Friedrich Gustav Jakob Henle (1809–1885), and others; it dominated German medical science in the second half of the nineteenth century. His *Handbuch der Physiologie des Menschen* published in parts between 1833 and 1840 was translated into English (*Handbook of Human Physiology*) and published in London in 1842. It was the leading textbook on the subject of human physiology and was revised and re-published several times. It was based on new concepts derived from his study of human and animal anatomy, chemistry, and other physical sciences, applying them to physiological

problems. He made extensive use of microscopy of pathological tissue and, in 1838, published a volume on the pathology of tumors. His work greatly influenced the young Rudolph Virchow. Müller's student Schwann introduced the "cell theory," declaring that human and animal tissues are the aggregate of cells, the building blocks of tissues.

In 1858, Rudolf Virchow (1821–1902), a German physician, anthropologist, and biologist, considered the father of human pathological study, published *Die Cellularpathologie in ihrer Begründung auf physiologische und pathologische Gewebenlehre* (*Cellular Pathology as Based upon Physiological and Pathological Histology*), a compendium of Virchow's 20 lectures delivered at the newly opened Pathological Institute of the University of Berlin [10]. Lecture VIII was entitled "Blood and Lymph." The lectures were dutifully recorded by a stenographer and Virchow used these verbatim transcripts to reproduce the lectures in his treatise on cellular pathology. Virchow extended concepts of disease from organs and tissues to cells. He opined, "All cells come from other cells… Where a cell originates it must have been preceded by another cell, just as animals are produced only by other animals and plants by other plants." He, also, proposed that disease is the result of disordered cellular function, a revolutionary concept.

Most of the major organs forming the lymphatic system (e.g., thymus, spleen, tonsils, lymph nodes) had been identified and unified as the site of production of the "colorless corpuscles" by Hewson and others well before Virchow's entry into medicine (discussed earlier in this chapter). The essential structures of lymph nodes and lymphatics were known and the structures of cortical lymph node follicles were interpreted as being similar to those of Peyerian patches, lymphatic nodules in the intestines, and the Malpighian corpuscles, lymphatic nodules in the spleen. Johann Conrad Peyer (1653–1712) was a Swiss physician and anatomist who had studied medicine in Paris and Montpellier, ultimately receiving his medical degree from the University of Basel [11]. He had observed the intestinal lymph follicles in 1673 and, in 1677, he published his findings under the title, *Exercitatio anatomico-medica de glandulis intestinorum earumque usu et affectionibus* (an anatomical-medical study on the intestinal glands, their functioning and diseases), which described the aggregated nodules found in the lining of the terminal small intestines, later to be named Peyer's patches. It, also, was later that they were determined to be part of the lymphatic system. Peyer who was an expert on the gastrointestinal tract thought they were digestive glands that emptied into the intestines through a duct (à la the pancreatic duct). Despite the fact that these intestinal lymphatic aggregates were first commented on by Marco Aurelio Severino (1580–1656), professor of anatomy and surgery in Naples, they were named for Peyer.

By the turn of the twentieth century, the essential description of the histological features of lymph nodes was incorporated into text books. For example, *The Principles of Pathological Histology* by Harvey Russell Gaylord (1872–1924), a professor of surgical pathology at the University of Buffalo, and Karl Albert Ludwig Aschoff (1846–1942), professor at the Pathological Institute at the University of Göttingen at that time, was published in 1901. Gaylord became the second director of what is today the Roswell Park Cancer Institute. In 1897, Dr. Roswell Park (1852–1914) and Mr. Edward H. Butler (1850–1914), publisher of the Buffalo Evening News, asked the New York State Legislature to introduce a bill that would provide a $7500 grant to establish a cancer research laboratory at the University of Buffalo School of Medicine. That bill was passed in 1898, and the New York State Pathological Laboratory of the University of Buffalo, the first facility in the world dedicated specifically to cancer research, was founded. The facility, which gave birth to what later would be known as Roswell Park Cancer (né Memorial) Institute, in honor of Buffalo's most prominent surgeon, has been cited as the earliest example of direct government support of cancer research. Gaylord and Aschoff's description of the histology of lymph nodes could just as well be in a histology text today [12]. However, there was no mention in the section of diseases of lymph nodes of lymphoma, Hodgkin's disease, or pseudoleukemia, the latter term used to encompass apparent malignant lymphoid diseases in which the white cell count was not prominently elevated. During the nineteenth and at the turn of the twentieth century, pseudoleukemia was one synonym for lymphoma and Hodgkin's disease, especially in Germany and some other nearby European countries (pseudoleukämie). The section of their text describing diseases of the spleen also had no discussion of lymphoma, lymphosarcoma, or Hodgkin's disease, indicating the slow and cumbersome means of spreading medical knowledge at that time. The changes of splenic histology with "leukemia" were described, but not in terms of specific leukemic types.

The Acceleration of Invention and Scientific Progress in the Eighteenth and Nineteenth Centuries

Advances in science and medicine, as today, are often the result of advances in industry, technology, the response to epidemics, and the demands of armies for better battlefield care of the wounded. The United States had achieved nationhood and was expanding westward fulfilling the principle of "Manifest Destiny." Its commercial and scientific achievements were to be unrivaled as a result of the rise of what would be the most innovative, industrious, and scientifically

oriented country in history, in large measure as a result of its openness to immigration of those constrained by autocratic governments, religious persecution, and nonprogressive societies and by its vigorous adherence to the separation of church and state. In France, the Monarchy had been replaced by a Republic of sorts. Antoine-Laurent de Lavoisier (1743–1794) had published *Traité Élémentaire de Chimie* (*Elementary Treatise of Chemistry*) in 1789. It was the first modern chemical textbook and presented a unified view of new theories of chemistry, contained a reinforcement of the law of conservation of mass, and repudiated the concept of "phlogiston." The latter was a theory that accepted the existence of a fire-like element called phlogiston that was contained within combustible bodies, which when released during combustion caused processes such as the rusting of metals, now understood to be oxidation. Lavoisier's textbook contained a list of elements that could not be broken down further, including oxygen, nitrogen, hydrogen, phosphorus, mercury, zinc, and sulfur. In his work, Lavoisier underscored the importance of experimentation rather than supposition. He wrote, "I have tried… to arrive at the truth by linking up facts; to suppress as much as possible the use of reasoning (sic. guess work), which is often an unreliable instrument which deceives us, in order to follow as much as possible the torch of observation and of experiment." Unfortunately, he was a victim of the early irrationality and brutality of the French Revolution (the Reign of Terror) and died on the guillotine because of his aristocratic heritage. When he requested a little time to complete some scientific experiments, the presiding judge purportedly responded, "The Republic needs neither scientists nor chemists; the course of justice cannot be delayed." Joseph Louis Lagrange (1736–1813), the most noted mathematician of that time upon hearing news of his friends execution remarked, "It took them an instant to cut off that head but France may not produce another like it for a century". Another giant of the day, Pierre-Simon Laplace (1749–1827) was advancing and revolutionizing mathematics, physics, and astronomy. His five-volume *Mécanique Céleste* (*Celestial Mechanics*) was monumental because it translated the geometrical study of mechanics, used by Isaac Newton, to one based on the calculus. Laplace also embraced probability theory in his treatise *Essai Philosophique sur les Probabilités* (Philosophical Essay on Probabilities) published in 1814. These thinkers exemplified the profound advances being made in science at that time.

In Britain, the aristocracy was losing its primacy, laws preventing child labor were to be enforced, and the institution of slavery was soon to be abolished in progressive countries. These changes fostered men of ingenuity, genius, and industriousness as opposed to members of the aristocracy, an essential element of progress. The entry of women as a force in science, with rare exception, awaited the more embracing atmosphere of the late twentieth century. Based on the previous observations and relatively crude inventions of many scientists (e.g., William Watson (1715–1787), Henry Cavendish (1731–1810), Charles-Augustin de Coulomb (1736–1806), Luigi Galvani (1737–1798), Alessandro Giuseppe Antonio Anastasio Volta (1745–1827), Georg Simon Ohm (1789–1854), and others) and incremental levels of understanding, Michael Faraday (1791–1867) devised an electric motor by 1821. Electricity would transform the way people lived and worked. The markedly improved steam engine devised by James Watt (1736–1819) and new means of transportation by land and sea, using steam energy, and its industrial applications would alter industry, commerce, and science and accelerate the industrial revolution that began in the early eighteenth century. The stethoscope and compound microscope would be applied to clinical medicine and pathology in new and dramatic ways and clinical and pathological medical findings would be integrated so as to advance our understanding of human disease.

Perhaps the most propitious of all the events of the time was Charles Darwin's (1809–1882) 5-year voyage on His Majesty's Ship Beagle in December 1831. This journey and his findings and their interpretation were to be the most significant scientific event of the nineteenth century and would provide a theoretical framework for all the biological sciences. One year after his return, in 1837, Alexandrina Victoria (1819–1901) would ascend to the throne of England at age 18 years and with her first cousin, husband and consort, His Royal Highness Prince Albert (Francis Albert Augustus Charles Emmanuel) (1819–1861), Duke of Saxony and Prince of Saxe-Coburg and Gotha, would oversee an era of profound artistic, industrial, and scientific advancement, and dramatic expansion of the British Empire, the Victorian Age, which encompassed her reign of 63 years and 7 months. During this period, the last 40 years of which followed Prince Albert's death, she appropriated an additional title, Empress of India.

An example of the broadening interest in science in the population at large was the enormous success of Arthur Conan Doyle's (1859–1930) fictional detective Sherlock Holmes, introduced in 1887 in "*A Study in Scarlet"* in which the magnifying glass was first used as an investigative tool in detective fiction. The character based on Joseph Bell (1837–1911), Conan Doyle's physician mentor at the Edinburgh Royal Infirmary, featured the skills of deductive reasoning and the ability to accumulate obscure clues and weave them into the fabric of enlightenment. His use of forensics, including analytical chemistry, toxicology, ballistics, and extraordinary skills of observation, reflected not only the advancement in science of that period but the acceptance of the importance of deductive reasoning, logic, and scientific methods. Indeed, when Conan Doyle, tired of his creation, killed him by sending him over Reichenbach Falls in the Swiss Alps with his adversary and archenemy, professor of

mathematics James Moriarty, the popular uproar of unhappiness was such that he later had to restore Holmes to his fictional life.

During this period, Claude Bernard (1813–1878), working at the Sorbonne, fostered the importance of the scientific method to ensure the objectivity of scientific conclusions in addition to making numerous advances in understanding human physiology, including the concept of homeostasis in the "milieu interieur." In 1865, he published *Introduction à l' Étude de la Médecine Expérimentale* (*An Introduction to the Study of Experimental Medicine*), a brilliant and insightful treatise on the objective approach to scientific inquiry. It was in this setting that medicine on the European Continent and in Britain was to see unprecedented progress and at which time the great universities and medical centers had been freed to follow new understandings in anatomy, physiology, and the embryonic discipline of biochemistry and to eschew dogma.

Hodgkin Lymphoma (Né Hodgkin's Disease)[2]

Evolution of Diagnostic Criteria

In 1832, a few months after Darwin set sail on the Beagle, a paper entitled *On Some Morbid Appearances of the Absorbent Glands and Spleen* was read to the Medico-Chirurgical Society of London by its Secretary, Robert Lee (1793–1877). In it, Thomas Hodgkin (1798–1866) described the clinical histories and gross postmortem findings of seven patients in whom the disease coupled prominent lymphadenopathy with splenomegaly [13]. Among the seven cases, one had been described by Robert Carswell (1793–1857), a Scottish physician and a gifted illustrator of medical pathology, who at age 35 years was named chair of pathology at London University. He was the first to illustrate the brain (pons) and spinal cord in multiple sclerosis [14]. He spent long periods of time in hospitals and mortuaries of Lyon and Paris painting watercolors and making pen and ink drawings of patients and postmortem specimens, completing 1034 paintings [15]. His atlas of brilliant watercolors, *Pathological Anatomy; Illustrations of the Elementary Forms of Disease*, was published in 1838, made possible by the invention of lithography in Germany 48 years earlier [16]. Much later, William Osler (1849–1919) remarked, "These illustrations have, for artistic merit and for fidelity, never been surpassed, while the matter represents the highest point which the science of morbid anatomy had reached before the introduction of the microscope" [17]. Carswell's images of cervico-clavicular-axillary lymphadenopathy, splenic involvement of the white pulp of the spleen, and perihepatic lymphadenopathy, among others, struck Hodgkin as an excellent representation of the disorder he was describing in his paper; he, therefore, included Carswell's case as the seventh in his report (Fig. 37.1). Unfortunately, journal publication techniques did not permit reproduction of Carswell's color paintings in Hodgkin's paper at that time.

At least two reports antedated Hodgkin's seven cases. David Craigie (1793–1866) in his text, *Elements of General and Pathological Anatomy* (1828), described a case with gradually enlarging glands, becoming hard and probably cancerous [18]. Craigie also cites a previous case reported in 1786 by William Cumberland Cruickshank (1745–1800) "in which the tracheobronchial lymphatic glands were affected with this morbid change to such an extent as to cause fatal suffocation." Cruikshank was an assistant to William Hunter in the latter's school of anatomy in London and was a gifted chemist as well as anatomist, first using chlorine for water purification and identifying carbon monoxide as being composed of carbon and oxygen, among other contributions. It was Hodgkin, however, who appreciated and articulated in his paper that these cases were a primary disease arising in the absorbent glands (lymph nodes) and not a process reacting to another "irritation." Although in retrospect several of Hodgkin's six cases may have represented different diseases (lymphoma of another type and infection), his paper was important because it was the first to call attention to diseases marked by lymphadenopathy associated with splenic enlargement in which it was proposed that the origin was in the lymphatic organs themselves, not secondary to another disorder [19].

Hodgkin was a remarkable man and in some ways his linkage with the earliest description of malignancies of lymphatic tissue has obscured his other contributions [20–22]. He was raised as a Quaker and wrote an essay at age 21 on the mistreatment of indigenous peoples, including the American Indians, by European colonists ("*Essay on the promotion of civilization*"). He was a physician's pupil at Guy's Hospital Medical School and attended the University of Edinburgh Medical School. He wrote his Doctor of Medicine thesis in Latin on the absorptive function of blood and lymph. This early interest in blood and lymph probably accounted for his focusing on lymphadenopathy in his seminal report. During Hodgkin's travels to France in 1821 he met René Laennec (1781–1826) who taught him how to use the stethoscope he had developed and, on his return to Guy's Hospital, he promoted the use of the stethoscope among

[2]For historical purposes, I have chosen to use the term Hodgkin's disease instead of Hodgkin lymphoma through most of this chapter. It took about 150 years after Wilks paper [25], in which he named the disease for Hodgkin, to establish the lymphocytic origin of the giant multinucleated cells in Hodgkin's disease and their clonal nature and, thus, through most of the time period discussed in this chapter Hodgkin's disease (later Hodgkin lymphoma) was the term used. The apostrophe "s" was deleted from eponymous medical designations in the mid-1980s (Editorial. Eponyms. *Ann Intern Med.* 1988;108:630–631.).

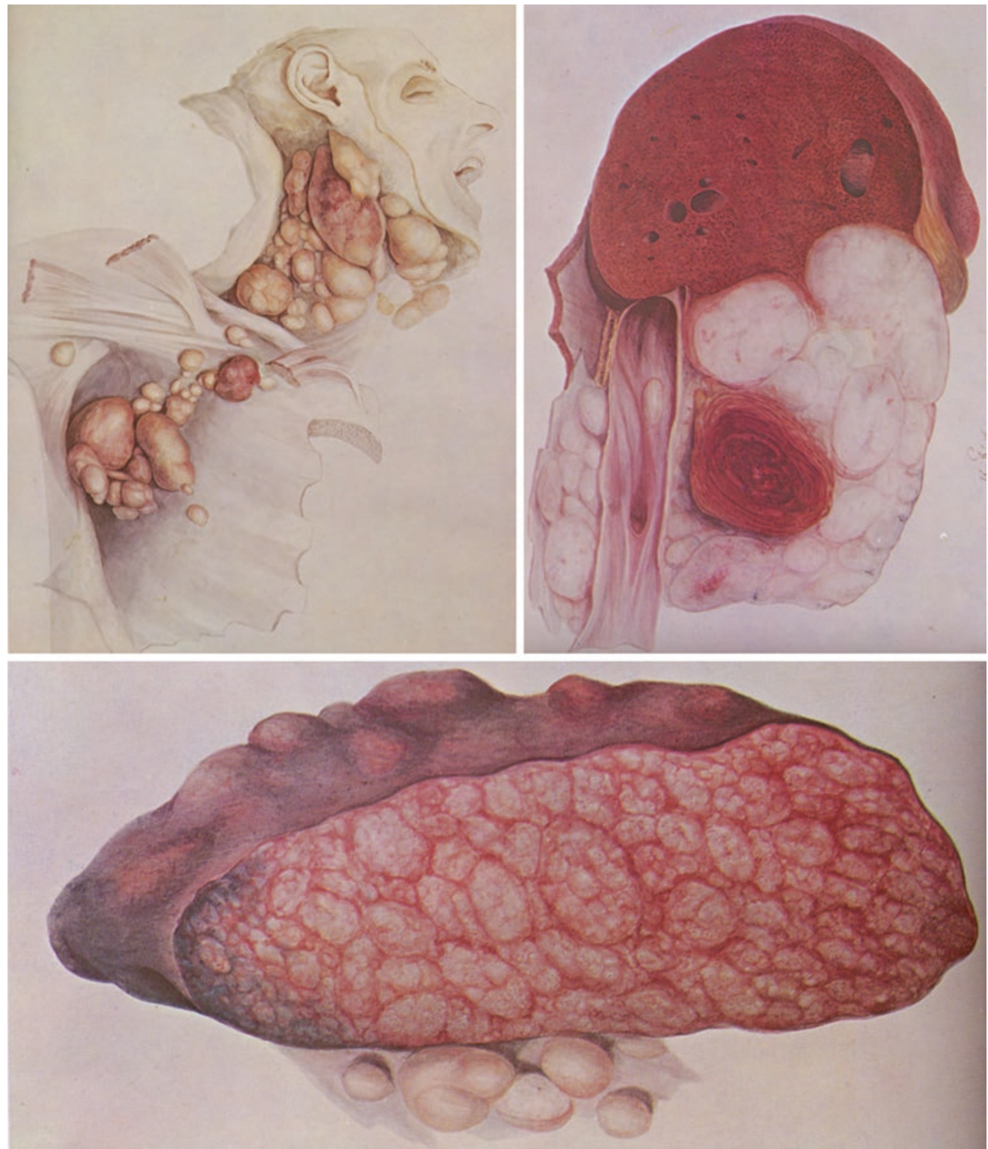

Fig. 37.1 Reproduction of Robert Carswell's vivid watercolor renditions of a patient he saw with lymphadenopathy and splenomegaly at the Hôpital Saint Louis during his travels to France [16, 17]. This patient was the seventh case used by Thomas Hodgkin in his paper of 1832 [13]. The patient was aged about 35 years with enlarged bilateral submandibular, cervical, axillary, and inguinal lymphatic glands ranging between a pea to a hen's egg in size according to Carswell. The drawings of the postmortem appearance of the cervico-clavicular-axillary lymph nodes, the perihepatic area, and the spleen are shown. The lymphatic glands under the liver surrounded the duodenum and "the great vessels of these parts." The tumor surrounded the aorta and vena cava, according to Carswell's description (These images were made available for reproduction through the generosity of University College Hospital and have been published previously in Dawson P. The original illustrations of Hodgkin's disease. Ann Diagn Pathol. 1999;3:386–89. Reprinted with permission of Elsevier)

British physicians. He became the curator of the pathological museum at Guy's Hospital and was one of the triumvirate of "the great men of Guy's," along with Richard Bright (1789–1858), a pioneering investigator of renal disease, and Thomas Addison (1793–1860), who described adrenal insufficiency in his classic monograph, *On the Constitutional and Local Effects of Diseases of the Suprarenal Capsules*. Although credited with the description of (Addisonian) pernicious anemia, the evidence is scant for this claim, as the anemia he described had few, if any, of the features expected. Several cases of lymphadenopathy Hodgkin used in his paper were patients under the care of Bright or Addison. Hodgkin had described aortic valve incompetence in a report entitled "On the retroversion of the valves of the aorta" published in 1829, 5 years before the Irish physician Dominic John Corrigan (1802–1880). Hodgkin described the nature and complications of appendiceal perforation 50 years before Fritz. Reginald Heber Fritz (1843–1913) was a pathologist at the Harvard Medical School who described the pathology of the appendix in appendicitis. Hodgkin was also interested in medical curricular innovations, arguing to increase science training for undergraduate medical students, and he was one of the earliest to propose a residency for physicians to improve postgraduate medical education (*An essay on medical education, 1828*).

Hodgkin was a proponent of analyzing clinical findings in the context of postmortem studies and he was both a skilled physician and the leading morbid anatomist of the day in Britain. Within 4 years of becoming museum curator, he had catalogued both the clinical and postmortem findings in 1600 specimens, arranged to show examples of the pathology of disease and their clinical correlations. He might be considered the father of the clinical–pathological conference, still highlighted today in the *New England*

Journal of Medicine. Because microscopy in the study of tissue was rudimentary at this time and infrequently used, only gross pathology was described. Richard Bright, Hodgkin's colleague at Guy's Hospital, reinforced Hodgkin's findings by including two of Hodgkin's cases in a detailed paper on abdominal tumors that he published in 1838, crediting Hodgkin with highlighting the malignant character and local origin of this disease of the absorbent glands, the term used for lymph nodes at the time. To his great disappointment, Hodgkin failed to be named to the position of Physician to Guy's Hospital after Bright's retirement. He devoted the later years of his life to humanitarian interests. He was a lifelong friend of and physician to Moses Hiam Montefiore (1784–1885), the renowned English financier, humanist, and, later, philanthropist. Montefiore was awarded a baronetcy by Queen Victoria. He was also briefly the Sheriff of London. Montefiore was deeply interested in rejuvenating the Jewish population of Palestine, then within the Ottoman empire. Hodgkin, as a Quaker, and Montefiore shared concern for the enslaved, dispossessed, and downtrodden of the world. Hodgkin was a strong opponent of the African slave trade and other inhuman behavior of the day. Montefiore shared these views and made major financial contributions to altering inhuman practices. Hodgkin died of a severe diarrheal disease while accompanying Montefiore on a trip to Palestine, the last of several they took together to Asia, Africa, and Europe, and is buried in what was at the time the Protestant cemetery in Jaffa. Montefiore erected a granite obelisk at his burial site on which he engraved a commeration to their 40 year friendship. Hodgkin's wife and brother included an inscription on the opposite side of the obelisk that included the phrase "*Humani nihil a se alienum putabit*" ("nothing human was foreign to him") [23, 24] (Fig. 37.2).

Fig. 37.2 Thomas Hodgkin was buried in the Protestant cemetery in Jaffa, Palestine, in 1866. He died of dysentery while on a trip with his close friend, Moses Montefiore. The inscription at the base of the obelisk that was erected by Montefiore, barely visible in this image, reads, "Here rests the body of Thomas Hodgkin, M.D., of Bedford Square, London, a man distinguished alike for scientific attainments, medical skill, and self-sacrificing philanthropy, died at Jaffa, the 4th day of April 1866, in the 68th year of his age, in the faith and hope of the Gospel. This epitaph is inscribed by his deeply sorrowing widow and brother to record their irreparable loss." They included in Latin "*Humani nihil a se alienum putabit*" ("nothing human was foreign to him"). On the reverse side of the obelisk, Montefiore's tribute is inscribed. A large blue plaque is affixed to the brick building in Bedford Square, London, that identifies it as Hodgkin's former home (This image of the obelisk was reproduced from http://en.wikipedia.org/wiki/Thomas_Hodgkin; image taken by Dr. Avishai Teicher)

Hodgkin's observations on diseases of lymphadenopathy with splenomegaly otherwise lay dormant for about 25 years, when in 1856, Samuel Wilks (1824–1911), independently, described ten cases in which he included four of Hodgkin's original cases [25]. The title "Cases of Lardaceous Disease and some allied affections" was principally related to cases of amyloidosis, which was the first such description of that disease. He separated the cases into four types and introduced a fifth type, which was exemplified by "a peculiar enlargement of the lymphatic glands frequently associated with disease of the spleen," which were four of Hodgkin's cases. Wilks thought at the time that his observations were original and hailed them as such. In his further research, Wilks uncovered Richard Bright's paper on abdominal tumors, in which Bright had included several of Hodgkin's case descriptions. Wilkes realized his error of omission and very generously made amends for his oversight by using the appellation, "Hodgkin's disease" in his paper "Cases with enlargement of the lymphatic glands and spleen (or Hodgkin's Disease)" in a subsequent series of 15 cases published in 1865 [26]. This eponymous designation has become ensconced in the medical lexicon.

In 1926, Herbert Fox (1880–1942), professor of pathology and director of the William Pepper Laboratory of Clinical Medicine at the University of Pennsylvania, traveled to Guy's Hospital and examined sections stained with hematoxylin and eosin prepared from the gross specimens of three of Hodgkin's six cases (Case II, IV, and VI), preserved in the Gordon Museum of Guy's Hospital in London [27]. The preservation of tissue in fixative was sufficient approximately 100 years later to permit Fox to confirm the histopathological diagnosis of Hodgkin's disease in two of the three cases and lymphoma of another type in the third. Fox was a distinguished bacteriologist and expert on typhoid fever and comparative bacteriology. He also had an interest in diseases of the blood and lymphoid organs. Seventy-three years later, in 1999, Fox's conclusions were supported by Robert (Robin) Nigel Poston (b.1944) in the Department of Experimental Pathology, King's College

and Guy's Hospital, London, who found Reed–Sternberg cells in the same two cases shown by Fox to be Hodgkin's disease on histological examination. He also established the multinucleated giant cells to be positive for Leu-M1 (CD15) using immunocytochemistry. Poston commented on the remarkable fact that this carbohydrate antigen survived the 160 years storage. The third case was compatible with another type of lymphoma in agreement with Fox's findings [28].

Hodgkin and his colleagues could not distinguish the various types of lymphoma and terms like primary lymphadenopathy or Hodgkin's disease in England, l'adenie or l'adenopathie in France, and pseudoleukämie in Germany, among others, were used to refer to what may have been Hodgkin's disease by today's understanding or various other types of lymphomas (malignant lymphadenopathy).

By the late nineteenth century, clinicians and pathologists had begun to define the histopathology of Hodgkin's disease more explicitly. The pathologists Paul Langerhans (1872), Auguste Ollivier and Louis-Antoine Ranvier (1876), William Smith Greenfield (1878), and William Richard Gowers (1879) had each described giant multinucleated cells, with multiple nuclei of large size, and distinct nucleoli in the lymph node sections of patients with a disease characterized by lymphadenopathy and often splenomegaly without abnormal cells in the blood [19]. The polychrome stains of Paul Ehrlich (1854–1915) had become available at the end of the nineteenth century and were used to describe the acidophilia of the nucleolus in the giant cells of Hodgkin's disease and the frequency of eosinophils in the lesion by Goldman in 1892 [29]. Greenfield was the first to publish drawings of the giant cells characteristic of the pathological appearance of Hodgkin's disease [30]. At a symposium on diseases of the lymphatic system, including lymphadenoma and leukemia, chaired by Wilks in 1878, vivid illustrations of lymphadenopathy were presented [30, 31]. At that symposium, Greenfield presented drawings of the pathology of lymph node sections in several cases of Hodgkin's disease showing their similarity and the large number of multinucleated cell that characterized the lesions. His description of the lymph node section in a case of lymphadenoma (another synonym for Hodgkin's disease at the time) read, "… a large number of multinucleated cells adherent to trabeculae, well seen on washing away the lymph cells. These multinucleated cells, containing from four to eight or twelve nuclei were often collected in clusters in the parts of the gland especially where the fibrous change was progressing (see Pl. XIII, Fig. 37.2)." He emphasized the distinction between metastatic carcinoma involving lymph nodes and lymphatic cancers originating in the nodes. He discussed lucidly the clinical basis with which to distinguish lymphadenoma from lymphatic leukemia. He also highlighted the characteristic contiguous spread of Hodgkin's disease to neighboring lymph nodes [30].

Paul Langerhans (1847–1888) [32] and Julius Dreschfeld (1845–1907) [33] further defined the breadth of the clinical and pathological presentations of Hodgkin's disease, a forerunner to modern classifications (Table 37.1). Langerhans

Table 37.1 Chronology of major advances in the histopathological classification, anatomical distribution (stage), and tissue of derivation of Hodgkin lymphoma: historical aspects

Year	Event	References
1832	Lymphadenopathy and splenomegaly considered a disease intrinsic to lymphatic tissue and not a reactive process	Hodgkin [13]
1838	Color paintings of the gross anatomical findings in the lymph node chains, spleen, and perihepatic nodes in Hodgkin's disease	Carswell [15, 16]
1856	Cases previously reported by Hodgkin's rediscovered	Wilks [25]
1865	More cases of lymphadenopathy and splenomegaly reported and Hodgkin given priority by calling the cases "Hodgkin's disease"	Wilks [26]
1870–1879	Multiple observers, notably Greenfield, describe and illustrate the multinucleated giant cells characteristic of the disease	Greenfield [30]
1892	Hodgkin's disease (syn. pseudoleucocythemia) distinguished from lymphosarcoma and classification of acute and chronic Hodgkin's disease proposed	Dreschfeld [33]
1898	Histological picture of Hodgkin's disease characterized, including diagnostic giant cells and mononuclear variant cells. Concludes disease caused by the tubercle bacillus because of striking coincidence of its presence in patients with Hodgkin's disease	Sternberg [34]
1902	Histological pattern characterized with elegant drawings of the appearance of lymph node lesions, including giant multinuclear cells. Concludes that it is a distinctive disease	Reed [35]
1947	Hodgkin's disease divided into three subtypes: paragranuloma, granuloma, and sarcoma	Jackson and Parker [36]
1950	Importance of clinical stage in the outcome of radiotherapy and a proposed system introduced that formed the basis for future staging classifications	Peters [37]
1952	Lower-extremity lymphangiography for visualization of pelvic and retroperitoneal lymph nodes	Kinmonth [38]
1966	Hodgkin's disease reclassified into six histopathological types	Lukes et al. [39]
1966	Rye conference arrives at consensus of simplifying classification into four histopathological types of Hodgkin's disease: lymphocyte predominance (15%), nodular sclerosis (40%), mixed cellularity (35%), lymphocyte depletion (10%)	Lukes et al. [40]

(continued)

Table 37.1 (continued)

Year	Event	References
1966	Rye proposal to stage the disease into four categories based on anatomical distribution and to split each into an (A) and (B) based on the absence or presence of constitutional symptoms (fever, night sweats, or pruritis)	Rosenberg [41]
1969	Laparotomy, abdominal lymph node biopsy, and splenectomy for staging of Hodgkin's disease	Glatstein et al. [42]
1971	Revised four-part Ann Arbor staging system for clinical and pathological staging of Hodgkin's disease	Carbone et al. [43]
1987	Identification of Epstein–Barr virus and its DNA in Hodgkin tissue and in Reed–Sternberg cells in about 40% of cases	Weiss et al. [44, 45]
1994	Identification of Reed–Sternberg cells as a clone derived from a germinal center B lymphocyte, conclusively designating Hodgkin's disease a B-cell lymphoma (Hodgkin lymphoma)	Küppers et al. [46–48]

was a distinguished anatomic pathologist who applied newer staining techniques to study tissue sections. He had worked with Virchow and Julius Cohnheim (1839–1884) in Berlin, where he finished his medical studies. He is most famous for his detailed description of the histological anatomy of the pancreas and the identification of the pancreatic islets (of Langerhans). He also identified a specific cell in the dermis, the Langerhans cell, but at the time was uncertain of its function and wondered if it was of neural origin because of its shape. He also identified phagocytic cells distributed in various organs, such as liver, spleen, and marrow, by their ingestion of cinnabar injected into the circulation. These were the scattered parts of the mononuclear phagocyte system, although that concept took some time to evolve after Aschoff dubbed it "the reticuloendothelial system," a system which in fact did not involve directly either reticular or endothelial cells, as we would learn subsequently. His conceptualization of a distributed system devoted to phagocytosis of foreign particles was important, however, regardless of the misnomer.

In 1892, Dreschfeld described what he termed "acute" and "chronic" Hodgkin disease [33]. He presented detailed descriptions of cases with cervical and mediastinal disease or abdominal disease to which he applied the designation typhoidal Hodgkin's disease because its manifestations simulated typhoid fever. He commented on the occasional high fever with intervals of nearly normal temperature, by that time already referred to as the fever pattern of Pel and Ebstein. Pieter Klazes Pel (1852–1919), a physician in Amsterdam, first reported this pattern of fever in a case of pseudoleukämie, a synonym used in continental Europe for lymphomatous diseases including Hodgkin's disease [49], 2 years before Wilhelm Ebstein's (1836–1912) description. Ebstein was a distinguished German academic physician and a world's authority on nutrition. Pel felt the fever was a manifestation of pseudoleukämie and Ebstein thought it represented a separate condition. Dreschfeld's descriptions of types of Hodgkin's disease were hampered by the inability of drawing histopathological distinctions among the various types of malignant diseases of lymph nodes. Dreschfeld was the most distinguished physician in North England in the late nineteenth century. Although born in Bavaria, he immigrated to Manchester, where he excelled in chemistry and mathematics and entered the Royal School of Medicine in Manchester. He continued medical studies in Würzburg at a time when the latter school was among the great medical schools in Europe with a distinguished faculty that included Heinrich von Bamberger (1822–1888), Virchow, Albert von Koelliker (1817–1905), and others. He became a skilled pathologist, microbiologist, practicing physician, and a renowned scholar. Upon his death, a biography of his life was published as a tribute by his admiring colleagues, which included his published papers, several seminal, and described his remarkable achievements in medicine [50].

Detailed histopathological descriptions of the large component of inflammatory cells, the significance of eosinophilia in some cases, and giant cells that were bi- or multinucleated with large nucleoli had by this time been published, as noted earlier. Dreschfeld and others considered the disease infectious, even though the term malignant was often applied.

In 1898, Carl Sternberg (1872–1935) in Vienna [34] and, shortly thereafter, Dorothy Reed in 1902 [35], working at John's Hopkins University in Baltimore, were credited with the first definitive and thorough histopathological descriptions of the disease and its characteristic, diagnostic giant cells, thereafter dubbed Sternberg–Reed or Reed–Sternberg cells, depending on the priority given to the earlier date of the description (Sternberg) or the more detailed drawing of the cells and the more astute description of their pathological significance (Reed). Sternberg not only carefully described the Sternberg–Reed cell but its mononuclear variant. He wrote, "There are also large pale eosinophilic protoplasmic bodies with a pale eosinophilic, large nucleus, structures corresponding to the large cells." Most of Sternberg's cases had evidence of tuberculosis and he became convinced that Hodgkin's disease was inflammatory, a reaction to infection with the tubercle bacillus. He considered his cases as tuberculosis masquerading as pseudoleukämie. He later modified his views slightly, forced to retreat by the cases of Hodgkin's disease in which careful search could not find evidence of the tubercle bacillus.

Dorothy Mabel Reed Mendenhall (1874–1964) did her undergraduate work at Smith College and additional premedical

studies at the Massachusetts Institute of Technology and became one of the few women up to that time to graduate from Johns Hopkins Medical School and intern at Johns Hopkins Hospital, where she served under William Osler. She, thereafter, became a Pathology fellow under the direction of William Henry Welch (1850–1934). From 1893, Welch directed the rise of Johns Hopkins University School of Medicine, where he started the country's first university department of pathology. He recruited William Osler, the first physician-in-chief, and William Stewart Halsted (1852–1922), the first chief of surgery, to the faculty and was the medical school's first dean. His curriculum revolutionized medicine in the United States by demanding that students study physical sciences and be actively involved in clinical duties and laboratory work. Among Reed's interests in pathology was the histological nature of Hodgkin's disease. Reed recognized Hodgkin's disease as an independent disorder and not a form of tuberculosis. She stated in her paper in 1902 (2 years after graduation from medical school) "… from the descriptions in the literature and the findings in eight cases examined, that Hodgkin's disease has a peculiar and typical histological picture and could rightly be considered a histopathological disease entity" [35]. Dorothy Reed according to autobiographical writings was not given the opportunity to advance her position at Hopkins because of her gender. She decided that she must leave and Welch arranged for her to work at the new Babies Hospital affiliated with the medical school at Columbia University in New York City. After a short interim residency position in New York City, she was accepted into the internship in pediatrics at the Babies Hospital. She worked under the direction of Luther Emmet Holt, Sr. (1855–1924), a pioneer in pediatrics, author of the first major textbook on the subject and author of "The care and feeding of children." Dorothy Reed left medicine to marry Charles Mendenhall who became Chair of Physics at the University of Wisconsin. She had four children, two of whom died in the first year of life. Her son, John "Blackjack" Mendenhall, became a prominent thoracic surgeon and another son, Thomas C. Mendenhall, was a professor of History at Yale University, and served as the sixth President of Smith College, Reed's alma mater. Dorothy Mabel Reed Mendenhall died of heart disease in 1964, at the age of 89. One can only speculate as to the contributions she would have made had she been given the opportunity to continue her work as an experimental pathologist.

Recognizing Histopathological Heterogeneity

As the histopathology of Hodgkin's disease was subject to more understanding and careful assessment, it was evident that the disease had several distinctive histological patterns. James Stephen Ewing (1866–1943), the first professor of pathology at Cornell University Medical College, in his classic textbook, *Neoplastic Disease; A Text-Book on Tumors*, published in 1919, describes the typical features of what he called "Hodgkin's granuloma" and, also, a clinically progressive disease in which the lymph node biopsy had pleomorphic variations of Reed–Sternberg cells to which he applied the designation, "Hodgkin's sarcoma" [51]. The disease was still thought to be the tissue manifestation of tuberculosis although cases in which the tubercle bacillus was not evident raised doubts in the minds of some observers. Sternberg still held to the idea that tuberculosis was the major cause; he conceded that there may be others. The idea that "tuberculosis follows Hodgkin's disease like a shadow," commented on in Ewing's chapter, was misinterpreted as the tubercle bacillus being an etiological agent rather than a secondary infection in a susceptible host. Eventually studies showed that only about one in four patients with Hodgkin's disease had coincidental tuberculosis and Hodgkin's disease was rare in patients with tuberculosis. Many prominent pathologists argued against the causal relationship and the concept withered.

In the mid-1940s, Henry Jackson, Jr. (1892–1968) and Frederic Parker, Jr. (1890–1969), at the Thorndike Memorial Laboratory and the Mallory Institute of Pathology at the Boston City Hospital and Harvard Medical School, built on earlier concepts and proposed three subtypes of Hodgkin's disease based on clinical presentation and histopathology: paragranuloma (small nodes in the neck, usually, and Reed–Sternberg cells in the pathological specimen), granuloma (much higher frequency of abdominal adenopathy, more effacement of nodes, more atypia to Reed–Sternberg cells), and sarcoma (notably retroperitoneal nodes, nodal confluence, invasion of neighboring intestinal structures, Reed–Sternberg cells, and many variants of such cells) [36]. The categories signified on average more rapidly progressive disease from paragranuloma to sarcoma. The classification suffered by the fact that about 90% of cases fell into the granuloma category and the histopathology of the cases classified as granuloma was very diverse, not uniform.

First, Robert J. Lukes (1922–1995) in 1963 and then Lukes, James J. Butler (d. 2004), and Ethel B. Hicks in 1966 presented a classification that provided six histopathological subtypes of Hodgkin disease, which addressed the criticism of the tripartite classification of Jackson and Parker and provided a distribution of cases among the six categories that was more discriminating. The distinctions were confirmed by a median survival that ranged from 12 to 2 years in parallel with advancing severity of the six categories [39]. At the time of this work, Robert Lukes was professor of pathology at the University of Southern California School of Medicine and chief of hematopathology at the Los Angeles County Hospital. Butler had collaborated with Lukes when both were at the Armed Forces

Institute of Pathology in Washington, D.C. where Lukes had been chief of hematopathology. Thereafter, Butler went to the M.D. Anderson Cancer Center in Houston, Texas. Lukes and Butler were leading authorities on the histopathology and classification of Hodgkin's disease and other lymphomas. Ethel Hicks was a statistician at the Armed Forces Institute of Pathology collaborating with Lukes and Butler on the analysis of their data. The six histopathological categories, although considered useful in the hands of experts, were difficult to reproduce by pathologists in various centers around the world and their proposal was modified in 1965 at a conference held in Rye, New York, in which the six histopathological subtypes were collapsed into four subtypes: lymphocyte-predominant, nodular sclerosis, mixed cellularity, and lymphocyte-depleted Hodgkin's disease [40]. Several modifications have superseded the Rye classification and the most current classification recommended by the World Health Organization panel on tumors of hematopoietic and lymphoid tissues has five categories of Hodgkin lymphoma, judged histopathologically [52].

Importance of Stage of Disease

In addition to histopathological classification of Hodgkin's disease, the distribution (stage) of the disease was determined to be important in assessing therapeutic approaches. Mildred Vera Peters (1911–1993), a Canadian radiotherapist, and a pioneer in the treatment of the disease with radiotherapy, described a clinical staging system in 1950, emphasizing the diagnostic evaluation of the anatomic extent of disease [37]. She proposed three stages depending on extent of disease and recognized the additional significance of constitutional symptoms of fever, night sweats, and weight loss. This proposal, describing three stages of the disease, formed the basis for future modifications, which split Peters' third stage into a third and fourth stage. In 1952, John Bernard Kinmonth (1916–1982), working at St. Bartholomew's Hospital, London, introduced lower-extremity lymphangiography that allowed visualization of the iliofemoral, pelvic, and retroperitoneal lymph nodes by imaging the size and pattern of injected contrast material in the lymphatic channels and nodes. This approach was more sensitive and specific than physical examination of the abdomen or other radiographic methods for these previously inaccessible regions [38]. Kinmonth had coauthored a textbook of vascular surgery and was both a pioneer and the leading surgical authority on lymphatic imaging. In 1972, he published his monograph entitled "*The Lymphatics*," which was updated in 1982 [53]. The frequency of unsuspected splenic involvement was appreciated when laparotomy with splenectomy and biopsy of splenic hilar, para-aortic and mesenteric lymph nodes, and liver was introduced for staging the disease [42]. These diagnostic procedures led to improved understanding of the pattern of dissemination of the disease and correlated well with prognosis, culminating in the advanced concepts of staging codified at the Rye conference in 1965 [41], and further refined at the Workshop on the Staging of Hodgkin's Disease in Ann Arbor, Michigan, in 1971 [43]. Although the introduction of computed tomography and positron emission tomography has superseded these invasive methods (lymphangiography and laparotomy), they were important at the time to correlate extent of disease with therapeutic approach and outcome.

The first commercially viable computed tomography scanner was invented by Godfrey Newbold Hounsfield (1919–2004), an engineer in Hayes, United Kingdom at EMI Central Research Laboratories using X-rays. Hounsfield conceived his idea in 1967 and it was publicly announced in 1972. Allan McLeod Cormack (1924–1988), a physicist, at Tufts University in Boston, Massachusetts, independently invented a similar process, and both Hounsfield and Cormack shared the 1979 Nobel Prize in Physiology or Medicine for this dramatic advance in diagnostic imaging by combining computer technology with X-ray technology. In May 1974, Siemens Medical Engineering introduced the first computed tomography system. This new technology was advanced 2 years later when Siemens marketed a computed tomography scanner that provided physicians with cross-sectional images of tumors. By 1977, Siemens had developed a system that integrated the radiation source and a detector system into a "gantry," a mechanism that permits the instrument to rotate around the patient to achieve whole-body computed tomography examinations. By 1985, it became possible to image anatomical features in three dimensions. The first spiral scanner was released in 1989, making it possible to scan a patient's lungs during a single breath-hold. Over the intervening decade and a half, computed tomography technology has been refined to the point that it can now visualize minute tumors, increasing diagnostic sensitivity.

In 1991, David Townsend (b.1945) and Ronald Nutt (b.1938) had what became known as "the epiphany in the Alps" in Geneva, Switzerland, when they first conceived coupling positron emission tomography (PET) with computerized axial tomography (CT). Townsend was on the faculty at the University of Geneva and at the Cantonal Hospital in Geneva from 1979 to 1993; he and an electrical engineer, Ronald Nutt, began exploring the idea of combining PET and CT to improve identification of human tumors. They were stimulated by a surgeon who indicated that each was helpful, but together they would be extraordinary. In 1993, the University of Pittsburgh hired Townsend to run the physics and instrumentation program of their PET facility. Nutt had started a company in Knoxville, Tennessee, and they continued collaborating on the combined PET-CT

device in the United States. Siemens launched a joint venture with Nutt's company to build the prototype instrument. Other manufacturers began developing versions of a combined scanner as well. One obstacle to use of PET-CT was the difficulty and cost of producing and transporting the radiopharmaceuticals used for PET imaging, which are usually short-lived. For instance, the half-life of radioactive fluoride used to trace glucose metabolism, using fluorodeoxyglucose (FDG) is 2 h. Its production requires a cyclotron as well as a production line for the radiopharmaceuticals. PET-CT has revolutionized many fields of medical diagnosis by adding precision of anatomic localization to functional imaging. This duality enhances cancer staging, surgical planning, radiation therapy, and the assessment of therapeutic results. Although the combined device is considerably more expensive, it has the advantage of providing both functions as stand-alone examinations, being, in fact, two devices in one.

The Cell of Origin and the Presence of Epstein–Barr Virus

Hodgkin suspected that the syndrome (disease) to which he was calling attention, lymphadenopathy, often with splenomegaly, without an apparent infectious cause was a disease intrinsic to lymphatic tissue. Bright and Wilkes reinforced that concept. At the beginning of the twentieth century, Hodgkin's disease was considered a neoplasm by some experts (e.g., James Ewing).

For most of the twentieth century, debate raged as to whether a lymphocyte or a macrophage was the closest analogue to the tumor cell. The proposal that some forms of Hodgkin's disease (slowly progressive in young persons) may be infectious persisted, especially for the first 65 years of the twentieth century. In part, this confusion was related to the inability to identify a clonal population of neoplastic cells in the various histopathological subtypes of the disease. The latter problem was related in large part to the extremely small proportion of clonal Reed–Sternberg cells and the large fraction of polyclonal lymphocytes, eosinophils, and macrophages in the lesion. Hodgkin's disease, like Langerhans cell histiocytosis, represents an example of a neoplastic transformation in which the tumor cells (monoclonal Reed–Sternberg or monoclonal Langerhans cells) are an extremely small proportion of the cellular infiltrate (<1%), a very unusual state for clonal (neoplastic) growths. The nature of the Reed–Sternberg cell remained a center of controversy until techniques became available to show that it has the phenotype and genotype of a monoclonal B lymphocyte and represented the neoplastic clone in all subtypes of Hodgkin's disease. Thus, Hodgkin disease could be renamed Hodgkin lymphoma with certainty. Ralf Küppers (b. 1962) and colleagues at the Institute for Genetics and Department of Pathology in Cologne developed techniques to isolate single Reed–Sternberg cells from frozen tissue sections of biopsies by micromanipulation and to do polymerase chain reaction testing on single cells. Their findings resulted in establishing that Reed–Sternberg cells had rearranged variable (V) region immunoglobulin genes and, thus, were derived from monoclonal B lymphocytes, since V gene rearrangements are restricted to B-lymphocytic lineage cells and are highly specific for a B-cell clone [46–48].

Hodgkin's disease was established as a neoplastic B-lymphocytic disorder with striking clinical, histopathological, and epidemiological heterogeneity. For this reason it has been debated as to whether it had several etiological initiators or was the variable host response to a single cause. An infectious inciting agent had been proposed since the nineteenth century during which time distinguished proponents of a role for *Mycobacterium tuberculosis* kept it in the forefront (Dreschfeld, Sternberg, and others). The presence of fever, reactive inflammatory cells dominating the lymph node infiltrate, a bimodal age incidence curve in Western societies, a younger age of incidence in a large proportion of affected persons than most neoplasms, and social-class-related relative risk had led some to consider it an unusual reaction to an infection in affected younger persons.

In 1987, Lawrence M. Weiss (b. 1956), currently Chair of Pathology at City of Hope, working with colleagues at Stanford University Medical Center reported the presence of Epstein–Barr virus DNA in the tissues of some patients with Hodgkin's disease [44]. Subsequently Epstein–Barr viral genomes [45] and viral messenger RNA [54] were identified in Reed–Sternberg cells. These findings have been replicated in several laboratories. Although Epstein–Barr virus sequences are found on average in four of ten patients, its relationship to the disease is found more intriguing if one looks more specifically at the association. The prevalence of Epstein–Barr virus is particularly notable in cases with either mixed cellularity or lymphocyte-depleted subtypes and is infrequent in nodular sclerosis or lymphocyte-rich classical Hodgkin disease. It is rarely present in nodular lymphocyte-predominant Hodgkin's disease. In Central and South American pediatric cases, the virus is present in over 90% of cases [55]. The significance of Epstein–Barr virus genomes in the tumor cells of patients with Hodgkin's lymphoma remains an intriguing association without as yet a full understanding of its role in the pathogenesis of the neoplasia. There are compelling findings, however, that an etiological role for the virus in cases in which it is found [55]. The Epstein–Barr virus is associated with three other diseases of B lymphocytes: infectious mononucleosis, endemic Burkitt lymphoma, and B-cell lymphoma in the setting of immunosuppression.

Therapy

Radiation Treatment

Wilhelm Conrad Röntgen (1845–1923) was a physicist with a background in mechanical engineering. While a professor of physics at the University of Würzburg, at which he had colleagues of the ilk of Hermann von Helmholtz and Ludvig Valentin Lorenz (1829–1891), he was studying the phenomenon of passing an electric current through a gas of very low pressure. His work was built on the discoveries of several predecessors, including William Crookes (1832–1919), Henrich Rudolph Hertz (1857–1894), and Eugen Goldstein (1850–1930), which had led to the development of the cathode ray tube. Röntgen's experiments on cathode rays led, however, to his discovery of a hitherto unknown ray form that he dubbed "X-rays," using the mathematical symbol "X" for an unknown quantity. When he exposed his wife's hand to these rays, while it was held over a photographic plate, he observed upon development of the plate the dark shadows of the bones of her hand and the ring on her finger with much lighter shadows from the outline of the skin of the hand. The first X-ray of human tissue had been made. Röntgen published his landmark paper on the discovery of a new type of electromagnetic ray, *Über eine neue Art von Strahlen* (On a New Kind of Ray), 50 days after his discovery, on 28 December 1895. The achievement resulted in his being named the first Nobel Prize Laureate in Physics in 1901, a very propitious start for the Nobel Foundation. Arguably, his discovery must be among only a handful that have had such an enormous and long-lasting impact on the understanding and diagnosis of human disease and an incalculable contribution to maintaining and restoring human health. Later, X-rays were shown to be of the same electromagnetic nature as light but vibrating at a much higher frequency.

In his will, Alfred Bernard Nobel (1833–1896) asked that the Prize be given to a discovery of benefit to mankind achieved in the previous year, a requirement to which the Nobel Foundation, wisely, did not adhere. Nonetheless, few if any Laureates made a discovery and contribution to medicine either recognized so quickly by the Nobel Foundation or of the magnitude of Röntgen. His discovery revolutionized the diagnosis and treatment of disease that continues today with the application of computed tomography and with advances in the instruments and techniques of radiotherapy.

By the first few years of the twentieth century, X-ray therapy was applied successfully to the treatment of Hodgkin's disease by William Allen Pusey (1865–1940) at the University of Illinois [56] and Nicholas Senn (1848–1908) at Rush Medical College in Chicago [57] (Fig. 37.3). In 1902, Pusey and, in 1903, Senn each published pretherapy and posttherapy images showing the disappearance of massive lymphadenopathy after X-radiation of the lymph nodes in patients with Hodgkin's disease. Pusey was a dermatologist in Chicago at the College of Physicians and Surgeons (later University of Illinois Medical School) who used radiotherapy for treatment of skin lesions and also tumors. He was the founder and first chief editor of the *Archives of Dermatology and Syphilology*. Senn, born in Switzerland, and chair of surgery

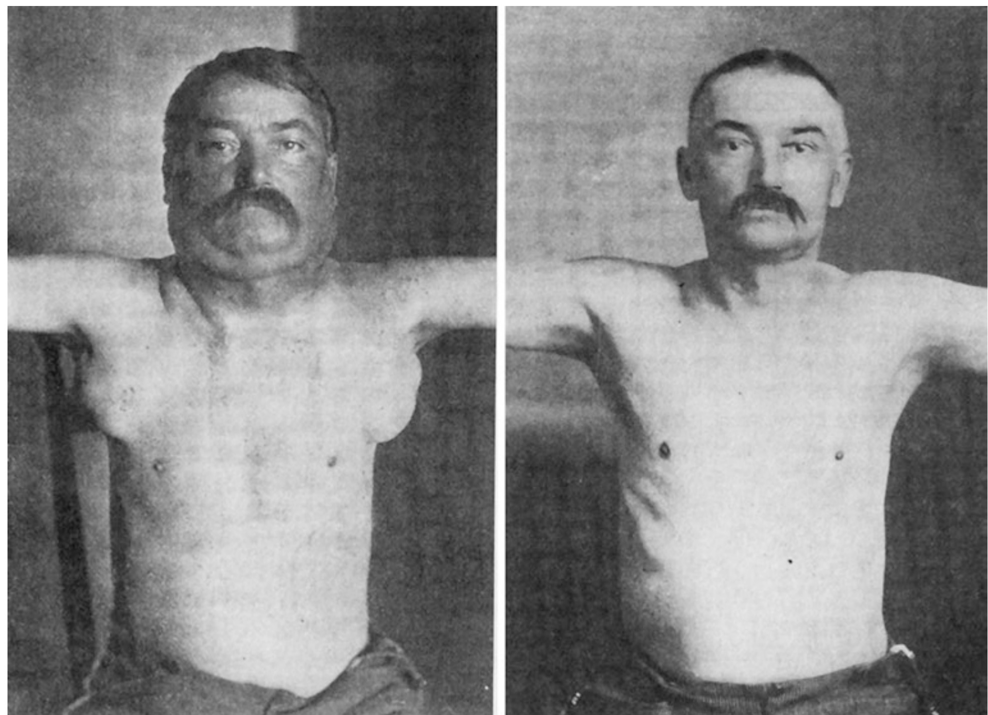

Fig. 37.3 An example of the salutary effects of early orthovoltage radiation therapy for Hodgkin's disease. *Left*, before radiation. *Right*, after radiation. Pusey in 1902 [55] and Senn in 1903 [56] reported the first use of radiotherapy, which dramatically shrank the lymph nodes of patients with Hodgkin's disease, at least transiently (Reproduced with permission from Senn N. Therapeutic value of Röntgen ray in treatment of pseudoleukemia. N Y Med J. 1903;77:665–68.)

at Rush Medical College in Chicago, was one of the most distinguished academic surgeons of his day. He authored numerous medical articles and several textbooks including *Principles of Surgery*. He was president of the American Medical Association. His fascinating life's story, travels, military service, bibliophilia, varied contributions to medicine, and other accomplishments are worthy of study for one interested in the history of medicine.

In 1896, stimulated by Röntgen's discovery, Antoine Henri Becquerel (1852–1908), working at the University of Paris, discovered that uranium salts emitted rays that resembled X-rays in their penetrating power. He demonstrated that this radiation did not depend on an external source of energy, but seemed to arise spontaneously from uranium itself. He was awarded the Nobel Prize in Physics in 1903 for this profound discovery. Energized by Becquerel's groundbreaking discovery, Marie Curie (Maria Salomea Sklodowska Curie) (1867–1934) and her husband, Pierre Curie (1859–1906), created the theory of radioactivity, developed techniques for isolating radioactive isotopes, and discovered two new elements, radium (named by Marie Curie for its "radioactivity") and polonium, the decay product of radium (named by Marie Curie for her country of birth). One gram of radium was found by the Curies to emit 3.7×10^{10} disintegrations per second, an amount of radioactivity since referred to as a Curie (Ci), named after Pierre Curie, as designated by his widow, Marie. In 1975 the General Conference on Weights and Measures made the unit the becquerel (Bq), equivalent to one reciprocal second, and gave it official status as the SI unit of activity. Thereafter, the Ci was defined as 3.7×10^{10} Bq or 37 GBq.

Soon after the discovery and purification of radium, it became commercially available from a company in Belgium. Marie Curie was the first to use it for cancer treatment. She became the first women professor at the University of Paris, the first women to be named a Nobel Prize Laureate (she shared the physics prize in 1903 with her husband and Becquerel), the first person to receive the Nobel Prize twice (the Chemistry Prize in 1911), and the first Laureate to have an offspring win the Nobel Prize. Her daughter was the second woman to be awarded the Nobel Prize in Chemistry a quarter of a century later. Irene Joliet-Curie, Marie Curie's daughter, and her son-in-law Frédéric Joliot shared the Nobel Prize in Chemistry in 1935. Marie Curie originally wanted to work in Poland after her studies in physics and mathematics were completed in Paris, but Kraków University denied her entry, ostensibly because she was a woman. Curie's first prize devolved from the conclusion that radiation did not depend on the arrangement of the atoms in a molecule; it must be linked to the interior of the atom itself. This discovery was revolutionary and conceptually was her most important contribution to the development of atomic physics. Chemists considered the discovery and isolation of radium the greatest event in chemistry since the discovery of oxygen. Her second prize devolved from the demonstration for the first time that an element could be transmuted into another element. This finding revolutionized chemistry and began a new epoch in the field.

The practical implications of the availability of X-ray machines and radium for therapy of cancer were soon evident in Europe and the United States. The establishment of a facility to study and treat cancer in Manchester, England, eventually developed into the Christie Hospital and Holt Radium Institute. It had begun using X-ray therapy in 1901 and radium treatments in 1905. In the United States, a Department of Cancer Surgery and Radiation Therapy was established at The New York Cancer Hospital (later the General Memorial Hospital for the Treatment of Cancer and Allied Diseases) in 1912 (see discussion later in this chapter). Surgeons saw radiation therapy as a treatment of cancer through its caustic effect, a dissolution instead of an excision.

Within a few years of Röntgen's primitive X-ray machine, more advanced diagnostic and therapeutic X-ray devices were being developed. The advances spawned by Röntgen's discovery have made an enormous contribution to the diagnosis and staging of lymphomas, using a series of imaging devices, each more sophisticated and useful than the last (e.g., from X-radiography to computed tomography to PET-CT). Pusey's and Senn's dramatic, but relatively short-lived, shrinkage of the lymph nodes in patients with Hodgkin's disease treated with X-ray therapy were the first efforts to bring a logical and effective approach to its treatment. Their X-ray equipment, using a Crookes' tube, generated beams of low energy and low intensity. One of the most significant advances in radiology and radiotherapy was developed by William D. Coolidge (1873–1975), Director of the General Electric Research Laboratory. His device, incorporating an extremely high vacuum, the use of a heated cathode as a source of electrons, and a tungsten anode, was revolutionary in radiological tube technology. The Coolidge tube described in 1913 produced X-rays generated at 140 kv and by 1922 a tube operating at 200 to 250 kv permitted "deep therapy." The 1920s through the 1950s was the era of kilovoltage radiation therapy [58].

Much debate existed on the best use of X-radiation for Hodgkin's disease; arguments about doses, fields, and treatment schedules raged during the first 30 years of the twentieth century. René Gilbert (1892–1962) working in Geneva, Switzerland, was a pioneer in the treatment of Hodgkin's disease with radiation. From the mid-1920s to the late 1930s, he pursued an approach that set the stage for the later advances in radiotherapy, which resulted in the prolonged survival for advanced disease and cure of more localized disease [59]. He was handicapped by having only relatively low voltage equipment, but he emphasized (1) formulating a treatment plan after careful assessment of the extent and location of the disease, (2) treating intensely as possible at the time of initial therapy by focusing on known sites of disease, and, thereafter (3) treating neighboring, apparently

uninvolved sites, as the patient's tolerance permitted, recognizing the likelihood of microscopic disease in those locations [60]. In 1931, he presented survival data for patients followed for nearly 10 years in some cases, extraordinary results for the time, given the limitation of the radiotherapeutic equipment of his day.

Charles Brigman Craft (1909–1979) in 1940, working at the University of Minnesota Hospital, published his more carefully designed comparison between untreated patients and those treated with radiation and confirmed, quantitatively, the impact of radiation therapy: untreated patients had a 5- and 10-year survival of 5.8 and 0% and radiotherapy-treated patients had a 5- and 10-year survival of 23.4 and 11%, respectively [61]. Indeed, since two patients were alive at 13 years after therapy, Craft's treatment may have resulted in the first cures of the disease. His publication in the proceedings of the staff meetings of the University of Minnesota Hospital did not gain wide attention.

Vera Peters was the first to report probable cures of Hodgkin's disease with radiation based on careful analysis of treated patients. Peters joined the faculty of the Radiotherapy Institute at the Toronto General Hospital working with its leader, Gordon Richards (1885–1949). Richards had installed a 400 kv radiotherapy machine and was using the principles espoused by Gilbert in his approach to therapy. In 1947, Richards suggested that Peters review their cases of Hodgkin's disease because he was impressed with the longevity of many of the patients he had treated [62]. She completed her review in 1949, but Richards had died in January of that year and never learned the results of the study he suggested. In her landmark paper, published in 1950, of 113 cases confirmed by histopathological examination to have Hodgkin's disease, she showed that the extent of the disease at the time of diagnosis was the most important correlate with survival, resulting in the Peters staging system commented on earlier [37]. She found that constitutional signs of fever, night sweats, and weight loss had a negative consequence on treatment outcome. The 10-year survival of patients classified by Peters as stage I was 79% and this resulted in a much more hopeful view of the treatment of the disease. Initially the phrase "curability of Hodgkin's disease" was met with disbelief. By the mid-1960s, the confirming work of others changed this attitude. Eric Craig Easson (1915–1983) and Marion Howard Russell (1907–1966) at the Holt Radium Institute and Christie Hospital in Manchester showed that the event-free survival at 15 and 20 years of their patients treated with radiation was little different from the rates at 10 years, implying that these patients were cured of their disease, as indicated in the audacious title of their paper "The cure of Hodgkin's disease" [63]. Thus, the term cure began to be used with confidence in discussing radiotherapy of early stage Hodgkin's disease, although the concept did not enter textbooks of medicine for another decade, such was the pessimism about the curability of cancer [61]. Peters was generous in her tributes to Gilbert, who developed the strategy for curative radiotherapy, and Richards, who treated most of the patients with an advanced (for the day) instrument. She shared credit with him for the insightful analysis expressed in her important paper (Table 37.2).

Table 37.2 Chronology of advances in the treatment of Hodgkin lymphoma

Year	Event	Citation
1902–1903	First cases of Hodgkin's disease treated with X-rays	Pusey [56], Senn [57]
1939	Anatomic and clinical foundations, and principles of radiation therapy of Hodgkin's disease established	Gilbert [58, 59]
1940	Long-term follow-up suggested cure of some patients with radiation therapy	Craft [60]
1946	Nitrogen mustard treatment of Hodgkin's disease	Goodman et al. [64], Jacobsen et al. [65], Wilkinson and Fletcher [66]
1950	Apparent cure of Hodgkin's disease by 400 kv radiation therapy of affected and adjacent, apparently uninvolved, lymphoid areas	Peters [37]
1962	Improved technique: tumoricidal dose, megavoltage equipment, irradiation of lymphoid areas in continuity (mantle and inverted Y radiation fields)	Kaplan [67, 68]
1962	Confirmation and extension of evidence for cure of early stage Hodgkin's disease by extended field megavoltage radiotherapy	Kaplan [68]
1963	Confirmation and extension of evidence of cures of early stage Hodgkin's disease with extended field megavoltage radiotherapy	Easson and Russell [63]
1970	Cure of advanced Hodgkin's disease with mechlorethamine, Oncovin (vincristine), prednisone, procarbazine (MOPP) chemotherapy	Devita et al. [69, 70]
1975	Treatment of Hodgkin's disease with noncross-resistant drugs doxorubicin (Adriamycin), bleomycin, vinblastine, decarbazine (ABVD), and with alternating MOPP and ABVD	Bonnadonna et al. [71, 72]
1984	Autologous hematopoietic stem cell transplantation for Hodgkin's disease	Spitzer et al. [73]
1985	Allogeneic hematopoietic stem cell transplantation for refractory Hodgkin's disease	Appelbaum, Thomas et al. [74]
1997	Seven drug chemotherapy introduced (BEACOPP)	Diehl et al. [75]

By the late 1950s, orthovoltage therapy had been replaced by megavoltage (MV) therapy. These machines included a Van De Graff electrostatic generator with a peak energy of 2 million electron volts, the radioactive cobalt-60 teletherapy unit emitting gamma rays with an energy equivalent of 3 MV, the betatron providing beams of electrons or X-rays at energies of approximately 30 MV and linear electron accelerators that provide electron and X-ray beams in the 6 MV energy range. Henry Kaplan (1918–1984), a radiotherapist, working at Stanford University had begun to use a 5 MV linear accelerator in the late 1950s and 1960s. The instrument was developed by engineers at Varian Company. Kaplan was collaborating closely with the internist-oncologist Saul Rosenberg (b.1927) [76]. Rosenberg and colleagues wrote a paper, published in the journal *Medicine* in 1961, describing the finding in 1269 patients with lymphoma. This report provided important descriptive information on the disease. Kaplan and Rosenberg carefully studied and tracked the spread of disease in patients and established more convincingly the early view of Greenfield expressed in 1878 [29] that the disease principally spread contiguously in a more-or-less orderly manner [77].

With their advanced devices, Kaplan and colleagues could apply high-dose extended field radiation to treat overt and unapparent involved neighboring areas. This approach evolved from the work of Gilbert and Peters. Their results with stage I and II patients were excellent and they extended radiotherapy to patients with more extensive disease. They were able to give radiotherapy at fractionated doses in the neighborhood of 4500 rads to involved areas in the upper body and lower body with acceptable toxicity to normal tissues. The radiation-absorbed dose (rad) had replaced the Röntgen (r) for calculating radiation dose. The latter was the dose measured by the ionization produced in air, whereas the former was the dose absorbed by the tissue being treated. This was particularly important as megavoltage instruments were generating beams that had their peak dose below the skin surface. Kaplan and his team developed approaches to treat the upper and lower body in fields known as the mantle (upper and lower neck, clavicular area, axilla and mediastinum) and inverted Y fields (para-aortic area, spleen, pelvic femoral, and iliac areas). The effort was aimed at curing patients with more widespread disease or markedly extending survival by defining and delivering a dose of radiation calculated to minimize relapse [67]. In his classic paper in 1962, Kaplan described his early results and, thereafter, was the leading authority on the treatment of Hodgkin lymphoma with radiation [68]. He wrote his *magnum opus* on Hodgkin disease in 1972 and published a second edition in 1980 that encompassed every aspect of the disease and detailed progress over the 150 years since Hodgkin's classic paper [19].

Chemotherapy

Alkylating Agents

The introduction of rational chemical therapy for the treatment of Hodgkin's disease (and other lymphoid and nonlymphoid tumors) sprang from military or paramilitary research, as has often been the case in medicine. To break the stalemate that existed during World War I, the Germans used artillery shells containing dichlorethylsulfide (sulfur mustard gas) at Ypres, resulting in casualties, deaths, and terror among the allied troops, but no influence on the outcome of the battle. The postmortem studies on the mustard gas victims showed not only epithelial vesication but destruction of tissues with rapid cell turnover, such as gastrointestinal epithelium [78]. In the periods between the World Wars, James Ewing who had served in the Army during World War I encouraged the study of the effect of mustard gas on neoplastic tissue. Frank E. Adair (1888–1982) and Halsey J. Bagg (1890–1947) at the Memorial Hospital for the Treatment of Cancer and Allied Diseases in New York City followed his suggestion and studied the application of sulfur mustard gas to treat human skin tumors [79]. Adair was the chief of the breast service, a very prominent cancer surgeon, and had been president of the American Cancer Society; Bagg was a cancer research biologist at Memorial Hospital.

At the outbreak of the Second World War, with the fear that Germany would again resort to poison gas, the United States Army and the Scientific Office of the British Commonwealth formed governmental structures and committed resources to support research into the biological effects and mechanism of action of mustard gas to prepare their armed forces for a chemical weapons attack. In the United States, the studies were under the aegis of the National Research Council's wartime committees, advisory to the Surgeon General. One of the committees was the Treatment of Gas Casualties under the chairmanship of Milton C. Winternitz (1985–1959). Winternitz had been professor of pathology at Yale and then Dean of the Yale School of Medicine [80]. In 1917, World War I was raging, gas warfare had begun, and Winternitz saw the need for biological study of these new agents. His appearance before an Advisory Committee of the Secretary of War is described by a member, in these words: "… of all the great scientists who appeared before it, he was the only one who had the courage to state things as he saw them, had the remedies always at hand, and at times almost ruthlessly, but necessarily, brushed aside opposition, compromise and mediocrity." He obtained the permission of Yale University to establish a center for the study of the biological effects of war gases, and also an Army training school for laboratory medicine. Winternitz authored a book entitled *The Pathology of War Gas Poisoning*, published in 1920 by the Yale University Press, the year he ascended to the deanship, which he occupied for 15 years.

In 1942, a contract between the United States Government and Yale University was executed to study the effects of mustard gas. The vesicant properties of the gases limited their experimental usefulness and to circumvent this problem the Yale scientists, Louis Sanford Goodman (1906–2000) and Alfred Gilman (1908–1984) and their colleagues, synthesized nitrogen mustards (as compared to sulfur mustards) that could be injected intravenously in animals and humans. During these secret wartime studies, these investigators confirmed the cytocidal effects of nitrogen mustard on proliferating tissue, including marrow, lymph nodes, and gastrointestinal mucosa. The effects on lymphoid tissue led to collaborations with members of the Yale Department of Anatomy who were working with experimental animal models. They injected nitrogen mustard into mice with a transplanted lymphoma and observed a striking reduction in tumor size. Further animal studies led to the testing of two nitrogen mustard compounds on human subjects with Hodgkin's disease, other lymphomas, leukemias, and other cancers. They were given the wartime code names of HN_2 for methyl-*bis*(β-chloroethyl)amine and HN_3 for *tris*(β-chloroethyl)amine. The first patient treated with nitrogen mustard was at New Haven Hospital. By 1943 the number of humans with cancer, notably lymphoid cancers, studied was quite small, but a war-related tragedy extended the human observations of mustard effects on highly proliferative tissue.

On December 2, 1943, the Italian port of Bari on the Adriatic Sea, the main supply base for the British Eighth Army, commanded by General Bernard Law Montgomery (1887–1976) was the scene of a massive influx of American and Allied ships bringing in supplies to support the 15th United States Army Air Force, recently moved from North Africa to liberated southern Italy to give the United States a bomber-base more proximate to the heart of Germany and the Balkans, especially the Romanian oil fields in Ploiesti. The 15th was commanded by major General James Harold (Jimmy) Doolittle (1896–1993). Doolittle was a heroic figure and an aviation pioneer. He led the raid of 16 B-25 medium bombers on five cities in Japan including Tokyo, 4 months after Pearl Harbor (April 18, 1942). Departing from the carrier United States Ship Hornet, they did not have sufficient fuel to return. They parachuted over Japanese occupied China and were smuggled through Japanese lines to friendly Chinese forces. The bombing of Japan was an enormous boost to the beleaguered allies at that point in the war.

One of the ships in the port of Bari was a liberty ship, the John Harvey, named for a member of the Continental Congress in 1777 and a signer of the Articles of Confederation. The American ship was loaded with two thousand, one hundred pound, bombs containing mustard. The allies were concerned that the Germans in desperation would use mustard gas against their forces and they planned to be prepared to retaliate. The night of December 2nd saw an unexpected air raid by over 100 German Junkers Ju-88 bombers. The bomber attack was planned by Field Marshal Freiherr von Richthofen (1895–1945), a distant cousin of Manfred von Richthofen (1892–1918), the World War I ace, referred to as The Red Baron, with the approval of Field Marshall Albert Kesserling (1885–1960), commander of all German troops in Italy. During the day of December 2nd, a German Messerschmitt-210 reconnaissance plane photographed Bari harbor choked with ships at anchor virtually touching each other and filling the port. Upon seeing these photographs, the Germans launched the raid that night catching the Americans and British off guard. They did not believe the retreating Germans and the decimated Luftwaffe in Italy could launch such an attack. British Air Vice Marshal Arthur Coningham (1895–1948), at a press conference on December 2nd, stated defiantly that the Luftwaffe in Italy was defeated and could never attack Bari. During the bombing raid the John Harvey caught fire as a result of hits by German bombs on neighboring ships. It exploded and released mustard gas leading to extensive deaths and casualties. Examination of some of the over 600 affected merchantmen and seamen confirmed the damage to the marrow, lymphatic tissues, and gastrointestinal mucosa and, of course, skin and lungs. This horrendous tragedy, many ships sunk or severely damaged, severe disruption of the flow of supplies (the civilian casualties were never accurately counted) was referred to as "the second Pearl Harbor." The only positive result of this horrendous tragedy was that the autopsy and medical findings, which supported the small number of human studies of mustards at that time, were thought to further accelerate the use of mustard compounds in cancer treatment and notably in Hodgkin's disease patients [81]. von Richthofen died of a tumor in Allied captivity in 1945 and Kesserling was convicted and sentenced to life in prison for war crimes committed in Italy.

In April 1946, Gilman and Frederick S. Philips published in the journal *Science* [82] a detailed report of the chemistry of the mustard compounds and their tissue effects in a variety of species. They commented on their nucleotoxic effects and indicated that the tissue effects were unlike any other chemical agent but closely simulated the effects of X-radiation (radiomimetic). They mentioned the results of the first six patients treated and indicated that there were results from treating approximately 150 patients, but the data were still under wartime secrecy and although the names of the investigators were noted in the bibliography, no source was given. It was noted that the most dramatic responses were seen in Hodgkin's disease and not in lymphosarcoma or acute or chronic leukemia.

Also, in 1946, Cornelius P. Rhoades (1898–1959), Chairman of a Committee of the National Research Council, reported a summary of the results of the clinical trials of

nitrogen mustards in patients with Hodgkin's disease and other malignancies in an Official Statement to the Medical Profession. Rhoades was the Director of the Sloan-Kettering Institute for Cancer Research and the Director of Memorial Hospital. Subsequently, lifting the cloak of wartime secrecy, the three detailed reports of the effect of nitrogen mustard in human cancer were published in the same year [64–66].

Goodman and Gilman's paper is given priority based on their synthesis of the mustard compounds, extensive preclinical studies, and careful clinical evaluation in concert with Maxwell Myer Wintrobe (1901–1986) and William Dameshek (1900–1969), two of the leading hematologists of their day [64]. In their classic paper, Goodman and colleagues reported the treatment of 67 patients with Hodgkin's disease, lymphosarcoma, and acute and chronic lymphocytic and myelogenous leukemia. Most were previously treated with X-irradiation and were in the late stages of their disease. Several dramatic responses occurred, especially in cases of Hodgkin's disease [64]. This finding was also reported by Leon Jacobsen (1911–1992) and colleagues at the University of Chicago [65] and John Frederick Wilkinson (1897–1998) and Frank Fletcher (d.1995) at the Manchester Royal Infirmary in their simultaneous studies [66]. The studies of Goodman and coworkers were conducted at hospitals in New Haven, Salt Lake City, Boston, and Portland presaging multicenter collaboration in order to accumulate enough cases in a reasonable period of time to draw conclusions of efficacy and toxicity of the drug(s) under examination. Nitrogen mustard, thereafter, became a mainstay of treatment for Hodgkin's disease, and 25 years later was incorporated into a curative multidrug regimen (see discussion later in this chapter).

The nitrogen mustards were difficult to use; therapists had to protect themselves from skin contact or inhalation and the patient could suffer burns from extravasation or vein damage. For these and other reasons (e.g., high toxicity on marrow and gastrointestinal tract, inability to penetrate the blood–brain barrier or to be used intrathecally), other molecules with similar tissue effects were developed. Nitrogen mustard was a relatively simple molecule and it was easy to modify it chemically. Hundreds of derivatives were tested. Busulfan and chlorambucil were synthesized and tested at the Chester Beatty Institute in London and their use described in 1953. Cyclophosphamide was synthesized in Germany and introduced to the clinic in about 1960 [83]. Busulfan, cyclophosphamide, and chlorambucil are pro-drugs and can be administered orally, requiring conversion in the body to their active forms. The specific tissue effects of nitrogen mustard and related compounds, including DNA cross-linking and alkylation of various molecules, notably DNA, took several decades to unravel [66].

Procarbazine, a methylhydrazine derivative, has several mechanisms of action but can also directly damage DNA through an alkylation reaction. It was developed in the early 1960s and was soon recognized as an active agent in the treatment of lymphoid malignancies [84]. During the last few decades, comprehensive studies have clarified cellular pathways involved in the modes of action of procarbazine and its drug resistance mechanisms. It was approved by the Food and Drug Administration for general use in 1969 and became one of the four drugs that would eventually be used to treat and cure advanced Hodgkin's disease (see section on Combined Drug Therapy).

Glucocorticoids

In the 1920s interest in the secretory products of the adrenal cortex led to extraction of an active principal which was named "cortin." Taddeus Reichstein (1897–1996), a Polish-born, Swiss chemist working at the University of Basel, and Edwin Calvin Kendall (1886–1972), an American biochemist, working at the Mayo Clinic in Rochester, Minnesota, were interested in characterizing this material. Reichstein used extraordinary numbers (thousands) of bovine adrenal glands from which to extract and prepare very small amounts of semi-purified material. He identified six principal constituents, which were further characterized by Kendall who named them compounds A through F. Compound E, later identified and named cortisone, and synthesized by Kendall in 1948, produced the most dramatic shrinkage of thymus and lymph nodes in experimental animals and could retard or even prevent the development of lymphoid tumors transferred to host animals. Adrenocorticotropic hormone produced similar results but could not generate the levels of cortisone in vivo that could be administered therapeutically and, as a protein, required injection. The limited supply of cortisone made human studies difficult. Kendall and Philip Showalter Hench (1896–1965) invited the collaboration of the Merck Company, and soon after World War II, synthetic material became available for human studies. This cooperation marked one of the earliest collaborations between an academic medical institution and a pharmaceutical company. As an aside, the dramatic anti-inflammatory effect on persons with severe rheumatoid arthritis and their near miraculous relief of pain and restoration of joint motion described by Kendall, Hench, Charles H. Slocumb (1905–1996), and Howard F. Polley (1913–2001) in 1949 led to Kendall, Hench, and Reichstein sharing the Nobel Prize in Physiology or Medicine in 1950 for the discovery and synthesis of cortisone and its use in ameliorating human disease. One year earlier in 1949, Olof H. Pearson (d. 1990) and Leonard Paul Eliel (1914–2004), working in the Division of Clinical Investigation, Sloan-Kettering Institute for Cancer Research and the Department of Medicine, Memorial Hospital, New York, published the usefulness of cortisone in the treatment of lymphocytic malignancies [85]. A cortisone derivative

would provide the third (mechlorethamine, procarbazine, and cortisone) of the four agents (plus vincristine) that would eventually cure advanced Hodgkin's disease. Subsequently more potent congeners of cortisone such as prednisone and dexamethasone were synthesized, and became the glucocorticoids of choice in the treatment of lymphoid malignancies. The first commercially feasible synthesis of prednisone was carried out in 1955 in the laboratories of Schering Corporation by Arthur Nobile (1920–2004) and coworkers. They discovered that cortisone could be oxidized microbiologically to prednisone by the bacterium *Corynebacterium simplex*. The same process was used to prepare prednisolone from hydrocortisone. Prednisone and prednisolone were introduced by Schering in the mid-1960s.

Vinca Alkaloids

Vinblastine, extracted from the Madagascan periwinkle *Catharanthus roseus*, was first discovered as an unexpected myelosuppressive agent in 1958 by Robert Laing Noble (1910–1990) and colleagues working in Canada during their search for an antidiabetic agent [86]. Independently, researchers at Eli Lilly Company found that extracts of *C. roseus* possessed activity against P-1534 leukemia in mice and isolated vinblastine as its active entity in 1959. The structure of a related compound, vincristine methiodide, was then determined by X-ray crystallography in 1965. Structural studies on these alkaloids revealed that both vinblastine and vincristine were bisindole alkaloids. These alkaloids inhibit assembly of tubulin units into microtubules, resulting in the arrest of cell division at metaphase. Although these compounds are very similar in structure and exhibit the same mode of action, they have different effects. Vincristine is most useful in acute lymphoblastic leukemia and Hodgkin's disease and other lymphomas and would be the fourth of four drugs used in combination to cure Hodgkin's disease (see next section). In 1993, the National Cancer Institute of Canada initiated the Robert L. Noble Prize (not to be confused with the Nobel Prize), which is awarded each year to the investigator whose contributions have led to a significant advance in cancer research. Noble was awarded the Gairdner Foundation International Award in 1984 and was inducted into the Canadian Medical Hall of Fame, posthumously, for his scientific contributions.

Combined Drug Therapy

Combining drugs for the treatment of disease was anathema among prominent internists and hematologists in the 1950s and early 1960s. It was considered reasonable to combine drugs to treat *Streptococcus viridans* subacute bacterial endocarditis (penicillin and streptomycin) or *Mycobacterium tuberculosis* (isoniazide, streptomycin, and the para-amino salt of salicylic acid) but not for other diseases. Indeed, a classic study of penicillin and tetracycline for pneumococcal meningitis showed a worse outcome with both drugs compared to penicillin alone. This reinforced the proscription to combining drugs, championed by the purists. At a Blood Cell Club meeting at the Hadden Hall Hotel in Atlantic City in the mid-1960s, the leading hematologists in the United States, aggressively castigated the group working at the National Cancer Institute, studying four drug combinations for acute lymphoblastic leukemia in children, a vituperative dispute that raged for a time: the oncology pioneers against the establishment. Over time, the utility of drug combinations in the treatment of malignant diseases, notably acute childhood lymphocytic leukemia, Hodgkin's disease, and lymphoma became irrefutable.

The initial studies of multidrug combinations in the treatment of advanced Hodgkin's disease began at the National Cancer Institute in Bethesda, Maryland. It had been preceded by studies of various single drugs, nitrogen mustard, cyclophosphamide, vinblastine, and vincristine. Several principals were established. One was that complete remission was an important goal as these patients fared better than those who did not enter a complete remission. This finding was already apparent to other investigators in the National Cancer Institute studying childhood acute leukemia. The first pilot protocol of combination therapy included vincristine, methotrexate, cyclophosphamide, and prednisone (the MOMP regimen) given for 2.5 months [87]. Vincristine was selected over vinblastine because it had less marrow toxicity and at that time support for patients with hematopoietic suppression was primitive. There were no indwelling catheters, no effective means of platelet transfusion, and a more limited array of antibiotics. Procarbazine had been shown to be an active agent in Hodgkin's disease by then and it replaced methotrexate in the next step. Each drug was used at its optimal dose and a cycle of administration was selected as every 28 days, the shortest interval that would allow marrow recovery between cycles. In 1967, David P. Rall (1926–1999), then chief of the Laboratory of Chemical Pharmacology at the National Cancer Institute and a mentor of Vincent DeVita, said to a colleague, "I just got back from an Institute intramural meeting at which the preliminary results of Hodgkin's disease treatments were being discussed, and it looks as if DeVita is going to cure Hodgkin's disease with MOPP before you guys cure childhood ALL." Vincent T. DeVita, Jr. (b. 1935) and colleagues, working at the National Cancer Institute, introduced the first highly effective combination chemotherapy for the treatment of advanced stages of Hodgkin's disease. The trial of this four-drug combination, initiated in 1964, **m**echlorethamine (nitrogen mustard), vincristine (**O**ncovin), **p**rocarbazine, and **p**rednisone, carrying

the acronym MOPP, was developed based on experimental studies indicating the desirability of combining agents with different mechanisms of action and with nonoverlapping toxicities. This drug combination, the results of which were reported in an abstract in 1967 and in a paper in 1970, extended curative treatment to the advanced stages of Hodgkin's disease [69]. However, with longer periods of observation late toxicities, especially secondary cancers and sterility, resulted in the search for drug combinations with a better safety profile [88, 89]. A substitute four-drug approach was introduced by Gianni Bonnadonna (1934–2015) and coworkers, called by its abbreviation ABVD, describing the four drugs, doxorubicin (*A*driamycin), *b*leomycin, *v*inblastine, *d*acarbazine, which produced a better response rate and a lower frequency of secondary leukemias and other serious complications than MOPP [71, 72]. Procarbazine, although earlier withdrawn from combination regimens used to treat Hodgkin's lymphomas, has reappeared in dose-intensified regimens and has yielded impressive results. A seven-drug regimen bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone referred to by the acronym BEACOPP or in varying doses, escalated BEACOPP, is being compared to ABVD for efficacy and safety [75].

Hematopoietic Stem Cell Transplantation

Although most patients with Hodgkin lymphoma can be cured with chemotherapy or radiation therapy, a modest proportion are refractory to therapy or relapse after entering a remission. Edward Donnall (Don) Thomas (1920–2012) and colleagues at the Fred Hutchinson Cancer Research Center presented early results of the use of stem cell transplantation for this disease [74]. Thomas shared the Nobel Prize in Physiology or Medicine in 1990 for his pioneering and singular research leading to the development of syngeneic and allogeneic hematopoietic stem cell transplantation for the curative therapy of aplastic anemia and hematological and lymphoid malignancies. His co-awardee was Joseph Edward Murray (1919–2012), a pioneer in developing the technique of syngeneic, allogeneic, and cadaveric kidney transplantation. They had been residents together at the Peter Bent Brigham Hospital in Boston. At about the same time that Thomas was exploring allogeneic transplantation for refractory or relapsed Hodgkin's disease, Gary Spitzer (b. 1944) and others at the University of Texas M.D. Anderson Hospital and Tumor Institute showed the potential usefulness of high-dose chemotherapy with autologous marrow stem cell infusions to restore hematopoiesis more rapidly [73]. Spitzer's office at M.D. Anderson Hospital was on a patient floor and he used the patients' coffee dispenser. One day at the coffee machine he was chatting with the mother of a patient in the hospital with her sixth relapse of Hodgkin's disease and with pulmonary involvement. The mother asked Spitzer what he did and after learning of his interest in transplantation suggested he transplant her daughter. The daughter's physician was supportive and Spitzer did his first autologous transplantation in Hodgkin disease after conditioning the patient with cyclophosphamide, 1,3-*bis*(2-chloroethyl)-1-nitrosourea (BCNU), and etoposide (VP-16). The patient's pulmonary nodules gradually disappeared and she had no return of disease, thereafter. This experience propelled Spitzer's autologous transplantation program for Hodgkin's disease. High-dose chemotherapy followed by autologous blood or marrow stem cell infusion to rescue the patient from potentially lethal therapeutically induced prolonged marrow aplasia is the current standard of care. Currently, the use of allogeneic stem cell transplantation with the latter's theoretical benefit of graft versus lymphoma effect and a potentially more robust stem cell product is a matter of debate in these heavily pretreated patients.

Historical Concepts of Lymphoma

Early Descriptions

The first descriptions of primary tumors of the lymph nodes, as specifically distinguished from Hodgkin lymphoma, can be attributed to Theodor Billroth (né Christian Albert Theodor Billroth) (1829–1894). Billroth was trained in internal medicine, experimental and anatomic pathology, and abdominal surgery. He published important papers in pathology and surgery. His was the first accurate description of the red pulp of the spleen, describing the sinus structure and cords, later called the sinuses and cords of Billroth. He competed with Virchow for the chair in pathology at the University of Berlin, but his outspoken opposition to unproven hypotheses promulgated in the authoritarian professorial system in Germany contributed to his losing that opportunity.

Billroth was an accomplished, indeed gifted, pianist, later took up the viola so that he could participate in string quartets, and was a student of music. His maternal grandparents were opera singers. He published a book on music and was a close confidant of Johannes Brahms (1833–1897). Brahms dedicated two of his three string quartets (the C minor and A minor quartets, Op. 51) to Billroth and gave him the original manuscripts of the music. Billroth had continued his work on the piano, intensively, while in medical school at the University of Göttingen and on one occasion provided piano accompaniment to Johanna Maria (Jenny) Lind (1820–1887), the Swedish soprano (dubbed the "Swedish Nightingale"), during an appearance in Germany [90, 91]. In Vienna, his relationship with Brahms grew, as the latter had

moved there also. Throughout the 1870s, the chamber music composed by Brahms was first played in Billroth's home before a select audience.

Billroth became one of the most distinguished surgeons of his time, practicing, teaching, and writing in Zurich, and then Vienna, and was one of the great pioneers of surgery, especially gastric and other abdominal surgery. As professor of surgery in Vienna he collaborated with Alex von Winiwarter (1848–1917), professor of surgery in Lüttich, and wrote a classic text of the day, *Die allgemeine chirurgische Pathologie und Therapie* (General Surgical Pathology and Therapy) in 1863 [92]. In Chap. 48 of this 1000 page text, he discusses the "Sarcome," which included a discussion of "Benigne and maligne lymphoma" and "Sarkome der lymphdrüsen." The term "sarcoma" has been attributed to Galen, who coined it to describe a soft tissue tumor. In a detailed paper published earlier in 1861 covering several topics related to lymph node pathology, Billroth devotes a section to "Sarcom der lymphdrüsen" as distinguished from "Die carcinomatösen lymphdrüsen" and other afflictions involving lymph nodes [93]. A later paper by Hans Kundrat (1845–1893) entitled "Uber Lympho-sarkomatosis" in 1893 [94] has been credited, apparently erroneously, for the first use of the term, lymphosarcoma. Kundrat was a younger colleague of Billroth and, it can be inferred, that he was introduced to the concept by Billroth. Indeed, Billroth reviewed Kundrat's paper for the *Wiener klinische Wochenschrift*. Nevertheless, Kundrat presented several cases, discussed the variations in the presentation of lymphosarcoma, and tried to distinguish it from the nonspecific term pseudoleukämie and some cases of Hodgkin's disease, which was an important addition to the relatively skimpy understanding of lymphoma at that time. He described the spread of the disease to other lymph node sites, involvement of liver and spleen, and local invasion of neighboring tissues, distinguishing "lymphophosarkom" from "lymphosarkomatosis." Cases in which the neoplastic cells remained confined to the lymphatic system were described also by others soon after, but as others before him, Kundrat did not have histopathological methods to distinguish Hodgkin's disease from other lymphomas with any certainty [94]. For a time, lymphosarcoma was called "Kundrat's disease" in Europe.

Virchow discussed lymphoma and lymphosarcoma quite extensively at about the time that Billroth did [95]. In his section on lymphosarkome, he discussed thoracic and abdominal spread and compression of mediastinal structures. However, in 1895, Virchow discussed cancer of various types in his lectures and referred to the splenic and lymphatic forms of leukemia [10]. In both the lymphatic and splenic form of leukemia, he emphasized the role of a large spleen. He stated, "Now, upon investigating whence this curious change in the blood takes its origin, we find in the great majority of cases that it is a certain, definite organ which presents itself over and over again with convincing constancy as the one essentially diseased, an organ which frequently, even at the onset of the malady, forms the chief object of the complaints and distress of the patients, namely, the *spleen*. In addition, a number of lymphatic glands are very frequently diseased, but the affection of the spleen stands in the foreground." From the descriptions, it is probable that he is describing chronic lymphocytic leukemia and chronic myelogenous leukemia, respectively, in his lymphatic and splenic forms. Nowhere is a primary tumor of the lymph nodes discussed although acute lymphadenitis and tuberculosis involving the lymph nodes were described. To the extent that chronic lymphocytic leukemia is analogous to small-cell lymphocytic lymphoma, Virchow's observations were seminal but the state of knowledge of lymphohematopoiesis, the inability to stain blood cells, and the late stage at which patients were assessed make interpretations of the descriptions of the day largely inferential. Because of Virchow's dominance in pathological thought at that time, the concept that tumors of lymph nodes arose from connective tissue cells, which he espoused, was slow in being replaced. Billroth had reluctantly accepted that his own concept of connective tissue as the source of lymphatic cells was in error. Virchow was less tractable.

By the early twentieth century burgeoning interest in lymphoma developed. Textbooks of pathology had entries in their table of contents recognizing lymphomas as a discrete type of cancer. In the text book published in 1914 by Frank Barr Mallory (1862–1941), pathologist at the Boston City Hospital and associate professor at Harvard Medical School, a 159-page section on "Tumors" contained seven pages describing "lymphoblastomas" with the parenthetical designations of lymphocytoma, lymphoma, lymphosarcoma, pseudoleukemia, lymphatic leukemia, and Hodgkin's disease [96]. He provided a description of large lymphoblasts found in the germinal centers of lymphatic structures, small lymphocytes, and the derivation of plasma cells from lymphocytes. He coupled Hodgkin disease with the scirrhous form of lymphoblastoma and, remarkably, felt that "The term Hodgkin's disease was inexact and should never be used. It always covers ignorance of the true nature of the lesion." This conclusion was reached despite Dorothy Reed's definitive work showing Hodgkin's disease to be a distinct entity a decade before and may reflect the absence of a unified medical reference source to search for recent papers. On page 329, Fig. 246 of his text [96], Mallory shows a drawing in color of the histological pattern of one form of lymphoblastoma that appears to be a case of Hodgkin lymphoma, including eosinophils and two giant tumor cells resembling Reed–Sternberg cells. On page 327, Fig. 243, he shows a histopathological replica of a lymph node containing a "lymphoblastoma growing rapidly," containing lymphoblasts with prominent nucleoli and frequent mitotic figures.

By the early twentieth century, cellular pathology had advanced and histopathological classification of a wide variety of human benign and malignant neoplasms had developed, the evolution of cancer as a specialized area of scientific and medical study was initiated, and the treatment of cancer by surgery, radiation therapy, and chemicals (principally arsenicals) was in its rudimentary stages.

In his textbook, Ewing (discussed earlier in this chapter) included a chapter entitled "Lymphoma and Lymphosarcoma," a topic to which he devoted 43 pages encompassing descriptions of various types of lymphocytic tumors [51]. He classified one such tumor as an endothelioma of lymph nodes. In an additional chapter, he described "The Thymus and its Tumors." Ewing was the leading American experimental oncologist of his day. In 1907, he helped found the American Association for Cancer Research, and in 1913, the American Society for the Control of Cancer, now the American Cancer Society.

In 1931 Ewing was elected to the presidency of the Medical Board of the General Memorial Hospital for the Treatment of Cancer and Allied Diseases, and became its director. (The designation "General" was dropped in 1916.) It was the earliest privately owned hospital devoted to cancer diagnosis and treatment and one of the earliest hospitals of any kind in the United States dedicated to the sole purpose of caring for cancer patients. It began in 1884 as The New York Cancer Hospital on the upper West Side of Manhattan, changed its name to the Memorial Hospital for the Treatment of Cancer and Allied Diseases (usually referred to as the Memorial Hospital), and moved to the East Side in 1939 [97]. In 1945 (Ewing had died 2 years earlier), Alfred P. Sloan, Jr. (1875–1966), Chairman of the General Motors Corporation, gave four million dollars to establish the Sloan-Kettering Institute for Cancer Research. Although geographically proximate to the Memorial Hospital, they did not become a unified corporate entity until 1960 when the Memorial Sloan-Kettering Cancer Center was established. Charles Kettering (1876–1958) was one of the great American innovators and inventors of the twentieth century. His many inventions resulted in the advancement of the automobile industry along with other contributions, such as refrigeration. His development of the electric automobile starter, first installed in Cadillacs in 1912, replacing the crank starter, revolutionized the automobile industry and propelled General Motors to the forefront of vehicle manufacturers. In 1945, Kettering helped Sloan found the Sloan-Kettering Institute for Cancer Research, later to become the Memorial Sloan-Kettering Cancer Center. His support was based on the premise that American industrial research techniques could be applied to cancer research.

Although a few centers devoted to cancer research and care developed in industrialized countries, including the United States, these represented a rudimentary approach to cancer treatment until the early 1970s. Most cancer patients were cared for by general surgeons or internal medicine specialists. Medicine was traditionally organized around organ systems. For example, nephrologists managed renal cancer and gastroenterologists managed gastrointestinal cancers. General surgeons excised cancers and administered the limited chemotherapy available for nonhematological cancers (e.g., 5-fluorouracil) and hematologists cared for patients with leukemia and lymphoma. Specialized therapists treated cancer by irradiation. The impetus to make oncology a broadly accepted discipline, a discipline that involves all organ systems, was provided by Richard Milhous Nixon (1913–1994), the 37th President of the United States. In his State of the Union address in 1970, he committed the government to decreasing and eventually eliminating the threat of cancer. As part of this national effort, in October 1971, the Army's Fort Detrick biological warfare facility in Maryland was converted to a cancer research center, eventually becoming the Frederick Cancer Research and Development Center, an internationally recognized center for cancer and, later, AIDS research. On December 23, 1971, President Nixon signed into law the National Cancer Act, declaring, "I hope in the years ahead we will look back on this action today as the most significant action taken during my Administration."

The National Cancer Act (Public Law 92–218), dubbed "The War on Cancer," gave the National Cancer Institute autonomy at the National Institutes of Health with special budgetary authority to be determined by Congress. The Cancer Chemotherapy National Service Center increased its efforts to acquire new compounds for testing with the awarding of an acquisition and inventory contract responsible for the collection and documentation of test agents. In 1973, the Surveillance Epidemiology and End Results Program of the National Cancer Institute was initiated as an authoritative source of information on cancer incidence and survival in the United States. The Program, known by the acronym SEER, currently collects and publishes cancer incidence and survival data from population-based cancer registries. Since cancer is not a reportable disease in the United States, this initiative was vital to measure the incidence, prevalence, and mortality of cancer and to track changes in incidence and mortality and, thus, measure progress. This agency confirmed the dramatic increase in lymphoma incidence (but not Hodgkin lymphoma incidence) between 1973 and 1995, which was seen in most First World (industrialized) countries, probably starting in the late 1940s, and still unexplained. In 1972, it was reorganized to consist of the office of the director and four divisions: cancer biology and diagnosis, cancer cause and prevention, cancer treatment, and cancer grants (later named division of extramural activities).

The increased focus on and money for cancer research resulted in the Cancer Centers Program of the National Cancer Institute. In 1973, the director of the National Cancer

Institute, Frank J. Raucsher, Jr. named eight institutions the first comprehensive cancer centers. Additional centers were funded thereafter. There was expansion of Institute-funded, cooperative, and multicenter cancer clinical trial groups. One of the most influential leaders at the National Cancer Institute from the mid-1950s through the mid-1970s was Charles Gordon Zubrod (1914–1999), who modeled the new attack on the leukemias after the highly successful malarial treatment and prophylaxis program he was involved with during the Second World War. He likened the attack on malaria, vital to the allies' success in the Asian theater of war, to the Manhattan Project in its organization. The medical scientific community was not enamored of targeted research, preferring investigator-initiated approaches, but Zubrod thought both approaches were needed so he set up the Acute Leukemia Task Force at the Cancer Institute [98]. He started the concept of regional multicenter groups, such as the Eastern Cooperative Oncology Group and the Southwestern Oncology Group. The infusion of money and concepts led to attractive opportunities for scientists and physicians to focus on the understanding and management of patients with cancer as well as its causation and pathogenesis. These initiatives fostered the development of the specialties within oncology (e.g., medical, pediatric, gynecologic, surgical, and radiation oncology), the development of departments of neoplastic diseases, the development of cancer centers in university medical centers, the expansion of basic research relevant to cancer genetics and cytogenetics, and the study of the pathobiology of cancer cell growth and survival.

Appreciating the Histopathological Heterogeneity and Attempts at Classification

The terms reticulosarcoma and reticuloendotheliosarcoma were first used by Charles Oberling (1895–1960) [99], likening it to the reticuloendothelioma of Ewing. Oberling believed that these tumors arose in marrow and that they were analogous to or derived from the same cells as tumors arising in lymph nodes. Some of these cases were likely tumors of bone. Oberling was one of the most highly regarded pathologists of his period. He was chair of microbiology and hygiene in Strasbourg where he worked on viral origins of cancer, having been influenced by Amédée Borrel (1867–1936), a French biologist. Borrel is considered the father of the virus theory of cancer and was also a distinguished microbiologist for whom the genus of bacteria *Borrelia* was named. Frédéric Charles Roulet (1902–1985), working in Switzerland [100], reinforced the use of the term "retothelsarcom" for a certain histological type of large-cell lymphoma, but his descriptions were vague and not sufficiently reproducible to separate it from other variants of lymphoma. Nevertheless, his concept of small- and large-cell lymphoma and reticulosarcoma had the seeds of a categorization. These terms did not enlighten, since no one actually knew what a reticulum cell was. The term was, therefore, transient because it did not describe accurately the cells involved; reticulum (reticular) cells or endothelial cells, after all, are not part of the cell clone in lymphoma.

It was Nathan Edwin Brill (1860–1925) who made the first and a lasting contribution to our understanding of the varied histopathological manifestations of lymphoma by identifying and specifying the distinction of lymphomas with a follicular pattern in the lymph nodes in his publication in 1925 [101]. Although Brill described only two cases, his histopathological and clinical descriptions and the effects of radiation therapy on his two patients were important findings at the time. He distinguished the lymph node pathological changes from benign lymphoid hyperplasia. Brill joined the staff of Mount Sinai Hospital in New York City after graduating from New York University College of Medicine and interning at Bellevue Hospital. He later became a professor of medicine at Columbia University College of Physicians and Surgeons. Thirteen years later in 1938, Douglas Symmers (1879–1952), a pathologist at Bellevue Hospital in New York City, described similar pathological findings in seven cases, and indicated that it was not an uncommon disease, thereby bringing increased attention to this form of lymphoma [102]. He concluded that giant follicular lymphadenopathy with or without splenomegaly was a distinct clinical and pathological entity. He also indicated that it could transform to a more malignant lymphoma phenotype. He recommended that the term "reticulum cell lymphosarcoma" be abandoned. He felt no such tumor existed. Giant follicular lymphoma was for a time referred to as Brill–Symmers disease. In effect, this was the beginning of lymphoma classification with the appreciation that follicular lymphomas represented a distinct subset of lymphoma.

In 1934, George Russell Callender (1884–1973) tried to develop a classification of the lymphomas from the several hundred cases collected by the Lymphocyte Tumor Registry of the American Association of Pathologists and Bacteriologists, established in 1925 and later moved to the Army Medical Museum, under the auspices of the National Research Council, and renamed the Lymphatic Tumor Division of the American Registry of Pathology. Callender tried to fuse three features: cytology, gross anatomy, and clinical distribution. The material was inadequate to do so and he continued to use the term "reticulum cell sarcoma" for some cases, lymphosarcoma, and giant follicular lymphadenopathy (of Brill and Symmers) for others [96]. Callender considered the reticulum cell a type of histiocyte. Callender had a military career. He served as pathologist at the Army Medical Center and wrote the monograph *Malaria in Panama*. He was Commandant of the Medical Professional Services Schools from 1940 to 1946 and retired as Brigadier General, having received the Distinguished Service Medal (Table 37.3).

Table 37.3 Evolution of the classification of lymphoma

Year	Classification	Comments and references
1861	Discussion of "Sarcom der lymphdrüsen" versus "Die carcinomatösen lymphdrüsen"	Billroth [93]
1863	*Die allgemeine chirurgische Pathologie und Therapie* (General Surgical Pathology and Therapy). Chapter 48, contains a discussion of "Benigne and maligne lymphoma" and "Sarkome der lymphdrüsen"	Billroth and Winiwarter's textbook [94]
1893	"Uber Lympho-sarkomatosis" Kundrat's paper discussing clinical presentations of "lymphosarkom" and "lymphosarkomatosis	[95]
1894	Lymphome and lymphosarcoma. Virchow's discussion of lymphoma	[96]
1914	*The Principles of Pathologic Histology*. Textbook by Frank B. Mallory. Describes "lymphoblastomas" with the parenthetical synonyms of lymphocytoma, lymphoma, lymphosarcoma, pseudoleukemia, lymphatic leukemia, and Hodgkin's disease	[97]
1925	Description of giant lymph follicle hyperplasia (follicular lymphoma) by Brill	[100]
1934	Giant follicular lymphoma, lymphosarcoma, reticulum cell sarcoma distinguished by Callender	[103]
1938	Expanded description of giant follicular lymphadenopathy by Symmers	[102]
1942	Gall and Mallory classified lymphomas into seven categories: two types of reticulum cell sarcoma (stem-cell lymphoma and clasmatocytic lymphoma), lymphoblastic lymphoma, lymphocytic lymphoma, follicular lymphoma, Hodgkin's lymphoma, and Hodgkin's sarcoma	[104]
1956	Rappaport highlights prognostic distinction between nodular and diffuse lymphomas	[105]
1966	Rappaport's morphological classification. Lymphocytic and histiocytic; large and small cell (see text for details)	[106]
1974	Kiel classification (morphology and immune markers)	[107]
1974	Lukes and Collins classification (morphology and immune markers)	[108]
1982	Working formulation (morphology and response to therapy)	[109]
1988	Updated Kiel classification	[110]
1994	Revised European-American Lymphoma (REAL) classification (morphology, biology, clinical features)	[111]
2001 (revised 2008, 2016)	World Health Organization classification	[112]

Further details of these progressive steps are discussed in the text of the chapter

In 1942, a proposal for classification of lymphomas was made by Edward A. Gall (1906–1979) and Tracy Burr Mallory (1896–1951) based on a clinicopathological survey of 618 cases [104]. Mallory, the son of Frank B. Mallory (1862–1941), a pathologist at the Boston City Hospital and Harvard Medical School, had succeeded James Homer Wright (1869–1928) as chief of pathology of the Massachusetts General Hospital in 1926 and Gall was, at that time, Chairman of Pathology at the University of Cincinnati School of Medicine. Working together, they felt it was relatively easy to divide all lymphomas into seven categories: two types of reticulum cell sarcoma (stem cell lymphoma and clasmatocytic lymphoma), lymphoblastic lymphoma, lymphocytic lymphoma, follicular lymphoma, Hodgkin's lymphoma, and Hodgkin's sarcoma. Clasmatocyte was a term used as a synonym for histiocyte. Here, as in Callender's efforts, we see the inability to distinguish certain types of malignant lymphocytes from histiocytes by microscopy alone.

A decade later, in the 1950s, Henry Rappaport (1913–2003) in a study of 253 carefully selected pathological specimens from the Lymphatic Tumor Registry of the Armed Forces Institute of Pathology archives described the features of several variations of follicular lymphoma, providing a detailed list of criteria to distinguish follicular lymphoma from follicular hyperplasia in the overwhelming proportion of cases [105]. By this time it had been appreciated that on average follicular patterns in histopathological lymph node specimens predicted for a more indolent course of the disease. Henry Rappaport was affiliated with the Armed Forces Institute of Pathology and Veterans Administration Central Laboratory for Anatomical Pathology. He later moved to the University of Chicago, Department of Pathology. Rappaport also developed a classification of non-Hodgkin's lymphomas based largely on histological criteria [106]. It was a milestone in the description of lymphoma phenotypic heterogeneity and became the most widely used classification of its day. The reticulum cell was thought to be a histiocyte by Callender, Gall, and Rappaport. Rappaport's classification also had a category of histiocytic lymphoma (né reticulum cell sarcoma), which was pathobiologically unsupportable because lymphomas are by definition diseases of a clone of lymphocytes and histiocytes are myeloid cells that develop from an unrelated lineage (histiocytoses). This paradox seemed not to bother these otherwise distinguished experts. Rappaport, also, questioned whether the follicles in follicular lymphoma were part of the neoplastic process and suggested that one use the terms "nodular" and "diffuse," the former a substitute for follicular. His categorization of lymphoma included two histopathological patterns in lymph nodes, nodular or diffuse proliferations, and four cytological patterns: well-differentiated (small cell),

poorly differentiated (large cell), and histiocytic, or a mixture of lymphocytic and histiocytic. It was attractive in its relative simplicity and had a strong relationship to histopathology and to the rate of clinical progression. Small cell nodular had the slowest rate of progression, and large cell diffuse the fastest. But, Rapport's classification was limited profoundly by the insensitivity of microscopic pathology not supplemented by other more specific and sensitive techniques. In addition, by the 1970s, at least six classifications of lymphoma were used in different parts of the world. This limited the power of international collaboration in interpreting and comparing treatment trials.

Development of Immunological Markers

For the first 55 years of the twentieth century progress had been made in the microscopic anatomy of lymphatic structures, the differences in the expression of immediate and delayed immune reactions, and the understanding of antibody production, but the functional organization of the immune system and the genetic and functional heterogeneity of lymphocytes had not been uncovered.

The bursa of Fabricius was named after the Italian anatomist Hieronymus Fabricius who described it as a result of his elaborate animal dissections in 1621. He also was an early expert in fetal anatomy and is considered by some as the first embryologist. William Harvey studied with Fabricius who was professor of anatomy and surgery in Padua. In 1955, an unexpected event dramatically accelerated the understanding of the organization of the immune system. Hens that had the bursa of Fabricius excised at an early age for a previous, unrelated experiment were later used to obtain antibodies to *Salmonella typhimurium.* Injection of samples from a heated-inactivated broth containing the organisms resulted in an unexpectedly high death rate and very poor antibody production. Bruce Glick (1927–2009) and coworkers, recognizing the significance of their serendipitous observation, went on to show that bursectomy at 2 weeks of age profoundly decreased antibody production after a challenge with bacteria [113, 114]. This discovery ultimately led to establishing that lymphopoiesis in the bursa generated antibody-producing lymphocytes. Subsequent studies by Noel L. Warner (b. 1939) and Aleksander Szenberg, a Rockefeller Foundation Travelling Fellow from Poland and subsequently a staff member at the Walter and Eliza Hall Institute of Medical Research, Melbourne, confirmed the individual role of the bursa and the thymus in the immune system of fowl [115]. Thus, it was determined that the thymus and the bursa were primary lymphoid organs, so designated because they generated lymphocytes without the mediation of antigens. The bursa produced lymphocytes that could later make antibodies; these cells came to be referred to as bursa-derived or B lymphocytes. The early removal of the thymus impaired delayed hypersensitivity and permitted homografts (allografts) to be accepted. The thymus in chickens was discovered to produce lymphocytes that mediated cellular immunity and were referred to as thymus-derived or T lymphocytes. Poultry science proved to be of dramatic consequence for understanding mammalian immunology [116]. These findings were confirmed in mammals [117], and although the exact homologue of the bursa in mammals had been elusive, it was later considered to include the bone marrow, preserving the relevance of the designation "B" lymphocytes, purely by coincidence.

Observations in children with immunological diseases had confirmed that humoral and cellular immunity was regulated by separate determinants. In 1950, Eduard Glanzmann (1887–1959), professor of pediatrics at the University of Bern and later director of the Children's Hospital, and Paul Riniker, professor of pathology at Bern, described an infant who had markedly decreased antibody levels and decreased delayed hypersensitivity with absolute lymphocytopenia and a rudimentary thymus without lymphoid cells. This dual disorder became known as thymic alymphoplasia or Swiss-type agammaglobulinemia to distinguish it from the agammaglobulinemia of Bruton in which affected children had normal delayed immunity but deficient production of gamma globulin (antibody). In 1952, Colonel Ogden C. Bruton (1908–2003), Medical Corps, United States Army, serving at the Walter Reed Army Hospital described the first case of a human being with a predisposition to infections found to be the result of an inability to generate antibodies to infectious challenges. He determined the child had an absence of serum gamma globulin using a device that separated proteins based on their net electrical charge, an instrument and technique developed by Arne Wilhelm Kaurin Tiselius (1902–1971), a Swedish biochemist. Tiselius had trained with Theodor H. E. Svedberg (1884–1971), the inventor of the ultracentrifuge, for which Svedberg won the Nobel Prize in Chemistry in 1926. The Tiselius device permitted the separation of proteins in the fluid phase, an accomplishment that had a profound effect on protein chemistry and diagnosis in medicine. Tiselius was awarded the Nobel Prize in Chemistry in 1948 for his achievement. Tiselius went on to become President of the Nobel Foundation. The electrophoretic technique was advanced by adapting it to a solid phase, such as paper, cellulose acetate, or a gel. In 1966, Vincent Anthony Fulginiti (1931–2013), a pediatrician, then at the University of Arizona, and colleagues described

two sets of siblings who had thymic alymphoplasia but normal antibody synthesizing capacity. Thus, the effect of bursectomy in fowl or thymectomy in fowl or mice was recapitulated in humans by the effects of an inherited absence of the thymus or bursa-equivalent or both.

By 1969, the accumulated evidence for two principal types of integrated immune effector pathways, one mediated by B lymphocytes that mature into plasma cells to produce antibodies and one mediated by T lymphocytes derived from the thymus, was compelling and brilliantly synthesized by Ivan M. Roitt (b.1927) and colleagues [118]. Roitt and Deborah Doniach (1912–2004) had been the first to identify autoantibodies in Hashimoto thyroiditis and were convinced that many diseases were of an autoimmune nature. Ernest Witebsky (1901–1969), a German immigrant escaping the inhumanity of the Third Reich, and a giant in immunology, who settled in Buffalo, New York, working at the University of Buffalo School of Medicine, developed a model of experimental autoimmune thyroiditis. Roitt and Doniach and Witebsky and Noel Richard Rose (b. 1927), then a young colleague, are credited with simultaneously and independently, introducing the concept of autoimmune diseases. While in Germany, Witebsky had been influenced by the teachings of chemist and immunologist and Nobel Laureate in Physiology or Medicine, Paul Ehrlich. Ehrlich espoused the dictum of "horror autotoxicus," the necessity of the human immune system not to react to self-antigens. Witebsky was the student of Hans Sachs (1877–1945), professor of immunology and serology and at one point director of the Cancer Institute in Heidelberg, who had worked and published research with Ehrlich. The influence of Ehrlich's views slowed Witebsky's publication with Rose, currently professor at Johns Hopkins University, by 3 years until he was very sure that he was correct. Witebsky also defined autoimmunity more precisely than we do today. He insisted that there be demonstration of an autoantigen, not just an autoantibody, to be certain the process was autoimmune. Witebsky received the Karl Landsteiner Award in 1959 for his groundbreaking earlier work on blood group antigens.

Studies of human blood lymphocytes for the purpose of identifying immunoglobulin determinants on their surface using indicator red cells were being conducted by Robert Royston Amos (Robin) Coombs (1921–2006) and coworkers [119]. Coombs was renowned for his conceptualization and implementation of the red cell antiglobulin test in 1945. In later work, Coombs found, surprisingly, unsensitized sheep red cells formed rosettes with a large proportion of human blood lymphocytes. Coombs also found that a smaller population of lymphocytes carried membrane determinants for immunoglobulin or formed rosettes with complement-coated red cells [120]. The two populations of human blood lymphocytes were shown to have the phenotype of either thymocytes, i.e., were T lymphocytes, or immunoglobulin synthesizing cells, i.e., B lymphocytes [121, 122].

Inevitably, the cells of lymphoid malignancies began to be examined to determine their immunophenotype. It had already been deduced that myeloma was a B-lymphocyte malignancy and studies of Burkitt lymphoma cells in culture revealed their immunoglobulin-carrying phenotype, later to be denoted B lymphocytes [123]. An expansion of B lymphocytes with poorly expressed membrane immunoglobulin was found to be present in patients with chronic lymphocyte leukemia [121, 124]. Patients with other types of lymphocytic leukemia and lymphomas were soon characterized as to their T- or B-cell phenotype and, later, natural killer cell phenotypes, denoting the third of the three major lymphoid cell lineages.

In 1969, Joseph (József) Géza Sinkovics (b. 1924), a physician-scientist and Hungarian émigré, working in the Section of Clinical Tumor Virology and Immunology at the M.D. Anderson Cancer Center, observed that his unprimed lymphocytes killed allogeneic tumor cells in vitro. He reported his findings shortly thereafter [125]. He also showed that the cells involved in attaching to and lysing tumor cells were large granular lymphocytes. Although his report was met with skepticism and rejection (a project site-visitor proclaimed "There is no immune reaction without preimmunization"), this work was confirmed and expanded to indicate that the unprimed lymphocytes also could kill virus-infected cells. In his monograph [126], Sinkovics reviewed the reaction of the scientific community to his finding that tumor-reactive lymphoid cells might be present without preimmunization of their host. He provided the first photomicrographs and tumor cell growth-inhibitory graphs describing such cells.

This rejection of new ideas was commented on 400 years earlier by no less a figure than the French Renaissance author Michel Eyquem Montaigne (1533–1592) who remarked on the matter of discovery, "Whenever a new discovery is reported in the scientific world, they say first, 'it is probably not true.' Thereafter when the truth of the proposition has been demonstrated beyond question, they say, 'yes, it is true but it is not important.' Finally, when sufficient time has elapsed to fully evidence its importance, they say, 'yes, surely it is true and important, but it is no longer new.'" The population of lymphocytes carrying those capabilities was dubbed "natural killer cells," because their effect was neither mediated by antibody nor surface receptors nor did it require prior immunization. At about the same time (1970), Sinkovics described a lymphoproliferative disease, which in

retrospect may have had a natural killer cell phenotype [127]. Several investigators, notably Ronald B. Herberman (1940–2013), then at the National Cancer Institute, and from 1985 to 2009 the founding Director of the University of Pittsburgh Cancer Center, began to examine this matter and natural killer cells were determined to be a third type of lymphocyte [128]. With these advances, normal and pathological lymphocytes could be classified into distinct lineages (B, T, and natural killer [NK] cell types), which could be determined by expression of lineage-specific surface antigens and, eventually, by analysis of B-cell immunoglobulin and T-cell receptor genes [129, 130].

Application of Advances in Immunology to Classification

With advances in identification of lymphocyte subtypes, the rudimentary and partially erroneous classification of lymphoma could be expanded and made more accurate. Two such efforts stood out. In 1974, Harald Stein (b.1942), Edwin Kaiserling, and Karl Lennert (1921–2012), at the Patholisches Institut der Universität Kiel, established that reticulum cell sarcomas were not tumors of reticulum cells or histiocytes but were tumors of B lymphocytes by showing their cellular expression of immunoglobulin [131]. Karl Lennert was one of the leading histopathologists of the twentieth century interested in the classification of lymphoma. Lennert was born in Fürth, Bavaria, in 1921 and graduated from the medical school at the University of Erlangen in 1945. He studied at the Institute of Pathology at the University of Frankfurt and, thereafter, spent time at the University of Erlangen, the Max Planck Institute in Göttingen, the University of Frankfurt-am-main, and the Institute of Pathology at the University of Heidelberg. From 1963 to 1989, he was director of the Institute of Pathology at Kiel, during which years he and his colleagues developed one of the leading classifications of the lymphomas, referred to as the Kiel classification. The Kiel classification was the first to recognize B- and T-cell subtypes [107] (Table 37.3).

In a parallel second effort in the United States, Robert J. Lukes (1922–1994) and Robert Collins (1928–2013) developed a classification using immunological features of lymphoma cells [108]. Lukes' biography was commented on earlier because of his contribution to the classification of Hodgkin's disease. Robert Collins (b.1928–2013) was professor of pathology, at Vanderbilt University School of Medicine. Collins, along with Lukes, developed a system of categorization referred to as the Lukes and Collins classification, which denoted malignant lymphomas by their lineage of origin (B-cell or T-cell types). Collins and colleagues were also among the first to describe splenic and nodal marginal zone lymphomas, peripheral T-cell lymphomas, and anaplastic large-cell lymphomas. The Kiel classification used in Europe and the Lukes and Collins classification in North America were the two most prominent, widely used classifications of lymphoma in the 1980s and early 1990s (Table 37.3).

Hematologists, oncologists, and experimental pharmacologists needed to interpret results of clinical drug trials performed in different institutions, worldwide, a situation made difficult by the use of different classification schemes that did not easily permit equivalencies among pathologists. The problem was addressed initially by the United States National Cancer Institute, which convened a large group of investigators to determine whether one classification scheme was better than another at predicting clinical outcome. None of the classifications predicted patient outcome better than another. Therefore, a "Working Formulation" was developed so that physicians could translate clinical data derived in different institutions, using different classification schemes [109]. In the latter Formulation, lymphomas were divided into ten categories based on morphological features, permitting physicians to deal with a large number of lymphoma subtypes. The lymphomas were further grouped into three clinical prognostic groups (aggressive, intermediate, and indolent). Although the Working Formulation was not intended to be a final classification scheme, it was used as such by many institutions, particularly in North America. However, the Working Formulation failed to distinguish the distinctive features of several newly described histological subtypes of lymphoma. Moreover, the Working Formulation categories did not include newly available immunological and molecular genetic analyses capable of distinguishing new subtypes of lymphomas, such as mantle cell, marginal zone, and peripheral T-cell lymphomas [110].

A new approach to lymphoma classification proposed by the International Lymphoma Study Group used clinical features, morphology, immunophenotype, and genetic alterations to define the unique lymphomas that could be diagnosed consistently by hematopathologists. This grouping, published in 1994, was known as the Revised European-American lymphoma (REAL) classification [111]. The cell lineage of origin of each lymphomas was defined as well [132] (Table 37.3).

In the late 1990s, a new World Health Organization (WHO) classification for clonal lymphocytic disorders was being developed, based on the REAL classification. First published in 2001, updated in 2008, and again in 2016, the WHO classification represented the consensus of an international group of hematopathologists, including contributions from a clinical advisory committee of hematologists and oncologists experienced in treating lymphomas [112]. This array of over 50 distinct lymphoma histopathological types derived from transformation of B, T, and NK progenitor cells has become the accepted classification, worldwide (Table 37.3).

Application of Technological Advances in Immunology and DNA Analysis to Classification

The progress in the identification of the lymphoma subtypes was dependent on several critical technical advances of importance. The process for developing monoclonal antibodies was one of the most important. César Milstein (1927–2002), a biochemist and émigré from Buenos Aires, working in Medical Research Council Laboratory of Molecular Biology in Cambridge, England, was studying methods of tumor cell fusion. Milstein's research career was devoted to studying the structure of antibodies and the mechanism by which antibody diversity is generated. Georges Jean Franz Köhler (1946–1995) working in Basel, Switzerland, was studying normal antibody-producing cells in tissue culture. His research was impaired as he could only get small quantities of cells to survive for short periods of time. Köhler, a young scientist, knew of Milstein work, and it seemed logical to see if normal antibody-forming cells could be fused with myeloma cells to produce long-lived hybrid cell lines that produce antibody. Köhler went to Milstein's laboratory as a postdoctoral fellow, and they solved the problem in 2 years, 1975–1976. They developed a method of lymphocyte fusion that provided a tool to overcome these limitations. Mouse myeloma tumor cells were fused to spleen cells derived from a mouse, which previously had been immunized with antigen. About 50% of the hybrid cells combined desired parental traits: vigorous growth in tissue culture derived from the myeloma tumor cell and antibody production coming from the immunized splenic B cells. Köhler and Milstein called these conjoined cells "hybridomas." A relatively high proportion of the hybridoma cells secreted antibody specific to the immunizing antigen. The technique provided specificity, since each hybrid produced only one antibody and an unlimited supply of antibody, since the hybrids were "immortal," growing as tumor cells. Also, impure antigens led to pure antibody reagents since the hybrids produced one principal antibody. The monoclonal antibody by definition characterizes only one antigen of the many injected into the mouse. Milstein and Köhler [and Niels K Jerne (1911–1994)] were jointly awarded the Nobel Prize in Physiology or Medicine in 1984 for their achievement. Milstein made many contributions to the improvement of monoclonal antibody technology, especially focusing on their use as markers that allow distinction among different cell types. He also foresaw the potential of ligand-binding reagents that could result from applying recombinant DNA technology to monoclonal antibodies and inspired the development of the field of antibody engineering.

Wallace Coulter's (1913–1998) development of the Coulter counter and the use of the Coulter principle on which it depended to develop the first particle (e.g., single cell) flow analyzer was an important contribution to science and medicine. The development of the electronic particle counter and flow cytometry and particle sorting has had a stunning and incalculable impact on research, diagnosis, and therapy. Adaptations that permit characterizing the phenotype or DNA content of cells, and sorting and isolating cells by their physical or surface properties have advanced studies of cells, dramatically. This remarkable instrument evolved from Coulter's earliest developments based on his idea that particles moving through a small aperture across which a current flowed would produce an impedance that could be recognized electronically. Moreover, the height of the signal could be made proportional to the volume of the particle. This, the Coulter principle, resulted in cell counters that were integral to medical research and diagnosis, and to industrial uses. A small subsidiary company owned by Coulter, Los Alamos Particle, Incorporated, in collaboration with the Health Physics Division of the Los Alamos National Laboratories used the ideas that Coulter had evolved to develop to count and size particles for the prototype flow cytometer. Mack Jett Fulwyler (1936–2001) and colleagues [133, 134] reported on the instrument they developed that used the Coulter principle to separate fluid droplets containing single cells by differences in cell volume. They could electrically charge droplets with cells of the desired volume and deflect them electrostatically into a collecting reservoir. A group of engineers and scientists, working at Stanford, advanced this technology by using cells stained with fluorescent dyes and measured cell size by light scatter and the fluorescence intensity generated by a laser [135]. The cell-containing droplets could be charged based on size and on the conversion of the laser-generated optical signal into an electronic pulse. These two variables (dual parameter) could be used to decide whether to deflect the cell into a collecting reservoir. The addition of laser light scatter to the Coulter principle of electronic counting and sizing resulted in VCS technology (**v**olume, **c**onductivity, **s**catter of laser light). The instrument, called a fluorescence-activated cell sorter (FACS), was invented in the late 1960s by Leonard A. Herzenberg (1931–2013), with the contribution of several colleagues, to do flow cytometry and cell sorting of viable cells [136]. Becton Dickinson Immunocytometry Systems introduced the commercial machines in the early 1970s, using the Stanford patent and expertise supplied by the Herzenberg laboratory and a Becton Dickinson engineering group under Bernard Shoor. Herzenberg won the Kyoto Prize in 2005 for his technological contribution to science and medicine. Wallace Coulter's ideas and the instruments they spawned were among the most important innovations in diagnostic and investigative hematology, immunology, and cell biology, among other disciplines, in the twentieth century.

The availability of monoclonal antibodies and flow cytometry led to advances in the classification and diagnosis

of clonal lymphoid diseases and, ultimately, to their therapy with monoclonal antibodies directed against cell surface proteins identified by cell flow analysis (discussion later in this chapter).

A third technological advance was made to further subclassify lymphomas by molecular differences. Development of techniques to array and identify the expression of a specific cell's genes on a microchip has permitted characterization of all or a subset of genes in a specific normal or neoplastic lymphocyte cell type, based on the pattern of its genic expression, overexpression, or under-expression. Using DNA microarray technology, the messenger RNA levels of the entire genome could be quantified in a single experiment. Louis Michael Staudt (b. 1955), at the National Cancer Institute, a pioneer in the use of this technology, developed the Lymphochip, a specialized array of 18,500 complementary DNAs containing human genes important in lymphocyte biology and the normal and pathological immune response [137]. Staudt, together with Arash A. Alizadeh (b.1972) and other colleagues, discovered that a pattern of gene expression within a homogeneous histopathological and immunological phenotype, diffuse large B-cell lymphoma, was heterogeneous with three subtypes by DNA microarray analysis of which two were indicative of the cell type of origin of the lymphoma [138]. Diffuse large B-cell lymphoma biopsy samples could be stratified into at least two gene expression subgroups based on the data obtained from complementary DNA microarrays. The germinal center B-cell-like subgroup expressed genes characteristic of normal germinal center B cells, whereas the activated B-cell-like subgroup expressed a subset of the genes that are characteristic of mitogenically activated blood B cells and other genes characteristic of plasma cells, particularly those encoding endoplasmic reticulum and Golgi zone proteins involved in secretion. The subgroups identified had significantly and dramatically different 5-year survival rates after identical multiagent chemotherapy. The germinal center B-cell-like subgroup had twice the proportion of 5-year survivors than did the activated B-cell-like subgroup. Thus, gene expression profiling could subclassify diffuse large B-cell lymphoma into biologically and clinically distinct groups. This approach has found important variations of prognostic significance within a single diagnostic category in other lymphomas and has identified molecular pathways that are targets for future drug development.

The emergence of DNA microarray technology and the gene chip involved the genius of several men and numerous academic and industry consultants [139]. Alejandro Zaffaroni (1923–2014), born, raised, and educated in Montevideo, Uruguay, came to the United States to obtain his Ph.D. in biochemistry at the University of Rochester School of Medicine. After receiving his degree, he joined the Syntex Corporation in Mexico City in 1951, then a small Mexican chemical company specializing in steroid research. Over the next 2 decades, Zaffaroni became its Chief Executive Officer and transformed Syntex into a major multinational pharmaceutical company based in Palo Alto, California. He was one of the most innovative scientists and business men of his age and focused on the areas of drug delivery and drug discovery. He left Syntex to start ALZA Corporation (named for the first two letters of his first and last name) to advance his work on transcutaneous ("the patch") drug delivery and later he established the DNAX company, among other ventures. In 1988, he started Affymax, recruiting outstanding scientists from Stanford and other universities to develop singular and innovative means of developing new drugs. They recruited a gifted young chemist Stephen Philip Allan Fodor (b. 1953) who received his Ph.D. in chemistry from Princeton. At the end of his postdoctoral fellowship at the University of California at Berkeley, Fodor was convinced to leave academia because of the brain trust recruited by Affymax. Fodor was attracted to the brilliance of the persons involved and the ideas to be pursued. They began by using semiconductor chip methodology and adapting it to generating peptide diversity on an array using a photolithographic process. Eventually, Fodor and the team turned from peptide microarrays to nucleic acid microarrays. The process of making the chip was perfected by Fodor and his team. First, photolithography was used to create a huge number of molecules on a silicon wafer or a glass surface. A single chip measuring 1.28 cm × 1.28 cm can hold more than 400,000 probe molecules. Next, a target molecule is labeled with fluorescent dye and is simultaneously hybridized to all the probes on the chip. A fluorescent image develops that is scanned by a laser, producing data for computer analysis. The intensity of the fluorescent light generated in this process depends on how avidly the target molecule hybridizes with the probe molecule attached at each position on the chip. All this began as a complex experimental procedure and eventually became fully automated. Patrick O. Brown (b.1954), professor of biochemistry at Stanford University, independently had developed microchip technology using complementary DNA rather than oligonucleotides, a useful and important advance in the methodology for the study of the human genome and that of lower species.

Fodor and Zaffaroni co-launched Affymetrix in 1991, a spin-off of Affymax, and developed the chip technology to identify large arrays of genes, permitting Staudt and others to apply these methods to studies of lymphoma diagnosis by genic rather than phenotypic characteristics and to explore the pathobiology of lymphoma by analyzing their gene expression patterns.

Perhaps, one of the most powerful and important techniques that can be applied to the diagnosis or management of lymphoma is the polymerase chain reaction The story of the antecedents to the development of the polymerase chain reaction is not detailed here, but can be found in "A Short

History of the Polymerase Chain Reaction" [140]. The Nobel Prize in Chemistry was awarded to Kary Bank Mullis (b.1944) for the idea and pursuit of the development of this momentous technology. It has been a profound contribution to the study of DNA molecular biology (e.g., sequencing), the diagnosis of inherited disorders, infectious diseases, various cancers, and to forensic sciences, among other disciplines. Mullis, a DNA chemist at Cetus Corporation in the early 1980s, had an epiphany about a method to amplify a small segment of DNA to millions of identical copies in just a few hours sufficient for analysis. The idea was met by disdain by his colleagues and supervisors at Cetus, initially. His recollections about the idea and its pursuit are described in his Nobel lecture [141]. This method allows clinicians to diagnose and monitor diseases using a minimal amount of blood or tissue sample. The detection of monoclonal expansions of the immunoglobulin heavy chain (IgH), the T-cell receptor-gamma (TCRgamma) chain, or the *BCL2* genes, for example, has become an important addition to the methods to diagnosis and manage patients with lymphomas.

Recognition of Cutaneous Lymphoma

Anne Charles Lorry (1768–1837) published, perhaps, the first textbook on skin diseases in which he described multiple and festering skin lesions he described as "fleischgewächse" (sarcome). It is not clear whether these lesions represented mycosis fungoides. Mycosis fungoides, as we know it today, was described by the French dermatologist Jean-Louis-Marc Alibert (1768–1837) working at l'hôpital Saint-Louis in Paris. He initially called the lesions pian fungoides in 1814 because of their similarity to Yaws (pian ruboide). In 1832, the year Hodgkin reported his seven cases of lymphadenopathy, Alibert described the skin tumors of this severe case as "a strange disorder of the skin with mushroom-like tumors"; hence, his use of the term mycosis fungoides in his treatise on skin pathology, Monographie des Dermatoses [142]. He knew it was not caused by a fungus. The patient, Lucas, began with a desquamating rash (éruption furfuracée) and it evolved into numerous facial and truncal tumors and death 5 years later (Fig. 37.4). Given the times, Alibert had no idea of the underlying pathology. In 1864 Heinrich Köbner (1838–1904) published one of the earliest descriptions of its histopathological appearance. He thought it a granulomatus disease. In 1869, Xavier Gillot (1842–1910) and Louis-Antoine Ranvier (1835–1922) connected mycosis fungoides with a proliferation of lymphocytes, referring to it as a cutaneous manifestation of lymphoma (lymphadénie cutanée). The former was a student working for his doctorate in medicine under Ranvier. Ranvier was one of the leading neuropathologists of that period. He published the first edition of his "*Manuel d'histologie*

Fig. 37.4 Alibert's patient with lesions he called "mycosis fungoides." The patient, Lucas, was pictured in the second volume of Alibert's treatise *Monographie des Dermatoses* in 1832. The disease was first manifest as a desquamating rash and progressed to the multiple lesions shown on the patient's face and trunk (Source: Jean Louis Marc Alibert's Monographie des Dermatoses. Paris, 1832)

pathologique"("*Manual of Pathological Histology*") in 1869 and "*Traité technique d'histologie*" ("*Treatise on Histological Techniques*") in 1875, the former based on private histopathology lessons he and a colleague offered to students in Paris. In his thesis, Gillot also described four stages of cutaneous lymphoma, starting with the erythematous stage and ending in the tumoral stage with ulcerations and hardening. Pierre-Antoine-Ernest Bazin (1807–1878) gave a comprehensive description of mycosis fungoides in 1870, 1 year after Gillot, describing the disease as having three stages: nonspecific erythematous (premycotic), plaque (lichenoid), and tumor (fungoid) phases. He saw these as a progression of one phase into another over an extended period of time. Subsequently, it was appreciated that the disease could start with a tumor stage without an earlier erythematous phase. For a time, the disease was referred to as Alibert-Bazin disease. Its relationship to lymphoma and its neoplastic, rather than inflammatory, nature was further highlighted by John Frank Fraser, a dermatologist at Cornell Medical School in 1925 [143]. In 1938, Albert Franz Sézary (1880–1956), a dermatologist who was born in Algiers but later studied and practiced in Paris, collaborating with Yves

Bouvrain (1910–2002), described a disease in which erythroderma was associated with unusual cells in the blood ("… cellules monstreuses dans le derme et le sang circulant") [144]. Sézary thought the cells were monocytes or histiocytes. In 1929, Sézary became chef de service at les hôpitals Broca and Saint-Louis. He was president of Société française de dermatologie in 1937 and was elected to l'Académie de Médecine in 1945. He was also Officier de la Légion d'Honneur. Bouvrain went on to be a noted student of cardiac rhythm disturbances and an expert in cardiac electrophysiology. In 1971, Peter E. Crossen and colleagues provided evidence that the cells in Sézary syndrome were lymphocytes, and in 1973, Jean-Claude Brouet, a French immunohematologist, and coworkers reported that the malignant lymphocytes in Sézary syndrome carry immunological features of T lymphocytes [145]. Marvin A. Lutzner, chief of the Dermatology Branch at the National Cancer Institute, had studied the ultrastructural and clinical features of these diseases and described the cerebriform nuclear shape of the cells in the blood in patients with Sézary syndrome. He recognized the closely related features of mycosis fungoides, Sézary syndrome, and psoriasis en plaque and in 1975 at a National Institutes of Health conference, he and his coworkers proposed that these disorders be grouped under the designation of cutaneous T-cell lymphomas [146].

Therapy of Lymphoma

By the early 1940s extensive series of cases of lymphoma had been published and awareness of the extranodal sites that could be involved, e.g., bone, gastrointestinal tract, genitourinary tract, and others, had become evident. In addition, the appreciation that a large proportion of cases had extranodal involvement or may be limited to extranodal sites was by then apparent. In 1940, Everett D. Sugarbaker (1910–2001) and Lloyd Freeman Craver (b.1892) had published a review of lymphosarcoma in the *Journal of the American Medical Association*. Maxwell M. Wintrobe, the most distinguished and accomplished hematologist of the first half of the twentieth century, had published the first edition of his now classic textbook *Clinical Hematology* in 1942 in which he reviewed the knowledge of lymphoma up to that time and described the multiple organ involvement that could ensue. The terminology of the lymphoma subtypes was largely that described by Gall and Mallory. Wintrobe classified treatment into three categories: Fowler's solution (solution potassium arsenate, U.S.P.), surgery (describing extended survival in a small proportion of patients with lymphoma and Hodgkin's disease after excision of nodes), and irradiation with X-rays or radium. An extensive discussion was provided about the X-ray energy levels favored, the duration of treatment, and the approach, e.g., localized versus generalized radiation. The treatment advances in the lymphomas were based on the advances made for the treatment of Hodgkin's disease. Initially, in the first half of the twentieth century, radiation therapy was used principally on localized lymphomas or used on selected troublesome areas for palliative therapy. Since lymphomas were (1) usually widely dispersed, even if not apparent by the diagnostic techniques of the day, (2) often had neighboring occult disease outside the radiation fields, and (3) were being treated with X-ray machines delivering orthovoltage radiation, an inadequate technique, radiation effects were usually short-lived.

In the 1950s and early 1960s, single-agent chemotherapy (nitrogen mustard or newer alkylating agents, methotrexate, vinca alkaloids, and glucocorticoids) or combination (two or three) agents provided more therapeutic approaches for lymphoma. It was the evolution to combinations of four or more drugs, in the 1970s, developed on the model of MOPP therapy for Hodgkin's disease that led to sustained remissions and cures of some aggressive lymphoma subtypes with drugs [147].

In the late 1990s, the introduction of monoclonal antibodies designed to target specific cluster of differentiation antigens (proteins) on the lymphocyte surface further enhanced therapy. In 1980, Philip Paul Stashenko (b. 1947) and colleagues described a B-lymphocyte marker (antigen), B1. In 1983, Lee Marshall Nadler (b.1947) and colleagues reported that a monoclonal antibody to B1 reacted with B-cell lymphomas and non-T-cell acute lymphoblastic leukemias. The B-lymphocyte antigen, B1, had been designated CD20, and was subsequently characterized and cloned. By the mid-1980s, studies of monoclonal antibodies for the treatment of lymphoma had been conceived and phase I and II trials were underway. After much study, in 1997, rituximab, a recombinant, chimeric anti-CD20 molecule, was the first monoclonal antibody approved for the treatment of follicular, CD20-positive, B-cell lymphoma; in 2006, it was approved for initial therapy of diffuse large B-cell lymphoma in combination with drug regimens containing an anthracycline antibiotic [148]. The addition of rituximab to multidrug chemotherapy regimens has enhanced the rate of and duration of remission in the lymphoma subtypes for which it is used. The development of techniques to chimerize mouse variable regions of antibodies or those of other species with the constant region of human immunoglobulin by a team of scientists from Columbia and Stanford Universities and Becton-Dickinson Company made these approaches practical [149]. A chimeric antibody is one in which the variable domains (antigen-binding sites) are from the species used for immunization (e.g., mouse) and the constant domains are protein chains derived from human isotypes. This chimerization with a human constant region reduces substantially the possibility of an immune response by the patient against the xenogenic portion of the protein [150]. In this case, the variable domains

are derived from the murine monoclonal antibody generated against CD20. The history of the commercial development of rituximab is detailed in the chapter, The Discovery of Rituxan, in the monograph *New Drug Discovery and Development* [151].

Discovery of Virus- and Bacteria-Related Lymphomas

Burkitt Lymphoma (Né African Lymphoma) and the Epstein–Barr Virus

In 1946, Denis Parsons Burkitt (1911–1993), after obtaining a degree as Doctor of Medicine from Trinity College, Dublin, and his surgical training at the University of Edinburgh, which he completed in 1938, took a position as a surgeon in the British Colonial Service in Uganda. His uncle, Roland Wilks Burkitt (1872–1946), was the first practicing surgeon in East Africa (Kenya). This family relationship and his desire to work with a mission resulted in Burkitt leaving studies in engineering, his father's profession, and pursuing medicine. Initially, he was refused an opportunity to work as a surgeon in Africa because he had lost one eye in a childhood fight on his way to the Protestant school he attended in Enniskillen at a time when the city was plagued by religious strife (now Northern Ireland). The onset of World War II resulted in his joining the Royal Army Medical Corps in 1941; he was initially stationed in England. From 1943 to 1945, ironically, he was posted to the British Colonial African Service in Kenya and Somaliland. After separation from military service, having proven his capabilities, despite having vision in one eye, he was accepted into the British Colonial Service in Uganda in 1946. He began his service in Lira, Lango District, Uganda, where he was placed in charge of the medical services of several hundred thousand persons with ill-equipped and primitive hospital facilities, essentially a 100 bed "bush hospital." There he provided medical and surgical services to the native inhabitants. He, in parallel, did some clinical research and published a paper on the high frequency of hydrocele in the eastern, but not the western, part of the District, which later proved to be the result of filariasis in the east. These experiences developed his interest for geographical medicine and epidemiology. He, thereafter, was transferred to Mulago Hospital of the Makerere College just outside Kampala. During the next decade of medical practice in that region, Burkitt saw with surprising frequency a rapidly progressive, destructive tumor of the jaws in African children. These tumors had rarely been reported and, in large part, they had been misclassified as soft tissue sarcomas, retinoblastoma if in the orbit, neuroblastoma if in the adrenals, or granulose cell tumors if in the ovaries.

Jaw tumors in Ugandan children had been observed in the first decade of the twentieth century and round cell sarcomas of the jaw and ovary were reported from Nigeria, French West Africa, the Belgian Congo, and the Cameroons. R.A. Hoyte and F.M. Simmonds practicing near Accra in the 1920s treated jaw tumors in children with a polypharmaceutical product made in France called Septicemine. The principal active ingredient of the concoction was hexamine and was used for the treatment of yaws, gonorrhea, typhus, and other infectious diseases in Africa. When Hoyte and Simmonds observed responses, they concluded the tumor was probably infectious in origin. Forty-years later, Burkitt, who learned of their observations, showed that the drug had transient efficacy and that Hoyte and Simmonds surely were treating the lymphoma that now bears Burkitt's name.

In 1957, the physician in charge of the pediatric ward at Mulago Hospital, Hugh Carey Trowell (1904–1989), asked Burkitt to see a 5-year-old child with masses involving both sides of the upper and lower jaws. The biopsy was interpreted as a granuloma. A few weeks later Burkitt was visiting a colleague at Jijoya hospital and saw a child in the courtyard with the same clinical features. He examined the child and found a coincidental abdominal mass. He concluded that one such case was a curiosity but not two. He decided to do a systematic inquiry into this unexplained disorder. On his return, he started by doing extensive record reviews of African children with tumors at Mulago Hospital and realized that the facial and abdominal tumors were linked and probably represented one disease. He published his classical description of jaw tumors in African children in 1958 [152]. Burkitt initially did not recognize the lymphoid origin of these tumors, but he deduced that the disease was a single entity, even when it was disseminated to ovaries, adrenals, heart, stomach, liver, pancreas, and the central nervous system, as it sometimes presented. He enlisted his colleagues in the Department of Pathology, Gregory Thomas O'Conor (1929–2012) and Jack Neville Phillip Davies (1915–1998), to review, retrospectively, the surgical biopsies from these cases and they found them to be identical and a type of lymphoma [153].

As Burkitt was publishing his first paper on the subject, he contacted Alfred George Oettlé (1919–1967), director of the Cancer Research Unit of the South African Institute for Medical Research, who was experienced in the variations in cancer expression. Oettlé responded that the tumor does not occur in South Africa! Prompted by this unexpected response, Burkitt set out to trace its distribution, first within the territory of his posting, and, subsequently, throughout the African continent. He traveled with two physician colleagues throughout Uganda and East and Southern Africa in a used Ford stationwagon covering about 16,000 km and visiting 60 hospitals. He, also, sent illustrated letters to the government and mission clinics on the continent, estimated to be nearly

1000 health facilities [154]. The study was supported by a grant of 250 pounds from the Medical Research Council of the United Kingdom and about 150 pounds from other agencies, some of which paid for the Ford wagon. This relatively inexpensive, homespun, but ingenious approach to population research led to the demonstration of a well-circumscribed area of prevalence, including not only Uganda, but also other central African countries and territories: Kenya, Tanganyika, Nigeria, and the Congo. All of these regions had tropical climates. By contrast the disease was not observed in South Africa or in Sudan or other semiarid or arid regions. Burkitt had mapped out the area of incidence of what he called "African lymphoma." Alexander John Haddow (1915–1978), Director of the East African Research Institute at Entebbe, noted that the altitude distribution was an index of temperature barrier of about 60 °F and areas of low rainfall defining a rainfall barrier. Haddow suggested to him that the geographical distribution of the disease, only in tropical areas, corresponded to the distribution of the tsetse fly and yellow fever, suggesting an arthropod-borne etiology (Fig. 37.5). An outbreak of o'nyong nyong fever in the African lymphoma belt in 1959, caused by a mosquito-transmitted alphavirus, added to the argument. This means of transmission proved not to be the case but it provoked a search for an infectious etiology.

Burkitt and Michael Anthony (Tony) Epstein (b.1921) met on March 22, 1961, in London during a lecture by Burkitt entitled "The commonest children's cancer in Tropical Africa: a hitherto unrecognized syndrome." [155] In the talk, delivered at the Middlesex Hospital in his enthusiastic style, Burkitt described the distribution of cases that he mapped out in his studies in Africa and postulated that there may be an infectious component to African lymphoma. Few in the small crowd at the lecture were excited by this proposition, but one attendee, Tony Epstein, a pathologist and tumor virologist working on Rous sarcoma virus in the Bland Sutton Institute of the Middlesex Hospital Medical School, was excited. This tumor sounded to him as if it could have a viral etiology. After the presentation, the two men met and Burkitt agreed to send Epstein frozen tumor specimens for him to analyze. Epstein's efforts to isolate a virus from these samples or to identify viral particles in transmission electron micrographs of biopsy tissue over several years were a failure. In 1964, Burkitt sent another tumor specimen to Epstein's laboratory. The flight, the overnight BOAC Comet flight from Kampala to Heathrow, was diverted to Manchester because of fog. By the time the specimen arrived in Epstein's laboratory it was cloudy, usually a sign of bacterial contamination. On closer inspection of a wet preparation no bacteria were seen. Epstein realized the cloudiness was the result of

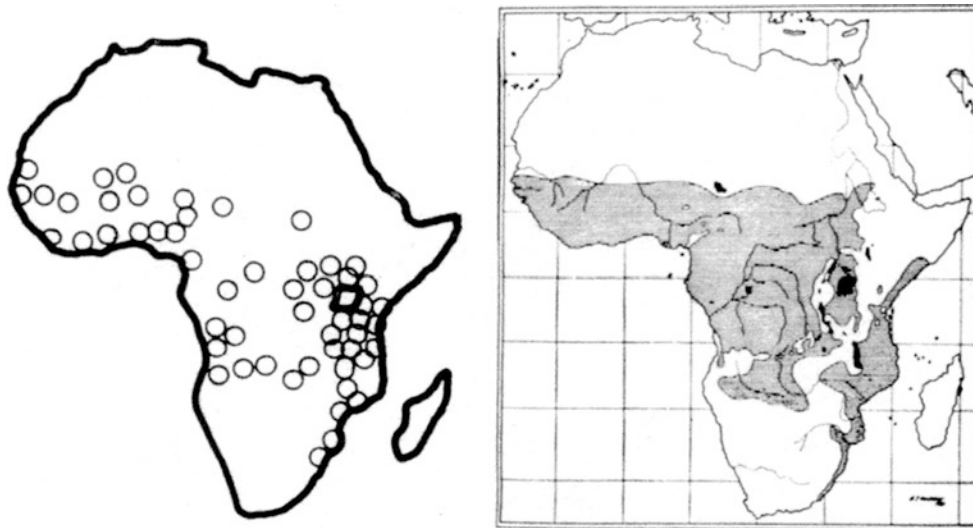

Fig. 37.5 Maps shown by Burkitt in his lecture delivered to the Royal College of Surgery on May 24, 1961. The map on the *left* indicates the localities in which Burkitt found cases of African lymphoma during his epidemiological safari through Africa or by correspondence with area hospitals. On the *right* is a map of Africa, prepared by Haddow showing in *white* the areas either over 5000 ft. elevation, where the seasonal mean temperature may fall to less than 60 °F, or areas with less than 20 in. of rainfall per year. Burkitt *highlighted* the concordance of the *shaded areas* in the map on the *right* with the areas with cases of African lymphoma on the *left*. Burkitt also was impressed with the similarity of tissue sites involved in polyoma virus-infected hamsters and African lymphoma. He got the latter idea from Davies working in the department of pathology at Makerere College Medical School, who proposed African lymphoma might be a virally induced disease. The lecture sponsored by the Royal College of Surgery had sparse attendance, such was the lack of interest in these findings at the time. It was at an earlier presentation of this lecture in March 1961 at Middlesex Hospital that Burkitt met Anthony Epstein and they solidified their future collaboration, leading to identification of the viral particles in the cell line of a patient with African lymphoma (Copyright The Royal College of Surgeons of England; reproduced with permission. Reproduced in O'Conor GT, Davies JNP. Malignant tumors in African children. With special reference to malignant lymphoma. J Pediatr. 1960;56:526–35)

sloughed tumor cells growing exponentially. He developed the first of several continuously growing cell lines (EB1) from that patient's sample and, when he examined the cells by electron microscopy, recognized they contained viral particles (Fig. 37.6). At that time, Uganda was a peaceful and prosperous country, referred to as The Pearl of Africa. Several years later it fell into the hands of Idi Amin Dada (1925–2003), a ruthless tyrant, after which time this remarkable collaboration and discovery might not have happened. The team of Epstein, Bert Geoffrey Achong (1928–1996), and Yvonne Barr (b.1932) published their dramatic results in 1964 [156]. The inability to grow the virus in tissue culture and the skepticism about electron microscopy as a means to discover viruses resulted in delay in broad acceptance of these findings. Eventually, further work made the findings irrefutable. The virus, which came to be known as the Epstein–Barr virus (EBV) and is classified as human herpesvirus-4 (HHV-4), is found in the cells of nearly all cases of the African or the endemic form of Burkitt lymphoma. Achong's training in preparing tissues for electron microscopy was a technical contribution to Epstein's research team, which included, Barr, a Ph.D. graduate student when she first joined the laboratory in the Sutton-Bland Pathology Institute on the first floor of Middlesex Hospital. Barr an Australian, later returned to that country. Ashong was able to produce electron micrographs of the lymphoma cells growing in culture,

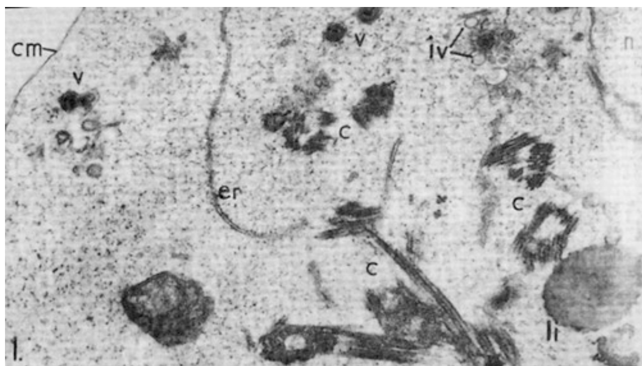

Fig. 37.6 The first visualization of viral particles in a transmission electron micrograph of a cell from a cell line of a patient with Burkitt (African) lymphoma. Epstein and Barr were unsuccessful in culturing the virus over several years of trying "a fruitless struggle," Epstein declared, but found it in his first micrograph of the cell-line developed from the tumor specimen sent to him by Burkitt. As soon as he examined the micrograph he knew he had viral particles. *cm* cell membrane; *n* nucleus; *v* mature viral particles; *iv* immature viral particles; *c* crystals cut in various planes; *li* lipid body; *er* endoplasmic reticulum; numerous free ribosomes in cytoplasm. Yvonne Barr Balding in a Youtube video in 2014 sending greetings to the participants at a conference in Oxford on the 50th anniversary of the discovery, recalls the Lancet calling their office asking if the paper was ready. The Journal was anxious to publish this extraordinary finding, perhaps evidence of the viral etiology of a lymphoma. (Reprinted with permission of Elsevier from Epstein MA, Achong BG, Barr Y. Virus particles in cultured lymphocytes from Burkitt's lymphoma. Lancet. 1964; 1(7335):702–3)

in which Epstein immediately recognized virus particles. The virus, not coincidentally, confers immortality on B cells in culture and was subsequently found to be the virus that causes infectious mononucleosis and is strongly associated with at least three other malignancies: Hodgkin lymphoma, lymphoma in immunodeficient individuals, and nasopharyngeal carcinoma. However, whereas the Epstein–Barr virus was isolated from almost all African cases, it was identified in only a fraction (~20%) of the biopsies of nonendemic cases that share the same cytogenetic translocations but differ in clinical behavior and slightly in molecular genotype. This virus has been identified in lymphomas that complicate a variety of inherited and acquired immunodeficiency states: ataxia-telangiectasia, Wiskott-Aldrich syndrome, severe combined and common variable immunodeficiencies, the X-linked immunodeficiency syndrome, and lymphoma associated with the immunosuppression of organ transplantation and of the acquired immunodeficiency syndrome, notably those with immunoblastic or primary central nervous system lymphomas. In all these conditions, the virus is clonal, but its role as a causal factor of the lymphoma, if any, remains to be elucidated.

At a conference sponsored by the Union Against Cancer in 1963 African lymphoma became commonly called "Burkitt's tumor" and, subsequently, "Burkitt's lymphoma."

In 1966, Burkitt returned to England and took a position with the Medical Research Council. He met a naval surgeon Thomas Latimer (Peter) Cleave (1906–1983), an insightful nutritionist, who had ideas about the relationship of dietary patterns in the population and certain diseases of developed countries. Together they studied and wrote about the importance of dietary fiber [157]. Burkitt did epidemiological studies on diseases in the developed world and their relationship to dietary fiber. In 1975, Burkitt coauthored a book entitled "*Refined carbohydrate foods and disease: some implications of dietary fiber*" with Hugh Trowell and, 10 years later, *Dietary Fibre, Fibre-Depleted Foods and Disease.* Trowell, his former colleague in Uganda, had first asked him to see a child with jaw masses, the case that kindled Burkitt's interest in the disease. Burkitt also published a book for popular consumption "*Don't forget fiber in your diet.*" Burkitt had made "stool rounds" strolling through the African bush, taking photographs of human feces. He found that Africans produce several times the amount of soft feces as Western people. He reasoned that we evolved to live off the land on vegetables and commented on the rarity in Africa of gallstones, diverticulitis, appendicitis, obesity and its sequelae, and several other diseases common in the West. He said that the health of a country's people could be better determined by the size of their stools and whether they floated or sunk than by the country's technological advancement. In 1971, he published a classic article in the journal *Cancer* on the relationship of dietary fiber to colon cancer.

Burkitt's tumor was characterized immunologically as a B-cell lymphoma. In 1972, two Bulgarian scientists, Georgi Manolov (1927–2004) and Yanka Manolòva (b.1928), a husband and wife team working at the Karolinska Institute in Stockholm, reported that there was additional chromosomal material on chromosome 14 (14q+) in the cells of Burkitt lymphoma [158]. This important finding initiated a cascade of additional genetic discoveries regarding Burkitt lymphoma cells. In 1969, Lore Zech (1924–2013), also working at the Karolinska Institute in the laboratory of Torbjörn Oskar Caspersson (1910–1997), had found that a stain, quinacrine mustard, resulted in chromosomes developing light and dark transverse bands along their length. This banding method permitted cytogeneticists to identify accurately each of the 22 autosomes and the X and Y chromosomes and to determine the region (band) at which a chromosome break occurs. Ultimately, Giemsa staining became the most utilized method of chromosome identification and banding. In 1976, Zech and coworkers proved that the extra material on chromosome 14 was the result of an unbalanced translocation between chromosomes 8 and 14 (t(8;l4)(q24;q32)) [159]. Subsequent investigation demonstrated that the translocation was present in approximately 80% of Burkitt lymphoma cell lines; the remaining 20% revealed one of two variant translocations between chromosome 8 and either chromosome 2 (t(2;8)(p12;q24)) or chromosome 22 (t(8;22)(q24;ql 1)). In 1982, both Philip Leder (b. 1934) and Carlo M. Croce (b. 1944) and their associates cloned the translocation breakpoint, and identified the *MYC* oncogene at the site of the break at band 24 on the long arm of chromosome 8 (8q24) [160, 161]. Transfer of *MYC* coupled to the immunoglobulin heavy chain or light chain genes by injection into the germline via the egg nucleus resulted in aggressive B-cell lymphomas in experimental animals, but complete or truncated *MYC* alone was inactive.

Thus, African Burkitt lymphoma cells were invariably found to have one of three chromosomal translocations, each involving the *MYC* proto-oncogene on chromosome 8 and the gene for the immunoglobulin heavy chain or the kappa or lambda light chain on chromosome 14, 2, and 22, [158, 162]. This discovery depended on the prior localization of the sites of normal immunoglobulin chain genes at chromosomal bands 14q32, 2p12, and 22q11, the three sites involved in all common and variant Burkitt translocations. The fusion of the *MYC* gene to one of the immunoglobulin chain genes results in loss of *MYC* regulation and an inability to stop affected cells from entering the mitotic cycle, accounting for the high proliferative rate of the tumor cells and the dramatic increase in tumor size over hours or days.

It was unclear what role, if any, Epstein–Barr virus infection plays in the development of the chromosome injury. One proposal was that the virus infection of B lymphocytes increases their proliferation and, thereby, the probability of the chromosome alteration. This proposal, however, is too simplistic to explain the invariable involvement of the *MYC* gene and immunoglobulin loci.

Shortly after the elucidation of the role of the *MYC* gene in Burkitt lymphoma, Yoshihide Tsujimoto and associates cloned the breakpoint of the 14;18 translocation characteristic of the cells of follicular lymphoma [163]. The breakpoints involved were at the junction of a joining segment of the immunoglobulin heavy chain gene at chromosome 14q32, and the *BCL*-2 proto-oncogene (at l8q21), the protein product of which inhibits programmed cell death [164]. Some years later, the 11;14 translocation characteristic of the cells of mantle cell lymphoma was found to juxtapose the *BCL-1* gene (the product of which is a cyclin that regulates the cell mitotic cycle) on chromosome 11q13 to the same immunoglobulin heavy chain gene (14q32) [165]. *BCL-6*, a proto-oncogene at chromosome 3q27, is translocated to several different chromosome sites in a proportion of large B-cell lymphomas [166]. In T-cell lymphomas, a frequent breakpoint is at chromosome 14ql1, the site at which the delta chain of the T-cell receptor is embedded in the T-cell receptor alpha chain gene [167]. Thus, stimulated by the findings of chromosome translocations involving proto-oncogenes in Burkitt lymphoma cells, various laboratories have uncovered prevalent translocations involving antigen receptor genes, immunoglobulin genes (in the case of B cells), and T-cell receptor genes (in the cases of T cells), as major factors in the cause of human lymphoma.

The stimulus to medical research provoked by this unusual African tumor was singular. Virology, immunology, molecular biology, cytogenetics, and cytokinetics all have benefited from the study of this highly proliferative neoplasm. Cancer therapy has also benefited. The disease could not be treated by surgical excision. A tumor that could double in size in a day or two was a therapeutic challenge, even when apparently localized. Furthermore, Uganda had no radiation therapy facility, then. Burkitt, however, could and did use antiproliferative drugs at hand, such as methotrexate, nitrogen mustard, and cyclophosphamide [168–170]. Joseph H. Burchenal (1912–2006), an early cancer therapist and chief of Sloan-Kettering's division of clinical chemotherapy in the 1960s, was in Nairobi with a team from Sloan-Kettering Cancer Institute and gave Burkitt a supply of methotrexate with instructions for its use in a multiple dose course based on the positive experience they had with its use in the treatment of choriocarcinoma [169]. Since patients who made the trek to his clinic in Kampala did not stay for more than a few days—if they survived, and because the untreated disease was rapidly progressive, Burkitt administered the drugs in short, intensive treatments after which the children disappeared with their families, presumably to die at home. He later recalled his astonishment at meeting some of these children on his epidemiological trips, active and free of

evidence of their tumors. The rapid proliferative rate of the neoplasm made it sometimes responsive to short courses of intensive chemotherapy and in a small number of early cases a prolonged remission resulted. Together with the success of high-dose methotrexate in choriocarcinoma, Burkitt's observations provided an impetus to the exploration of short-term, high-dose chemotherapy in other malignancies. In cases of acute leukemia, high-grade lymphoma, and testicular cancer, this approach has been especially helpful. In 1972, Burchenal and Burkitt, along with several others, received the Albert and Mary Lasker Foundation Award for clinical medical research for their work in cancer pharmacotherapy. Mary Woodard Lasker (1900–1994) was an influential American philanthropist and health activist. She worked to raise funds for medical research and founded the Albert and Mary Lasker Foundation, which gives recognition and monetary prizes to outstanding basic scientists and clinical medical investigators for a notable achievement.

Few people have had the impact that Burkitt had in oncology and few achieved it with so little public support. Working in a poor Third World country with limited medical facilities was not a likely setting for such important discoveries in cancer research. But Burkitt did not let this circumstance dampen his interest when confronted with an unknown and uncharacterized disease. With the limited resources at hand, largely his curiosity, insight, and determination, Burkitt lymphoma became well known throughout the world. Burkitt said to a medical historian in an interview, "I didn't go out to Africa for science but because of what I believed to be God's call, and I've no complaints. I gave a spoonful and got back a shovel full." He received many awards and honors, but never lost his perspective. He was quoted as saying "… attitudes are more important than abilities, motives… than methods, character … than cleverness…, perseverance … than power." In 1994 Trinity College, Dublin, established the Denis Burkitt Research Institute, posthumously.

Adult T-Cell Leukemia–Lymphoma and the Human T-Lymphocytotropic Virus-1

At the beginning of the twentieth century (circa 1908), Vilhelm Ellermann (1871–1924) and Oluf Bang (1881–1937) at the University of Copenhagen first demonstrated that avian leukosis virus could be transmitted into chickens by a cell-free filtrate resulting in leukemia. In 1910, Peyton Rous (1879–1970) at the Rockefeller Institute in New York City extended Bang and Ellerman's experiments to show that a cell-free filtrate could transmit a solid tumor, a sarcoma (as well as leukemia) to chickens. Chickens have unusual characteristics in the behavior of endogenous retroviruses making them a good model for these experiments. Approximately 20 years later, Richard Edwin Shope (1901–1966) discovered the cottontail rabbit papillomavirus, dubbed the Shope papillomavirus, the first mammalian tumor virus. These observations were disputed and neglected for several decades until in 1951 Ludwik Gross (1904–1999), working at the Bronx Veterans Administration Medical Center in New York City, isolated murine polyomavirus, which could cause a variety of salivary gland and other tumors in specific strains of newborn mice. This observation could not be replicated and was not accepted until the findings were confirmed by scientists at the National Institutes of Health by reproducing the experiments under precisely the same conditions as used by Gross. Subsequently, in rapid order Charlotte Friend (1921–1987), then at the Sloan-Kettering Institute for Cancer Research, Arnold Graffi (1910–2006), at the Paul Ehrlich Institute in Frankfort, John Bromley Moloney (b.1924), Frank J. Rauscher, Jr. (1932–1993), and Werner H. Kirsten (1925–1992), the latter three at the National Cancer Institute in the United States, and others established that murine malignancies could be transferred by what we now know to be tumor viruses. Rauscher was named Director of the National Cancer Institute in 1972 to help lead President Nixon's war on cancer. By 1961, electron microscopy of putative tumor virus particles uncovered ultrastructural features in animal tumors that permitted their separation into types A, B, and C; the latter type viral particles are found in the cells of leukemias, lymphomas, and some sarcomas in vertebrates.

Based on these discoveries, the National Cancer Institute in the United States established the Special Virus Leukemia Program, which evolved into the Virus Cancer Program, and received generous and enthusiastic support for nearly 30 years. Initially, it was thought that human malignant cells could be propagated readily in animals or in cell culture and then used to search for tumor-associated viruses. A large industry of animal and cell culture support services was funded and mice, dogs, and apes received inoculations of human leukemic tissue. Soon these rudimentary experiments were replaced by scientifically more advanced investigations, but, through it all, human cancer viruses remained elusive.

Great advances occurred during this era in understanding viral replication and virus infectivity. Reverse transcriptase was discovered independently by Howard Martin Temin (1934–1994) at the University of Wisconsin in Madison and David L. Baltimore (b.1938), working at the Massachusetts Institute of Technology in Boston, the discovery for which they shared the Nobel Prize for Physiology or Medicine in 1970 with Renato Dulbecco (1914–2012), Temin's mentor. Dulbecco discovered that the infection of normal cells with certain oncoviruses led to the incorporation of virus-derived genes into the host-cell genome, and that this event lead to the transformation of the cells (the acquisition of a tumor phenotype), setting the stage for Baltimore and Temin's

discovery. This enzyme, a requirement for the survival of RNA viruses in host cells, enables the formation of DNA complementary to the viral RNA, permitting the virus to leave a permanent residue within the infected cell's genome. This property was required for the malignant transformation of cells by oncogenic RNA viruses, later referred to as oncornaviruses. All of the avian and mammalian leukemia viruses fell into the category of RNA viruses and, thus, were found to contain a reverse transcriptase. Although oncornaviruses caused malignancies in mice, cats, chickens, cattle, and apes, by the mid-1970s they had not been found to cause a single human cancer. During almost 20 years, and despite massive expenditures, the goal of the Cancer Virus Program remained was not achieved. Enthusiasm was replaced by skepticism and ridicule, not the least of which came from classic virologists who had felt that the expensive program was ill-advised from its beginning.

In the 1970s, one laboratory in particular remained dedicated to the quest of finding a human leukemogenic virus [171]. Despite the increasing disenchantment of others in the virological community, and despite having been set back by reporting a contaminating virus to be the long-sought human tumor virus (their finding that an oncornavirus caused acute myelogenous leukemia was not confirmed), Robert Gallo (b.1937) and his associates sought to prove that RNA viruses could cause human leukemia. Gallo's laboratory found a cell-derived chemical that supported T-lymphocyte growth in culture [172]. This T-cell growth factor was identified (later further characterized and renamed interleukin-2) and, in combination with the T-cell mitogen, phytohemagglutinin, permitted the continuous growth of normal T lymphocytes in culture. It was then noted that some T lymphocytes could be cultured with interleukin-2 alone; they did not need phytohemagglutinin for immortalization. With this critical new growth factor, normal and malignant T cells could be sustained in long-term culture. In this setting, the lymph node and blood T lymphocytes of a patient, with what was thought to be cutaneous T-cell lymphoma at the time, were used to develop two cell lines. Both the lymph node and the blood cell lines were found to contain an oncornavirus in which the reverse transcriptase was unlike that of any other known virus. The report by Bernard J. Poiesz (b.1948), Robert Gallo, and colleagues in 1980 was the first conclusive isolation of a human tumor virus. This virus was called human T-lymphocytotropic virus, number one, commonly referred to as HTLV-1 [173, 174].

The discovery of the HTLV-1 retrovirus in the cells from a patient with a cutaneous T-cell lymphoma turned out to be remarkable since no more than one in one hundred such patients have serological evidence of exposure to this agent. In retrospect, it is probable that the patient had adult T-cell leukemia–lymphoma with prominent cutaneous involvement, which can simulate cutaneous T-cell lymphoma. At that time, physicians, especially in nonendemic areas, were not sufficiently aware of the features of adult T-cell leukemia–lymphoma and grouped all T-lymphocyte malignancies involving the skin in the category of cutaneous T-cell lymphoma.

In 1977, Takashi Uchiyama (b.1946), Junji Yodoi (b. 1946), Kiyoshi Takatsuki (b.1930), and colleagues, at the Kyoto University School of Medicine, described a leukemia that they called "adult T-cell leukemia," in which most of the patients were from the Southwestern islands of Japan, especially Kyushi [175, 176]. Although rare in the United States and Europe, the disease also was found to be endemic in the Caribbean basin and Central Africa. One of the characteristics of this newly discovered lymphocytic leukemia was the lobulated appearance of the neoplastic lymphocyte nuclei. In 1980, Isao Miyoshi established cell lines of the neoplastic lymphocytes by co-culturing them with cord blood lymphocytes. Later, it was discovered that the cell lines were largely from cord blood cells that had become infected with what was found to be the etiological retrovirus. In 1981, an antigen was detected in a cell line from a patient with the disease, which was not shared with any other lymphoid lines studied [177]. Antibodies to this antigen were present in all patients with adult T-cell leukemia and some healthy subjects in endemic areas but were not found in patients with other lymphoproliferative diseases and in only occasional healthy persons in nonendemic areas. A cell line from a patient with the disease contained type C viral particles; the putative unique virus was called the adult T-cell leukemia virus (ATLV). The provirus DNA was cloned from the cell line of the patient with human adult T-cell leukemia [178]. In 1982, Motoharu Seiki (b.1949), Mistuaki Yoshida (b.1939), and colleagues at the Department of Viral Oncology of the Cancer Institute in Tokyo reported the isolation and characterization of the virus that is the cause of this form of adult T-cell leukemia–lymphoma [179]. The virus was found to be identical to HTLV-1, described in Gallo's laboratory 2 years earlier. The virus was shown to be the cause of adult T-cell leukemia–lymphoma [180]. The American and Japanese groups had met at Lake Miwa, near Kyoto, in March 1981 and shared data and established a collegial working relationship. Later, they agreed to call the virus "HTLV-1" recognizing the Gallo laboratory's priority, and to call the disease, adult T-cell leukemia–lymphoma, so carefully described by the Japanese [174, 176]. The Japanese found that the virus was transmitted principally from mother to child (T cells in breast milk), spouse to spouse (T cells in semen), and by blood transfusion of infected lymphocytes. In Japan, pregnant women are tested for HTLV-1 antibodies and, if positive, bottle feeding of their infant is urged. The potential for the virus's transmission by blood transfusion has resulted in a Food and Drug Administration requirement that a test for HTLV-1 be included among the panel of microbial agents for

which screening of blood must be carried out. There has been no success preparing a human vaccine. William A. Blattner (b. 1943) at the United States National Cancer Institute and Guy Marie Gérard Blaudin de Thé (1930–2014) did epidemiological studies to indicate that the distribution of the disease in persons in the Caribbean region was dependent on the particular tribes in Africa to which the Caribbean residents were related.

Not only did the discovery of HTLV-1 resuscitate the field of human viral oncology, and silence the critics of the by then defunct Cancer Virus Program, but the retrovirological techniques and pathophysiological insights developed during the search for and discovery of HTLV-1 prepared the scientific world for research into the etiology, diagnosis, and management of the late twentieth century's greatest infectious disease challenge, the human immunodeficiency virus (HIV), another RNA (retrovirus) virus, and the cause of the acquired immunodeficiency syndrome (AIDS). The work in Gallo's laboratory resulted in a technology to grow primary cultures of human T lymphocytes with IL-2, the development of a sensitive and specific assay for reverse transcriptase as a surrogate marker for the presence of a retrovirus, the demonstration that humans could be and were infected with retroviruses, and that retroviruses could cause a human disease and, at least in this case, a human cancer, among other important results. Dispute surrounded the priority of discovery of the human immunodeficiency virus, the discovery of which has been assigned to the laboratory of Luc Antoine Montagnie (b. 1932), a French scientist. Robert Gallo's laboratory's identification of prototypic human T-lymphocytotropic virus facilitated the discovery of the human immunodeficiency virus. Together with his colleague Françoise Barré-Sinoussi (b.1947), director of the Unité de Régulation des Infections Rétrovirales at the Institut Pasteur in Paris, Montagnier was awarded the 2008 Nobel Prize in Physiology or Medicine for his discovery of the human immunodeficiency virus. Harald zur Hausen (b.1936), a German virologist, also shared the Prize for his discovery that the human papilloma virus leads to cervical cancer. Robert Gallo was not recognized by the Nobel Foundation.

Helicobacter pylori-Related Lymphoma

At the beginning of the twentieth century, human cancer was well recognized but was a disease of mysterious origins. At a time of explosion of progress in identifying the causes of infectious diseases, medicine had no framework within which to place these sudden and unwelcome intrusions on human health. It was thought that an irritant or repetitive injury to tissue might induce uncontrolled growth of cells. Factors such as extreme heat, chemical exposures, radiation, or severe recurrent friction might be involved.

In 1926, Johannes Andreas Grib Fibiger (1867–1928), a Danish physician and professor of pathological anatomy, received the Nobel Prize in Physiology or Medicine for experiments he began in 1907. He conducted what by today's standards was a bizarre set of experiments that he interpreted as proving that gastric carcinoma in rats was caused by the larvae of a worm he named *Spiroptera carcinoma.* He found that the larvae acted as a carcinogen if fed to rats as the parasites of an unusual species of cockroach! He argued that after ingestion of the cockroaches, the larvae matured in the intestines of the rat leading to stomach cancer. The Nobel Committee highlighted the importance of the development of animal models to study cancer and the need to learn more of the external, possibly preventable, causes of the dread diseases. Although this may be the only Nobel Prize in Physiology or Medicine for work that was not confirmed, perhaps it served some unintended positive purpose. It is a curious irony that a spiral bacterium was found to be a cause for stomach cancer 90 years later. A greater irony was that in 1915 Katsusaburo Yamagiwa (1863–1930) induced squamous cell carcinoma by painting crude coal tar on the inner surface of rabbits' ears. Yamagiwa's work became the prototype for research on exogenous carcinogens but was not recognized by the Nobel Foundation in favor of the cockroach's parasitic larvae.

By the post World War I period, coal tar, aniline dyes, chimney soot, X-radiation, and some other agents had been linked to the causation of human cancer. In the early twentieth century, Theodor Heinrich Boveri (1862–1915), a German biologist, had brilliant insights into the importance of quantitative and qualitative changes in chromosomes in the pathogenesis of malignant tumors. He focused his interest on embryonic development in the nucleus of the cell. By the late nineteenth century, mitosis and chromosome movement during mitosis had been described. Mendelian genetics was being revisited and the question of the units of heredity was being explored. Boveri discovered the centrosome and its role in mitosis. He reasoned that a cancerous tumor may begin within a single cell in which chromosomes become disordered, causing the cells to divide uncontrollably [181]. He developed this remarkably prescient idea of the development of cancer from his study of the development of sea urchin eggs, manipulated experimentally, such that he could determine the normalcy of embryonic development from blastomeres with normal or abnormal chromosome complements. The origin of neoplasms in the somatic mutations of a single cell derived from the discovery of random inactivation of either the maternally or paternally derived X chromosome in the mammalian female, early in embryogenesis, and the use of that event to determine the unicellular origin of neoplasms in informative women who were heterozygous for a protein encoding X-linked gene. Inactivation of the X chromosome was first established by Mary Lyon (1925–2014),

a British geneticist, studying the genetic basis of patchy mouse coat color and, soon thereafter, in the human female using the X-linked enzyme glucose-phosphate dehydrogenase by Ernest Beutler (1928–2008), an American physician-scientist. The latter X-linked enzyme was used, initially, to demonstrate the single cell origin of neoplasms by David Linder (1923–1999), a pathologist and postdoctoral fellow, and Stanley Michael Gartler (b.1923), a geneticist at the University of Washington in 1965. The history and significance of the discovery of the X chromosome, its random inactivation in females, and the application of the latter phenomenon to identifying monoclonal tissue growths (neoplasms) are reviewed in [182].

In contrast to Fibiger's recognition by the Nobel Committee for an infectious etiology of cancer, the report by Peyton Rous (1879–1970) in 1911, working at the Rockefeller Institute for Medical Research that cell-free filtrates from chicken sarcomas could induce sarcomas in unaffected chickens, was met with marked skepticism by his peers and Rous changed his research direction [183]. After tumor viruses were established beyond question, including the Rous sarcoma virus, and the study of DNA and RNA tumor viruses became a centerpiece of cancer research, Rous was belatedly awarded the Nobel Prize in Physiology or Medicine in 1966, at age 85, 56 years after his discovery. Happily, his longevity permitted correction of the Nobel Committee's oversight, since the Nobel Prize is never awarded posthumously.

Today, human viruses are established as "causal" agents in human cancer in the epidemiological sense. The definition being that in their absence the disease would not occur. Papilloma virus, Epstein–Barr virus, hepatitis B and C viruses, human immunodeficiency virus, and HTLV-1 have been established as either causative or predisposing agents or are of high probability of being found to be so.

In 1981, William Richard Shaboe Doll (1912–2005) and his colleague Richard Peto (b.1943) published a treatise on the causes of cancer and concluded at that time that about 5% of cancers were the result of infections, principally viral, but that at least another 5% probably were induced by infectious agents [184]. Their estimates preceded the evidence for the role of several additional viruses in human cancer causation. They also suggested that bacteria in the intestines could convert nitrates to nitrites or to *N*-nitroso compounds that are potential carcinogens and that schistosomiasis in parts of Africa and clonorchiasis in China may be etiological in the development of bladder cancer and cholangiocarcinoma, respectively. Doll was among the foremost epidemiologist of the twentieth century being credited with establishing the link between smoking and lung cancer through a prospective study in British physicians in the 1950s. He also confirmed the link between smoking and heart disease.

In 1979, the possible direct relationship of bacteria to gastric cancer resurfaced, approximately 70 years after the start of Fibiger's improbable experiments. In 1983, J. Robin Warren (b. 1937) reported Campylobacter-like bacteria in the gastric antral mucosa in biopsies of patients with active gastritis [185]. Despite the prevailing view that the acidic gastric environment was hostile to bacteria with the exception of mycobacteria and other related "acid fast" organisms, careful analysis of the mucosa using silver stains demonstrated colonization of the surface epithelium in the gastric lining by small S-shaped bacteria. The bacteria were closely associated with antral gastritis. The mucosa was infiltrated with neutrophils and smaller concentrations of lymphocytes and plasma cells. Warren lamented the prior inattention to the microbiology of the stomach, and although the organisms looked like Campylobacter, he felt they were unclassifiable. Simultaneously, Barry J. Marshall (b. 1951), Warren's colleague at The Royal Perth Hospital, using techniques to grow Campylobacter, was able to culture the organisms and characterize their ultrastructure. He alluded to their potential significance as a cause of inflammatory and neoplastic disease in the stomach [186]. The two scientists speculated that a close and, perhaps, causal relationship existed between the organisms and either gastritis, gastric ulcer, or gastric cancer.

At least six reports of "spirochetes" or bacteria observed under the light microscope and associated with stomach ulcers or inflammation had been published from 1874 to the time that Warren and Marshall unequivocally found and grew their strange microaerophilic, multiflagellated, argyrophilic bacteria. Perhaps, the two most notable were, first, the report of Abraham Stone Freedberg (1908–2009) and a colleague in 1940 describing spirochetes in the gastric mucosa associated with gastric ulcers [187]. Freedberg had identified spiral organisms in about one-third of sections of stomachs removed for ulcers he received from surgery. Attempts to culture the organisms failed. His work was discouraged by his mentors because of the acceptance that ulcers were the result of stress. (Medical science has been more often the victim of hypotheses regarding stress as an etiology of disease than it has been the beneficiary.) In the discussion after Freedberg's paper, Frank DeVore Gorham (b.1888) described the microbiological basis on which he used intramuscular bismuth for chronic gastric ulcers that refused to heal. Today, bismuth is one of the antimicrobial agents used for the purpose of treating *Helicobacter pylori*-related peptic ulcer. Freedberg went on to become chief of medicine and cardiology at the Beth Israel Hospital, an affiliate of the Harvard Medical School. About 60 years was lost in the search for the cause of peptic ulcers, gastric carcinoma, and gastric lymphoma, as a result of the skepticism and lack of encouragement by Freedberg's advisors. In 1975, Howard William Steer (b.1943) and Duncan G. Colin-Jones observed that

80% of 50 patients with gastric ulcers they examined had gram-negative bacteria in the gastric mucosa and the bacteria did not disappear after the ulcers healed with treatment, in keeping with later observations that histamine-2 receptor antagonists, such as cimetidine, resulted in healing of ulcer craters but not the antral gastritis and duodenitis and was associated with a high ulcer relapse rate [188]. Unbeknownst to the therapist, the underlying microbial incitant had not been eradicated.

The spiral gastric bacterium, referred to as *Campylobacter pyloris* (né *pylorides*), was shown to be incompatible structurally and biochemically with that genus. In 1989, in recognition of these dissimilarities a new genus, *Helicobacter*, was established and the organism renamed *Helicobacter pylori*. A series of papers from 1989 to 1992 provided strong circumstantial evidence that *Helicobacter pylori* is causally associated with about two-thirds of patients with carcinoma of the stomach, worldwide [189]. In 1988, Judith Irene Wyatt (b.1956) and Barrie John Rathbone (b.1955) [190] working in the Department of Pathology at St James University Hospital, Leeds, and in 1989 Manfred Stolte and Sebastian Eidt [191], then at the Institute of Pathology, University of Cologne, had shown that the development of organized lymphatic tissue in the gastric mucosa is nearly invariably a response to *Helicobacter pylori* infection. In 1992, Andrew Charles Wotherspoon (b. 1960) and colleagues, working in the Department of Histopathology at the Royal Marsden Hospital, London, reported that one-third of patients with *Helicobacter pylori*-associated gastritis had prominent lymphoid follicles in the gastric wall and that eight had pathological features of mucosa-associated lymphoid tissue lymphoma [192]. The normal stomach does not harbor any lymphatic tissue.

Primary lymphoma of the stomach closely simulates the features of mucosa-associated lymphoid tissue (MALT) lymphoma [193]. These lymphomas arise in the stomach, salivary gland, or thyroid and require a promoting factor to induce lymphoid infiltration, accumulation, and organization, since these sites are normally devoid of lymphoid tissue. Autoimmune reactions account for the evolution of lymphoid tissue in the salivary gland (Sjögren's syndrome) and the thyroid (Hashimoto's syndrome). In that setting, a B-lymphocytic mucosa-associated lymphoma may develop. In their classic paper, Wotherspoon and colleagues also observed that among 100 cases of gastric mucosa-associated lymphoma, 92% of patients had evidence of *Helicobacter pylori* infection. In striking validation of the potential role of bacterial antigen in provoking these lymphoid tumors, treatment of six patients with B-cell gastric lymphoma and *Helicobacter pylori* infection with a combination of antimicrobial drugs resulted in disappearance of the lymphoma in five subjects and near disappearance in a sixth [192].

Wotherspoon and coworker's implication that *Helicobacter pylori* is the "cause" of gastric B-cell lymphoma of the stomach is built on the work of several prior observations and their own discoveries: the identification of the organism in the stomach, the culture and characterization of the organism, the association of the organism with antral gastritis, the association of the organism with the development of gastric mucosal lymphoid tissue, which is otherwise absent, and the association of the organism with gastric carcinoma. Unlike Fibiger's hypothesis regarding a microbial causation for gastric cancer in the rat, 85 years ago, the evidence supporting the Wotherspoon hypothesis is more compelling. This remarkable relationship provided the opportunity for both novel treatment and prevention of this lymphoma.

In 2005, Barry J. Marshall (b. 1951) and J. Robin Warren (b.1937) shared the Nobel Prize in Physiology or Medicine for discovering *Helicobacter pylori*, leading to the awareness of its significance in the cause of inflammatory and neoplastic diseases [194].

38 Genetics in Lymphomagenesis

James R. Cerhan, Esteban Braggio, Susan L. Slager, and Anne J. Novak

Introduction

Lymphomas are a heterogeneous group of over 60 neoplasms that arise from lymphocytes and produce tumors in the lymph nodes, lymphatic organs and extranodal lymphatic tissue (i.e., lymphomas), as well as the bone marrow (i.e., multiple myeloma) or peripheral blood (i.e., leukemias). Lymphoid neoplasms as a group are some of the most common cancers in the US, with an estimated 112,380 cases in 2016 [1].

Lymphoma subtypes are considered to be clonal tumors of immature or mature B-cells, T-cells, or natural killer (NK) cells arrested at various stages of differentiation [2]. B-cell neoplasms appear to recapitulate the normal stages of B-cell differentiation, and many B-cell lymphomas can be linked to a presumed normal cell counterpart. The normal counterparts of T-cells and NK-cells are not as well characterized as B-cells, but they do share many immunophenotypic and functional properties and are currently grouped together. Based on this, the current World Health Organization (WHO) classification system [3], which has been incorporated into the International Classification of Diseases—Oncology (ICD-O) [4], recognizes precursor lymphoid neoplasm (B- and T-cell), mature B-cell neoplasms, mature T-cell and natural killer (NK)-cell neoplasms, Hodgkin lymphoma (HL), and histocytic and dendritic cell neoplasms. Acute and chronic lymphocytic leukemia (ALL and CLL, respectively), and multiple myeloma (MM) are classified as B-cell neoplasms [2]. A revision of the 4th edition of the WHO Classification was recently released, and although it did not allow for any new definitive entities, it incorporated new genetic/molecular and clinical data into current disease entities and added a limited number of new provisional entities [5].

From a tumor genomics perspective, our current understanding supports the hypothesis that lymphomas are aberrant outcomes of normal physiologic mechanisms used by both the innate and the adaptive immune system [6]. In the bone marrow and thymus, V(D)J gene recombination, which involves DNA double strand breaks, is used by both immature B- and T-cells for the assembly of immunoglobulin heavy- and light-chain (B-cells) and T-cell receptor α and β chain (T-cells) loci. Once B-cells have matured from the bone marrow, they migrate to peripheral lymphoid organs, where they can go through the germinal center reaction, which includes clonal expansion, somatic hypermutation affecting the variable regions of Ig genes, class-switch recombination, and affinity maturation/apoptosis. While these physiologic mechanisms allow for the creation of immense antibody diversity and specificity, they come with a trade-off of susceptibility to neoplasia mainly by generating reciprocal chromosomal translocations (leading to dysregulated expression of proto-oncogenes placed near Ig enhancers) and off-target somatic hypermutation of proto-oncogenes, ultimately leading to aberrant expression of oncogenes and/or inactivation of tumor suppressor genes [7, 8]. Thus, chromosomal translocations involving Ig genes and several partners are a hallmark of many lymphoma subtypes [6]. Additional drivers of lymphomagenesis include chromosomal copy number alterations (gains and deletions) and somatic mutations.

From a host perspective, while there has been a long history of case reports of familial clustering of lymphomas and leukemias, it has only been relatively recently that these malignancies were considered to have an important inherited genetic component outside of very rare hereditary cancer syndromes [9, 10]. Most of our current understanding of the genetic epidemiology of lymphoid neoplasms has been from

studies of familial clustering and use of genome-wide association studies (GWAS), and most of this has been focused on understanding etiology, although there are growing data on host genetics in response to therapy and prognosis as well.

In this chapter, we first review the tumor (somatic) genomics of the major lymphoma subtypes, excluding MM, with a focus on somatic mutations identified through next-generation sequencing (NGS) and related technologies. We next review the strongest data addressing familial predisposition (including twin, case-control, and registry-based studies) to lymphomas broadly defined (i.e., HL, NHL, CLL/SLL, and MM). Finally, we review host (germline) genetics (including family and genetic association studies) for lymphoid neoplasms covering the major lymphoma subtypes (excluding MM). Within each section, we address both etiology (risk) and prognosis (outcome). Finally, we complete the chapter with a discussion of some clinical implications and future directions.

Tumor (Somatic) Genomics

NGS technologies have played an essential role in our understanding of the somatic genomic landscape of hematologic malignancies. Compared to Sanger sequencing, NGS provides numerous advantages, including the higher sensitivity and more comprehensive scope, allowing the detection and quantification of small subclones and characterizing the tumor architecture and evolution in an unprecedented fashion [11]. Many different approaches have been developed for DNA sequencing, from targeted sequencing to whole-exome sequencing (WES) and whole-genome sequencing (WGS). These comprehensive approaches allow the simultaneous detection of single nucleotide variants (SNV), small insertions and deletions (INDELs), as well as copy number alterations (CNAs). Furthermore, modification of WGS, such as mate-pair sequencing, has been successfully used in the detection of structural variants and complex genomic rearrangements. Similar advances have been observed in the study of the transcriptome through RNA sequencing (RNA-Seq), leading to the simultaneous screening of gene expression, alternative gene-spliced transcripts, gene fusions, and mutations/single-nucleotide polymorphisms (SNPs) [11]. Together, these technologies have significantly advanced our understanding of the molecular pathways that drive tumor development, helped to further classify tumor subtypes, and identified both prognostic and therapeutic genetic biomarkers. However, some technologic and analytic challenges remain, including management of large "omics" data sets, variation in the use of computational methods and analysis tools, and the public availability of data for comprehensive analysis [12]. The catalogue of somatic mutations in cancer (COSMIC) is the largest and most comprehensive resource for exploring mutations in human cancers. There are limitations to this resource however, as it only collects data that is described in original work and made publically available [13]. Nevertheless, because it is the broadest database for cancer mutations and expertly curated, we used information from COSMIC to generate a summary of the top 20 genes with mutations in each lymphoma subtype described below (Fig. 38.1). In this section, we further review the major somatic findings recently identified in lymphomas through NGS studies.

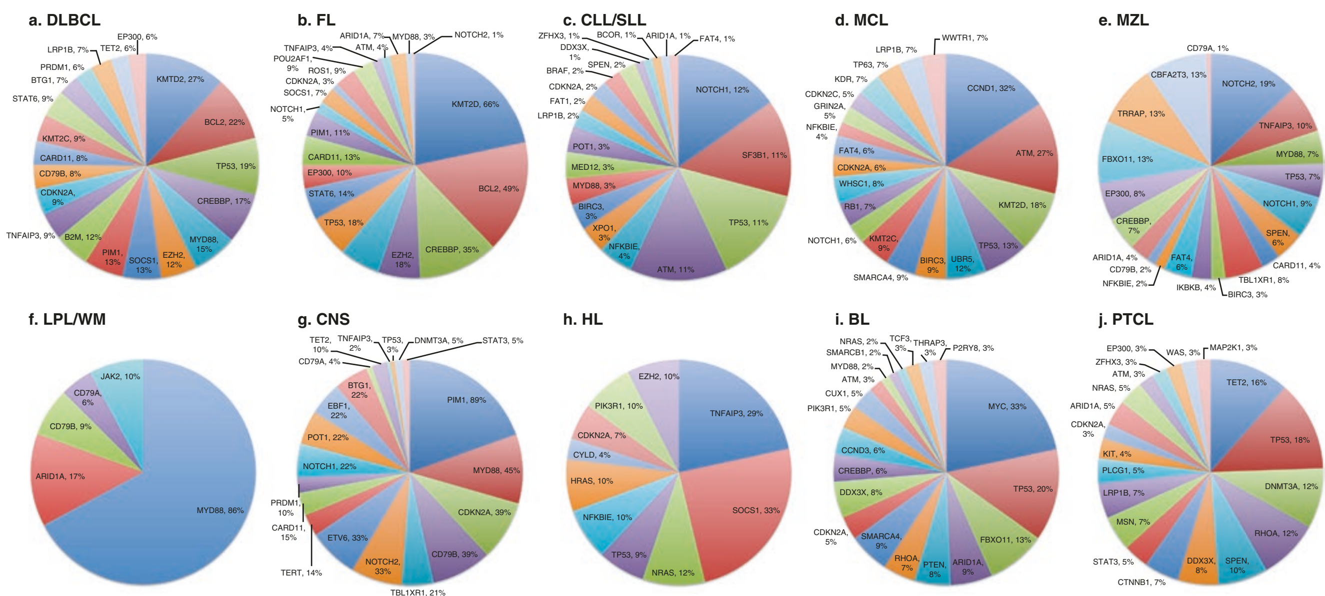

Fig. 38.1 The Mutational Landscape of Individual Hematologic Malignancies. Data on hematopoietic and lymphoid tissue, including lymphoid neoplasms, reported in COSMIC were used to graph the top 20 genes with mutations within each subtype

Diffuse Large B-Cell Lymphoma (DLBCL)

DLBCL is the most common NHL subtype, and is an aggressive lymphoma that can be potentially cured with immunochemotherapy in many patients. Advances in molecular profiling by gene expression profiling (GEP) allowed for the identification of major DLBCL subtypes defined by cell of origin (COO): germinal B-cell (GBC) subtype, an activated B-cell (ABC) type, and unclassifiable subtype [14]. Beyond COO, NGS of DLBCL tumors have revealed a heterogeneous genetic landscape with mutations in genes involved in antigen receptor/NF-κB signaling (*MYD88*, *CD79B*, *CARD11*, *TNFAIP3*, *PRDM1*), epigenetic regulation and chromatin modification, (*KMTD2*, *EZH2*, *CREBBP*, *EP300*, *MEF2B, HIST1H1C*), immune regulation (*B2M*, *CIITA*, *CD58*, CD70, *TNFRSF14*), cell cycle/apoptosis (*TP53, CDKN2A, FOXO1, GNA13, P2RY8, BCL2*, *MYC, BTG1*), and JAK/STAT signaling (*SOCS1, STAT3*) [15–19]. In addition to mutations, frequent CNAs include deletions at 17p (*TP53*), 9p21 (*CDKN2B*), 10q11 (*PTEN*), and 6q21 (*PRDM1, TNFAIP3*) and gains at 18q21 (*BCL2*) and 2p13 (*REL*) [20, 21]. The translocation t(14;18) has been detected in 12–30% of DLBCL patients [22–24].

Although a majority of the mutations identified in DLBCL are found in both COO subtypes, suggesting common mechanisms of pathogenesis, there are additional driver events unique to COO subtypes. ABC-DLBCL is frequently associated with constitutive activity of the NF-κB pathway and mutations in upstream activators such as *MYD88* [25], *CARD11* [26], and *CD79B* [27]. In contrast, GCB-DLBCL is dominated by mutations in *GNA13*, *P2RY8*, *TNFRSF14* and genes involved in epigenetic regulation and chromatin modification (*EZH2*, *CREBBP*, *EP300*, *CREBBP*). *MYC* rearrangements or *MYC* “double hits” (DH, *MYC* and *BCL2/IGH* fusion or a *BCL6* rearrangement) detected by FISH occur in 6–14% of DLBCL and are typically seen in GCB-DLBCL [28–31].

DLBCL heterogeneity is also exemplified by variability in treatment response. While a majority of DLBCL patients are potentially cured after front-line treatment with immunochemotherapy (R-CHOP), lack of remission or early relapse remains an important clinical issue [32]. WES data from 51 newly diagnosed and R-CHOP-treated DLBCL patients were used to explore the association of somatic genomic alterations with the novel endpoint event-free survival at 24 months (EFS24) [33] and a set of genes with mutations, chromosomal gains, and chromosomal losses were identified [34]. Integration of CNAs and mutation data revealed that 77% of patients who fail to achieve EFS24 have a combination of four variants: *FOXO1* mutation and gains in 3q27.3, 11q23.3, and 19q13.32. Because of the small sample size, further validation of these findings is needed.

Additional work has shown the significance of mutations in *TP53* [35, 36], *FOXO1* [37], and *MYD88* [38] with inferior DLBCL outcomes, and mutations in these genes were also more prevalent in cases that failed to achieve EFS24 [34]. Studies have shown that mutations in *TNFAIP3* and *GNA13* are linked to worse prognosis in R-CHOP-treated ABC [39]. Analyses have also been performed to identify genes that may be associated with disease relapse and *TP53*, *FOXO1, KMT2C, CCND3*, *NFKBIZ*, and *STAT6* emerged as top candidate genes implicated in therapeutic resistance [40]. Lastly, MYC-DH cases, which are associated with transcriptional dysregulation of c-myc, have been correlated with poor prognosis in patients treated with chemotherapy alone or with the addition of rituximab [28, 30, 31, 41, 42].

Follicular Lymphoma (FL)

FL is the second most common form of NHL and often follows an indolent disease course with slow progression [43, 44]. However, patients may develop resistant disease and transformation to a more aggressive subtype of lymphoma occurs at a rate of 2–3% per year [45–48]. FL arises from germinal center B-cells and the most common molecular defect is the translocation t(14;18)(q32;q21), which is found in 85–90% of the cases and results in the *IGH-BCL2* leading to the overexpression of the anti-apoptotic oncogene *BCL2* [49, 50]. However, the t(14;18) is also observed in healthy individuals and FL patients who are in long-term remission [44] suggesting the existence of additional genomic alternations that impact disease course.

Recently, WES and WGS of FL tumors and follow-up validation studies have discovered that point mutations in genes involved in epigenetic regulation and chromatin modification, including *MLL2*, *EZH2*, *CREBBP*, *EP300*, and *MEF2B*, dominate the FL genomic landscape [16, 51, 52]. Mutations in *JAK-STAT* pathway genes and B-cell receptor (*BCR*)/*NF-κB* signaling genes have also been identified, but with lower frequencies. WES and WGS studies to date have primarily focused on identification of small site mutations that are recurrent in FL tumorigenesis. However, additional studies have focused on defining genetic events associated with tumor clonal evolution and transformation. Longitudinal analysis of FL tumors identified early driver mutations in chromatin modifying genes (*CREBBP*, *EZH2,* and *MLL2*), whereas mutations in *EBF1* and regulators of NF-κB signaling (*MYD88* and *TNFAIP3*) and *TNFRSF14* were gained at transformation [53, 54]. In addition to mutations, inactivation of *TP53* and deregulated expression of *MYC* is commonly associated with a transformation of FL to DLBCL [55].

More recently, efforts have been put forth to identify genetic predictors of outcome in FL. Targeted deep sequencing

of 74 genes in immunochemotherapy-treated FL identified a panel of 7 genes (*EZH2, ARID1A, MEF2B, EP300, FOXO1, CREBBP,* and *CARD11*), that when combined with the Follicular International Prognostic Index (FLIPI) and ECOG performance status ("m7-FLIPI") showed better prognostic value than the FLIPI alone [56]. Further, the m7-FLIPI also predicted progression of disease within 24 months after therapy in both the German Low Grade Lymphoma Study Group and a British Columbia cohort [57]. While extremely promising, these models were based on a candidate gene approach, using known "drivers," which can miss other predictors that can be identified only by a comprehensive and agnostic approach. These models also do not evaluate other tumor genomic alterations, most prominently CNAs.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma (CLL/SLL)

CLL and SLL are indolent B-cell malignancies, with CLL presenting in the bone marrow or peripheral blood and SLL presenting in the peripheral lymphatic tissue. Two seminal WGS/WES studies [58, 59] of large cohorts ($N = 452$ and 538, respectively) of CLL patients have been recently conducted that provide over 90% power to detect recurring driver genes with >3% mutation frequency. Together, these studies and prior sequencing studies [60–66] have identified or confirmed 58 recurring somatic driver or copy number alterations with 91% of CLL patients having at least one driver alteration. The most commonly mutated genes (>5% CLL cases) included *NOTCH1, ATM, SF3B1,* and *TP53*, whereas the most common copy number alterations included the well-known structural variants del(13q), del(11q), del(17p), and tri(12). Combining these drivers, the main pathways that are frequently altered include B-cell receptor signaling, cell cycle regulation, apoptosis, DNA damage response, NF-κB signaling, NOTCH1 signaling, RNA metabolism, and chromatin remodeling. When correlating these drivers with clinical characteristics, higher mutation load was seen in CLL cases who have unmutated status in the immunoglobulin heavy-chain variable region (*IGHV*), a strong CLL prognostic marker, supporting the clinical aggressiveness of *IGHV* unmutated CLL. A number of these somatic mutations have been found to be associated with OS or time to first treatment independent of stage and IGHV mutational status [58, 59]. However, other than *TP53* mutational status or del(17p), none of the common drivers show independent prognostic information beyond a model that included clinical stage, age, *IGHV* mutational status, and serum β_2-microglobulin [67]. Studies are needed to determine whether any of these drivers are associated with response to therapy.

Mantle Cell Lymphoma (MCL)

MCL is a B-cell lymphoma that arises from naïve pre-germinal center cells originating from the mantle region of secondary lymphoid follicles. Two main morphologic subtypes have been identified, classical and blastoid, with poor prognosis observed in the blastoid variant. The cytogenetic hallmark of MCL is the translocation t(11;14)(q13;q32), which juxtaposes *CCND1* to the *IGH* locus resulting in overexpression of cyclin D1, a cell cycle regulator not normally expressed in B-cells [68, 69]. A rare subset of MCLs lacks a *CCND1* rearrangement and does not express cyclin D1. However, these cases have similar clinical behavior, biological features, gene expression profiles, and genomic complexity as that of cyclin D1-positive MCL [70, 71]. The cyclin D1-related genes *INK4A*, *CDK4*, and *RB1* are also genetically altered in MCL [72, 73] and contribute to dysregulation of the cell cycle. In addition to the role of *CCND1*, mutations or deletions in genes that regulate the DNA-damage response, including *ATM, TP53,* and *RB1*, are commonly found in MCL tumors [74–76]. Genetic alterations that impact the NF-κB pathway have also been identified and include deletion of *TNFAIP3*. Recent NGS studies have led to the discovery of additional oncogenic mechanisms. Mutations in *NOTCH1* [77], *UBR5* [78], as well as genes involved in chromatin modification (*KMTD2, KMTD3, MEF2B, WHSC1, SMARC4),* cell cycle/apoptosis *(POT1, SMC1A, BIRC3),* and NF-κB activation *(CARD1, TRAF21)* [77–81], have been identified. *SOX11*, which is expressed in virtually all aggressive MCL, has recently been recognized as a diagnostic and prognostic antigen in MCL and may play a central role in regulation of cell growth [82].

In addition to mutations, numerous structural and numerical chromosomal alterations are recurrent in MCL [83]. Most cases of the blastoid variant also have complex karyotypes with three or more chromosomal abnormalities in addition to t(11;14) [69, 84]. A high number of recurrent CNAs have been described in MCL, including gains at 3q, 8q, 15q, and 18q and loss at 1p, 6q, 8p, 9p, 9q 11q, 13q, and 17p [85, 86]. These regions encode for *ATM*, *TP53*, *MYC*, *BCL2*, and *CDKN2,* all of which are important for MCL pathogenesis. Gene expression profiling in MCL has revealed a proliferation gene signature that is associated with poor prognosis [87] and correlates with copy number loss at losses of 1p, 1q, 9p, and gain of 7p [85].

Marginal Zone B-Cell Lymphoma (MZL)

MZL comprises a heterogeneous group of indolent B-cell lymphomas with overlapping morphological and clinical characteristics, and can be divided into three subtypes: extranodal marginal zone lymphoma of MALT type

(MALT lymphoma), splenic marginal zone lymphoma (SMZL), and nodal marginal zone lymphoma (NMZL).

MALT lymphomas are associated with chronic microbial infection and/or autoimmune disorders and are originated at diverse mucosal sites, including the stomach, lung, ocular adnexa, and thyroid [88]. MALT lymphomas are mainly driven by chromosomal translocations leading to the constitutive activation of the NF-κB signaling pathways, a common pathogenesis pathway in MALT lymphomas [88–103]. The t(11;18)(q21;q21) causes fusion of the genes *BIRC3* (API2) and *MALT1*, resulting in the expression of an API2–MALT1 fusion protein, while the t(1;14)(p22;q32) and t(14;18)(q32;q21) result in the overexpression of *BCL10* and *MALT1*, respectively, as a result of juxtaposition with the *IGH* enhancer. The translocations are limited to MALT lymphomas, and are not seen in other MZL. Furthermore, *TNFAIP3* is recurrently inactivated by deletion and/or mutation in MALT lymphomas [96, 97, 104]. *TNFAIP3* alterations occurred mostly in ocular adnexa, salivary gland, and thyroid, but rarely in the lung, stomach, and skin [96, 104–106]. Additional genes associated with the NF-κB signaling pathway, including *CARD11, CD79B,* and *MYD88,* are mutated in a small subset of MALT lymphomas [25, 105, 107]. Additional driver genes corresponding to other cancer-relevant pathways, such as *TP53*, *KMT2D, NOTCH1,* and *NOTCH2,* are found mutated in 5–25% of cases [108, 109].

SMZL is an indolent malignancy of splenic B-lymphocytes characterized by splenomegaly, peripheral leukocytosis, and cytopenias. Mutations in *NOTCH2*, a gene required for marginal-zone B-cell development, represent the most frequent abnormality in SMZL, accounting for 20–25% of cases [110–113]. Most mutations are nonsense or frameshift indels in the C-terminal PEST domain. *NOTCH2* mutations are associated with adverse clinical outcome in SMZL [111]. *NOTCH2* mutations are rare or absent in the remaining late B-cell malignancies, reinforcing its specificity to SMZL pathogenesis. Furthermore, other members of the NOTCH pathway (*NOTCH1, SPEN,* and *DTX1*) are mutated in 5–10% of SMZL [113].

The Krüppel-like factor 2 gene (*KLF2*) is mutated in 20–40% of SMZL [110, 114], but rarely in related malignancies. KLF2 encodes a transcription factor essential for the homeostasis and differentiation of peripheral B-cell subsets [115, 116]. Most mutations are nonsense or frameshift indels, leading to inactivation of the capability of KLF2 to suppress NF-κB activation through TLR, BCR, BAFFR, and TNFR signaling [110]. The NF-κB signaling pathway is also affected by mutations in *IKBKB, TNFAIP3, BIRC3,* and *TRAF3,* which affect approximately a third of SMZL cases [113]. Collectively, mutations of genes regulating MZL development and NF-κB activation are found in 60–70% of SMZLs [111, 113]. Furthermore, genes regulating chromatin remodeling and transcriptional regulation are mutated in ~35% of SMZL [113]. The MLL2 histone methyltransferase (*KMT2D*) is mutated in 15%, *ARID1A*, member of the SWI-SNF chromatin remodeling family, in 10%, and the acetyltransferases *EP300* and *CREBBP*, in ~5% each [113]. SMZL is mainly characterized by the presence of recurrent deletions on 7q32-q35 [96, 104, 117–119]. Whole or partial gains of chromosomes 3 and 12 and losses of 17p have also been recurrently identified [119, 120].

NMZL is a rare and indolent malignancy that is distinguished from SMZL by the different pattern of dissemination. The knowledge surrounding the NMZL genomic landscape is very limited. The only comprehensive study performed in NMZL shows a large overlapping with SMZL, excepting the high prevalence of *PTPRD* mutations, otherwise absent in SMZL [121]. Mutations in *PTPRD*, a protein tyrosine phosphatase that regulates cell growth, cause loss of phosphatase activity, and are associated with increased proliferation index in NMZL. Furthermore, aberrant methylation of PTPRD-promoter CpG sites was found in cases with monoallelic mutation or deletion [121], suggesting epigenetic downregulation of the remaining allele. Studies in NMZL have identified the presence of whole or partial gains on chromosomes 3, 6p, 12, and 18 [95, 96], but no unique abnormalities have been identified in this subtype.

Lymphoplasmacytic Lymphoma/Waldenström Macroglobulinemia (LPL/WM)

LPL/WM is a rare neoplasm of small B lymphocytes, plasmacytoid lymphocytes, and plasma cells that commonly have an IgM paraproteinemia. One of the most representative paradigms of a cancer with a common somatic mutation shared by most patients is LPL/WM. *MYD88* shows the p.L265P mutation in nearly all LPL/WM patients [107]. Several studies using a variety of approaches confirmed the presence of *MYD88* p.L265P in 70–100% WM [122–129]. The same mutation is found in IgM monoclonal gammopathy of undetermined significance (IgM-MGUS), but only in ~50% of cases [125, 126]. Such difference in mutation prevalence could either support that p.L265P is a universal event required for the progression from IgM-MGUS to LPL/WM or the existence of different biologic subtypes of IgM-MGUS, with the p.L265P only found in cases evolving to WM [126, 130].

Allele specific PCR (AS-PCR) showed to be a useful tool for *MYD88* p.L265P screening in WM. Matched paired peripheral blood and bone marrow CD19+ populations showed comparable detection values of p.L265P by AS-PCR (89% in bone marrow versus 85% in peripheral blood) [131]. The results obtained from AS-PCR are promising, providing a less invasive method, eliminating the need for a bone marrow biopsy for molecular tests. Additionally, the mutation

screening has been indicated as a biomarker for measuring tumor burden and response assessment. Therefore, the identification p.L265P after therapy shows sensitivity comparable to flow cytometry [124].

Nonsense and frameshift mutations affecting C-X-C chemokine receptor type 4 (*CXCR4*) are found in nearly 30% of WM [129, 132, 133]. The mutations target the same hotspot previously described in warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM). *CXCR4* mutations were associated with tumor growth and propagation to extramedullary organs [132]. An anti-CXCR4 antibody leads to tumor reduction in a C1013G/CXCR4 WM model, demonstrating its potential use as a therapeutic target [132]. Other recurrently mutated genes in WM included *ARID1A* (17%), *CD79B* (7–9%), *TP53* (7%), and *CD79A* (5%) [129, 134]. Further studies are needed to clarify the effect (if any) of such mutations in WM pathogenesis.

Regarding the importance of *MYD88* and *CXCR4* mutations in patient outcome, a recent study showed that LPL/WM patients with p.L265P presented at earlier age [133]. Furthermore, patients with mutation were associated with higher bone marrow involvement, higher serum IgM, and lower IgA and IgG levels [127]. Additionally, IgM-MGUS with p.L265P showed a higher risk of progression to WM [126]. Patients with mutations in both, *MYD88* and *CXCR4,* showed the highest BM involvement and serum IgM levels, compared with intermediate levels in cases with mutated *MYD88* and wild-type *CXCR4,* and low levels in patients without mutations in any of those genes [133]. Moreover, patients with both mutations presented more commonly with symptomatic disease requiring therapy at diagnosis [133]. On the other hand, *CXCR4* mutations were not associated with worse overall survival (OS).

MYD88 is a promising therapeutic target. In vitro studies show that *MYD88* p.L265P leads to the NF-κB signaling pathway activation through two independent pathways involving Bruton's tyrosine kinase (BTK) and IRAK1 and IRAK4 [135]. BTK is targeted by Ibrutinib, an FDA approved drug widely used in the treatment of CLL. In a recent clinical trial performed in WM patients who had received at least one previous therapy, the use of Ibrutinib was associated with a decreased IgM level and bone marrow involvement and an increased hemoglobin level [136]. The best response rates are found in patients with mutant *MYD88* and wild-type *CXCR4* (100% overall response rate and 91% major response rate), followed by double mutants (86% and 62%, respectively) and finally by patients without mutations in both genes (71% and 29%) [136]. Overall, *MYD88* p.L265P has the potential to become a powerful biomarker for diagnosis, prognosis, response assessment, and treatment in WM.

Regarding CNAs, LPL/WM has a very low-complexity karyotype, with a median of 3 chromosomal abnormalities per case [134, 137, 138]. Deletion of 6q is the most common chromosomal abnormality, reported in 30–50% of cases [134, 137–141]. Deletion of 6q has been associated with low albumin, high B2M [140, 142], anemia [142], and low IgM production [143, 144]. No association has been found between the deletion and response rate, progression-free survival (PFS) or OS. Trisomy 4, found in nearly 20% of LPL/WM, is a distinctive feature of LPL/WM compared with the remaining low-grade B-cell lymphomas [137, 138, 140, 145]. Additional recurrent abnormalities found between 5–20% of LPL/WM include gains of chromosomes 3, 6p, 12, and 18 and deletions of 7q, 11q23 (*ATM*), 13q14 (*MIRN15a-16*), 17p13 (*TP53*), and Xq26 [95, 104, 137, 138, 140, 141, 146, 147]. Translocations involving IgH locus are rare in LPL/WM, found in less than 3% of cases [140, 141, 143, 145].

Primary Central Nervous System Lymphomas (PCNSL)

PCNSLs are extranodal NHLs confined to the central nervous system, and the majority of cases (90%) are observed in immunocompetent individuals. PCNSLs show a considerable genetic heterogeneity, affecting multiple genes and pathways. Genomic data integration highlights that practically all patients show genetic lesions affecting a variety of signaling pathways that share their ability to induce the NF-κB transcription complex, including the B-cell receptor (BCR), CD40, and Toll-like receptor (TLR) pathways. The most commonly mutated gene is *MYD88*, found altered in up to 90% of cases [148–153]. The mutational hotspots are similar to nodal ABC-DLBCL, although the mutation prevalence is nearly three times more frequent in PCNSLs [16, 25, 52]. Several other genes of the BCR/TLR/NF-κB pathways are recurrently mutated, especially *CD79B*, which is found mutated in approximately 40–60% of PCNSL [148–152]. The high prevalence of concurrent *CD79B* and *MYD88* mutations is an additional distinguishing feature of PCNSLs compared with ABC-DLBCLs [148, 149]. Other recurrently mutated genes in the NF-κB signaling pathway are *CARD11, TNFAIP3,* and *TBL1XR1*, found in 20–30% of cases each [148–152].

Immune surveillance is another pathway recurrently affected in PCNSL. Therefore, Human Leukocyte Antigen (HLA) genes are found deleted in 50–80% of cases [149, 153, 154], *B2M* and *CD58* are mutated and/or deleted in 20–30% [148, 149, 154], and *CIITA* has been involved in chromosomal translocations [148]. More recently, copy gain and translocations involving *PD-L1* and *PD-L2* have been reported [148].

PRDM1, a crucial gene in lymphocyte differentiation is impaired in nearly 30% of PCNSL. Even though only small cohorts have been analyzed so far, independent survival

analyses suggested that loss of *PRDM1* is a poor prognosis marker in PCNSL [149, 153]. Another key gene in lymphocyte differentiation recurrently mutated is *IRF4*, which has been mutated in 10–20% of cases [148, 149, 152]. Several other genes associated with relevant pathways are also shared by nodal DLBCL, such as *GNA13, TMEM30A, BTG1,* and *BTG2*, between others. Furthermore, SHM also targets genes at high frequency in PCNSL, such as *PIM1* and *MYC* [149, 150, 152, 155]. Several recurrent chromosomal abnormalities have been identified in PCNSL, including translocations of *IgH-BCL6* [156], deletions of 6p21, 6q, 8q12, and 9p21, and gains of 7q, 11q, and chromosome 12 [149, 154, 157–159].

Despite all these similarities with ABC-DLBCL, there is a subset of PCSNL-specific alterations, thus reinforcing the idea that PCNSLs are a pathogenically distinct group. In contrast to nodal DLBCL, PCNSLs rarely have *TP53* mutations, although p53 is indirectly impacted via loss of *CDKN2A*, which has been described as mutated and/or biallelically deleted in more than half of PCNSL cases [148, 149, 153, 154]. Other features unique to PCNSL include recurrent abnormalities in *PRKCD* and *TOX* [149, 152–154]. *PRKCD*, a proapoptotic protein kinase, is associated with a wide variety of cellular processes, including growth, differentiation, secretion, apoptosis, and tumor development [160–163]. Moreover, several studies have suggested that loss of *PRKCD* is associated with defective B-cell apoptosis, B-cell hyperproliferation, and autoimmune disorders [164–167]. Another interesting finding is the identification of recurrent alterations affecting *TOX* [149, 153, 154], a gene that plays a key role in T-cell development [168, 169]. The absence of *TOX* prevents CD4 lineage T-cell development, including natural killer T (NKT) and T regulatory (Treg) CD4 T-cell sublineages, but has only modest effects on CD8 T-cell development [170]. Furthermore, TOX-deficient mice (TKO) lacked lymph nodes and had a significant decrease in the frequency and size of Peyer's patches [171]. A recent study provides data that support an important role of *TOX* expression in B-cell biology [172].

Hodgkin Lymphoma (HL)

Classical HL (cHL), which compromises approximately 95% of all HL [3], involves various inflammatory cells with only about 1% of the cellular infiltrate being the neoplastic Hodgkin and Reed-Sternberg (HRS) tumor cells [173]. The low prevalence of HRS cells brought into question the cellular origin of this disease, however, molecular cloning techniques allowed for the discovery of its B-cell origin [174, 175]. HRS cells show dysregulation of numerous signaling pathways, which is partly mediated by cellular interactions in the lymphoma microenvironment and partly by genetic alterations. Epstein–Barr virus (EBV) has also been shown to play a pathogenic role in HL, although not all HRS cells are EBV positive [176].

Genetic analysis on cHL has been hampered by the low content of the HRS cell within the tumor microenvironment. However, cytogenetic analyses have identified recurrent chromosomal breakpoints on chromosome arms 1p, 6q, 7q, 11q, and 14q, recurrent gains of chromosomes 2, 5, 9, and 12 and losses on chromosomes 13, 21, and Y [177–183]. Using array-based comparative genomic hybridization (aCGH), HRS cell have recurrent gains on 2p12-16, 5q15-23, 6p22, 8q13, 8q24, 9p21-24, 9q34, 12q13-14, 17q12, 19p13, 19q13, and 20q11 whereas losses involved Xp21, 6q23-24, and 13q22 [184].

Constitutive activation of the NF-κB signaling pathway is central to proliferation and survival of HRS cells [185]. This finding is supported by genetic studies identifying mutations in the NF-κB negative regulators *NFKBIA* and *NFKBIE* in 10–20% of cases [186, 187]. Genomic gains of *REL* and *BCL11A* are present in about 30% of HL [188, 189] and chromosomal loss or inactivating mutations in *TNFAIP3* are also commonly found [190, 191]. Genetic alterations in other regulators of NF-κB, including *TRAF3*, *BCL3*, and *CYLD,* are also present in HRS, but with less frequency [180, 192, 193].

More recent data point to an important role for immune evasion in the survival of HRS cells. The genes encoding the PD-1 ligands, *PDL1* and *PDL2* (also called *CD274* and *PDCD1LG2,* respectively), are targets of chromosome 9p24.1 amplification, a recurrent genetic abnormality in HRS cells [194]. The 9p24.1 amplicon also includes *JAK2.* Chromosomal amplification leads to overexpression of the PD-1 ligands on HRS cells and supporting data suggests that EVB infection also increases the expression of PD-1 ligands in EBV-positive HL [195]. These studies have led to the use of PD-1 blockade (Nivolumab) as a highly effective therapy in relapsed or refractory HL [196].

Burkitt Lymphoma (BL)

BL is derived from germinal center B-cells [197] and is classified into three distinct entities based on clinical presentation, morphology, and biology. Endemic BL (eBL) represents the most common childhood malignancy in equatorial Africa and is associated with EBV, nearly all tumor cells carry the viral genome. Sporadic BL (sBL), which is histologically indistinguishable from eBL, is seen throughout the world with only 10–20% of tumors being EBV positive. A third BL variant, immunodeficiency related-BL, was identified in patients with HIV/AIDS [3, 198].

A hallmark feature of BL is the presence of the translocation t(8;14) [199], juxtaposing *IGH* and *MYC* [200, 201].

MYC translocation partners also include *IGK* at 2p11 and *IGL* at 22q11 [202]. The identification of *MYC* deregulation in BL and the characterization of *MYC* transgenic mice clearly demonstrated a central role for MYC overexpression in lymphoma pathogenesis [203]. However, the delay in lymphoma development in the *MYC* transgenic mouse model suggests that *MYC* alone is not sufficient for malignant transformation. Inactivating mutations in *TP53* are common in BL and occur in 35% of cases [204, 205]. Next-generation sequencing of BL has revealed novel oncogenic mechanisms and identified mutations in *CCND3*, *CDKN2A*, *IDH3,* and *TCF3* [206–208].

Peripheral T-Cell Lymphomas (PTCL)

PTCL are composed by a heterogeneous group of generally aggressive NHL originated from post-thymic lymphocytes. Adult T-cell leukemia/lymphoma (ATL) is a PTCL associated with human T-cell leukemia virus type-1 infection. Almost all ATL are characterized by genetic abnormalities affecting the TCR signaling, the NF-κB signaling or downstream pathways [209]. *PLCG1*, which encodes the phospholipase PLCγ1, a key regulator of proximal TCR signaling, is mutated in 35% of ATLs [209]. Other recurrent mutations affecting the TCR pathway include *VAV1* (18%) and *FYN* (4%). *VAV1* encodes a guanine nucleotide exchange factor that is phosphorylated by the Src family kinases (including FYN) and interacts with PLCγ1 [209]. *PRKCB*, which encodes PKCβ, a signaling molecule downstream of PLCγ, is mutated in 33% of the cases. Downstream of PKC is located *CARD11*, which is mutated in 25% of ATL. Mutations in *CARD11* and *PRKCB* are significantly correlated, suggesting a synergistic effect between them [209]. Additional genes of the TCR–NF-κB signaling, including *CBLB, TRAF3, TNFAIP3, ERC1, IKBKB, RELA, NFKBIA,* and *PTPRC,* are also recurrently affected in ATL [209].

Another pathway connected with TCR signaling and recurrently affected in ATL is the B7-CD28 co-stimulatory signaling. Recurrent chimeric fusions affecting CD28 (CTLA4-CD28 and ICOS-CD28) were found by mRNAseq analyses [209]. B7-CD28 signaling molecules, including CD28, CTLA4, and ICOS co-receptors, are involved in TCR signaling regulation [210, 211].

Similar to B-cell malignancies [17, 148, 149, 154, 212], half of ATLs have genetic abnormalities affecting immune checkpoint genes, including *HLA* genes, *B2M, CD58, CD274, PDCD1,* and *FAS* [209]. Furthermore, genes involved in epigenetic regulation (*TET2, DNMT3A, IDH2, EP300, SETD2,* and *KDM6A*) are also recurrently affected in ATL. Another class of genes commonly affected in ATL is G protein-coupled receptors (GPCRs) involved in T-cell trafficking, including *CCR4*, *CCR7,* and *GPR183*, found mutated in 10–30% of ATL [209]. Additional altered pathways are the JAK-STAT (*JAK3, STAT3,* and *PTPN1*), NOTCH (*NOTCH1, ATXN1,* and *ZFP36L2*), PI3K-AKT (*PI3KCD* and *INPP4B*), and casein kinase 2 (*CSNK2A1* and *CSNK2B*) signaling pathway [209].

Many recurrent CNAs have been described in ATL, including gains of 2q33 (*CD28*), 6p25 (*IRF4*), 7q22 (*CARD11*), 10p15 (*PRKCQ*), 14q32 (*BCL11B*), and 19p13 (*SMARCA4*) and losses of 1p13 (*CD58*), 2q34 (*IKZF2*), 6p22 (*ATXN1*), 6q (*TNFAIP3*), 9p21 (*CDKN2A*), 10p14 (*GATA3*), and 12q12 (*ARID2*) [209].

Systemic anaplastic large cell lymphoma (ALCL) is an aggressive CD30$^+$ NHL. Approximately 60% of ALCLs show expression of protein ALK (ALK+). The genetics landscape associated with ALK+ ALCL is driven by translocations of the ALK proto-oncogene leading to ALK fusion proteins [213]. The most common translocation is the t(2;5) *NPM-ALK* found in 80% of cases [213]. The ALK chimeras activate STAT3, which is required for the maintenance of the neoplastic phenotype in ALK+ ALCL [214].

Interestingly, the initial genomics analysis on ALK-negative (ALK−) ALCL cases also identified recurrent genetic abnormalities leading to the activation of the JAK/STAT3 pathway, suggesting that the STAT3 activation is a unifying event in ALCL, regarding the ALK status. Therefore, activating mutations in the JAK-STAT pathway genes (*STAT3* and *JAK1*) are found in nearly 40% of the systemic ALK− ALCL cases [215]. Furthermore, mRNAseq screening of ALK− ALCL identified recurrent fusion transcripts of tyrosine kinases with different partners, including *NFKB2-ROAS1* and *NFKB2-TYK2* [215]. Additional studies identified the t(6;7) *DUSP22-IRF4* [216] and translocations involving *TP63* [217], in 30% and 8% of ALK− ALCL, respectively, but absent in ALK+ ALCL. Overall, ALK+ ALCL affects younger patients and has a more favorable clinical course than ALK-negative (ALK−) ALCL [218].

Angioimmunoblastic T-cell lymphoma (AITL) is a common subtype of PTCL with a poor prognosis. DNA sequencing analysis indicates a key role of epigenetic regulation in the pathogenesis of AITL, with almost 70% of cases showing mutations in *TET2, DNMT3A, RHOA,* and *IDH2* [219]. *IDH2* mutations are specific to AITL, whereas mutations of the other 3 genes are broadly distributed across other types of PTCL [220]. Furthermore, *FYN* (SRC family kinase), *ATM* (DNA damage response), *B2M, CD58* (immune surveillance), and *CD28* (TCR signaling regulation) are recurrently mutated in AITL [220, 221].

Sézary syndrome and Mycosis fungoides are cutaneous T-cell malignancies derived from CD4+ skin-homing T-cells [222]. Sézary syndrome shows mutations in genes involved in epigenetic regulation (*TET2*, *CREBBP*, *KMT2D*, *KMT2C*, *BRD9*, *SMARCA4,* and *CHD3*), NF-κB (*TNFR2, CARD11,* and *PRKG1*), and MAPK (*MAPK1* and *BRAF*) [223, 224].

Sezary is characterized by recurrent gains of chromosome 7, 8q, and 17q and losses of 2p23 (*DNMT3A*), 10q23 (*PTEN*), 12p13 (*CDKN1B*), 13q14 (*RB1*), and 17p13 (*TP53*) [223]. Analysis of mycosis fungoides identified somatic mutations in *SMARCA4, KMT2D,* and *KMT2C* [223].

Summary

Significant advances have been made in our understanding of the somatic genomic landscape of hematologic malignancies and this contributes to our understanding of disease biology, identifies unique subsets of tumors, provides insight on patient outcome, and identifies new therapeutic targets. Additionally, it allows us to comprehensively examine mutations across hematologic malignancies and identify common genes and pathways that are dysregulated. In Fig. 38.2, using data from COSMIC we show the top 20 genes most recurrently mutated across diseases. These data reveal that genes involved in NF-κB regulation (*MYD88*, *CD79B*, *TNFAIP3*, *CARD11*), DNA repair (*TP53*, *ATM*), control of the cell cycle (*CDKN2A*, *CCND1*, *PIM1*), histone modification (*KMT2D*, *EZH2*, *CREBBP*, *TET2*), gene transcription (*ETV6*, *ARID1A*), and the NOTCH pathway (*NOTCH1*, *NOTCH2*) are key drivers of hematologic malignancies.

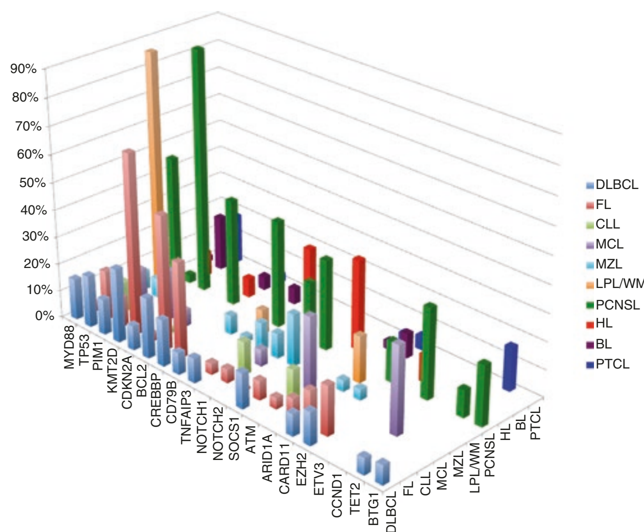

Fig. 38.2 Genes Mutated Across Hematologic Malignancies. Comparison of the most recurrently mutated genes across entities. These data highlight genes in NF-κB and NOTCH pathways, DNA repair, control of the cell cycle, histone modification and gene transcription

Familial Predisposition and Host Genetics

Environmental factors and somatic events are thought to be the predominant contributors to the development of lymphomas, and in uniformly treated patients, clinical characteristics along with the biology of the tumor clone (particularly genomic alterations) as well as the microenvironment are thought to be the predominant contributors to treatment response, lymphoma progression, and OS [225, 226]. However, there has been a growing interest in the role of inherited genetic susceptibility to lymphoma risk and prognosis. A variety of study designs have been used to identify inherited predisposition to lymphoma risk and prognosis, and new genotyping and sequencing technologies have allowed the identification of chromosomal locations underlying these associations.

Familial Predisposition

Etiology

Twin and Registry-Based Studies

In the largest published population-based study of over 200,000 twins from Denmark, Finland, Norway, and Sweden [227], familial cancer risk for non-acute leukemia (mainly CLL) was high in monozygotic (15.2%, 95% CI 6.1–33.2) versus dizygotic (4.1%, 95% CI 1.3–11.9) twins and heritability was estimated at 57% (95% CI 0–100%) with 0% estimated for shared environment. There were too few concordant twins with HL, NHL, or MM to estimate familial risk or heritability. In a twin study of lymphomas [228], there was a 100-fold higher risk of HL in monozygotic twins of patients with HL compared background rates (SIR = 99; 95% CI 48–182), while there was no excess risk in dizygotic twins; in contrast, there was a 23-fold higher risk of NHL in monozygotic twins of patients with NHL and a 14-fold higher risk in dizygotic twins, suggesting a stronger role for shared environment for NHL.

Based on data from the Utah Population Database and the Utah Cancer Registry [229], the risk of NHL was increased 1.7-fold in first-degree relatives of a proband with NHL (familial RR = 1.68, 95% CI 1.04–2.48); the risk of lymphocytic leukemia was >5-fold in first-degree relatives of a proband with lymphocytic leukemia (familial RR = 5.69, 95% CI 2.58–10.0); and the risk of MM was 4.3-fold higher in relatives of a proband with MM (familial RR = 4.34, 95% CI 1.97–7.63). In contrast, the risk of HL was only elevated 1.3-fold in first-degree relatives of a HL proband (familial RR = 1.27, 95% CI 0.12–3.65), although power for this estimate was low (only 2 exposed cases). Using updated data and a complementary analytic approach that estimates the Genealogical Index of Familiality [230], excess relatedness

was observed for NHL, CLL, and MM, but was only borderline significant for HL. CLL had the highest index of all cancer sites tested. For NHL, CLL, and MM, the excess relatedness was also observed for distant relatedness (i.e., for distant relatives), which may be interpreted as providing evidence that familial clustering is more likely due to shared genetic versus shared environmental contribution, as the latter would be lower in distant relationships.

The most comprehensive data available on familial aggregation by lymphoma subtypes has been published using registry data from Scandinavia (summarized across studies in Table 38.1). This approach compares the cancer experience in first-degree relatives of lymphoma patients with the cancer experience in relatives of matched population controls. First-degree relatives of cases with NHL were at higher risk of developing NHL (RR = 1.7) and HL (RR = 1.4), while this was slightly weaker for CLL (RR = 1.3) and not associated with MM (RR = 1.1) [231]. First-degree relatives of cases with CLL were at particularly high risk of CLL (RR = 8.5), as well as risk of NHL (RR = 1.9) and HL (RR = 1.5), but were not at increased risk of MM (RR = 1.2) [232]; first-degree relatives of cases with HL were at higher risk of developing HL (RR = 3.1) and CLL (RR = 2.1), while this was much weaker for NHL (RR = 1.3) and was not associated with MM (RR = 1.0) [233]. Consistent with these results, first-degree relatives of cases with MM were only at elevated risk of MM (RR = 2.1), with no excess risk of NHL, CLL, or HL [234].

The most recent analysis from five Nordic countries of 169,830 first-degree relatives of 45,406 NHL patients who were diagnosed from 1955 to 2010 reported that the lifetime cumulative risk of NHL was 1.6% in siblings (representing an SIR of 1.6, 95% CI 1.2–1.9) and 1.4% in parent–offspring pairs (representing an SIR of 1.4, 95% CI 1.3–1.5), and that familial risk did not significantly change by age at diagnosis of NHL in relatives [235]. In a similar analysis of 57,475 first-degree relatives of 13,922 HL patients, the lifetime cumulative risk of HL was 0.9% (representing an SIR of 6.0, 95% CI 4.8–7.4) and 0.4% in parent–offspring pairs (representing an SIR of 2.1, 95% CI 1.6–2.6), and familial risk was higher for sisters (versus brothers or unlike-sex siblings) and for younger age at diagnosis of HL in relatives [236].

Familial aggregation by specific lymphoma subtypes has been more difficult to estimate due to changes in classification over time and the need for very large studies. As shown in Table 38.1, a family history of a given NHL subtype was associated with an increased risk of concordant as well as some discordant subtypes. Concordant associations were strongest for LPL/WM (RR = 25), MCL (RR = 9.0), CLL (RR = 8.5), and FL (RR = 2.1), but discordant associations of similar or only slightly weaker effect size were also commonly observed [235]. In contrast, DLBCL risk was stronger for a first-degree relative with LPL/WM (RR = 3.5) or FL (RR = 2.6) than for DLBCL (RR = 1.9). There are very limited data on PTCL, and registry-based studies suggested no increased risk among first-degree relatives with HL, CLL, DLBCL, or FL [237]. Similar to NHL subtypes, familial risks were elevated for both concordant and discordant HL subtypes, and some of the strongest associations were for concordant subtypes, including lymphocyte-rich (SIR = 81, 95% CI 30–177), lymphocyte-depleted (SIR = 40, 95% CI 1–225), mixed cellularity (SIR = 5.0, 95% CI 0.6–18), and nodular sclerosis (SIR = 4.6, 95% CI 2.9–7.0) [236]. While familial risk is determined by both shared genetics and environment, there was no increase in risk of concordant NHL, leukemia, HL, or MM among spouses [238], suggesting that familial risk is less likely to be associated with the environment shared during adulthood.

Case-Control and Cohort Studies

In a pooled analysis of 17,471 NHL cases and 23,096 controls from 20 case-control studies in the International Lymphoma Epidemiology (InterLymph) Consortium [239], risk of NHL (which included CLL) was associated with a family history of NHL (OR = 1.8), CLL (OR = 1.5), HL (OR = 1.7), and MM (OR = 1.8) (Table 38.1). The InterLymph analysis also reported risks for the common subtypes of CLL, DLBCL, FL, MCL, MZL, LPL/WM, and PTCL. A family history of NHL was associated with each subtype except LPL/WM, while a family history of leukemia was associated with each subtype except DLBCL and FL, with the strongest association for risk of CLL (OR = 2.4). A family history of HL was only associated with increased risk of DLBCL (OR = 2.1) and MZL (OR = 2.7) while a family history of MM was associated with FL (OR = 1.9), MCL (OR = 3.1), and PTCL (OR = 2.9).

Next, in an analysis of all subtypes simultaneously, there was no statistically significant heterogeneity across risk of most common NHL subtypes for either a family history of NHL ($P_{\text{Homogeneity}} = 0.52$) or HL ($P_{\text{Homogeneity}} = 0.47$) [239]. In contrast, there was strong evidence for heterogeneity for a family history of leukemia ($P_{\text{Homogeneity}} = 3.9 \times 10^{-5}$), with family history of leukemia most strongly associated with risk of CLL, LPL/WM, MCL, and PTCL. Also, there was modest evidence for heterogeneity for a family history of MM ($P_{\text{Homogeneity}} = 0.022$), with a family history of MM most strongly associated with MF/SS. Of note, the associations for family history of NHL with risk of NHL [239] or specific NHL subtypes (e.g., DLBCL [240], FL [241], CLL [242], MCL [243], MZL [244], LPL/WM [245], and PTCL [246]) remained unchanged after adjusting for extensive subtype-specific risk factors, suggesting that the association of family history may be predominately driven by shared genetics over shared environment.

While InterLymph did not have pooled results for risk of HL or MM, a large case-control study conducted in

[a]Odds ratios (for case-control design) or relative risk (for registry design) and 95% confidence intervals
[b]CLL for registry studies; leukemia for case-control
[c]Estimate not reported

Scandinavia [247] reported elevated risk of HL with a family history of HL (OR = 3.3), NHL (OR = 3.3), CLL (OR = 6.3), and more weakly with MM (OR = 1.7); some smaller studies have reported larger ORs for risk of HL with a family history of HL [248, 249]. In a pooled analysis of 2843 cases and 11,470 controls from 11 studies, an elevated risk of MM was observed with a family history of MM (OR = 1.9), but no significant associations with NHL (OR = 1.4), leukemia (OR = 1.2), and HL (OR = 1.0) [250]. For blacks, the association for family history of MM was much stronger (OR = 5.5).

There are few cohort studies that have had detailed data on lymphoma in family members or a sufficient number of lymphoma outcomes to assess risk of specific NHL subtypes. In a national cohort study of 3.5 million people in Sweden born 1973–2008, family history of HL in a parent or sibling was associated with an 7.2 and 8.8-fold higher risk of childhood/young adult HL, respectively [251], while another study reported a sixfold higher risk for siblings [252], both much stronger than the associations shown in Table 38.1, perhaps due to the focus on childhood and young adult HL (and suggesting a stronger genetic predisposition in younger onset HL). In a cohort study of over 120,000 female California teachers [253], a history of lymphoma in a first-degree relative was associated with a 1.7-fold higher risk of B-cell NHL (RR = 1.74, 95% CI 1.16–2.60) based on 478 cases; data on risk for NHL subtypes were not available. This finding was highly consistent with pooled case-control data (Table 38.1).

Summary

Most of the risk estimates from population-based registry studies in Table 38.1 are broadly consistent with the estimates from case-control studies, with the most notable exception for a family history of MM with risk of NHL, CLL, and HL, where case-control studies show weak positive associations while the registry studies show no association. Taken together, these data provide strong evidence for familial predisposition across lymphoma subtypes, with the exception of MM. Further, familial risk does not seem to be confounded by nongenetic risk factors, although there are likely unidentified risk factors and clustering of known (and unknown) risk factors within families is difficult to exclude. This suggests a role for shared genetics underlying the familial aggregation. Although not universal, there is also clear evidence that family history of a specific lymphoma subtype is most strongly associated with risk for that specific lymphoma, suggesting that there may be some genetic factors unique to a subtype.

Prognosis

In contrast to etiology, there are relatively few data on the role of familial aggregation in NHL prognosis. The most comprehensive data are from a study using population-based registries in Sweden and Denmark that identified 41,026 patients with lymphoma, of whom 206 patients with NHL, 85 patients with CLL, and 95 patients with HL had a family history of any lymphoma [254]. Compared to patients without a family history of lymphoma, 5-year mortality for patients with a family history of lymphoma was similar for NHL (HR = 0.91, 95% CI 0.74–1.12), CLL (HR = 1.28, 95% CI 0.95–1.72), and HL (HR = 0.78, 95% CI 0.49–1.25), and these results were similar for 10-year mortality. NHL subtype was available on 28% of the cases, and there were no associations of family history with survival for high grade B-cell or low grade B-cell lymphoma, while there was a suggestive association for T-cell/anaplastic lymphoma (HR = 5.38, 95% CI 1.65–17.5). In other analyses limited to the Swedish registries, there was no difference in cause-specific or overall survival for patients with sporadic NHL compared to patients with a parent or offspring with NHL [255, 256] or lymphatic leukemia [256]. In an Italian clinical registry, patients with sporadic CLL had a similar rate of requiring therapy and 10-year survival as CLL patients with a family history of any hematologic malignancy or a first-degree relative with CLL [257]. Using cases enrolled in a population-based case-control study from Sweden [258], a family history of hematologic malignancy was not associated with all-cause or cause-specific survival after DLBCL, FL, MCL, or T-cell lymphoma. In summary, the current literature, although not extensive, suggests that familial aggregation does not play a major role in the prognosis of NHL or the most common NHL subtypes.

Host (Germline) Genetics

While the studies of familial aggregation are consistent with an important role for genetics in lymphoma development (but perhaps not prognosis), they cannot definitively separate shared genetics from shared environment. We next review studies that show not only clear evidence of a genetic contribution to lymphoma risk and prognosis, but also provide chromosomal locations that are associated with risk.

Etiology

Family Genetic Linkage Studies

A limited number of lymphoma family studies have been conducted to identify genes with major susceptibility effect. These studies are based on the idea that related individuals who are affected with lymphoma have a shared genetic exposure. Linkage studies in HL have identified both HLA class I (for EBV+) and class II (for EBV−) risk and protective alleles and haplotypes [259, 260]. Beyond HLA, linkage

studies in CLL [261], HL [262], and WM [263] have not definitively identified genes with large effects, and there are no published studies in FL, DLBCL, or other NHL subtypes. For CLL, significant linkage was localized to 2q21.2, which contains the chemokine receptor (*CXCR4*) gene and for which rare coding mutations have been identified [264]. Using more recent NGS technology, additional family studies of WM [265], HL [266, 267], and CLL [268, 269] have been done. These studies have identified rare variants in a small number of families, but still need further validation. A lack of strong findings for these family studies may be due to small sample sizes or the relatively private nature of these rare variants segregating in only a few families, but also raises the hypothesis that multiple, low to moderate risk variants that are common in the population, defined as minor allele frequency (MAF) >5%, may be more relevant in lymphoma etiology than single, highly penetrant variants that are very rare.

Candidate Gene Studies

The choice of a candidate gene or pathway has been mainly driven by a priori biologic knowledge of lymphoma and conditions associated with lymphoma such as autoimmune and infectious diseases as well as other cancers, and have been reviewed extensively [260, 270–274]. Most findings from these studies have failed to replicate, likely due to issues related to study design, bias from population stratification (i.e., confounding by race or ethnicity), small sample size (low power), uncontrolled multiple testing (leading to false positive associations), and unrealistic expectations in our ability to choose variants and genes [275]. The most robust findings have been for an *LTA-TNF* haplotype with DLBCL ($P = 2.93 \times 10^{-8}$) [276, 277]; a SNP (rs3789068) in the *BCL2L11* and risk for B-cell NHL (OR = 1.21, $P = 2.21 \times 10^{-11}$) [278]; a SNP (rs2266690) in *CCNH* with CLL risk (OR = 0.63, $P = 1.62 \times 10^{-8}$) [279]; a SNP (rs3132453) in *PRRC2A* in HLA class III and risk of B-cell NHL (OR = 0.68, $P = 1.07 \times 10^{-9}$) [278]; and certain HLA alleles in class I (including *HLA-A*01* and **02*) with EBV+ HL and class II (including *HLA-DRB1*) with EBV− HL [260].

GWAS

In contrast to candidate gene/pathway studies, GWA studies have definitively identified multiple susceptibility loci for lymphoma, which are summarized in Table 38.2. This success is in part due to the stringent level of evidence (currently $P < 5 \times 10^{-8}$) and independent replication across multiple independent studies. Most GWAS has also been based on specific lymphoma subtypes, with only one GWAS based on all lymphomas (which included HL, MM, and other NHL subtypes) in both discovery and validation stages, and a SNP at 11q12.1 (near *LPXN*) was identified, and the associations were consistent (but not genome-wide significant) in analysis of subtypes [280]. However, this locus has not been replicated in larger GWAS studies based on specific subtypes.

CLL

The estimated contribution of all common variation to the heritability of CLL is 46–59% [281, 282]. The first GWAS in a lymphoid malignancy was conducted for CLL [283] and to date, GWAS analyses [281, 284–290] have identified 45 SNPs from 39 loci for CLL, which accounts for approximately 25% of familial risk of CLL [290]. Many of these GWAS SNPs are near or in genes plausibly linked to CLL, including genes involved in apoptosis (including *FAS, PMAIP1, BAK1, BCL2, BCL2L11, BMF, CASP8/CASP10*), telomere function (*POT1, TERT, TERC*), transcription factors important in B-cell differentiation (*IRF8, LEF1, PRKD3, SP140*), and B-cell receptor activation (*IRF3, HLA-DQA1*). Although there has been little evidence of statistical interaction among these GWAS SNPs, there is clear evidence of biological interaction among the proteins of the genes in proximity to the GWAS SNPs [290]. None of the GWAS SNPs have individually shown a strong relationship with age at diagnosis, although cases diagnosed at a younger age tended to carry a greater number of risk alleles [287], supporting the hypothesis that early onset CLL is enriched for genetic susceptibility.

In an East Asian population of 71 CLL cases and 1273 controls, GWAS-discovered SNPs for CLL near *IRF4* (rs872071), *SP140* (rs13397985), and *ACOXL* (rs17483466) were associated with CLL risk at nominal significant level ($P < 0.05$), with a suggestive association with *GRAMD1B* (rs735665) [291]. The minor allele frequencies of these SNPs were much lower than in populations of European descent, supporting the hypothesis that the lower prevalence of CLL genetic risk factors might explain part of the lower incidence of CLL in East Asian populations. In a separate study of 117 Mexican mestizos CLL cases, the rs872071 SNP in *IRF4* was found to be statistically associated with CLL risk with similar minor allele frequencies as that of Caucasians. Finally, in a study of 110 African American CLL cases, none of the 15 evaluated GWAS SNPs was found to be associated with CLL risk at nominal level of statistical significance ($P < 0.05$).

Hodgkin Lymphoma

Classical HL (cHL) makes up approximately 95% of HL, and cHL compromises several subtypes: in young children and older adults, mixed cellularity HL (typically EBV+) predominates, while in adolescents and young adults, nodular sclerosing HL (typically EBV−) predominates [292]. Five GWAS analyses have been published in HL [293–297], and the strongest findings have been for SNPs mapping to HLA class II [293–295] in close proximity to *HLA-DRA* and

HLA-DRB1, regions previously linked to HL by HLA-typing studies [298, 299]. The 6p21.32 locus marked by rs6903608 (near *HLA-DRA*), was associated with cHL overall and more specifically to EBV-negative cHL [293, 294], early onset [294, 300] and young adult nodular sclerosing HL (largely EBV−) [295]. Additional GWAS signals at 6p21 have been identified in HLA class I [293], with statistically independent associations for rs2248462 (near *MICB*) for all cHL (irrespective of EBV status), and rs2734986 (3′ untranslated region of *HLA-G* and near *HLA-A*) and rs6904029 (near *HCG9*) for EBV+ cHL. These results confirm earlier studies linking *HLA-A*01* and **02* to EBV+ cHL [301–303] and support a role for class I but not class II genes in EBV+ HL. Using SNPs to impute classic HLA alleles, two independent signals in the HLA class II region (rs6903608 and rs2281389) were linked to early onset HL, but no specific classical HLA alleles from this region were significant after conditioning on these two SNPs [300]. The class II SNP rs6903608 was estimated to account for ~6% of the familial risk in HL [300].

Outside of the HLA complex, GWAS-discovered loci for HL include 2p16.1 [294] (near *REL*), 10p14 (near *GATA3*) [294], 8q24.21 (telomeric to *PVT1* and near *MYC*) [294], 5q31 (a nonsynonymous SNP in *IL13*) [293], 3p24.1 (5′ to *EOMES*) [297], 6q23.3 (intergenic to *HBS1L* and *MYB*) [297], and 19p13.3 (in intron 2 of *TCF3*) [296], with only the 2p16.1 and 5q31 loci showing stronger associations with EBV (negative) status. Genes from these non-HLA regions are involved in hematopoiesis and immunoregulation, making them plausible susceptibility loci for cHL. HLA and non-HLA-linked loci appear to be independent, and non-HLA loci were estimated to account for ~7% of the familial risk in

HL [297]. A recent comparison of heritability estimates on using a genomic versus a population approach supported an underlying polygenic basis for HL susceptibility and that there were likely additional loci outside of chromosome 6 (HLA) remain to be detected [304].

These studies have been mainly conducted in studies of European ancestry. In a study of cHL in a northern Chinese population [305], HLA-A*02:07 was a predisposing allele for EBV+ cHL and a protective allele for EBV− cHL, and this allele was more common in the Chinese vs. European populations, emphasizing the need for more studies in diverse populations.

Follicular Lymphoma

Three early GWA studies based on small discovery sets (<400 cases) identified loci at 6p21.33 [306] and 6p21.32 [50, 307] in the HLA region associated with FL. In a meta-analysis of those studies plus a new GWAS of over 2100 cases, the HLA region showed overwhelming association with FL, with over 8000 SNPs achieving genome-wide significance. After additional validation, a top SNP from this region (rs12195582) reached $P = 5.35 \times 10^{-100}$ [308]. HLA alleles and amino acids (AA) were imputed and the top signal mapped to four linked DRβ1 multi-allelic AA at positions 11, 13, 28, and 30, suggesting an important role for DRβ1 peptide presentation in FL [308]. Additional independent signals were also identified in HLA class II (rs17203612) and class I (rs3130437, near *HLA-C*); after accounting for all of these signals, no other previously identified SNP from the HLA region achieved genome-wide significance. Outside of the HLA region, five novel loci have been identified including 11q23.3 (near *CXCR5*), 11q24.3 (near *ETS1*), 3q28 (in *LPP*), 18q21.33 (near *BCL2*), and 8q24 (near *PVT1*) [308]. These genes are linked to B-cell biology making them plausible in the etiology of FL.

DLBCL

In a large GWAS of European ancestry [309], novel loci identified included 6p25.3 (*EXOC2*), 6p21.33 (*HLA-B*), 2p23.3 (*NCOA1*), and 8q24.21 (near *PVT1* and *MYC*); the strongest finding after imputing HLA alleles and AA was with *HLA-B*08:01*, although this could not be statistically distinguished from the *HLA-B* SNP due to high LD. That study further estimated that common SNPs, including but not limited to the GWAS-discovered loci, explained approximately 16% of the variance in DLBCL risk overall. To date, no GWAS study has published DLBCL results by cell-of-origin (i.e., germinal center versus activated B-cell).

Three of the five GWAS-discovered SNPs for DLBCL in Europeans were significantly associated with DLBCL in an East Asian population [310], including *EXOC2* (OR = 2.04, $P = 3.9 \times 10^{-10}$), *PVT1* (OR = 1.34, $P = 2.1 \times 10^{-6}$), and *HLA-B* (OR = 3.05, $P = 0.009$). Overall, MAFs were similar or only modestly lower in the East Asian population for all SNPs except for one of the 8q24 SNPs, which was much rarer. In a GWAS conducted in an East Asian population, a locus at 3q27 (near *BCL6* and *LPP*) was identified [311], although this could not be replicated in independent studies of East Asian [310] or European ancestry [309].

Other Subtypes

A GWAS of MZL [312] identified two distinct loci at 6p21.32 (intragenic to *BTNL2*, in HLA class II) and 6p21.33 (*HLA-B*, in HLA class I); these two loci were in low LD and were statistically independent of each other. There was no strong heterogeneity in these results when stratified on MALT versus non-MALT (SMZL and NMZL) subtypes, although this was based on a modest sample size. These loci have been associated with autoimmune diseases and immune response, suggesting shared biologic underpinnings with MZL. A GWAS of extranodal natural kill T-cell lymphoma (NKTCL) in Asians identified a locus at 6p21.32 (*HLA-DPB1* in HLA class II), and imputation-based fine-mapping implicated four AA residues (Gly84-Gly85-Pro86-Met87) at the edge of the HLA-DPB1 peptide-binding groove as accounting for most of the association of the top SNP in this region. Furthermore, none of the other published FL, DLBCL, or MZL GWAS SNPs was associated with NKTCL [313]. While NKTCL in Asia has been linked to EBV, the genetic associations are distinct from those in EBV+ HL (see above).

Gene × Environment Interaction

Given the lack of validated candidate genes, there have been even fewer robust studies of gene–environment interaction. The most robust results are from large pooled studies, which suggest an interaction of B-cell-mediated autoimmune conditions and the *TNF* SNP rs1800629 with NHL risk [314] and body mass index and the *TNF* SNP rs1800629 with DLCBL risk [315]. A large pooled analysis found no association of current cigarette smoking and genetic variation in N-acetyltransferase enzymes and FL risk [316].

Summary

To date, GWAS have successfully identified 78 SNPs from 65 genetic loci, mainly associated with specific subtypes (Fig. 38.3), with only three regions—the HLA region, 8q24, and 3p24.1—associated with multiple lymphoma subtypes. However, even the associations for the common regions are heterogeneous, particularly for HLA [274]. The established SNPs are common (MAF > 5%) and generally have small effect sizes (ORs 0.6 to 2.0). In contrast to GWAS, candidate gene studies in lymphoma have had only minimal success, similar to other cancers [317]. Linkage studies have also not been successful in identifying rare alleles causing Mendelian disease, and the evaluation of low-frequency

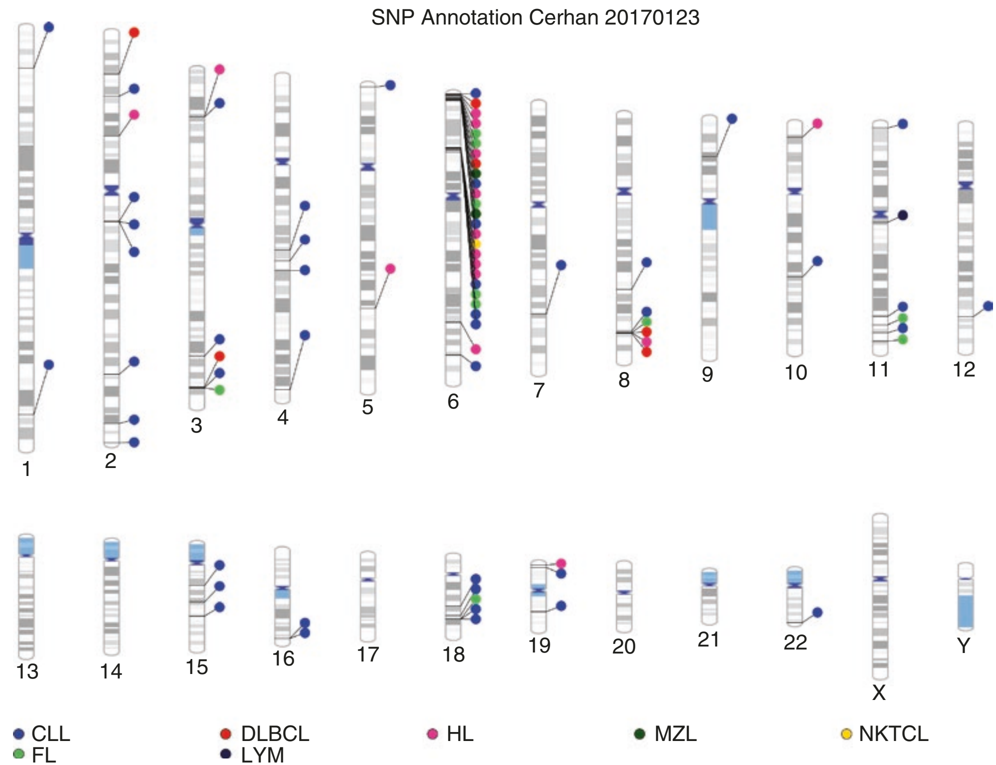

Fig. 38.3 GWAS-discovered loci for lymphoma subtypes mapped to chromosomal location. Except for 6p21, 8q24, and 3p24.1, most susceptibility loci are unique to only one lymphoma subtype

variants with intermediate effects is still in early research phases for lymphoma, but will be challenged by sample size issues [318]. The GWAS-identified SNPs that have been identified are largely of unknown function, and this is a major task in the "post-GWAS" era. One leading hypothesis on the mechanistic role of these common SNPs is their effect on gene expression (e.g., through effects on promoters or enhancers), but this effect is difficult to identify given an expected modest impact of these SNPs on gene expression and the fact that this impact could occur at any time before diagnosis [287].

Prognosis

Candidate Gene/Pathway Studies

Germline genetics as predictors of outcome after a diagnosis of lymphoma, including treatment response, toxicity (e.g., neutropenia and cardiotoxicity), event-free (EFS)/PFS, and OS are still relatively limited. Most have been candidate gene/pathway studies, with a focus on immunologic and metabolism (particularly drug metabolism) pathways, as well as downstream mechanisms of action of treatments including reactive oxygen species (ROS) and DNA repair; there have only been two published GWAS analyses, both of which were re-purposed from etiology studies. We review the most robust findings based on larger studies and replication in at least one independent study.

Cytokine Genes

The first report in the literature on germline SNPs and prognosis in lymphoma were from genes encoding the pro-inflammatory cytokines tumor necrosis factor (TNF) and lymphotoxin (LT)-α. Specifically, a long-range haplotype consisting of alleles associated with higher gene expression from *TNF* (rs1800629, A allele) and *LTA* (rs909253, A allele) were associated with shorter PFS (HR = 2.33, $P = 0.0053$) and OS (HR = 1.92, $P = 0.081$) in DLBCL after adjustment for the International Prognostic Index (IPI), while there was no association with FL [319]. The positive findings for DLBCL [320, 321] and null findings for FL [322, 323] were confirmed in other pre-rituximab era patient cohorts, while in rituximab-treated DLBCL patients there was no association for either *TNF* (HR = 0.94, $P = 0.79$) or *LTA* (HR = 0.90, $P = 0.66$) [321], highlighting that changes in treatment can impact prognostic associations, as reported for some tumor markers in the rituximab era [324]. In CLL, the *TNF* SNP was associated with OS after adjustment for Rai stage and IGHV mutation status ($HR_{AA/AG} = 2.1$, $P = 0.01$), but was not associated with treatment-free survival [325]. The *TNF* SNP was not associated with PFS in cHL overall, but in a meta-analysis of two cohorts, it was associated with PFS in EBV− (but not EBV+) cHL ($HR_{AA/AG} = 2.11$, $P = 0.01$) [326].

Only two other cytokine SNP markers in *IL8* and *CD46* have shown some promising results. IL-8 is a potent chemoattractant for neutrophils and monocytes, and the A allele of *IL8* rs4073 has been associated with increased production

of IL-8 [327] and inferior OS in a cohort of 278 FL patients ($HR_{AA/AT}$ = 0.47, P = 0.06) [323] and PFS (but not OS) in a cohort of 231 FL patients ($HR_{per\ A\ allele}$ = 0.78, P = 0.02) [328]; however, a smaller cohort of 117 FL patients found the opposite association for OS [329]. CD46 regulates complement and regulatory T-cell function, and the *CD46* rs2466571 SNP was associated with inferior EFS in a US ($HR_{CC\ vs.\ AA}$ = 1.96, P = 0.049) [330] and a Swedish ($HR_{per\ C\ allele}$ = 1.37, P = 0.006) cohort of FL patients [328], with the former study also finding a stronger association in patients who were observed. Other early leads, including associations with *IL10*, *IL8RB*, *IL1A* and *IL4* and *IL4R* in DLBCL [320, 321, 329] and *IL2*, *IL12B* and *IL1RN* in FL [323, 328], *IL10* and *IL6* in HL [326, 331, 332] as well as attempts at multi-gene modeling [320, 323, 328, 333], have yet to be replicated.

FCGR2A and *FCGR3A*

Preclinical studies suggest that SNPs in Fc gamma receptor (*FCGR*) genes could influence response to rituximab related to efficacy of Fc binding and triggering of antibody-dependent cell-mediated cytotoxicity [334]. Early studies of rituximab monotherapy for FL found that the *FCGR3A* (rs396991, V158F) VV genotype (compared to F carriers) and/or the *FCGR2A* (rs1801274, H131R) HH genotype (compared to R carriers) (the two genes are in LD [335]) was associated with better response rate and/or longer time to progression [336–338]. However, subsequent studies have been mixed [271], and a recent large prospective evaluation of this hypothesis embedded in the RESORT trial of treatment naïve, low tumor burden patients treated with R-monotherapy, found no evidence for either SNP with response or outcome [339]. In addition, neither SNP appears to predict response or prognosis in FL patients treated with CHOP [340, 341] or R-CHOP [342], including the large PRIMA trial [343], nor in patients treated for DLBCL [344, 345], HL [346], or CLL [347].

Pharmacogenetics and Metabolism

Interindividual variability in efficacy and toxicity of pharmacologic agents is affected in part by host genetic background in drug metabolism, detoxification, and transport and underlies the field of pharmacogenetics [348], but studies in lymphoma have been fairly limited. HL patients with the wild-type *UGT1A1* TA6/TA6 genotype (a phase 2 enzyme involved in the metabolism of anthracyclines and other xenobiotics) had inferior OS (HR = 2.54, P = 0.04) and freedom from progression (HR = 2.70, P = 0.004) compared to those with a least one *UGT1A1*28* allele in a cohort of 313 HL patients [349], and this was replicated for OS (HR = 4.20, P = 0.003) but not EFS (HR = 0.73, P = 0.25) in a cohort of 224 HL patients [350]. In a study of 106 R-CHOP21-treated DLBCL patients, the *CYBA* SNP rs4673 was associated with inferior EFS (HR_{TT} = 2.06, P = 0.038) after adjusting for IPI [351]. While the latter association was not replicated in a study of aggressive NHL which used a discovery (N = 401) and validation (N = 477) design [352], another *CYBA* SNP, rs1049255, was associated with inferior EFS (HR_{GG} = 1.58, P = 0.00005) and OS (HR_{GG} = 1.38, P = 0.018). Further functional analysis showed that the G allele of *CYBA* rs1049255 was associated with lower NAD(P)H activity, mRNA and protein expression [352].

In DLBCL and other aggressive NHLs, the *NCF4* rs1883112 SNP A allele was associated with greater hematologic [351, 353] and anthracycline-induced cardiotoxicity [354], as well as with superior EFS in two independent studies (meta-RR_{AA} = 0.66, P < 0.01) [353], although this was not observed in two other studies [351, 352]. *CYBA* encodes a membrane-bound p22phox subunit and *NCF4* encodes a cytosolic p40phox subunit of the NAD(P)H oxidase complex. NAD(P)H is a multi-unit complex that generates reactive oxygen species (ROS), which is one of the antitumor mechanisms of doxorubicin [355]. Genetic variation in other NAD(P)H subunits (*CYBB*, *NCF2*, *RAC2*) have not been associated with DLBCL prognosis [351, 352]. While other genes encoding metabolic enzymes, including cytochrome p450 (e.g., *CYP2C19*, *CYP3A4, CYP3A5*), detoxification (e.g., *GSTA1, GSTM1, GSTP1*), ATP-binding cassette transporters (e.g., *ABCB1*, *ABCC2*, *ABCG2*) have been evaluated with outcomes in HL, FL, or DLBCL, none have been robustly replicated [260, 271, 351].

DNA and Chromosomal Integrity

DNA damage signaling and repair, as well as one-carbon metabolism pathways, have important functions in maintaining DNA and chromosomal integrity, and many of the chemotherapeutic agents used to treat lymphomas rely on DNA damage as part of their mechanism of action in tumor cell killing. Using a discovery (N = 163) and validation (N = 145) study design, the *MLH1* rs1799977 AG/GG genotype was associated with inferior OS (HR = 3.14, P < 0.001) and PFS (HR = 1.96, P = 0.010) after adjusting for IPI and other clinical factors in R-CHOP21-treated DLBCL patients, and these results replicated in the validation set [356]. Furthermore, DLBCL patients with a risk (G) allele had significantly lower MLH1 expression in their tumors, consistent with its role in triggering apoptosis induced by chemotherapy [357]. In a study of 215 CHOP-treated DLBCL patients from the pre-rituximab era, the *MLH1* SNP was only weakly associated with OS (HR = 1.56, 95% CI 0.89–2.72) [358]. Other SNPs from these pathways for DLBCL and FL outcomes have not replicated [356, 358].

GWAS

There are only two published GWAS of prognosis in lymphoma, and both have struggled to meet the genome-wide

significance level used in etiology studies ($P < 5 \times 10^{-8}$). In a multistage GWAS of immunochemotherapy-treated DLBCL ($N = 852$ discovery, $N = 623$ validation), rs7712513 at 5q23.2 (near *SNX2* and *SNCAIP*) was associated with EFS (HR = 1.39, $P = 2.08 \times 10^{-7}$) and OS (HR = 1.49, $P = 3.53 \times 10^{-8}$) and rs7765004 at 6q21 (near *MARCKS* and *HDAC2*) was associated with EFS (HR = 1.38, $P = 7.09 \times 10^{-7}$) and OS (HR = 1.47, $P = 5.36 \times 10^{-7}$) [359]. The study provided encouraging evidence for these novel loci, which were distinct from DLBCL risk loci discussed above, and suggested both novel biology and the potential contribution of host genetics to DLBCL prognosis. In a GWAS of 586 FL patients (treatments unknown), a locus at 17q24 near *ABCA10* and *ABCA6* (rs10491178 HR = 3.17, $P = 5.24 \times 10^{-8}$) was associated with lymphoma-specific survival, were distinct from the risk loci, and implicated genetic variation in multidrug resistance for FL outcome [328]. When GWAS-identified susceptibility loci for HL (*HLA-DRA*, *REL*, *MYC/PVT1*, *GATA3*, and *TCF3*) were evaluated for prognosis in a meta-analysis of two large cohort studies, only the *MYC/PVT1* SNP rs2608053 was associated with EFS (HR = 1.94, $P = 0.01$) and OS (HR = 1.80, $P = 0.04$), and this association remained after adjustment for the International Prognostic Score (IPS) [360].

GWAS can also be used to identify specific adverse outcomes. In a GWAS study of children with HL who were treated with radiation therapy, two variants (rs4946728 OR = 3.32, $P = 5.99 \times 10^{-10}$ and rs1040411 OR = 2.39, $P = 1.18 \times 10^{-7}$) at 6q21 were associated with risk of second malignant neoplasms [361]. The risk haplotype was associated with lower expression of *PRDM1* and impacted induction of the protein after radiation exposure.

Summary

Similar to etiology studies, most candidate gene studies of prognosis have failed to replicate, likely due to the same issues for case-control studies discussed above, with additional issues that many prognosis studies included use of heterogeneous patient populations (i.e., mix of de novo and relapsed cases; multiple subtypes mixed together), study designs (randomized trials vs. observational studies), treatments (e.g., often heterogeneous, and sometimes out of date), and study endpoints (e.g., EFS, lymphoma-specific survival, OS), further complicating interpretation of the literature. The prognostic significance may also change with changes in treatment over time. Overall, there is a need for larger studies with more homogeneous treatments and clinically relevant endpoints beyond just OS. While results have not been particularly robust to date and more studies are needed, one early and potentially important theme is that loci associated with lymphoma risk largely do not overlap the loci associated with prognosis.

Practice Implications

Genomics underlies much of the goal towards precision medicine [362, 363], including tumor detection, accurate diagnosis and characterization (precision oncology), choice of treatment ("targeted" therapy), response to therapy (pharmacogenomics), predictive and prognostic models, tumor monitoring, and other outcomes such as second cancers and other morbidities. Applying genomics for precision prevention is a related goal, both for high risk families and the general population [364].

Use of Tumor Genomic Data in the Clinic

Currently there are numerous clinical grade molecular diagnostic tests that can be used for identification of somatic mutations in clinical practice, such as FoundationOne® Heme. Additionally, mutation profiles are now being used as therapeutic targets and for design of clinical trials. While the field is moving rapidly and advances have been made, many unanswered questions remain, most importantly, we currently do not consider the entire genomic landscape (genome, transcriptome, epigenome) when making clinical decisions. Moving forward a key challenge for use of NGS data in clinical practice will be our ability to understand the significance of mutations alone or in combination, to gain insight on the biologic significance of mutations, and to gain a better understanding of which mutations drive tumor formation versus those that impact response to therapy and patient outcome. Bioinformatic and technologic advances will be key to moving forward. Finally, tumor genomic evaluation is often paired with germline evaluation, with rapidly evolving implications for patients and families of clinically actionable secondary germline findings [365].

Use of Host (Germline) Genetics in Risk Assessment

Given the estimated lifetime risk of NHL is 1 in 48 (2.1%) in the United States [366] and an RR of 1.7 for the risk of NHL in a first-degree relative, then the absolute lifetime risk of NHL is 3.6% in first-degree relatives of an NHL patient. The absolute risk is even lower for specific lymphoma subtypes, which are less common. While the absolute lifetime risk of NHL is not trivial, the relatively low incidence of lymphoma, the modest familial risk, and the lack of a screening test and associated intervention all argue against active clinical surveillance of family members of lymphoma patients based on their family history at this time. The clinical management of familial hematologic cancer syndromes with known germline variants mainly involves AML/MDS and ALL [10].

Such germline variants have not been identified for most lymphomas, and as discussed most inherited risk appears to be due to common variants of weak risk, limiting clinical utility. However, by combing these variants in genetic risk scores, alone or in combination with other risk factors, might improve prediction ability to the level needed in the clinic [367]. While there are currently no validated risk scores for lymphoma, this advance is anticipated as more loci are characterized.

Use of Host (Germline) Genetics in Prognostication

Similarly, evaluation of germline genetics to predict response to therapy, toxicity, and prognosis as part of precision medicine is also largely not yet ready for the clinic. Using germline genomic markers is attractive, since they can be obtained from multiple types of biologic specimens (peripheral blood, buccal cells) and are relatively easily and reliably measured (i.e., genotyped). While some early results suggest germline genetic markers can add important additional prediction beyond clinical and tumor factors or may be used to select treatment type or treatment dose (pharmacogenetics), this remains a future goal in lymphoma. It appears that most SNP markers will only be modestly associated with prognosis (HRs 1.5–2.0), which will require large studies to identify and validate. While these may be individually less useful in a clinical setting, it is hypothesized that by combining multiple markers we can strengthen prediction ability, consistent with a polygenic model of disease pathogenesis. Ultimately, the clinical validity (by assessing sensitivity, specificity, and positive and negative predictive values) will need to be established for genetic markers, along with demonstrated clinical utility to improve the management of lymphoma patients.

Future Directions

In the last few years, large cohorts of most lymphoma and leukemia subtypes have been sequenced, essentially defining the mutation landscape of the diseases. Overall, most diseases are characterized by a considerable genetic heterogeneity and the lack of a pathognomonic genetic event. Furthermore, most of this work has yet to link tumor genomic alterations with treatment response or prognosis. Finally, one of the foremost challenges in the "post-genomic" era is the functional validation of this large number of mutated genes in order to dissect their role in disease pathogenesis.

A major limitation of studying bulk tumors is the inability to resolve cellular states. Currently, we have the ability to monitor global mutation profile in hundreds or even thousands of individual cells in a single experiment, therefore becoming a powerful tool to characterize the tumor architecture and fully characterize the different subclones and their dynamics overtime. Furthermore, single cell data will define the exact combination of driver mutations in each subclone, some of which have targeted therapies in clinical testing or under development and may ultimately translate into novel, individualized treatment approaches. Similar opportunities are originated from the study of circulating tumor cells and cell-free DNAs, which might provide a powerful tool for diagnostic, prognostic and therapeutic approaches in a non-invasive way.

New challenges and research opportunities are also offered by the study of premalignant conditions, especially focusing on the identification of more precise methods to determine which individuals with premalignant precursors will have a clinically significant health condition. Some individuals with premalignant conditions experience relatively rapid progression within 1–2 years while others live for decades without requiring treatment. The prevalence of such conditions will likely increase in the next 2 decades with the aging of the U.S. population. Paradigms in the hematological malignancies are monoclonal B-cell lymphocytosis (MBL) and MGUS, premalignant conditions of CLL and MM, respectively. The feasibility of obtaining sequential samples makes the study of hematological pre-malignancies attractive models to study early carcinogenesis in a longitudinal fashion

At the host level, characterization of genetic susceptibility in lymphoma is rapidly evolving. It is expected that additional common variants will be discovered for the different lymphoma subtypes [304, 368], and perhaps pan-lymphoma loci will also be identified; this genetic architecture should provide new biologic insights to the commonalities and heterogeneity across subtypes. As new lymphoma entities and precursor lesions are defined, evaluation of heritability and genetic susceptibility should be addressed. Additional work needs to occur in other racial and ethnic groups, particularly with contrasting lymphoma incidence rates. It is not yet clear if rare and low-frequency variants will play a major role in lymphoma susceptibility. This will be challenging to address due to phenotype heterogeneity and the need for large sample sizes for these relatively rare entities, and both family and association study designs along with bioinformatics and laboratory-based studies will all need to be integrated to achieve progress [318]. Other genetic mechanisms (e.g., copy number variation), epigenetics, and gene–environment interactions are additional frontiers [317]. Host genetics may also help with prognostication, including immunologic and treatment response, toxicity, and general host response may help to improve prognostic models, individualize cancer treatment (increase efficacy and decrease toxicity), and identify novel treatment targets or approaches.

Finally, integrating somatic and germline genomics is still in its infancy [369], and should provide new insights into lymphoma etiology and pathogenesis, which can be translated to prevention and clinical management, and hopefully provide novel insights into how to prevent and treat this malignancy.

Conclusion

NGS technologies have played an essential role in defining the somatic genomic landscape of lymphomas, with most characterized by a considerable heterogeneity and the lack of a pathognomonic genomic event. From the host perspective, there is strong evidence for familial aggregation across lymphoma subtypes, and this does not appear to be confounded by nongenetic factors, supporting a shared genetic etiology across subtypes. However, a family history of a specific lymphoma subtype is also generally most strongly associated with risk for that specific lymphoma, supporting etiologic heterogeneity. While no major genes have been identified for lymphomas, GWAS have identified over 60 common (MAF > 5%) risk loci, nearly all are associated with specific subtypes. Host genetics has long been hypothesized to influence treatment response, toxicity, and prognosis, but current studies are limited. Ongoing challenges in the "post-genomic" era relate to the functional validation of the large number of mutated genes in the tumor and GWAS loci in the germline, in order to dissect their role in lymphomagenesis. While the use of somatic and host genomics for precision diagnosis, treatment and prevention remains very promising, additional discovery and translational research will be needed before widespread adoption in the clinic.

39 Epidemiology and Hereditary Aspects of Hodgkin and Non-Hodgkin Lymphomas

Seymour Grufferman

Introduction

The lymphomas have been of unusually great interest to epidemiologists for several reasons. First, both Hodgkin lymphoma and the non-Hodgkin lymphomas have long been suspected of having an infectious etiology and both have been associated with immunosuppression. Second, Hodgkin lymphoma has an unusual pattern of incidence with age, which has suggested that it is at least two different diseases with important underlying environmental determinants. In contrast to Hodgkin lymphoma, the likelihood on clinical and histopathologic grounds that the non-Hodgkin lymphomas are several different disease entities has probably impeded epidemiologic and other research interest in this group of diseases.

The lymphomas have some important common features, however. They are malignancies of the lymphatic system and its precursor cells, which play major roles in the body's defenses against infection and in antibody production. The first isolation of the Epstein–Barr virus (EBV) was from an African Burkitt lymphoma patient. Patients with infectious mononucleosis, caused by EBV, have at least a threefold increased risk of developing Hodgkin lymphoma. Thus, it is not surprising that the lymphomas have frequently been thought to be of viral etiology. Additionally, this group of malignancies is seen with very high frequency in persons with immune deficiencies, ranging from that due to pharmacologic immunosuppression in transplantation to congenital immunodeficiency syndromes or to the acquired immunodeficiency syndrome (AIDS). Interestingly, immunosuppression leads to a remarkably increased risk of non-Hodgkin lymphoma, but only to a slightly increased risk of Hodgkin lymphoma. New evidence has shown that chronic hepatitis-C infection is a cause of non-Hodgkin but not Hodgkin lymphoma [1]. Other infectious agents such as Kaposi sarcoma herpes virus, the human t-lymphotropic virus, and *Helicobacter pylori* have been linked with uncommon subtypes of non-Hodgkin lymphoma but not Hodgkin lymphoma [1]. The lymphomas as a group lead to impaired immune function per se. A clear-cut familial aggregation of the lymphomas is also seen, although family members of a Hodgkin lymphoma patient are likely to have more of that disease but little excess of non-Hodgkin lymphoma and vice versa.

On the basis of known etiologic factors, the two diseases appear to have little in common. EBV is found in up to 50% of all Hodgkin lymphoma tumors, but infrequently in tumors from non-Hodgkin lymphoma patients other than those with endemic Burkitt lymphoma. Environmental and occupational exposures, such as to chemicals, have inconsistently been linked to risk of both diseases. In general, the results of such studies, as presented next, have not been very persuasive. An interesting difference between the two diseases is the much greater frequency with which the non-Hodgkin lymphomas appear as second malignancies when compared with Hodgkin lymphoma. Whereas it appears that heredity plays a large role in the occurrence of both conditions, the patterns of familial aggregation in the two are quite different. Another major difference between the two diseases lies in incidence trends over recent years. The incidence of non-Hodgkin lymphoma worldwide had been increasing at the rate of 3–4% per year, although this increase has tapered off since 1995 in males but not in females (Fig. 39.1). In contrast to this, the incidence of Hodgkin lymphoma has changed little over time and has decreased slightly (Fig. 39.2). Curiously, the increasing trend in non-Hodgkin lymphoma incidence is not evident in China and Japan, countries in which the incidence rates of lymphomas are much lower than in the US. New US data for all ages, races, and both sexes combined (Fig. 39.3) show that the increase in non-Hodgkin lymphoma incidence in the US peaked in about 2007 and has turned down since then. For reasons such as these, the epidemiology and genetics of the two diseases are discussed separately.

Hodgkin Lymphoma

Incidence

Hodgkin lymphoma is a relatively uncommon malignancy. The current overall annual incidence in the US is 2.6/100,000 (3.0/100,000 in males and 2.3 in females) [2]. As can be seen in Table 39.1, incidence rates are higher in whites than in blacks. The overall 5-year survival rate is now up to 88.5% [2]. The improvement in survival is one of modern oncology's greatest triumphs. It should not be forgotten that 50–60 years ago, a diagnosis of Hodgkin lymphoma was a virtual death pronouncement. Unfortunately, progress in effecting greater survival in the elderly Hodgkin lymphoma patient has lagged behind. Table 39.1 shows a diminishing survival with increasing age. Five-year relative survival for patients aged 65 years or older at diagnosis is only 54.2%, possibly because of less aggressive diagnosis, staging, and treatment in this age group [2, 3]. Given the improving general health status of the elderly, this poorer survival should improve in the future.

Table 39.1 Important statistics on Hodgkin lymphoma

Population	Incidence
US incidence per 100,000 population per year, 2009–2013	
Overall US rate	2.6
Males	3.0
Females	2.3
Whites	2.8
Blacks	2.6
0–14 years	0.6
<65 years	2.4
Males	2.7
Females	2.2
65+ years	3.8
Males	4.8
Females	3.1
Population	Survival (%)
US 5-year relative survival, 2006–2012	
Overall	88.5
Males	87.3
Females	89.8
Whites	89.0
Blacks	85.6
Survival by age at diagnosis	
0–14	97.7
<45 years	94.3
65+ years	54.2

Rates are adjusted to the 2000 US standard population
Based on SEER data, 2009–2013 and 2006–2012

By Age and Sex

Hodgkin lymphoma incidence varies greatly with age. MacMahon, in 1957, first noted a bimodal age–incidence curve with modal peaks in young adults (aged 15–34 years at diagnosis) and old adults (50 years or more) [4]. He postulated that these represented two different diseases, an inflammatory granulomatous infectious disease in young adults and a true neoplasm in the old adults. He noted that the young–adult disease was probably infectious in nature, although of very low infectivity [5]. He also observed that no young–adult incidence peak was seen in Japan and that certain epidemiologic features of childhood Hodgkin lymphoma, such as a striking male excess, suggested that it represented a third type.

The incidence of Hodgkin lymphoma at different ages also varies by sex. A marked excess of males is seen in the childhood form [5]. At the young–adult and old–adult incidence peaks, little or no difference by sex is seen, but a marked male excess is found during middle age (35–59 years). It has been suggested that this gap might be due to a protective effect of childbearing [6], and Glaser [7] presented some data to support this hypothesis. If it is correct, it implies that hormonal factors play a role in the etiology.

International Variation

Observed large international incidence differences have suggested an important etiologic role for environmental factors. The most intriguing observation is that reported in 1971 by Correa and O'Conor [8], who observed that in developed countries such as Sweden and Denmark incidence rates for young–adult onset Hodgkin lymphoma (20–34 years at diagnosis) were quite high and (reciprocally) incidence rates for childhood onset (5–14 years) were quite low. In less developed countries such as Columbia and Nigeria, an inverse pattern was observed—incidence rates were high for childhood disease and reciprocally low for young–adult disease. These observations provided important support for the "poliomyelitis model" or "late-host–response model" of etiology, which is discussed below.

Macfarlane et al. [9] revisited the issue of international variations in incidence. Since the Correa and O'Conor paper was published, diverging incidence trends in childhood (stable rates) and young adults (increasing rates) have been observed [9]. Using incidence rates (1983–1987) from the same source as Correa and O'Conor, Macfarlane et al. [9] found no association between young–adult and childhood incidence. They also found that incidence rates for Latin American countries had shifted toward patterns observed in

more economically developed countries. Thus, the international incidence of the disease is not only different between countries but has changed over time. Such observations suggest that environmental factors play an etiologic role.

Another observation on international variation similarly has not stood the test of time. MacMahon noted in 1966 [5] that no young–adult peak in the age–incidence curve was found in Japan. As seen in Figs. 39.4 and 39.5, the Japanese incidence data from the International Agency for Research on Cancer (1998–2002) now show a definite young–adult incidence peak in males and females [10].

Figures 39.4 and 39.5 depict age–incidence patterns for the United States and two selected Asian countries, Japan and China. These countries were chosen because they have registries that provide stable rates and to demonstrate the overall lower incidence in Asia than in the United States. It is important to note that semi-logarithmic scales are used so that equal distances between curves represent equal proportional differences. In the countries illustrated, male rates are generally higher than those for females, particularly at older ages. Asian incidence rates are several-fold lower than those in the United States. New data plotted on an arithmetic scale (Fig. 39.6) show more clearly that the young adult incidence peaks in Japan and China persist but are of very low magnitude compared to the US. Whether these observations are due to different genetic susceptibility in Asia or to different environmental exposures is unknown. The observation of an emerging young–adult incidence peak in Japan and China coupled with the Westernization of many environmental exposures in these countries suggests that environmental

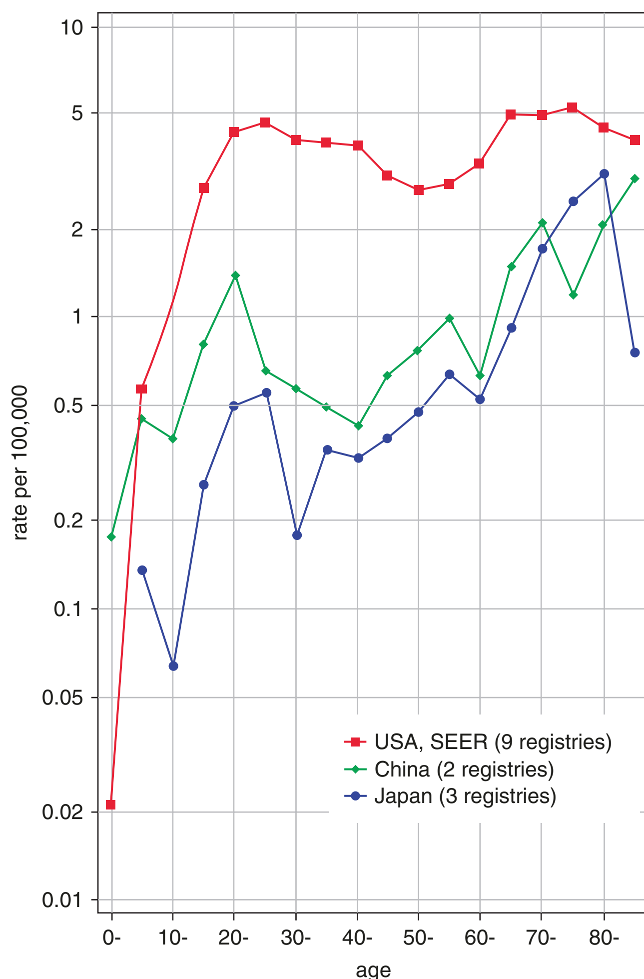

Fig. 39.4 Hodgkin lymphoma, 1998–2002: Male. (Modified with permission from Ferley J, Parkin DM, Curado MP, Bray F, Edwards B, Shin HR, Forman D. Cancer Incidence in Five Continents, Volumes I to IX: IARC CancerBase No. 9 [Internet]. Lyon, France: International Agency for Research on Cancer; 2010. Available from: http://ci5.iarc.fr/)

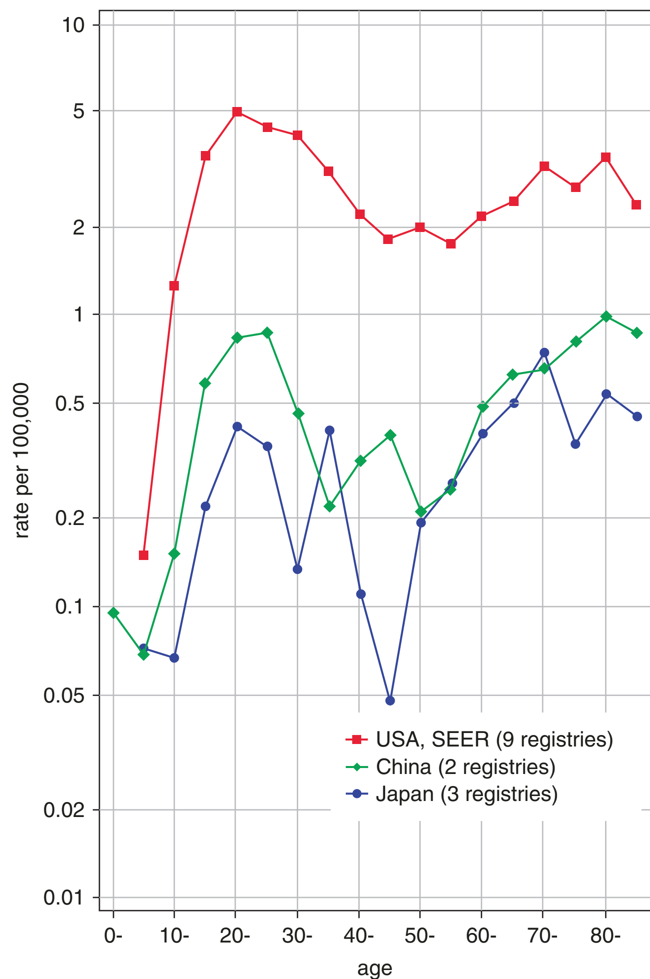

Fig. 39.5 Hodgkin lymphoma, 1998–2002: Female. (Modified with permission from Ferley J, Parkin DM, Curado MP, Bray F, Edwards B, Shin HR, Forman D. Cancer Incidence in Five Continents, Volumes I to IX: IARC CancerBase No. 9 [Internet]. Lyon, France: International Agency for Research on Cancer; 2010. Available from: http://ci5.iarc.fr/)

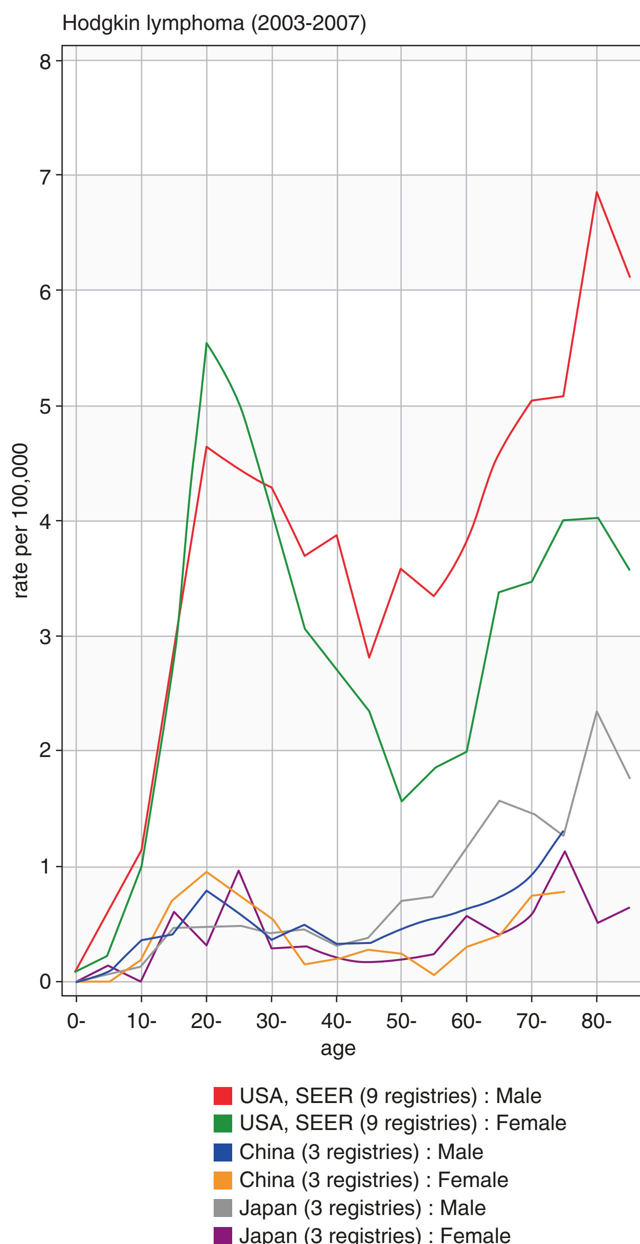

Fig. 39.6 Hodgkin lymphoma, 2003–2007: Age-standardized incidence rates (World), males and females, ages 0–85+

factors may play a greater role than genetic factors at least for young–adult Hodgkin lymphoma.

In summary, large differences are found in the incidence of Hodgkin lymphoma internationally, and they vary by age. Whereas the previously reported reciprocal variation internationally between childhood and young–adult incidence and the virtual absence of young–adult cases in Asian countries are no longer found, there is still very low incidence of the disease in Asia. Observations such as these make a strong case for the importance of environmental factors. They also suggest to some degree that genetic susceptibility plays a role.

Socioeconomic Status

Several intriguing associations between socioeconomic status (SES) and Hodgkin lymphoma risk have been noted. The descriptive epidemiologic findings regarding international variations suggest that less developed countries with their less affluent populations have relatively more childhood and fewer young–adult cases than do developed and more affluent countries. The inverse is seen in more affluent countries. These findings have become less striking with time as observed by MacFarlane et al. [9].

LeShan et al. [11] used data from World War II servicemen to show that men who developed Hodgkin lymphoma generally had higher IQs as measured by the Army General Classification Test. Cohen et al. [12] found that Hodgkin lymphoma patients had more education and were from higher preservice occupational classes compared with World War II servicemen without the disease. Gutensohn and Cole [13] showed that patients with young–adult disease came from smaller families, had fewer playmates, tended to live in more single family dwellings, and came from more affluent and more highly educated families than did controls. Two more recent studies found further results to support the hypothesis of Gutensohn and Cole [14, 15]. Glaser et al. in 2002, reported that Hodgkin lymphoma was weakly associated with a few social class markers but more strongly with combinations of markers in young–adult women. Mack et al. in 2015, reported that among military servicemen serving during 1950–1968, protection from the environment in childhood, but not in adulthood, increased the risk of young–adult Hodgkin lymphoma. Interestingly, they did not confirm the finding of LeShan et al. and Cohen et al. While they found a similar association in servicemen between markers of intelligence and disease risk, these differences were reduced to near unity when more modern adjusted analyses were performed.

Such data support the notion that Hodgkin lymphoma shares epidemiologic features with infectious diseases such as poliomyelitis and infectious mononucleosis. This hypothesis, first proposed by Newell [16], is based on the analogy with paralytic poliomyelitis in the prevaccination era [6]. In less developed countries, exposure to polioviruses occurred early in life, which usually led to a mild or inapparent infection (or both). However, in more affluent countries with better sanitation levels, infection in childhood is much less common. When a nonimmune adult host is infected with the virus, a severe paralytic disease tends to develop rather than the largely inapparent infections of early childhood. This model has also been called the EBV and the late-host–response hypotheses. Young–adult disease would be a rare manifestation of a common exposure.

The first test of this hypothesis was by Paffenbarger et al. [17]. Using data from a follow-up study of college students, they were able to identify alumni at Harvard and the University of Pennsylvania who had developed Hodgkin lymphoma. Data collected at the time of entry to college were used to show that (well in advance of their diagnosis), Hodgkin lymphoma patients reported having had significantly fewer of the common childhood infectious diseases than did matched controls. The later data by Gutensohn and Cole [13] confirm this hypothesis.

In summary, it appears that young–adult-onset patients fit the poliomyelitis model quite well. Unfortunately, extensive data are not available for childhood and old–adult cases to see how these groups may relate to this hypothesis. Nevertheless, the findings strongly suggest that environmental factors play a role, with exposure to viruses best fitting the model. Interestingly, the commonest histologic subtype observed in young–adult disease, nodular sclerosis, has a much lower prevalence of EBV in tumor tissues than does the mixed cellularity subtype [18]. It was the young–adult disease that MacMahon had hypothesized had an infectious etiology [5].

Role of the Epstein–Barr Virus

The possibility that EBV might play a role in Hodgkin lymphoma etiology was suggested by the isolation of the virus from a patient with another lymphoma, African Burkitt lymphoma. Until relatively recently, available laboratory methods could not detect EBV in Hodgkin lymphoma tumor tissues. However, several seroepidemiologic observations had earlier suggested etiologic links between the two conditions [6, 19]. It was well known that patients with Hodgkin lymphoma had higher titers of anti-EBV antibodies than did matched controls, but this was believed to be caused by the immunosuppression of Hodgkin lymphoma per se as well as the immunosuppressive effects of its treatment. In the 1970s, several cohort studies of individuals with serologically confirmed infectious mononucleosis showed that these patients had about a threefold increased risk of eventually developing Hodgkin lymphoma [6, 19]. It could not be discerned from these studies whether the infectious mononucleosis might have been caused by the immunosuppression of underlying (as yet undiagnosed) Hodgkin lymphoma. This concern was dispelled by two nested case–control studies in which serum banks were used to examine antibody status of patients based on blood samples drawn well in advance of any possible diagnosis of Hodgkin lymphoma [20, 21]. These studies showed that tests for anti-EBV antibodies were more apt to be positive and antibody titers higher in patients destined to develop Hodgkin lymphoma than in matched non-Hodgkin lymphoma controls. Thus it would appear that individuals who eventually develop the disease either have different immunologic responses to EBV than the general population or that EBV might be the cause.

Weiss et al. [22] used DNA hybridization to show that EBV DNA could be demonstrated in Hodgkin lymphoma tumor tissues. This innovative work was followed by a large series of studies showing that 30–50% of all adult Hodgkin lymphoma patients will have EBV in their tumors. In situ hybridization studies have since provided direct evidence that the virus is in the malignant cells of Hodgkin lymphoma tumors (Reed–Sternberg cells and their variants) [23].

Additionally, there is molecular evidence that the EBV genome in Hodgkin lymphoma is clonal; it has a restricted latent phenotype of LMP-1 expression and is found in the Reed–Sternberg cells. The consistency of these findings has led the International Agency for Research on Cancer to conclude that the EBV "is a causal factor in the etiology of Hodgkin lymphoma," and they have classified it as a group I human carcinogen [24]. However, not all Hodgkin lymphoma tumors are found to contain EBV, suggesting that there may be etiologic heterogeneity and that not all Hodgkin lymphoma is caused by EBV.

Understanding of the relationship between the EBV and Hodgkin lymphoma is further complicated by the observations of Sleckman et al. [25] that there was no association observed between case's history of infectious mononucleosis and EBV-positivity of their tumors. Further, they also found no association between childhood environmental risk factors and EBV tumor positivity. It must also be recognized that infection by EBV is virtually ubiquitous and 90% or more of most adult populations have serologic evidence of prior infection. Thus, although investigators and the IARC have concluded that EBV is a cause of Hodgkin lymphoma, the causal mechanism is as yet unexplained [18, 24].

In terms of epidemiologic characteristics of EBV-positive cases, 30–50% of all Hodgkin lymphoma cases are EBV-positive, EBV-positivity is greater in less developed countries (>90%) and in HIV-associated cases (>95%), is more common in mixed cellularity than in nodular sclerosis cases, and is more common in the <10 year and >45 year age groups [15].

Genetics

Familial aggregation of Hodgkin lymphoma is well documented, with close relatives having about a threefold increased risk of the disease [26]. Siblings of young–adult cases have a sevenfold increased risk [27]. However, like-sex siblings have a ninefold increase in risk and discordant-sex siblings a fivefold increased risk. No simple

Mendelian genetic mechanism can explain the finding of excesses of male–male and female–female sibling pairs [27]. These excesses suggest that environmental factors might interact with genetic susceptibility. Similar findings of excess sibling sex concordance have also been found in Behçet's disease, multiple sclerosis, and sarcoidosis, a group of diseases with suspected infectious etiology [28]. The underlying assumption is that like-sex siblings have more shared environmental exposures than do unlike-sex siblings. This hypothesis was dealt a setback by a twin study of Mack et al. [29] who found that among twins in which at least one member had young–adult disease, monozygotic twins of patients had a 99-fold increased risk, but dizygotic twins had no increase in risk. These data strongly suggest that the observed familial aggregation is entirely due to shared genetic susceptibility. However, if this were the case, a lower, but still increased, risk should have been observed in dizygotic twins as well. Since this study identified twin pairs by a variety of methods, including advertisements, the results may be due to selection bias and thus need to be confirmed in another, more systematic, study.

Some research suggests that there may be "genetic anticipation" in familial Hodgkin lymphoma. Genetic anticipation is a phenomenon in which each successive generation of a familial disease is diagnosed at earlier ages [30, 31]. This work, if valid, would lend further credence to there being a genetic basis for Hodgkin lymphoma. However, a more recent large, population-based study from Scandinavia found no evidence of anticipation for Hodgkin lymphoma [32]. Thus, there is need for further research on this subject.

Two studies have assessed genetic anticipation in families with a variety of hematologic malignancies that include Hodgkin lymphoma [33, 34]. Both of these studies found significant evidence of anticipation, i.e., younger ages at diagnosis for successive generations. A potential problem with these studies is that they group together several diseases with very different ages of usual onset, so that, for example, greater occurrence of Hodgkin disease in later generations could produce apparent younger ages at diagnosis. Also, follow-up of pedigrees may not be complete enough to include all relatives who go on to develop chronic lymphocytic lymphoma which occurs in the elderly. Nevertheless, the data suggest familial aggregation of several hematologic malignancies and a genetic basis for these diseases.

An interesting study found an apparent genetic parallel between Hodgkin lymphoma and Leri–Weill dyschondrosteosis (LWD) [35]. Based on observations of a sibship in which two sisters had both LWD and Hodgkin lymphoma and of excess sex concordance in Hodgkin lymphoma sibling pairs, the investigators conducted a large study analyzing familial cases. Since LWD has been found to be caused by the homeobox gene SHOX that localizes to the short arm pseudoautosomal region (PAR) of the X and Y chromosomes, they conducted a linkage analysis that suggested that the putative gene for familial Hodgkin lymphoma was in proximity to the site of the SHOX gene in the PAR. Using statistical genetic analyses, they found that PAR- and HLA-linked loci accounted for 29% and 40%, respectively, of the heritability of Hodgkin lymphoma in the US population.

However, the analyses used were questioned by others who used different statistical methods on the same data to find a significant excess of like-sex sibling pairs in Hodgkin lymphoma, unlike the first analysis. They concluded that relying on the analytic methods used, "it is not possible to infer the location or relative importance of a PAR gene for Hodgkin disease" [36]. So this potentially important genetic finding needs further evaluation.

Two studies addressed the question of whether familial Hodgkin lymphoma patients would be more or less apt to have EBV in their tumors. Using similar in situ hybridization techniques, both studies found identical results. In a study of 11 patients from France, 27% had evidence of EBV in their tumors' Reed–Sternberg cells [37]. In a second study of 46 familial cases from the US, 28% of their tumors were EBV positive [38]. Thus, the prevalence of EBV in tumors from familial cases, most of which were of the nodular sclerosis subtype, is similar to that found in nonfamilial patients.

First-degree relatives of Hodgkin lymphoma patients may also be at increased risk of other lymphomas. A very large study by Goldin et al. [39, 40] found a 3.1-fold significantly increased risk of Hodgkin lymphoma in first-degree relatives of cases. However, they also found a 2.1-fold statistically significantly increased risk of chronic lymphocytic leukemia and a 1.3-fold nonsignificantly increased risk of non-Hodgkin lymphoma in first-degree relatives.

Case Clustering

Case clustering in Hodgkin lymphoma has been reported numerous times. Whereas case clustering is characteristic of infectious diseases it can also be a hallmark of common-source exposure to a noninfectious etiologic agent. Vianna et al. [41] noted an unusual cluster of 31 cases that occurred over 23 years and centered around a single graduating class of the Albany (NY) High School. The diagnoses occurred at varying periods after the time of attendance. Twenty-three cases could be directly linked to one another and an additional eight could be linked as case-to-contact-to-case. This was a truly remarkable observation due to the sheer size of the cluster, which is the largest reported so far. Unfortunately, no appropriate statistical methods were used to evaluate its

significance. The Albany study looked at clustering from a different viewpoint, that of shared exposures at a period in time well in advance of diagnosis. This phenomenon has been termed *aggregation of exposures* [42]. It differs from *clustering,* which is defined as increased closeness in time and place of cases at the time the disease is diagnosed. For diseases with suspected long latency periods, aggregation of exposures studies would be much more meaningful than clustering studies.

The Albany results led to another study in high school students on Long Island, NY. Vianna and Polan [43] found that children attending high schools in which a diagnosed Hodgkin lymphoma patient was in attendance had remarkably increased risks of subsequently developing the disease. The estimates of risk ranged from 2.3 to infinity among students exposed to other student cases. This was a remarkable finding that stimulated further research. Unfortunately, an exact replication of the Long Island study conducted in Boston could not confirm the findings [44]. A similar study conducted in Oxford, UK, also could not confirm the Long Island findings [45]. Thus, it appears that no actual confirmed aggregation of exposures related to risk exists in the school setting. More recent studies have used newer biostatistical methods for the study of spatial clustering. Using complicated techniques, Alexander et al. [46]. have shown a possible slight excess of close case pairs over that expected by chance. On balance, there appears to be little or no clustering at the time of diagnosis and no excess of common exposures. Thus, contacts of a patient with Hodgkin lymphoma have no increased risk of developing the disease or other malignancies.

Other Environmental and Occupational Exposures as Risk Factors
