52 Therapeutic Cytapheresis, Plasmapheresis, and Plasma Exchange in Neoplastic Diseases of the Blood

Janice P. Dutcher

Introduction

Apheresis is defined as the process of removing a specific component of blood and returning the rest of the blood to the donor [1–3]. This is an automated procedure in the case of donors, and allows the collection of greater amounts of the product than could be prepared from removal of a single unit of blood with centrifugation into its components in the laboratory. The apheresis process is currently utilized extensively for collection of platelets, plasma, and less frequently, granulocytes. One donation can amount to a full transfusion, equivalent to the number of platelets, for example, derived from 6 units of whole blood [1–3].

The concept of therapeutic apheresis utilizes the process of automated collection of whole blood or components thereof to improve/reverse/temporize a potentially dangerous clinical situation by removal of blood or blood components that are considered harmful or excessive in amount [4, 5]. The component may be whole blood in the case of symptomatic polycythemia, or leukapheresis or plateletpheresis in situations of dangerous excesses of white blood cells (WBC) or platelets. Plasmapheresis is conducted to remove components of plasma that are contributing to disease. In hematologic malignancies, this is most frequently a clonal immunoglobulin, in the setting of symptomatic hyperviscosity or cryoglobulinemia. Apheresis/red cell exchange has an additional role in certain situations in sickle cell anemia patients with organ- or life-threatening crisis, or in the setting of prior stroke as prevention. Plasmapheresis has an additional role in removal of immunoglobulins in paraproteinemic polyneuropathies, but beyond these entities, most plasmapheresis is done for nonmalignant diseases. Plasmapheresis has also been explored for antibody removal in organ transplantation. There are varying levels of evidence to support its role in nonmalignant diseases, but the clinical scenarios described earlier are supported by clinical evidence in the medical literature [4, 5]. This chapter will focus on the evidence for therapeutic apheresis in neoplastic/hematologic diseases. As treatment for the various hematologic malignancies has improved, the frequency of use of therapeutic apheresis has decreased, but it remains an important therapeutic option in emergent situations, as will be discussed.

The successful application of apheresis has been greatly enhanced over the past 30–50 years by remarkable technological developments. Initial developments, in the 1950s, demonstrated that blood components could be separated from one another in the laboratory by techniques of differential centrifugation, with the heavier components (red blood cells and granulocytes) in the lower levels and platelets and plasma above [6, 7]. Subsequent technology utilized an intermittent technique where, as blood was collected in a conical bowl (Latham bowl), the blood components separated into layers with centrifugation and were visualized over the bowl curvature, with red blood cells (RBCs) at the bottom and plasma on top, and this procedure allowed removal of plasma and could be used to wash red cells. Once the collection was completed, the remainder in the bowl contents was returned to the donor, and the cycle was then repeated. This approach was eventually utilized to separate out and collect platelets and plasma with the return of the red cells and some plasma to the donor. This process was repeated for 6–10 times over the course of 2–4 h to collect sufficient platelets for a transfusion [8]. Simultaneously, the concept of continuous flow centrifugation was evaluated and implemented in studies at the National Cancer Institute in a collaboration between Dr. Emil Freireich and an engineer from IBM, George Judson, whose son was a patient. They developed a prototype machine that allowed collection of excess leukemia cells with continuous return of plasma and red cells to the subject [9]. The continuous flow approach and collection techniques have been refined with numerous improvements in the technology over the past 30 years, which have led to efficient donor collection techniques, and

safer therapeutic collections [5, 10, 11, 12]. While manual collections are still feasible, the majority of therapeutic procedures are conducted using automated cell separators. The notable exception is the use of manual phlebotomy in polycythemia.

Complications of apheresis are related to the procedure itself, including the venipuncture, or placement of a central venous line in the case of high volume plasmapheresis, with occasional problems of venous access (pseudoaneurysm, bleeding, and clotting). All apheresis procedures require that the blood being processed be anticoagulated to avoid clotting in the system, usually with citrate solutions, either acid citrate dextrose (ACD) or citrate-phosphated dextrose (CPD), both of which work by binding calcium. Occasionally in the procedure, with the return of citrated plasma, symptoms of hypocalcemia can develop, including at a minimum circumoral paresthesias, but more seriously irritability or rarely tetany [13]. These symptoms can be ameliorated with oral calcium carbonate lozenges and with slowing down the rate of flow of the procedure. The use of these anticoagulants does not cause systemic anticoagulation in the donor or subject.

Hydroxyethyl starch is used in granulocyte collections, to rouleaux RBCs and allow separation of granulocytes from the red cell layer. Although no long-term toxicities have been noted, acute reactions such as volume expansion and hypersensitivity have been reported [14, 15].

Another side effect that can occur is hypotension due to loss of volume, either from the extracorporeal volume removed in the apheresis tubing and system, or as a result of removal of the components. For therapeutic cytapheresis in patients with neoplastic diseases, some subjects may start with anemia and this can be worsened by the infusion of additional return fluids with hemodilution. Such patients may become symptomatic during or after the procedure.

Cytapheresis

Leukapheresis/Hyperleukocytosis

Acute and Chronic Myeloid Leukemia

Historically, hyperleukocytosis was not an infrequent presentation of acute myeloid leukemia (AML), blastic crisis of chronic myeloid leukemia (CML-BC), and less commonly, the initial presentation of chronic phase of CML. Hyperleukocytosis is defined as a WBC count of greater than 100,000/μL and in acute leukemia, this can be composed almost exclusively of blast cells. The effect of elevated WBC on blood viscosity is a function of the size and shape of the cell involved, causing stasis in the microvascular bed or forming cellular aggregates [16–18]. As the blast cells divide in situ, they may rupture fragile capillary vessels, leading to hemorrhage. These multiple effects of hyperleukocytosis are particularly dangerous in the capillary beds of the lungs and brain, and can lead to early death [19–23]. Metabolic effects from the cells utilizing oxygen in situ can lead to organ hypoxia as well.

Blast cells are the least deformable WBC, so a high WBC count consisting of mostly blasts is the most dangerous situation, and must be rapidly reduced to avoid serious hemorrhagic complications [16–18]. Patients may also have nonhemorrhagic symptoms such as impaired mental status, headache, or respiratory distress. In patients with significant hyperleukocytosis, or those needing a rapid reversal of symptoms, or in whom there are delays in administering systemic therapy, leukapheresis should be considered.

There is a three decade long series of reports demonstrating reduction in blast cell counts with leukapheresis, with improvement of symptoms and the ability to proceed with antileukemic therapy. Several groups have looked specifically at the effect of leukapheresis on early mortality (within the first 7–21 days of treatment) and on long-term survival in patients with leukemia, presenting with very high WBC counts [24–26] (Table 52.1). In a French study, all 53 patients with an initial WBC count of greater than 100,000/μL (median 160,000/μL) underwent leukapheresis, which significantly reduced the WBC count to less than 100,000/μL in 32 patients (60%) and the median WBC at start of chemotherapy for all patients was 85,000/μL [24]. The early death rate was 2 of 53 patients, which is lower than previously published data in such a group of patients [24, 27]. A retrospective study from M.D. Anderson Cancer Center evaluated 146 patients with an initial WBC count of greater than 50,000/ul. 71 of these patients underwent prechemotherapy leukapheresis directed by the treating physi-

Table 52.1 Leukapheresis in AML presenting with hyperleukocytosis

Ref.	No. of patients	Pre-apheresis	Patients	Early death
		Minimum WBC	No. of apheresis	
		Median WBC	No. of no apheresis	Within 7–21 days
Thiebaut et al. [24]	53	100,000/μL	53	2 (4%) within 1st 21 days
		160,000/μL	0	
Giles et al. [25]	146	50,000/μL	71	13%
			75	23%
				Within 1st 14 days
				In multivariate analysis, $p = 0.006$
Bug et al. [26]	53	100,000/μL	25	16%
			28	32%
				Within 1st 21 days

cian and 75 did not [25]. They found a reduction in initial 2-week mortality, 13% vs. 23%, for those who underwent initial apheresis, compared to those who did not. There was no evidence of effect on longer term or overall survival [25]. Similarly, Bug et al. evaluated 53 patients who presented with a WBC count of greater than 100,000/μL, among whom 28 received chemotherapy without leukapheresis and 25 underwent leukapheresis prior to chemotherapy [26]. By day 21, there was a 25% mortality overall. However, there was significantly less mortality among the cohort who underwent leukapheresis compared to those who did not undergo leukapheresis (16% vs. 32%, $p = 0.005$). Again, the overall survival was similar in both groups and apheresis did not impact on the long-term outcome [26]. As has been noted previously, patients with hyperleukocytosis and hyperproliferative AML have a worse long-term prognosis even with a similar remission rate compared with patients presenting with lower WBC counts [27].

These were all retrospective evaluations, and it is therefore difficult to account fully for other biological factors contributing to early death, or to account for factors leading to the initiation of apheresis. Nevertheless, there does appear to be consistency in reducing the risk of early death and allowing these patients to proceed with antileukemic therapy. Single institution series in the era of modern antileukemic therapy continue to recommend initial leukapheresis for symptomatic hyperleukocytosis to allow subsequent definitive systemic treatment, at the same time suggesting that improved supportive care and chemotherapy regimens may reduce the necessity of leukapheresis [28, 29].

In the initial phase of evaluation, it is usually advisable to not administer red blood cell transfusions until the WBC count is lowered to avoid exacerbation of elevated viscosity [30].

Of interest, a meta-analysis review of 20 studies from 1980 to 2012 utilizing leukapheresis for patients with AML and hyperleukocytosis was recently published [31]. This reflects treatment of 1500 patients from 1975 to 2012, and clearly there has been an evolution over time of induction chemotherapy and rapid initiation of treatment and supportive care including urate oxidase. Nevertheless, the interesting finding is that no change in early mortality has been noted over the course of three decades of early intervention for hyperleukocytosis, either with leukapheresis or low dose chemotherapy/hydroxyurea. This analysis likely reflects the actual biology of the disease of these patients, with limited ability to actually change the course. These authors call into question the continued use of initial leukapheresis with the current ability to rapidly initiate antileukemic therapy and supportive care. At the same time, they discuss the limitations of such a report, in terms of confounding bias and retrospective observations with selection bias. Nevertheless this work requires additional discussion and evaluation of an approach that has been accepted for three decades.

Recent guidelines from a working committee of the American Society for Apheresis continue to list hyperleukocytosis with symptoms of leukostasis as a level 1 indication for leukapheresis, but it is advised that the decision to employ leukapheresis should be individualized in the asymptomatic high WBC count setting [5]. Thus, therapeutic leukapheresis is considered an appropriate intervention in patients with myeloid leukemias presenting with extremely high WBC counts. This is done in conjunction with systemic therapy, and usually achieves a rapid reduction in WBC count. It is rarely an ongoing process, since systemic chemotherapy will continue to further reduce the WBC.

Acute Lymphocytic Leukemia

Hyperleukocytosis can occur in patients with acute lymphoblastic leukemia, although less commonly than in myeloid leukemias, and the symptoms are less likely to be severe, since the rheology of the lymphoblasts is such that they are more deformable than myeloid blasts. Therefore, symptoms may not occur until there is an extremely high WBC count in acute lymphocytic leukemia. Again, leukapheresis can produce a rapid reduction in WBC count, but should be accomplished in conjunction with the rapid initiation of systemic therapy. Early studies suggested benefit of this approach in reducing early complications [32, 33]. Prior to effective systemic therapy, studies in children utilized multiple leukapheresis procedures to attempt to "debulk" the disease [32, 33]. More recently, the role of leukapheresis is being called into question in childhood ALL in the era of rapid onset of induction therapy and urate oxidase and other means of supportive care [34].

Sezary Syndrome (Cutaneous T-Cell Lymphoma)

The Sezary syndrome (SS), usually associated with the erythrodermal variant of cutaneous T-cell lymphoma (CTCL), reflects the presence of circulating malignant CD4+ T cells, with characteristic clonal immunophenotypes. These circulating clones are the same as the T-cell clones noted in the cutaneous lymphocytic infiltrates. Given the known sensitivity of cutaneous involvement of CTCL to psoralen and ultraviolet irradiation [35–37], Edelson and colleagues devised the approach of extracorporeal photopheresis (ECP) which is currently utilized particularly in the setting of Sezary syndrome [38]. In this approach, peripheral blood lymphocytes are removed by apheresis, exposed to a photosensitizing agent, and then exposed to ultraviolet A radiation in an extracorporeal circuit, and then returned to the patients [37, 38]. The original system was developed by Therakos, and since that time, additional systems and modifications of the original have occurred over the past 30 years, increasing efficiency, adapting to venous

access needs, and to allow administration to pediatric patients for graft-versus-host disease (see below) [39]. Although a number of systemic agents are available for CTCL, these are usually reserved for more advanced disease, and consensus guidelines in the USA and Europe recommend the utilization of ECP in the erythrodermal/SS stage of disease without bulky nodal involvement, and with the presence of a circulating T-cell clone [37, 39–42]. In carefully selected patients, durable responses to ECP are not uncommon [39]. Systemic therapy has been combined with ECP including bexarotene, interferon-alpha, low dose methotrexate, and, most recently, the monoclonal antibody, alemtuzumab, directed against CD52 [43, 44]. Alemtuzumab appears to be more effective in this entity and current trials are combining this agent with ECP [45, 46]. Histone deacetylase inhibitors have also been approved for relapsed CTCL and are used second-line in SS [37]. Multiple mechanisms have been theorized for the effectiveness of ECP, most notably the induction of apoptosis of the malignant cells, with antigen presentation initiating an immune response against the damaged CD4+ cells in vivo, cytokine production (both pro-and anti-inflammatory), and generation of regulatory T-cells [39, 47, 48]. The appearance of these immunological alterations has led to the use of ECP in chronic graft-versus-host disease (see below). In centers treating CTCL, the majority find a role for ECP in SS/erythroderma that leads to quality skin responses and clinical benefit [5, 37, 39, 42].

Graft-Versus-Host Disease

For more than 20 years, the immunomodulatory technique of extracorporeal photopheresis has been utilized and evaluated in chronic graft-versus-host disease (cGVHD) and it is more commonly being utilized in acute GVHD as well [5, 39, 42]. As experience with the technique and a better understanding of the immunomodulatory effects have developed, there has been a greater interest in utilizing this approach. Whereas early reports described treatment of patients with refractory, steroid-resistant cGVHD [49–52], its use is widely recognized as a second-line approach to cGVHD, allowing rapid tapering of steroids even with the advent of newer immunosuppressive therapies, and its safety profile is excellent [39, 42]. In 2008, Flowers et al. reported the first randomized prospective trial conducted at multiple centers, designed to evaluate the addition of ECP to conventional treatment in terms of total skin score (TSS) after 12 weeks of treatment [53]. Among the 95 patients enrolled, greater than 90% in each arm had extensive cGVHD and half of the patients had been on corticosteroids for more than 1 year. In this randomized trial, there was no statistical difference in TSS at week 12 (15% improvement for ECP containing arm vs. 9% improvement in control arm). However, there were differences in secondary endpoints, suggesting an additive beneficial effect. At week 12, 25% of patients who received ECP in addition to conventional therapy had a >50% reduction in total daily dose of corticosteroids compared to 12.8% of those on conventional therapy alone. Also at week 12, the percentage of patients with a 50% or greater reduction in dose of steroids and at 25% or greater improvement in TSS was higher for the ECP group, 8.3% vs. 0% for controls. Extracutaneous cGVHD in other organ systems that showed greater benefit from the addition of ECP included the eye (30% vs. 7%, $p = 0.04$), oral mucosa (53% vs. 27%, $p = 0.06$), and joints (22% vs. 12%, $p = 0.06$) [53]. In the subsequent decade, numerous studies have been reported, confirming response in cutaneous cGVHD, including complete responses, as well as in those patients with hepatic and mucosal involvement, and two randomized multicenter trials are ongoing [39, 54, 55].

Current apheresis guidelines from Europe and the United States list ECP for steroid-refractory cGVHD [5, 39, 42]. The North American guidelines delineate that the best evidence of response is for cutaneous cGVHD, with acute skin GVHD and non-skin GVHD as lesser recommendations [5]. Immunomodulatory events that have been noted include apoptosis of lymphocytes, with antigen presentation, modulation of dendritic cells, a switch to anti-inflammatory cytokines, and apparent activation of regulatory T-cells to modulate the prior immune response [56–59].

Chronic Lymphocytic Leukemia

Historically, chronic lymphocytic leukemia (CLL) was an appealing target of therapeutic leukapheresis in view of the slow accumulation of mature lymphocytes, and with disease progression defined by accumulation of such cells [60–62]. Essentially, a process of debulking by cellular removal could lead to reductions in WBC count, hepatosplenomegaly, improvement in marrow function, and modest clinical improvement [60, 62]. Additionally, in patients whose disease led to hemolytic anemia with rising WBC counts, leukapheresis has been used to control this complication of the disease by controlling the WBC count. More recently, with the use of rituximab in CLL, occasional reports utilize leukapheresis to reduce the WBC count below 25,000/μL prior to initiating rituximab therapy, to avoid complications when rituximab is administered to patients with high lymphocyte counts. For the most part, symptoms of hyperleukocytosis are exceedingly rare in CLL, given the small size and low viscosity of the cells, and symptoms of leukostasis have only rarely been reported, but at WBC counts in excess of 500,000/μL [63].

There is rarely an indication for leukapheresis in CLL, even with the potential for "debulking." The possible exceptions may be to reduce the WBC count to control hemolysis, should systemic therapy be contraindicated (i.e., contraindication to

or poor tolerance of corticosteroids), and if rapid WBC count reduction is deemed necessary prior to administration of rituximab.

Plateletpheresis/Thrombocytosis

Thrombocytosis is usually an incidental laboratory finding, defined as a platelet count > 450,000/μL. However, platelet counts as high as 1,000,000/μL may be noted in asymptomatic patients. When discovered, differentiation between a reactive thrombocytosis (and the search for other medical diagnoses) versus a clonal myeloproliferative disorder must be sought [64]. The most common causes of reactive thrombocytosis include bleeding, iron deficiency, or inflammatory conditions, including malignancy and autoimmune disorders. Increased normal platelets almost never predispose to thrombosis or vascular complications. However, thrombocytosis associated with myeloproliferative disorders, such as essential thrombocytosis, CML, and polycythemia vera, is often associated with vascular events, including thrombosis and bleeding [59, 60]. Abnormalities of platelet function have also been described in clonal thrombocytosis, possibly contributing to these adverse events [64, 65].

The need to lower the platelet count by pharmacologic measures depends on the risk of bleeding or thrombosis or whether such events have already occurred. Patients with cardiovascular risk factors, age greater than 60 years, or a history of bleeding or thrombosis are at increased risk, and their platelet counts should be controlled with medication and aspirin, if able to tolerate aspirin [64]. Asymptomatic patients with no risk factors remain a dilemma, whether to treat and when [66].

The role of plateletpheresis is relatively limited in clonal thrombocytosis, and has been primarily utilized in patients with acute thrombotic symptoms, such as microvascular ischemic complications that are unresponsive to antiplatelet agents [67–69]. Additionally, there are reports describing prophylactic plateletpheresis in patients at higher risk categories during periods of stress, such as pregnancy [70]. Plateletpheresis is a consideration in other acute clinical situations at risk for thrombosis such as emergency surgery, since this approach provides the most efficient and rapid means of reducing the platelet count, far more rapidly than with medication alone [71, 72].

Erythrocytapheresis (Red Cell Exchange)

In contrast to the management of hyperleukocytosis or thrombocytosis in patients with clonal disorders, when it comes to removal of red blood cells in the management of clonal erythrocytosis (polycythemia vera), the recommendation is to utilize manual phlebotomy, 1 or 2 units at a time. There is no need for an automated procedure with a blood cell separator since the goal is just removal of whole blood and there is no need for a continuous flow approach.

However, red cell exchange, either manually or using a blood cell separator, is recommended in selected cases of sickle cell anemia crises [73]. The hypoxic sickled blood has a higher viscosity than unsickled SS blood, and viscosity is much higher than that of normal hemoglobin A blood. The combination of increased viscosity in small vessel beds and decreased oxygen in sickled red blood cells leads to tissue hypoxia and damage. The goal of an exchange of red cells is to both remove the hemoglobin S cells and infuse red cells with hemoglobin A and normal oxygen carrying capacity. Many patients with SS disease are maintained with simple transfusion or partial manual exchange to maintain a low hemoglobin S percentage of cells to prevent complications, such as recurrences of acute chest syndrome, or frequent pain crises which limit normal life function. Additionally, prophylactic transfusion has been adopted as a preventative measure to decrease the incidence of stroke in SS children with abnormal transcranial Doppler studies [73–76].

However, in serious acute situations, such as acute stroke or severe acute chest syndrome not responsive to simple red cell transfusion, a more aggressive apheresis approach is often indicated [73, 77, 78]. Since acute chest syndrome is the leading cause of death among patients with SS disease, diagnosis and management are critical [77]. Automated exchange is more efficient and there is rapid removal of sickled blood with simultaneous replacement with hemoglobin A red cells. There is often a very rapid clinical benefit. Currently, red cell exchange is considered appropriate in the setting of acute stroke, acute chest syndrome, and as prophylaxis for primary or secondary stroke [73, 77, 78]. Although exchange transfusion is occasionally done in the setting of multiorgan failure and for acute priapism, there are less data demonstrating benefit.

Stem Cell Collection

Over the past 15 years, leukapheresis collection of peripheral blood stem cells from stimulated donors, either autologous or allogeneic, has largely replaced the need for bone marrow stem cell collection. This is discussed in detail in Chap. 55, but suffice it to say that improvements in apheresis technology have led to a much more streamlined, efficient, and comfortable process of collecting stem cells for marrow reconstitution.

Plasmapheresis/Plasma Exchange

Hyperviscosity Syndrome

The clinical syndrome of blood hyperviscosity is observed when there is an excessive amount of circulating immunoglobulin, produced by a clonal plasma cell disorder, most commonly Waldenström's macroglobulinemia (WM) [79, 80]. In WM, there is production of an IgM paraprotein, which is a pentamer and thus very large, and by virtue of its size and intravascular localization, high levels lead to increased serum viscosity [79–81]. Similarly, in IgA myeloma, in which the paraprotein is a dimer, and in myeloma-producing IgG subtype 3, a subtype that can polymerize, high levels can lead to increased blood viscosity [79, 80]. These larger paraprotein molecules remain in the vasculature and do not distribute into the tissues, and thus impact directly on the intravascular blood viscosity [81–83]. Thus, plasmapheresis is highly effective in removing intravascular paraproteins, and a single procedure can result in a significant reduction in the paraprotein level and a significant reduction in serum viscosity [81–84]. This can lead to very rapid resolution of symptoms, and is the initial treatment of choice for patients with symptomatic hyperviscosity. Complete resolution may require 2–3 sessions with each involving a complete plasma exchange.

Symptoms of hyperviscosity may include headaches, blurred vision, retinal hemorrhages, epistaxis, and impaired mentation [84, 85]. Some of the ophthalmologic findings have the appearance of central retinal vein occlusion, and in one study, nine symptomatic WM patients were evaluated by temporal retinal vein blood flow using laser Doppler, before and after plasmapheresis [86]. In this study, plasmapheresis resulted in a significant reduction in serum IgM concentration and serum viscosity (46.5% and 44.7% reductions, respectively) and the appearance of the retinopathy also improved immediately after plasmapheresis. After treatment, the venous diameter decreased in each patient by an average of 15%, and this was accompanied by an average of 55% increase in retinal venous blood speed [86].

It is important to keep in mind that in more recent treatment approaches for WM, with the usage of rituximab as part of the therapy, there is described a phenomenon of rituximab-mediated IgM flare. In patients with already high IgM levels, this can precipitate symptomatic hyperviscosity or other IgM-related complications, such as cryoglobulinemia [84, 87, 88]. Some recommend plasmapheresis for patients with high levels of IgM in anticipation of starting rituximab treatment [84, 88].

Another indication for plasmapheresis is in the management of paraproteinemic neuropathy, which may occur in the context of myeloma, cryoglobulinemia, WM, or monoclonal gammopathy of undetermined significance [5, 89]. This remains a difficult cluster of symptoms and often requires additional treatment of the underlying hematologic disorder.

Cryoglobulinemia

Cryoglobulinemia is a syndrome occasionally observed in hematologic malignancies, and of these, most commonly WM with its clonal IgM protein. Mixed cryoglobulinemia is most commonly associated with hepatitis B and C infections [5]. In this syndrome, the paraprotein or mixed globulins (but including IgM antibodies) precipitate in cooler vascular beds, such as extremities and earlobes, causing damage due to poor perfusion [90]. Again, since the antibodies are largely intravascular, they are amenable to removal by plasmapheresis. Plasmapheresis is efficient in removing these antibodies and is used in all forms of cryoglobulinemia, usually in conjunction with treatment of the underlying illness [5, 84, 91].

The clinical findings are related to poor perfusion due to this precipitation, and may include leg cramps, acrocyanosis, Raynaud phenomenon, ulcers, and purpura. This poor tissue perfusion may lead to infarction or ischemia. Plasmapheresis has been documented to enhance tissue healing after removal of cryoglobulins [92]. One recent analysis of the current literature of plasma exchange in cryoglobulinemia remains critical of this approach, but confirms that the published studies that they reviewed do support the use of plasma exchange, primarily for the bulk removal of the abnormal proteins [93].

ABO Incompatible Stem Cell Transplantation

As discussed in Chap. 56, in the supportive care of transplant patients, transplantation of ABO incompatible grafts can lead to acute and delayed hemolysis and delays, some of which can be quite prolonged, in red cell engraftment. Whereas there are fewer red blood cells in a peripheral blood stem cell collection, there are also more lymphocytes, which may increase the frequency of delayed antibody production by the graft [94]. Apheresis is used to deplete high donor titers of iso-agglutinins, and red cell depletion of the graft can also be accomplished through blood bank reduction techniques. Other approaches are discussed in detail in Chap. 59.

Summary

Apheresis techniques have long been utilized in the management of hematologic malignancies and continue to fulfill a role. Much of the utilization has become specialized to acute situations, when rapid reduction of an abnormal blood component is required for clinical safety and management. The hematologic disease-specific guidelines for utilization presented here are reflective of the hematologic literature and of recent guideline publications. Both the American Society for Apheresis and the British Transfusion Society/British

Society of Haematology have reported guidance for apheresis across the specialties of hematology, nephrology, and neurology [95, 96]. Apheresis remains an important tool in the acute management of some patients with hematologic malignancies and has well-documented benefit in these situations.

Red Cell Transfusions in Patients with Hematologic Malignancies

53

Karen E. King and Paul M. Ness

Introduction

Although the transfusion of red cells is a relatively common clinical event, patients with hematologic malignancies have special requirements for their red cell products and are at increased risk for certain adverse effects of transfusion. This chapter will provide an overview of many of the basic principles of transfusion medicine with a focus on the issues which are relevant to the restoration of oxygen carrying capacity in the patient with a hematologic malignancy.

Red Blood Cell Components

Currently, the clinical practices of transfusion medicine are based on component therapy, in which a unit of whole blood can be separated into red blood cells, platelets, and plasma. Component therapy is advantageous since it provides maximal use of a limited resource, blood. In addition, with the awareness of transfusion-transmitted diseases and other adverse effects of transfusion, the use of component therapy should limit donor exposures and patients should receive only the blood products which they require. Several types of red cell components are available; they are described next and summarized in Table 53.1.

Table 53.1 Red blood cell components and their indications

Red cell component	Characteristics	Clinical indication
Whole blood	High volume	Replacement of combined red cell and volume deficit (massive blood loss)
	Good flow	
Red blood cells	Lower volume	Replacement of red cell deficit
	Higher hematocrit (65–80%) Good flow with AS-1	
Leukocyte reduced red blood cells	Less than 5×10^6 white cells per unit	Prevention of febrile, nonhemolytic transfusion reactions
		Prevention of alloimmunization
		Prevention of CMV transmission
Washed red blood cells	Plasma depleted	Prevention of severe, allergic transfusion reactions
Frozen red blood cells	Storage for at least 10 years	Storage of rare donor units
	Plasma depleted	

Whole Blood

Due to the predominant use of component therapy and the difficulty in predicting the need for whole blood, most blood banks do not maintain an inventory of whole blood. Obviously, for use in the setting of massive blood loss, a large amount of whole blood would be optimal. Since this inventory is not usually available, red cells in combination with a volume expander should be used. If the volume loss is moderate in amount, a crystalloid, such as normal saline, can be used. Crystalloids have the advantages of being sterile and inexpensive. For more extensive volume replacement, colloids such as albumin [1, 2] and starch solutions are available. These preparations are much more expensive than crystalloids; however, they are preferable over plasma in that they carry no risk of disease transmission. After receiving the equivalent of approximately one blood volume, the

patient is at risk for a dilutional coagulopathy. At this point, plasma should be administered to replace coagulation factors and platelets should be given [3]. It should be remembered that platelets are suspended in plasma; when giving both platelets and plasma, one can give less plasma taking into account the plasma contained in the platelet product. With the use of platelet additive solutions, these products will contain less plasma than routine platelets.

A unit of whole blood has a volume of approximately 510 mL, consisting of 450 mL of whole blood and 63 mL of an anticoagulant–preservative solution. When this product is collected in CPDA-1, it has a shelf life of 35 days. During the first 24 h of storage, the platelets become nonfunctional [4]. In addition, there is a gradual decrease in the activity of coagulation Factors V and VIII. By day 21 of storage, Factor V levels range from approximately 20 to 100%. At this same time, Factor VIII levels range from about 15 to 50% [5]. The other coagulation factors are stable in stored whole blood.

Whole blood simultaneously replaces both red cells and plasma. Thus it can provide improved oxygen carrying capacity, colloid osmotic pressure, volume replacement, and many of the plasma coagulation factors. Whole blood is appropriately used for massive blood loss such as in trauma or in surgery with extensive blood loss. Although whole blood is not likely to be of major use for patients with hematologic malignancies, there is increased interest among surgeons and treaters of massive hemorrhage for the use of whole blood in massive transfusion protocols; although the platelets in whole blood may have shorter survival than platelets stored at room temperature, whole blood may be more effective in providing rapid hemostatic improvement.

Red Blood Cells

Red blood cells are commonly prepared from a unit of donor whole blood following the removal of most of the plasma [6], which may be achieved by either sedimentation or centrifugation. The removed platelet-rich plasma may then be used for the preparation of another component, such as fresh frozen plasma or platelets. Red blood cells can also be produced by apheresis techniques, in which up to 2 units can be harvested from one donor at a single donation [7]. A unit of red cells has an average volume of 300 mL and has a hematocrit ranging between 65 and 80%. An additive solution, such as AS-1 or AS-3, is often used to extend the storage life to 42 days. The additive solution will decrease the hematocrit, so that the product will have flow properties similar to whole blood [8].

Red blood cells are indicated for the improvement of oxygen carrying capacity especially if it is an isolated problem. With their relatively high hematocrit, red blood cell units can efficiently provide red cells in a small volume. They are the product of choice in the setting of chronic anemia from bone marrow failure. Red blood cells are especially helpful in patients with cardiovascular compromise who may not tolerate the additional volume of whole blood.

Leukocyte Reduced Red Blood Cells

An average unit of red blood cells contains approximately 2×10^9 to 5×10^9 leukocytes [9]. Several methods have historically been used to reduce the leukocyte content of a unit of red cells; these methods have varied in their capacity for leukocyte reduction. All leukocyte reduced red cell products must retain at least 85% of their original red cell content and their total white cell content must be less than 5×10^6 [6].

Advanced leukocyte removing filters have been developed to reduce the leukocyte content of red cells. These “third generation” filters use two mechanisms: a barrier on the basis of pore size and retention by adsorption; thus, they are sometimes called leukocyte adsorption filters [10]. Several studies have evaluated the efficacy of these filters and have found that they can reliably reduce the white cell content of a unit of red cells by as much as 99.9%, which is a 3 log reduction [11–15]. Prestorage leukocyte reduction has the additional advantage of preventing cytokine accumulation. Both whole blood derived red cells and red cells harvested by apheresis can be leukocyte reduced.

There are several indications for the use of leukocyte reduced red cells, including the prevention of febrile, nonhemolytic transfusion reactions, the prevention of alloimmunization to HLA antigens (especially for patients who will require future platelet transfusions or a possible progenitor cell transplant), and the prevention of cytomegalovirus (CMV) transmission. In addition, there is evidence that transfusion-associated immunomodulation is mediated by contaminating white cells in blood products and these potential complications would be prevented with the use of leukocyte reduced blood products [16]. Many hospitals have moved to a universal leukocyte reduction policy, although some hospitals only provide leukocyte reduced blood for patients meeting specific indications. We believe most patients with hematologic malignancies will benefit from leukocyte reduced red cells.

Washed Red Blood Cells

Washed red blood cells are prepared by either manual or automated washing with isotonic saline. Washing red cells removes plasma and some of the leukocytes and platelets. This procedure can be repeated several times depending on the indication and the degree of plasma removal necessary, but there is red cell loss with each washing. Since the washing

procedure is performed in an open system, washed red cells must be transfused within 24 h of initiation of manipulation.

Since washing primarily removes the plasma proteins from red cells, the main indication for washed red cells is the prevention of severe allergic transfusion reactions. These severe allergic transfusion reactions are felt to be due to recipient antibodies directed against donor plasma proteins. Washing is indicated when a patient has recurrent severe allergic reactions that are refractory to antihistamine treatment. Patients with IgA deficiency and antibodies to IgA can have anaphylactic reactions to plasma containing IgA [17]. These patients may tolerate red cells which have undergone several washes [18] or they may require products from IgA deficient donors [19]. It has been suggested that patients with paroxysmal nocturnal hemoglobinuria (PNH) receive washed red cells. Since the red cells in PNH are more sensitive to complement, it was hypothesized that washing removes the complement and the washed red cells would be less likely to exacerbate the hemolytic process of PNH [20]. One retrospective study has shown that patients with PNH do not require washed red cells [21, 22].

Frozen Red Blood Cells

Red blood cells may be frozen using glycerol as a cryopreservative. The concentration of glycerol used in the freezing procedure depends on the rate and the temperature of freezing [23, 24]. Other contaminating cellular elements are destroyed in the freezing process, except for a small number of lymphocytes [25]. Thus, frozen red cells contain a decreased number of leukocytes. When the cells are needed for transfusion, the unit is thawed and washed repeatedly with progressively less hypertonic saline solutions to remove the glycerol from the cells. If the process is not performed appropriately, hemolysis will occur upon transfusion. The repeated washings remove associated plasma and any other debris. The red cells are resuspended in isotonic saline with glucose. Once thawed, these red cells have been shown to be more fragile than conventional liquid-stored red cells [26]. Frozen red cells may be stored for at least 10 years; however, they have been shown to have good viability even after longer periods of storage. Once thawed, the product is an open system and will outdate in 24 h.

This process is expensive and the indications for this product are limited. The major indication for frozen red cells is for preservation of rare donor units required by patients with unusual phenotypes who have developed multiple alloantibodies. These patients should be encouraged to donate autologously when they are clinically able and have their cells frozen for future needs. Autologous blood may also be frozen when a surgery date is postponed or if more blood is needed than can be donated within the time limitations of liquid storage (35–42 days). Frozen red cells have been used in patients with aplastic anemia who are awaiting bone marrow transplantation, since frozen cells have shown the least adverse effect on subsequent graft survival [27]. Leukocyte reduced red cells have replaced frozen red cells for this indication. Occasionally, there are patients with severe, repeated febrile nonhemolytic transfusion reactions who fail medications and other forms of leukocyte reduction, and these patients may have uneventful transfusions when given frozen red cells.

Modifications and Attributes of Red Blood Cell Products

Red cells can have additional modifications or attributes which meet the special needs of patients with hematologic malignancies.

Gamma Irradiation

Gamma irradiation is used to prevent transfusion-associated graft-versus-host disease. This disease occurs when immunocompetent lymphocytes are transfused which are capable of engrafting and reacting against the host tissues [28]. This entity is of concern in any patient who is severely immunocompromised. Transfusion-associated graft-versus-host disease is also a risk in situations of partial HLA identity between the donor and the recipient [29, 30]. Because transfusion-associated graft-versus-host disease is associated with significant mortality, prevention is critical. Thus, gamma irradiation is recommended for all cellular products that are given to patients at risk for transfusion-associated graft-versus-host disease, including those with congenital immunodeficiency syndromes, recipients of units from relatives, recipients of HLA selected products (either by typing or crossmatching of platelets), and bone marrow or progenitor cell recipients. It has been shown that patients with chronic lymphocytic leukemia (CLL) who are undergoing treatment with fludarabine are at risk for transfusion-associated graft-versus-host disease [31, 32]. Additionally, other patients receiving fludarabine therapy, such as those with systemic lupus erythematosus, are also at risk for transfusion-associated graft-versus-host disease [33]. Some oncology centers routinely gamma irradiate all cellular blood components to avoid the often fatal complications of transfusion-associated graft-versus-host disease.

Gamma irradiation inactivates immunocompetent lymphocytes, preventing proliferation of transfused T lymphocytes. It is recommended that a minimum of 25 Gy be delivered to the center of the irradiation field with at least 15 Gy delivered to all parts of the blood

component [6, 34]. Although this dosage should not affect the function of the red cells, irradiation damages red cell membranes and does have an effect on the overall viability, requiring a shortened outdate. Due to the devastating repercussions of this disease, the lack of effective treatment, and the relative ease of irradiation, prevention is the focus and most centers err on the side of irradiating for less than well-documented indications. Gamma irradiation does not produce a leukocyte reduced product or a CMV-safe product.

Cytomegalovirus Seronegative Products

Cellular blood products can be tested for antibodies against CMV by a variety of methods. Products that are seronegative for CMV are recommended in situations in which immunosuppressed patients would be at risk for getting primary CMV infection. Patients at risk for transfusion-transmitted CMV include CMV seronegative patients undergoing bone marrow transplantation from a CMV seronegative donor and CMV seronegative patients with AIDS [35, 36].

Since this virus is associated with leukocytes, it has been proposed that leukocyte reduced blood products would be useful in the prevention of CMV transmission. Studies have shown that leukocyte reduction by filtration is helpful in preventing CMV transmission [37–39]. One study has shown that filtration can remove any detectable CMV DNA from previously positive red cell products even following amplification by the polymerase chain reaction (PCR) technique [40]. A randomized study comparing seronegative blood products and leukocyte reduced products using bedside filters has shown that these products are equivalent in preventing CMV infection in patients undergoing marrow transplantation [41].

Controversy exists in both the literature and in clinical practice regarding the role of leukocyte reduced blood products in clinical situations requiring CMV-safe blood [42, 43]. Currently, many institutions are using leukocyte reduced blood products when CMV seronegative products are not available. Other institutions are routinely using leukocyte reduced and CMV seronegative products as equally CMV safe. When leukocyte reduced red cell products are used to prevent CMV transmission, the red cells must have less than 5×10^6 leukocytes.

Special Clinical Situations for Red Cell Transfusion

Although most of the principles of transfusion medicine are applicable to patients with hematologic malignancies, there are a few unique situations which should be noted.

Indications for Red Cell Transfusion

Due to the risks of transfusion, the indications for transfusion should be clear and unnecessary transfusion should be avoided [44]. Frequent reference is made to a transfusion trigger or a suggested minimum hemoglobin or hematocrit level at which red cells are transfused. Obviously, the need for red cells or increased oxygen carrying capacity depends upon numerous factors which are specific to the individual patient [45]. The etiology of the low hemoglobin is crucial in this evaluation. Patients with chronic anemias which have been well compensated will tolerate a more severe degree of anemia than the patient who has suffered an acute blood loss. The patient's underlying health condition is also important in deciding when to transfuse. A young and relatively healthy person with good cardiovascular function will tolerate a lower hemoglobin than an older patient with impaired cardiac function [46, 47].

Previously, it was felt that perioperative patients should have a hemoglobin of at least 10 g/dL. A National Institutes of Health Consensus Development Conference on perioperative red blood cell usage has recommended that the transfusion trigger be changed to a hemoglobin of 7 g/dL [48]. Currently, there is no single transfusion trigger that applies to all patients. In patients with hematologic malignancies, the hematocrit level should be maintained to alleviate the symptoms of anemia and will vary with the patient's age and other medical problems. A landmark study by Carson et al. in hip fracture patients demonstrated no advantages in providing more red cells by liberal triggers of 8–9 g/dL than conservative triggers of 9–10 g/dL [49]. Similar studies have now been performed in many other medical and surgical settings with similar results showing no advantage to liberal red cell transfusion practices [50]. A pilot study in patients with acute leukemia also showed no advantage to liberal red cell transfusion practices, and hopefully other studies will be performed to confirm these results in patients with other hematologic malignancies [51]. Although most studies have focused on other patient populations, it is reasonable to extrapolate that patients with hematologic malignancies will tolerate hemoglobin levels between 7 and 10 g/dL [52]. More liberal, higher transfusion thresholds may be important in patients with underlying cardiac disease [53]. A pilot study in patients with cardiac ischemia and anemia suggested that patients had better outcomes with conservative triggers of 9–10 g/dL [54] and a larger adequately powered study is now underway to answer this critical question.

The measured response to a transfusion varies depending upon the patient. It is generally accepted that transfusion of 1 unit of red cells should increase the hematocrit by 3% or the hemoglobin by 1 g/dL. The FDA requires 75% of the transfused red cells in the circulation at 24 h, when evaluating collection systems and anticoagulant–preservative solutions.

Hyperviscosity

Hyperviscosity becomes problematic in two clinical situations involving patients with hematologic malignancies. Patients with multiple myeloma and plasma cell dyscrasias can have difficulties due to hyperviscosity. These patients are frequently anemic and it is difficult to determine if their symptoms of poor oxygenation are due to hyperviscosity or their severe anemia. A relative serum viscosity measurement should be determined; many patients will become symptomatic at a relative serum viscosity above 4. A patient with hyperviscosity will not tolerate red cell transfusions unless their viscosity is first reduced. In this situation, plasmapheresis can be performed to reduce the amount of circulating paraprotein which is creating the hyperviscosity [55, 56].

Hyperleukocytic leukostasis occurs in patients with markedly elevated white cell counts, frequently due to acute myelogenous leukemia. Although white cells do not usually contribute significantly to whole blood viscosity, hyperleukocytosis with malignant white cells can have associated hyperviscosity since the malignant white cells may not have normal flow characteristics. These patients frequently present with hyperleukocytosis, anemia, and evidence of poor perfusion which may be due to leukostasis or to infiltration of blood vessels by leukemic cells. In these patients, the white cell count should be reduced by leukocytapheresis before the patient is given red cell transfusions [52]. If leukocytapheresis technology is not available, the patient's white cell count can be reduced by manual whole blood exchange or chemotherapy [57, 58].

Bone Marrow and Progenitor Cell Transplants

Patients who are undergoing bone marrow or progenitor cell transplantation have several special needs. They will be transfusion dependent until engraftment occurs. All bone marrow transplant patients should receive irradiated red cells to prevent the development of transfusion-associated graft-versus-host disease. In addition, CMV negative patients who receive autologous bone marrow transplants, autologous peripheral stem cells, or CMV negative allogeneic transplants should receive CMV-safe blood products.

In cases of bone marrow transplantation in which there is a major ABO incompatibilty (a group O patient given bone marrow from a group A, group B, or group AB donor), the marrow infusion can be depleted of contaminating red cells. When engraftment occurs, the transplanted marrow will begin to produce red cells with A and/or B substance and the recipient may still be producing ABO antibodies. In this situation, the new red cells may be hemolyzed by the ABO antibodies. This period of hemolysis may be brief or it may last for an extended period of time. If transfusions are required during this period, the patient should be given group O red cells. Of course, these cells should be irradiated and CMV seronegative cells may also be indicated.

Minor ABO incompatibilty in bone marrow transplants occurs when group O donor marrow is transplanted into a non-group O recipient. Plasma should be removed from the marrow product to reduce the amount of incompatible ABO antibodies given to the recipient. However, as in the case of solid organ transplants, passenger lymphocyte syndrome may occur and contaminating lymphocytes are capable of producing anti-A and anti-B. In many of these cases, hemolysis may occur [59]. If transfusions are required, irradiated group O red cells should be given.

Autoimmune Hemolytic Anemia

Autoantibodies directed against red cells occur frequently in patients with hematologic malignancies. Patients with CLL are notorious for the development of red cell autoantibodies, often with an autoimmune hemolytic anemia. It has been estimated that 10–20% of patients with CLL will develop red cell autoantibodies at some time during the course of their disease. The mechanism of autoimmune hemolytic anemia in patients with CLL is controversial. Some believe that these patients have an imbalance in their T helper and T suppressor lymphocyte subsets. One study showed that the neoplastic clones of CLL were capable of in vitro production of monoclonal antibodies which could bind red cells. This study suggests that the autoantibodies may actually be produced by the malignant clonal B cell population [60]. The use of fludarabine in the treatment of CLL has been associated with the development of severe autoimmune hemolytic anemia. The mechanism of this association is unclear, but it has been proposed that fludarabine results in a further disruption of the T lymphocyte subsets [61, 62].

Red cell autoantibodies are detected in the laboratory by the direct antiglobulin test (DAT, direct Coombs test). This test can detect the presence of IgG and/or complement on the surface of red cells. The indirect antiglobulin test (IAT, indirect Coombs test) may reveal a panagglutinin in the serum of patients with an autoantibody. Warm autoimmune hemolytic anemia is usually due to IgG antibodies which react at 37 °C and may or may not fix complement. Thus, in warm autoimmune hemolytic anemia, the DAT will reveal IgG and/or complement on the red cells. Cold autoantibodies (cold agglutinin syndrome) are usually IgM antibodies which react at 4 °C and are able to fix complement. In cold agglutinin syndrome, the DAT will show the presence of complement on the red cell surface with an absence of IgG.

Clinically, it is important to determine if a patient with a hematologic malignancy and red cell autoantibodies is

actually hemolyzing. The diagnosis of autoimmune hemolytic anemia requires both the laboratory features and the clinical evidence of hemolysis. Patients with autoimmune hemolytic anemia may require red cell transfusions. It is important to rule out the presence of underlying red cell alloantibodies which may be masked by the panagglutinin, since alloantibodies may complicate transfusion therapy. Even after underlying alloantibodies have been excluded, the panagglutinin will result in incompatible crossmatches. These patients should be transfused with red cells which lack any alloantigens for which the patient has corresponding underlying alloantibodies or phenotypically matched red cells [63]. Use of leukocyte reduced red cells is recommended to minimize the occurrence of febrile nonhemolytic transfusion reactions which would confound an already difficult clinical situation. We recommend that these patients be transfused when they clinically require red cells, with the understanding that the transfused cells will have a shortened survival comparable to the patient's own red cells.

Erythropoiesis Stimulating Agents

Erythropoietin is a hormone which is capable of promoting the proliferation and maintaining the viability of erythroid progenitor cells. This hormone is produced predominantly by renal peritubular interstitial cells and also by the liver [64–66]. In 1985, the erythropoietin gene was cloned and expressed [67, 68]. Erythropoiesis stimulating agents, including recombinant erythropoietin and the closely related recombinant darbepoetin, have been used in the treatment of anemias secondary to malignancies, including multiple myeloma and myelodysplastic syndromes [69, 70]. In responsive patients, erythropoiesis stimulating agents can effectively alleviate anemia and reduce transfusion requirements [71, 72]. Due to concerns about erythropoiesis stimulating agent therapy being associated with tumor progression, venous thromboembolism, and/or survival, an update committee of the American Society of Hematology/American Society of Clinical Oncology has reviewed the literature related to erythropoiesis stimulating agent use in adult patients with cancer [72]. Their revised recommendations include weighing the risks and benefits of erythropoiesis stimulating agents with the risks and benefits of transfusion for the specific patient undergoing myelosuppressive chemotherapy who has a hemoglobin <10 g/dL. If used, erythropoiesis stimulating agents should be used at the lowest dose which successfully increases the patient's hemoglobin to a level where transfusion is no longer required. For patients who do not respond to therapy, the erythropoiesis stimulating agent should be discontinued after 6–8 weeks.

Red Blood Cell Preservation and Storage

Whole blood and red cell components are stored in a liquid state at a temperature between 1 and 6 °C. Red cells are stored in an anticoagulant–preservative solution with or without an additive solution. Most anticoagulant–preservative solutions contain trisodium citrate, citric acid, dextrose, and phosphate (ACD, CPD, and CP2D). The appropriate storage time or shelf life for red cells is based on the FDA criteria that 75% of the transfused cells should be in circulation 24 h after the transfusion. Red cells stored in a standard anticoagulant–preservative solution, such as ACD, CPD, and CP2D, have a shelf life of 21 days. CPDA-1 contains adenine and blood collected in CPDA-1 has a shelf life of 35 days. Additive solutions, such as AS-1 or AS-3, contain additional dextrose, adenine, and sodium chloride. AS-1 also includes mannitol. Red cells stored with an additive solution may be stored for up to 42 days [6].

Adenosine Triphosphate

It has been shown that adenosine triphosphate (ATP) levels in stored red cells correlate with the viability of the red cells following transfusion. As the red cell ATP level drops during storage, the red cells undergo changes in shape from disc to sphere followed by an increase in cellular rigidity. There is also a loss of cell membrane with decreased volume [73]. Dextrose in the preservative solution is crucial in supporting the glycolytic pathway for continued generation of ATP. The additional adenine in CPDA-1 and in the additive solutions provides substrate for the formation of ATP. Although other factors may also influence the overall viability of red cells following storage, ATP remains the best defined factor as an indicator of acceptable red cell survival without performing red cell survival studies.

2,3-Diphosphoglycerate

2,3-Diphosphoglycerate (2,3-DPG) plays a crucial role in the delivery of oxygen from the red cell by influencing the position of the oxygen dissociation curve. With high 2,3-DPG levels, more oxygen is released at the same PO2. With lower red cell 2,3-DPG levels, there is greater affinity of hemoglobin for oxygen and less oxygen is delivered to the tissues. Although 2,3-DPG levels decrease in stored red cells, there is restoration of these levels in vivo following transfusion. In fact, studies have shown that over 50% of 2,3-DPG is restored within the first 24 h following transfusion. Based on these observations, blood at any point in its permissible storage period is acceptable for patients with hematologic malignancies [74].

Byproducts of Red Cell Storage

Due to the presence of citrate in the anticoagulant–preservative solutions, the possibility of citrate toxicity must be considered in situations of massive transfusion. This clinical entity rarely occurs, but the risk is greater in instances of impaired liver function, since the liver metabolizes citrate. The danger of infusing high volumes of citrate over a short period of time is due to the chelation of calcium by citrate. Consequently, the patient's ionized calcium level may drop and lead to cardiac arrhythmias. Usually, this adverse effect can be treated by slowing the infusion rate or by the administration of calcium gluconate. If citrate toxicity occurs and calcium supplementation is required, it is recommended to follow ionized calcium levels, since hypercalcemia can also lead to cardiovascular sequelae [75].

With prolonged storage of blood, the level of extracellular potassium gradually increases. Since the sodium–potassium pump is relatively nonfunctional at red cell storage temperatures, the intracellular and extracellular potassium equilibrate resulting in an increase in the extracellular potassium. This situation is exacerbated by any hemolysis which occurs during the storage period. The plasma potassium concentration of red cells stored in CPDA-1 is approximately 78 mEq/L on day 35 as compared to 5 mEq/L in freshly collected blood [76]. Of course, the total plasma volume of a unit of red cells is about 70 mL, yielding a total potassium load of only 5.5 mEq in each unit of red cells. The vast majority of patients are able to tolerate this increase in potassium; however, in some situations, this elevation in potassium may cause cardiac complications. In patients with renal failure and hyperkalemia or in patients with very low blood volumes, the increased potassium may be a problem. In this situation, fresher units should be selected, or if not available, an older unit of red cells may be washed.

During the storage process, microaggregates of platelets, white cells, and fibrin can form. These microaggregates may measure up to 200 μm in diameter [77]. The clinical impact of these microaggregates remains controversial. Some studies have shown that in massive transfusion, the degree of hypoxia is related to the amount of blood transfused, thus implicating microaggregates as the cause of the pulmonary dysfunction [78, 79]. Others have argued that in cases of traumatic shock, massive transfusion, and pulmonary dysfunction, microaggregates may be contributory to the hypoxia, but their role is relatively minor [80]. Animal studies have been unable to confirm the role of microaggregates in this clinical situation [81]. Some have suggested the use of microaggregate filters when more than 5 units have been transfused [82], but one should be aware that these filters slow the rate of infusion.

The 1960s brought about the development of the plastic blood bag for the storage of red cells. This was a major innovation and a significant step toward the current trend of component therapy. These plastic bags are made from polyvinylchloride containing the plasticizer di(2-ethyl)phthalate (DEHP). DEHP is lipophilic and is known to leach out of the bag during storage [83, 84]. Since the development of this bag, there has been much concern about its safety. Numerous animal studies have shown significant toxicity ranging from a shock lung-like picture to teratogenicity [85]. The AABB issued a statement in June 2003 acknowledging the risks of the plasticizer, DEHP, in polyvinylchloride blood bags, and recognizing the need for development and availability of newer plasticizers for blood bags [86]. Other potential materials have been proposed for use in blood storage bags, including polyvinylchloride plasticized with butyryl-*n*-trihexyl-citrate (BTHC). The BTHC undergoes less leaching and the bags have good red cell recovery [87, 88].

Adverse Effects of Red Cell Transfusions

There has been an ongoing increased awareness of the potential adverse effects of blood transfusions. Although this heightened awareness was initially stimulated in large part by transfusion-transmitted human immunodeficiency virus (HIV), there are several other potential deleterious effects of transfusion which can have devastating implications. These adverse effects are described next and are shown in Table 53.2.

Table 53.2 Adverse effects of red cell transfusions

Adverse effect
Transfusion-associated circulatory overload
Iron overload
Transfusion reactions
Hemolytic transfusion reactions
Septic transfusion reactions
Febrile nonhemolytic transfusion reactions
Allergic transfusion reactions
Transfusion-related acute lung injury
Transfusion-transmitted diseases
Hepatitis B
Hepatitis C
Cytomegalovirus
Human immunodeficiency virus
Other microbiologic agents
Transfusion-associated graft-versus-host disease
Alloimmunization
Antibodies to red cell antigens
Antibodies to neutrophil antigens
Antibodies to HLA antigens
Immunomodulation

Transfusion-Associated Circulatory Overload

Previously referred to as volume overload, transfusion-associated circulatory overload is a problem in patients with cardiovascular compromise. This complication can result in congestive heart failure and pulmonary edema. Patients should be followed closely and given diuretics if this problem arises. The red cells should be infused at a slow rate or in smaller volumes.

Iron Overload

Iron overload can occur in chronically transfused patients. Each unit of red cells contains 200–250 mg of iron. Following approximately 100 units of red cells, the problem of iron accumulation may occur. Iron will accumulate within the mitochondria which ultimately may affect function in the heart, liver, and endocrine glands. Patients with hematologic malignancies who have had extensive red cell transfusion support are at risk for iron overload. Iron chelation therapy should be considered to reduce their iron burden and potentially improve outcome and survival [89, 90]. Currently, deferoxamine and deferasirox are approved for use in the USA.

Transfusion Reactions

Acute hemolytic transfusion reactions are the most severe transfusion reactions and they have potentially devastating outcomes. These reactions are mediated by antigen–antibody interaction. The most severe hemolytic transfusion reactions occur when ABO incompatible blood is transfused. Clinically, patients develop fever, chills, nausea, and back pain. Patients have hemoglobinuria, hemoglobinemia, and hypotension progressing to shock. The process leads to complement activation, initiation of the coagulation system, and release of bradykinin, catecholamines, and vasoactive amines. Disseminated intravascular coagulation develops; in surgical patients, the coagulopathy may be the first indication of the transfusion reaction. Treatment of these reactions includes supportive care, blood pressure support, fluids and diuretics to maintain renal perfusion, and dialysis if acute renal failure develops.

Septic transfusion reactions are usually related to a platelet product and not a red cell component. Since platelets are stored at room temperature for up to 5 days, they are particularly susceptible to bacterial contamination. When red cells are involved in a septic transfusion reaction, the organisms are usually Yersinia enterocolitica or the psychrophilic pseudomonads. Yersinia enterocolitica is a gram-negative bacillus that clinically causes enterocolitis. The growth of the organism is enhanced by the presence of iron and it grows well at 4 °C. The organism rapidly multiplies after 21 days of storage, potentially giving older units very high bacterial concentrations. Thus, red cells provide an ideal environment for this organism. *Pseudomonas putida* and *Pseudomonas fluorescens* have also been implicated in septic transfusion reactions. These organisms are gram-negative rods and they grow well at 4 °C [91, 92].

Febrile nonhemolytic transfusion reactions clinically occur when a patient experiences a rise in temperature of 1 °C or more reaching an oral temperature of greater than or equal to 38 °C or chills and rigors in association with a transfusion and without any other explanation. These reactions are generally felt to be due to leukoagglutinins or recipient antibody against donor leukocytes [93–95]. Patients with recurrent febrile, nonhemolytic transfusion reactions are given leukocyte reduced blood products [96, 97]. In many cases, leukocyte reduced blood products are effective in preventing further febrile transfusion reactions [98]. Some patients, however, continue to have reactions despite leukoreduction; in fact, one study has shown that in patients receiving platelet transfusions, leukoreduction had limited efficacy in the prevention of febrile reactions [99]. There has been much interest in the role of cytokines in the pathogenesis of febrile transfusion reactions which cannot be attributed to leukoagglutinins [100]. Many reactions to platelets have now been shown to be due to the cytokines remaining in the plasma derived from contaminating leukocytes in the product [101]. Prestorage leukocyte reduction can prevent the production and accumulation of cytokines in stored products.

Mild allergic transfusion reactions or urticarial reactions present with cutaneous symptoms of itching and hives. These reactions are often treated with antihistamines, but with limited efficacy. If the reactions become more severe in nature, washed blood products may be helpful in further prevention. These reactions are felt to be due to antibodies in the recipient against donor plasma proteins.

Severe allergic reactions or anaphylactic reactions present clinically with bronchospasm, respiratory distress, and vascular instability leading to shock and loss of consciousness. Treatment includes supportive care and epinephrine. Steroid therapy may be useful. These reactions are often felt to be related to recipient antibodies against donor plasma proteins. These reactions also occur in patients who are IgA deficient and have antibodies to IgA. It is recommended that patients with IgA deficiency and antibodies to IgA receive blood products from IgA deficient donors or washed red cells.

Transfusion-related acute lung injury (TRALI) occurs in patients who develop new onset of acute lung injury with hypoxemia during or within 6 h of a transfusion. Clinically, patients present with respiratory distress, hypoxia, hypotension, fever, and bilateral pulmonary edema [102]. Patients should have no evidence of left atrial hypertension

and circulatory overload or any other temporally associated alternative risk factor for acute lung injury. It is felt that these reactions are mediated by the infusion of HLA- or granulocyte-specific antibodies present in the transfused product which reacts with the recipient's antigens [103]. Because these antibodies are associated with multiparous females, the exclusion of female plasma donors is becoming more prevalent [104]. An alternate pathogenesis involves the oxidation of membrane lipids by donor leukocytes which may prime the recipient neutrophils, such that a second stimulus can cause the release of vasoactive mediators [105]. Treatment consists of supportive care, including blood pressure and respiratory support.

Transfusion-Transmitted Diseases

As the number of documented transfusion-transmitted diseases has grown, donor testing has expanded in an effort to preemptively identify these pathogens and prevent transfusion [106]. Despite the routine testing of all blood products for hepatitis B surface antigen (HBsAg), antibodies to hepatitis B core (anti-HBc), hepatitis B virus nucleic acid amplification testing (HBV NAT), antibodies to hepatitis C virus (anti-HCV), and hepatitis C virus nucleic acid amplification testing (HCV NAT), transfusion-associated hepatitis can still occur. The risk of transfusion-associated hepatitis B was estimated to be 1 in 220,000 components transfused in 2003 [107]. The incidence of transfusion-associated hepatitis C has been greatly reduced with the development of better testing. The estimated risk of hepatitis C virus transmission by screened blood was 1 in 1,800,000 units transfused in 2005 [108]. More recent publications suggest that the risk of HBV and HCV are less than 1 in 1,000,000 [109].

Transfusion-associated AIDS was first reported in late 1982 [110]. Serologic testing for HIV became available in 1985 [111]. Currently, blood is tested for HIV serology, including HIV-1 and HIV-2 antibodies, and by HIV-1 nucleic acid amplication testing. The estimated risk of HIV transmission from screened blood was 1 in 2,300,000 units transfused in 2005 and the risk continues to fall with current practices [108].

CMV is a herpes virus. It is a double stranded, DNA virus, capable of remaining latent in tissues following primary disease. Clinical disease due to this virus may be on the basis of primary infection, reactivation, or reinfection. CMV is felt to be harbored within white cells. Clinical CMV disease can be quite variable; however, primary disease is usually more severe than reactivation. Although there have been significant improvements in pharmacologic approaches to the prevention of CMV, this infection remains a significant source of disease and mortality in recipients of allogeneic progenitor cell transplants [112]. In patients at risk for CMV infection, CMV-safe blood products should be administered. Because of the presence of the virus in white cells, leukoreduction has become an alternative approach to seronegative blood products for some patient populations.

Other infectious risks continue to be of concern for transfusion recipients. Donor blood is now tested for West Nile Virus as a result of a transfusion epidemic that was documented [113]. Babesia transmission has been noted from donors in New England and testing programs are being studied [114]. Dengue virus is a problem in Puerto Rico [115] and donor blood in the US is now tested to prevent transfusion transmission of Zika [116].

Although pathogen inactivation is now available for platelets and plasma in the US, there are no licensed red cell products that have undergone pathogen inactivation processing. Two commercial systems are in development and will undergo clinical trials in the near future [117]. A recent study of one system using riboflavin and UV light was demonstrated to reduce transfusion-transmitted malaria in an endemic area of Africa [118]. In addition to eliminating most of the infectious risks of viruses, bacteria, and parasites, evolving pathogen inactivation systems will also inactivate white cells in blood components, eliminating the need for gamma irradiation and may also reduce alloimmunization to platelets [117].

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease is a virtually fatal complication of transfusion. The disease occurs when immunocompetent lymphocytes are given to an immunoincompetent recipient. The disease presents usually 7–10 days after transfusion. Patients develop fever and an erythematous, maculopapular rash. The disease also affects the gastrointestinal tract, liver, and lymphoid tissues, especially the thymus [119]. In patients who have not undergone a bone marrow transplant, the disease can involve the bone marrow and can produce a profound aplasia. This disease has a more aggressive and rapid course than the graft-versus-host disease following bone marrow transplantation. Patients usually die within 3 weeks due to infection or a bleeding complication [28].

Transfusion-associated graft-versus-host disease has been reported in several clinical situations including patients with congenital immunodeficiency syndromes such as severe combined immunodeficiency syndrome (SCIDS). Patients at risk for transfusion-associated graft-versus-host disease include those undergoing bone marrow or progenitor cell transplantation and those receiving products donated by a blood relative who may share one HLA haplotype. All of these patients should receive gamma irradiated cellular blood

products [28]. Additionally, there are several reports of transfusion-associated graft-versus-host disease in patients with CLL being treated with fludarabine [31, 32]. Patients with malignancies are at variable degrees of risk for transfusion-associated graft-versus-host disease, including patients with Hodgkin's disease, non-Hodgkin's lymphomas, leukemia, and some solid tumors. In some institutions, all patients with hematologic–oncologic diseases receive irradiated cellular blood products to eliminate the possibility of this transfusion-related complication. Leukoreduced red cells contain enough remaining white cells to initiate graft-versus-host disease and should not be used instead of gamma irradiation for patients at risk.

Alloimmunization

Since red cell products contain some contaminating white blood cells, patients who receive red cells are at risk for the development of alloantibodies directed against red cell, neutrophil, platelet, and/or HLA antigens. The development of antibodies is multifactorial and involves variables such as the immunogenicity of the antigen, the immune competence of the patient, and the number of exposures.

Retrospective studies have shown that patients with lymphocytic leukemia have a markedly decreased rate of development of red cell alloantibodies. In two studies, none of the 112 total patients became alloimmunized to red cell antigens. It is unclear if this decrease in the incidence of antibody formation is related to the disease or the treatment. Increased rates of alloimmunization to red cell antigens were seen in patients with chronic myeloproliferative diseases (25%) and the myelodysplastic syndromes (31.3%). Intermediate rates of alloimmunization were found in patients with multiple myeloma (11.8%) and the myeloid leukemias (16%) [120–122].

The formation of anti-leukocyte antibodies is of interest because of their role in the pathogenesis of febrile nonhemolytic transfusion reactions. Patients who are multiply transfused may develop complications of repeated febrile nonhemolytic transfusion reactions which can be attributed to anti-leukocyte antibodies; these patients should receive leukocyte reduced red cells. Many of these patients will have uneventful transfusions with leukocyte reduced ($<5 \times 10^6$ white cells) red cells, especially with prestorage leukoreduction [98].

Due to the presence of white cells in red cell products, the multiply transfused patient is at risk for the development of anti-HLA alloantibodies which can complicate platelet transfusion therapy and result in platelet refractoriness. Several studies have shown that multiply transfused patients with hematologic malignancies have reduced HLA alloimmunization and reduced platelet refractoriness when given leukocyte reduced red cell and platelet products [123–126]. A large multicenter clinical trial, the Trial to Reduce Alloimmunization to Platelets (TRAP), compared various strategies to reduce alloimmunization in patients with leukemia. This study confirmed that the use of leukocyte reduced blood products results in decreased alloimmunization to platelets [127]. Further, a Canadian study performed a retrospective analysis of 13,902 platelet transfusions occurring before and after the introduction of universal prestorage leukoreduction of red cell and platelet products [128]. A total of 617 patients undergoing chemotherapy and stem cell transplantation were evaluated. The authors found a reduction in alloimmunization, refractoriness, and the requirement for HLA-matched platelets following the implementation of universal leukoreduction.

Immunomodulation

The effect of transfusion therapy on immune function has generated considerable controversy. Some feel that blood transfusions have an immunomodulatory effect resulting in transfusion-induced immunosuppression. Some studies have shown an increase in tumor recurrence in patients who have been transfused although other studies have shown no effect [129]. The mechanism of transfusion-induced immunosuppression is unclear, although tolerance and anergy have been proposed as possible mechanisms [130]. Animal studies have shown that the tumor growth enhancement associated with transfusions is mediated by donor leukocytes. They also found that the use of leukocyte reduced blood products ameliorates this tumor enhancing effect in animals [131]. The use of leukocyte reduced blood products for leukemic patients has previously been greatly debated, because it has been suggested that the donor leukocytes may exert a graft-versus-leukemia effect. Subsequent studies have failed to show a graft-versus-leukemia effect of transfused leukocytes and others have seen no difference in duration of first remissions in leukemic patients receiving leukocyte reduced blood products [132, 133]. The Finnish Leukemia Group studied patients with acute myeloid leukemia and found that the patients receiving leukocyte reduced blood products had longer median relapse-free survival, shorter periods of aplasia with decreased blood product usage, and decreased occurrence of infections [134]. Despite continued research in this area, definitive evidence of transfusion-associated immunomodulation remains elusive and the controversy continues [135].

Adverse Effects of Prolonged Blood Storage

Red cells stored in anticoagulant–preservative solutions undergo biochemical and physiological changes that are well known but current FDA guidelines still permit 42 days

of red cell storage [136, 137]. An alarming report of cardiac surgery patients suggested that patients receiving older blood had increased mortality and complications ignited considerable interest in this area [138] and led to many studies of blood storage to investigate possible reasons for toxicity [139] and many clinical trials attempting to reproduce the results from the earlier retrospective study [50]. Many clinical trials, including a large study of over 30,000 patients have failed to demonstrate adverse effects on patients receiving blood of any age, and showing no particular advantage to fresher red cells [140]. There is some data suggesting that blood at the end of the storage period may cause some adverse effects; if the in vitro data are confirmed with clinical studies, limiting the storage period of additive red cell to 35 days may become a prudent option [141–144].

54 Platelet and Granulocyte Transfusion

Janice P. Dutcher

Introduction

A major advance in our ability to treat patients with hematologic malignancies (particularly those with acute leukemia) has been the development of cell component transfusion support during the pancytopenia resulting from remission induction therapy and subsequent intensive consolidation and bone marrow transplantation. The first therapeutic "platelet transfusions" occurred when Duke [1] transfused fresh whole blood in 1910, after noting an association between thrombocytopenia and bleeding and observing that correction of bleeding was associated with an increase in platelet count. However, 50 years were required to develop the technology for separating platelets efficiently from blood and allowing their administration as a separate blood component. In 1963 Freireich et al. [2] demonstrated the clinical effectiveness of platelet transfusions in children with acute leukemia, using platelet-rich plasma as the transfused blood product. The ability to provide platelets as a separate concentrated blood component has substantially improved the hematologic support of leukemia patients and has decreased the incidence of deaths caused by hemorrhage. Further technical advances have improved the quality of this blood product, and careful studies of transfusion practices have led to specific guidelines to optimize platelet transfusion support.

The success of platelet transfusion therapy led to attempts to separate granulocytes as a blood component, to help combat the other major problem in leukemia supportive care—the management of infection. The initial granulocyte transfusions were from patients with untreated chronic myelocytic leukemia and high white blood cell (WBC) counts whose WBCs could more easily be separated from the red cells by gravity [3]. Separating granulocytes from red cells, especially in donors with normal WBC counts, was initially extremely problematic, since little difference in density exists between red cells and granulocytes. Such separation was first attempted by filtration techniques, in which the white cells adhered to filters as whole blood passed through and then the granulocytes were literally hammered off the filters [4]. However, technology quickly advanced for collection of both platelets and granulocytes, particularly with newer cell separator technology, allowing collection of cellular components from whole blood of normal donors [5, 6] with demonstration of clinical efficacy [7].

The use of platelet transfusion support has increased dramatically in the past 20 years, in large part because of more aggressive chemotherapy (for leukemia and solid tumors) and more frequent use of hematopoietic stem cell transplantation (HSCT). In response to the increased usage, as well as concerns about transfusion reactions, transfusion-transmitted infection and alloimmunization, new technological changes have also developed rapidly and are ongoing [8].

Granulocyte transfusion therapy, over the course of the past 25 years, has markedly decreased in frequency. In the late 1970s and early 1980s, granulocyte transfusions were used and studied extensively, to combat neutropenic sepsis in leukemia patients. Two factors impacted on the decline in usage: (1) the development of more effective broad-spectrum antibiotics and the adoption of the policy of empiric initiation of antibiotics for febrile neutropenia and (2) concern that insufficient doses of granulocytes were being obtained from normal donors, even with enhanced technology, to provide sufficient granulocyte numbers for effective anti-infective therapy. However, new approaches to granulocyte procurement have led to greater donor yields, and there appears to be renewed interest in appropriately utilizing granulocyte transfusions. The clinical criteria for such transfusions remain unresponsive sepsis and fungal infections. Ongoing studies are attempting to determine whether the enhanced yields will be sufficient to improve the outcome in these settings.

Platelet Transfusion Therapy

Platelet Collection

Although platelet-rich plasma (PRP) was shown to diminish or stop bleeding in thrombocytopenic leukemic children, PRP is a large-volume transfusion product and is not practical for general use. The ability to concentrate platelets into a smaller volume of plasma was facilitated by Mourad's [9] discovery that the addition of extra amounts of acid citrate dextrose anticoagulant to the platelet-rich plasma before centrifugation allowed easy resuspension of the platelets, rather than clumping.

Platelets for transfusion are currently prepared from the routine processing of whole blood units (U) into packed red blood cells (pRBCs) and platelets by differential centrifugation (random donor platelets) or by apheresis of single donors (single donor platelets). The method for producing single units of platelets currently utilized in the USA involves separating whole blood into pRBCs and platelet-rich plasma (PRP) [10]. Platelets are subsequently concentrated from PRP, with a minimum of 50 cm^3 of plasma per concentrate. In Europe and in Canada, the separation technique utilizes the hard centrifugation of a whole RBC unit to produce a buffy coat (BC) of WBCs and platelets. This BC is suspended and recentrifuged to yield platelets [11]. With these single-unit processing techniques, 1 U of platelets (from 1 U of blood) contains $0.55–1.1 \times 10^{11}$ platelets. Several units are then pooled to produce a transfusion (4–8 U/transfusion for adults). Units are pooled just prior to releasing a transfusion, and once pooled, they should be transfused within 4 h due to the risks of bacterial contamination once units are opened for pooling. Comparisons of these separation techniques have been made with at least one analysis suggesting less platelet activation with the BC technique [11]. Both methods have substantial leukocyte contamination which requires leukodepletion prior to administration (either prestorage or poststorage—see subsequent discussion).

The other method of collecting platelets involves the use of apheresis machines that can obtain multiple units of platelets from individual donors in a single procedure, lasting 1–2 h. The principle of apheresis, using either intermittent or continuous flow, is similar to that used in the preparation of individual platelet units: separation of blood components by density centrifugation. With an apheresis machine, however, whole blood is withdrawn from the donor into a collection bowl, belt, or chamber within the machine, and the blood is then centrifuged continuously into layers. The platelet or other cellular component is then extracted through a collection port, and the RBCs and plasma and other cellular components are returned to the donor. This process is continued until a sufficient number of platelets are collected. All of the currently utilized apheresis machines have been through numerous updates to maximize platelet yield and to meet the current standards requiring reduced leukocytes in the product [12–16]. Through new technology, donors may frequently supply sufficient platelets for multiple transfusions, during a single apheresis session lasting 1.5 h or less [16]. The clinical practice guidelines of the American Society of Clinical Oncology (ASCO) on platelet transfusions states that either pooled platelets or apheresis platelets for non-alloimmunized recipients are interchangeable [17].

The United States has almost totally adopted apheresis platelets, and has an infrastructure of donor centers designed to utilize this approach. In contrast, Europe and Canada, with National Blood Services, utilize a combination of pooled platelets (the majority) and single donor platelets and have developed infrastructure to support the pooled platelet approach. The technology to support either approach is clearly in place and both utilized leukodepletion techniques. Pros and cons of each approach continue to be debated. Risks of pooled platelets are multiple donor exposures and bacterial contamination from the manipulation, whereas risks of apheresis platelets appear to be increased risk of transfusion-related acute lung injury (TRALI) from antibodies as well as plasma-related adverse events (see section on hazards of platelet transfusions) [18, 19]. The two approaches appear to be equivalent in terms of cost and risk of alloimmunization [17–21].

Apheresis donor-related issues include transient decreases in platelet count that are not significant unless there is supra-frequent donation (in the setting of a necessary HLA-matched donor). Since donors have a normal pre-procedure platelet count, this is rarely a clinical problem. Although the risk of bleeding may be negligible, bleeding times are abnormal with platelet counts of less than 100,000/μL, so platelet counts in individuals who donate frequently must be monitored. Glowitz and Slichter [22] observed serial decreases in donor pre-apheresis counts with frequent donation, but have noted an apparent rebound rise in platelet counts after several donations, suggesting a marrow response with increased production. No adverse effect on donor platelet count was observed with repeated multiunit donation [22]. Additional donor-related problems with apheresis include symptoms of hypovolemia or vasovagal reactions, the discomfort of venipuncture, or mild reactions to citrate anticoagulant (which can be reversed by slowing the flow rate of the procedure). These adverse effects should not prevent the necessary collection of single-donor histocompatible platelets, but must remain a consideration in selecting and repeating procedures in certain donors, particularly when not required for histocompatibility.

Current American Association of Blood Banks (AABB) standards recommend platelet-apheresis donation no more frequently than weekly, or 24 times in a year except in unusual circumstances. These would be decided in conjunction with the treating physician and the approval of the blood bank director [23]. It is recognized that platelets from

a specific histocompatible donor may be essential to the survival of a specific patient and thus donations may exceed the limits indicated by the standards, which has been done safely [22, 24]. The donor must undergo serial clinical and laboratory evaluations by the supervising physician.

A recent report regarding the effect of citrate anticoagulant on bone and mineral metabolism suggests that in regular apheresis platelet or plasma donors, there is a reduction in bone mineral density. In this report, there was a significant reduction in lumbar spine and a less than significant reduction in the femoral neck and total femur. If confirmed, this will need to be addressed for donor safety and to retain regular donors [25].

Commentaries comparing apheresis-donor platelets and single-blood unit-derived platelets consider these products to be interchangeable and suggest that cost factors and donor availability will largely influence the frequency with which each approach is utilized for random donor platelets [8, 15, 17, 18, 26]. However, the recent report on hemovigilance by Daurat suggests an evaluation of recipient toxicity requires further evaluation and will also enter into decision-making [18, 19].

Leukodepletion

Recommended current transfusion practice involves leukodepletion of blood products to remove immunogenic lymphocytes and antigen-presenting cells, to prevent alloimmunization (discussed in detail later). Leukodepletion also reduces the risk of transfusion-transmitted viral disease when the virus is harbored in the leukocytes (see Hazards of Transfusion section later in this chapter). Since lymphocytes are similar in density to platelets, numerous technical difficulties have arisen, and considerable effort has been expended in developing techniques to separate leukocytes from platelets in PRP and in buffy coat-derived platelets.

Leukodepletion of apheresis products relies primarily on the modifications that have been made in the technology of the apheresis machines to reduce leukocyte contamination and retain adequate numbers of platelets per collection [12–16] (Table 54.1).

Single units of platelets derived from PRP or BC can be leukodepleted upon pooling, prior to transfusion, in the blood center, or at the bedside. Leukocyte-adherent filters are utilized for this process. The initial materials utilized were cotton wool and cellulose (Imugard) [27].

Initial studies of nonwoven polyester filters were utilized at bedside or in the blood bank producing adherence of the leukocytes to the filters (Sepacel, Baxter/Fenwal; Pall, Pall Corp) [27–30]. Table 54.1 summarizes the content of the resulting platelet products. Additional investigations of materials and different structures of materials for leukodepletion have been and continue to be conducted [27–31].

Table 54.1 Characteristics of leukodepleted platelet products

Method	Total white blood cells	Platelets $\times 10^{11}$	References
Mechanical apheresis			
Cobe spectra V5-LRS	$<1 \times 10^6$	2.56–7.41	[16]
Fenwal amicus	$<1 \times 10^6$	2.82–7.14	[16]
Cobe V7 turbo	$<1 \times 10^6$	2.80–7.54	[16]
Filtration—6 pooled units			
Imugard IG 500	$0.5–2 \times 10^6$	3.1–4.0	[27]
PALL PL100	$5–6 \times 10^5$	3.5–4.0	[28]
Sepacell PL	$0.1–5 \times 10^6$	3.1–4.0	[29, 30]
Historical centrifugation studies of 6 pooled units	$5–7 \times 10^8$	3.0–4.0	[10]

Many blood centers have also evaluated the prefiltering of products for distribution, and in-line filters have been tested for use during red cell collection and during apheresis. One study has shown no increased risk of bacterial growth in platelet concentrates as a result of prestorage white cell reduction [32]. There has been advocacy for prestorage leukodepletion to diminish cytokine production by leukocytes during storage [33, 34]. Others have demonstrated that poststorage leukodepletion may be more useful in removing complement and reducing reactions [35]. Additional research in leukodepletion technology is attempting to design filters capable of removing prions [36]. These issues point out the complexity of the ongoing clinical investigation of leukodepleted blood products and attempts to define the role and extent of leukodepletion of blood products. Issues not previously discussed include the cost in universal acceptance of this approach [37].

Platelet Storage

The increased demand for platelet transfusions as well as the delay imposed by requirements for multiple pretransfusion infectious agent product screenings has stimulated ongoing research in the technology of platelet storage and methods for evaluation of platelet survival. Many physical factors influence successful platelet storage. These include optimal storage temperature, maintenance of a certain range of plasma pH, suspension in an adequate volume of plasma, proper agitation during storage, and attention to the characteristics of the storage bag [38–45].

Storage conditions for individual platelet units derived from whole blood donations as well as for the storage of apheresis platelet collections have been defined and optimized based on the stability of storage pH and durability of platelet function [39–41]. Current practice based on numerous investigations considers room temperature (22–24 °C) storage as optimal for platelets stored in plasma [39, 40, 42, 43]. Despite the increased metabolic activity that occurs in

platelets stored at 22 °C, significantly better poststorage platelet viability at this temperature (compared with platelet concentrates stored at 4 °C) has been confirmed by studies of transfusion response after storage at the two different temperatures [39, 40, 42].

The storage bag characteristics have also been shown to be important in the maintenance of platelet viability [38, 39]. The development of new plastics and plasticizers and the production of larger and thinner bags have established a more stable storage environment, making possible extended storage of platelet concentrates and single-donor apheresis platelets [43–45]. Storage bag qualities help to regulate oxygen and carbon dioxide exchange across the bag, which in turn regulates pH. The maintenance of plasma pH above 6.0 during storage preserves cell viability, although a very high pH can lead to irreversible platelet clumping [38–42]. Entry of adequate oxygen permits the maintenance of oxidative metabolism in platelets stored at room temperature, thus suppressing glycolysis (with its production of lactic acid) and preventing a fall in pH level. The egress of carbon dioxide across the bag surface also helps to maintain pH. The newer plastic bags provide increased oxygen transfer compared with the first-generation bags and have allowed stable, prolonged, storage with viability demonstrated after 5 or more days [38–44].

Agitation during storage of platelets is also important, since it prevents platelet "packing" and is believed to facilitate gas exchange through the storage bag [45, 46]. With the use of the permeable storage bags, it seems that the mode of agitation is less critical to platelet viability, and a variety of platelet rotators appear to be suitable for maintaining function [45, 46].

These conditions have yielded functional platelets, despite storage for 5 days under these conditions. Most recently, modifications in storage systems have demonstrated equivalent outcome for 7 day storage in plasma and this has led to regulatory approval [47]. This approach requires pre-infusion bacterial testing [48].

However, even with the many improvements in technology, the collection and storage of platelets leads to platelet activation with a subsequent "storage lesion" [49, 50]. Platelets appear to be activated throughout the process of collection, processing, and storage, demonstrating metabolic and functional signs of activation [49]. Thus, stored platelets show less sensitivity to aggregating agents [51] and release of increased amounts of platelet-specific proteins such as β-thromboglobulin [52, 53] with membrane expression of activation proteins such as P-selectin (CD62P) and glycoprotein IIb/IIIA [53–55]. Stored platelets have reduced platelet survival corresponding to the duration of storage [49, 50]. Snyder et al. have delineated multiple factors that impact platelet storage viability (Table 54.2) [8]. Research in storage technology has included the inactivation of platelets during storage [56, 57] and the use of non-plasma-buffered storage solutions as well as additive solutions with plasma reduction [58–63]. Evaluation of quality of such platelets is ongoing. Additionally, pathogen reduction storage systems are undergoing evaluation [64–66].

Platelet Cryopreservation

The technology for long-term frozen platelet storage has proved clinically helpful in the management of alloimmunized patients at the University of Maryland and Albert Einstein Cancer Centers [67, 68], and in Europe [69]. During recovery from chemotherapy-induced aplasia and achievement of remission, such patients often have rapidly rising platelet counts, and plateletpheresis during this period often provides a high yield of platelets for cryopreservation. Both autologous and HLA-typed platelets have been frozen for subsequent use in alloimmunized patients. Initial cryopreservation techniques using either dimethyl sulfoxide (DMSO) [70, 71] or glycerol [72, 73] have been described, but to date only the DMSO methodology has been reproducible enough for general usage. This technology calls for a slow infusion of DMSO into PRP to a concentration of 5%. This is similar to the methodology used for marrow and stem cell cryopreservation. Recoveries are 50–70% of fresh platelets, and satisfactory hemostatic results are documented; occasional alloimmunized patients are supported solely by cryopreserved autologous platelets [67, 68, 74].

Successful transfusion of platelets that have been stored at liquid nitrogen temperatures (−120 °C) for 3 years or more has been documented [74]. This freezing methodology is also potentially applicable to collection and storage of platelets with specific HLA types or for the maintenance of emergency supplies. One report suggests that the addition of a small percentage of epinephrine to the DMSO cryopreservation solution may enhance the quality of the cryopreserved platelets, by increasing post-thawing function [75]. Finally, recent studies to attempt to improve on the frozen platelet

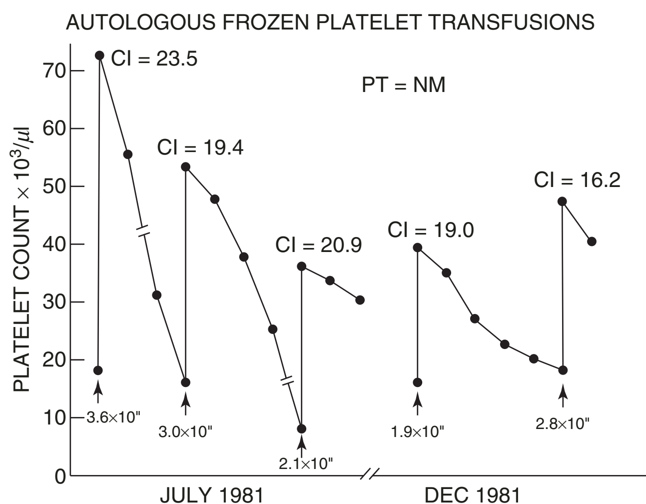

Fig. 54.1 Clinical effectiveness of autologous frozen platelets in an alloimmunized patient. This patient had episodes of mild bleeding, which responded to transfusions of autologous frozen platelet transfusions. The increments following transfusion were consistently good. *CI* corrected increment

methodology have confirmed prior data that despite the freezing injury, the platelets retain function and are able to aggregate, and that there is an in vivo improvement in function once the previously frozen platelets circulate [76].

Figure 54.1 shows the consistently good response to transfusion of autologous frozen platelets in a patient who was alloimmunized and refractory to transfusion from random donors. The patient received multiple courses of intensive postremission chemotherapy, each requiring transfusion support. As shown, the patient was an excellent and readily available source of platelets for herself.

Although the above data are historical, at that time, these approaches produced evidence of major benefit, particularly for alloimmunized patients. Now, there has been a resurgence of interest in cryopreservation of platelets which has paralleled the increase in demand for platelet transfusion support. Evaluations of functionality are being performed and an initial phase I trial in healthy subjects demonstrated impressive survival of cryopreserved platelets [77]. Others are further investigating the hemostatic activity after cryopreservation and have demonstrated such activity associated with formation of platelet microparticles [78–81]. Other cryopreservatives continue to be studied as this approach gains more interest to provide further availability of this component [82].

Therapeutic and Prophylactic Platelet Transfusions

A direct relationship exists between the platelet count and the bleeding time, which is used to assess platelet function in vivo [83]. The bleeding time will begin to lengthen as the platelet count falls to less than 100,000/μL, although clinically apparent bleeding problems may not develop until the platelet count is substantially lower (less than 20,000/μL). Early studies of patients with acute leukemia described the quantitative relationship between low platelet counts, duration of thrombocytopenia, and episodes of serious bleeding [2, 84] (see Chaps. 21 and 59). It was subsequently demonstrated that platelet transfusions could diminish the severity of bleeding in thrombocytopenic leukemia patients with ongoing hemorrhage. The effectiveness of therapeutic platelets transfusions is well documented [2, 84]. This observation led to the suggestion that platelets given prophylactically for low platelet counts might therefore help prevent bleeding. Since life-threatening hemorrhage can develop rapidly in the absence of prior signs of minor bleeding, particularly in patients with concurrent clinical problems, prophylactic platelet transfusion given for a platelet count of 10,000–20,000/μL is usually the practice, rather than waiting for bleeding to occur, and this remains a part of clinical guidelines for management of therapy-induced hypoproliferative thrombocytopenia [17, 85, 86]. This practice continues to be refined as will be discussed.

It has become apparent that thrombocytopenic patients vary greatly in their likelihood to develop serious bleeding as well as in their ability to respond to random donor platelet transfusions. Therefore, assessment of the clinical setting should determine whether prophylactic platelet transfusions are indicated [17, 85–87].

Many patients with chronic hematologic disorders who maintain platelet counts of less than 20,000/μL or even less than 10,000/μL have no or minimal bleeding. In such patients, a low but stable platelet count is tolerated without transfusion unless other clinical factors are also present, such as infection or a bleeding site [17, 85, 87].

The other example is in chemotherapy-treated patients with solid tumors who are not treated at doses designed to achieve marrow aplasia and who have functional marrow reserve. A review of more than 1200 such patients who experienced transient thrombocytopenia (less than 20,000/μL for a median of 2 days) showed no bleeding as a result of thrombocytopenia alone [88]. Those who did experience hemorrhage demonstrated the other clinical complications that have been shown to predispose to bleeding during thrombocytopenia, such as mucositis, a bleeding necrotic tumor, fever, and/or sepsis; bleeding frequently occurred at platelet counts above 20,000/μL [88].

Elting and a group from MD Anderson Cancer Center have also evaluated the risk of bleeding in patients with lymphoma and solid tumors who are being treated [89]. They have derived a bleeding risk index, with clinical factors similar to those in leukemia, which predicts for bleeding in this patient group, more than does a specific platelet count threshold [89].

Table 54.3 Clinical conditions affecting platelet transfusion outcome

Clinical factor[a]	Shorten 1-h count	Shorten 24-h count
Fever	No	±
Infection, controlled	No	±
Pre-platelet count <10,000	No	+
Bleeding: ooze	No	±
Daily RBC transfusion	±	+

Table 54.4 Factors affecting posttransfusion platelet increments and refractoriness

Patient factors
Reduced response and/or refractory to transfusions
More than two prior pregnancies
Presence of lymphocytotoxic antibody (LCTAb)
Male gender
Bleeding
Fever, infection
Increased body surface area/weight
Increasing number of platelet transfusions
Heparin therapy
Reduced platelet increment, additional factors
Splenomegaly
Disseminated intravascular coagulopathy
Amphotericin B therapy
Improved platelet increment response
Splenectomy
Increased patient age
Improved response to refractoriness
Increased platelet dose
Filtered apheresis platelets
Platelet factors
Improved response
ABO compatible
Storage <48 h
Large doses of platelets
Decreased response
UVB or Gamma irradiation[a]

Data from Slichter SJ, Davis K, Enright H et al. Factors affecting posttransfusion platelet increments, platelet refractoriness, and platelet transfusion intervals in thrombocytopenic patients. Blood 2005; 105:4106–4114
[a]In alloimmunized, LCTAb + patients, UVB-irradiated platelets had longer survival than other products

By contrast, patients with acute leukemia and those undergoing highly intensive chemotherapy for other hematologic malignancies, whose treatment usually leads to marrow aplasia and in whom marrow regeneration may not be expected for a prolonged time period, even weeks, are usually treated prophylactically with platelet transfusions for expected prolonged severe thrombocytopenia. These patients frequently develop concurrent clinical conditions that add to the risk of thrombocytopenic bleeding: mucositis, fever, infection, and many of the other clinical complications listed in Table 54.3 [87, 90, 91]. Prophylactic platelet transfusions given to those patients who respond to transfusions with a posttransfusion increment are indicated in this setting [17, 87, 91].

The demand for platelet support for patients with hematologic malignancies has greatly increased, given the ability to successfully treat even frail patients and the increasing numbers of hematopoietic stem cell transplants (HSCT) (Chap 57), both autologous and allogeneic, and a spectrum of conditioning approaches. This high demand has prompted investigations to optimally conserve this important resource. This includes studies of the threshold platelet count for transfusion, optimization of dose of platelets per transfusion and patient size, and most recently, evaluations of prophylactic platelet transfusions versus therapeutic transfusions for bleeding episodes. Additionally, the ability to nearly universally leukodeplete all blood products has greatly reduced the incidence of transfusion-induced alloimmunization (TRAP Study) lowering the demand for specially matched platelets [92]. The TRAP study also provided a contemporary listing of patient and platelet factors associated with reduced transfusion responsiveness and refractoriness (Table 54.4).

With respect to transfusion threshold, the platelet count trigger to initiate prophylactic platelet transfusion has been a matter of debate, and the count plus the clinical setting seems the best approach. Three randomized trials have evaluated using a platelet count trigger of 10,000/μL vs. 20,000/μL in patients with acute leukemia [93–95]. In all three studies, there was no difference in major bleeding [93–95]; however, only one found no difference in red blood cell transfusion requirements [93], and only one found that fewer platelet transfusions were administered [95].

A statistical analysis of the risk of bleeding in the Rebulla study determined that the risk factors for mild bleeding were increased body temperature and decreased platelet count [96]. Risk factors for clinically significant bleeding were grade 1 bleeding the previous day, low platelet count, and fever. Thus, as noted in many prior studies, clinical factors in the setting of profound thrombocytopenia markedly enhance the risk of bleeding (Table 54.3) [17, 91, 96]. Additional studies have demonstrated maintenance of endothelial integrity with platelet counts of ≥5000/μL [97].

In addition to the conditions discussed previously, patients who demonstrate a rapidly falling platelet count appear to be predisposed to bleeding. Patients with hyperleukocytosis, particularly consisting of blasts, are also at greater risk and should receive platelet transfusions if they are thrombocytopenic. Finally, patients with coagulopathy, as is common in patients with acute promyelocytic leukemia (discussed in detail in Chap. 21), are at much greater risk of bleeding from their ongoing coagulopathy. They have been managed with heparin therapy, although this need may diminish in the future, and they often require frequent platelet transfusions, and coagulation factors [98, 99]. Patients with liver dysfunction and decreased production of clotting factors are also at greater risk for bleeding, from the combined effect of both coagulopathy and thrombocytopenia. More frequent platelet transfusion may be necessary in such patients since they are very likely to have ongoing bleeding. Hematologic malignancy patients with other types of coagulopathies undergoing treatment may also require intensive platelet support (Chap 59). Patients who are refractory to platelet transfusion in these acute settings pose a difficult dilemma, and this will be discussed subsequently. In general, if there is no platelet product that yields a posttransfusion increment, careful observation without transfusion (unless active bleeding is present) is the recommended course of action. This is stressful for staff and patient but is unusually manageable and is the safest course in the long run.

The increased availability of platelet transfusions has also permitted the safe performance of diagnostic and therapeutic procedures in thrombocytopenic patients. Platelets can be transfused just before or during invasive diagnostic procedures, such as bronchoscopy or endoscopy, and may permit the safe performance of brushings or biopsy. Therapeutic procedures such as the placement of permanent central intravenous lines (Hickman catheters), the drainage of infected paranasal sinuses, tooth extractions, or even emergency major surgery can be safely accomplished in thrombocytopenic patients with the use of platelet transfusions [100, 101]. Although no count threshold has been proven, we and others have observed that platelet counts of more than 50,000/μL provide a margin of safety for invasive procedures [100, 101], and the AABB has recently provided guidance for platelet transfusion in these settings [85]. It is very important to document a satisfactory posttransfusion count increment before initiating the procedure, to be confident that hemorrhage can be controlled during the procedure. It is equally important to maintain the platelet count at 50,000/μL or more for several days immediately following an invasive procedure, particularly after a biopsy or surgery.

To some degree, the debate regarding platelet count trigger for prophylactic platelet transfusion has been resolved with the randomized trials and the definitions of at risk clinical situations. However, the other debate among transfusion support providers is the dose of platelets necessary for a successful prophylactic transfusion. The goal is to provide sufficient patient support with the least exposure to risks of transfusion [infections, transfusion-related acute lung injury (TRALI)], and with the managed costs and preservation of platelet availability.

Two randomized, multicenter trials evaluating dose of platelets have been reported [102, 103]. The SToP trial was conducted at centers in Canada, the USA, and Europe, and compared standard-dose platelet transfusions to transfusions of 50% less platelets [102]. Transfusions were a fixed dose per product transfused. In this study, there was more bleeding in the low dose arm, including more grade 4 bleeding, which led to the trial being stopped by the Data Safety and Monitoring Committee [102]. It may be that the fixed dose was part of the issue, although there was an upper weight limit, since in the other study described next, platelets were dosed based on BSA. In the PLADO study in the USA, there were three dose levels of platelets: $1.1 \times 10^{11}/m^2$, $2.2 \times 10^{11}/m^2$, and $4.4 \times 10^{11}/m^2$ [103]. The transfusion trigger was a platelet count of 10,000/μL and this was adhered to in 90–94% of patient days and was similar in all three transfusion groups. The percentage of patients having grade 2 or higher bleeding was not significantly different, 71%, 69%, and 70% in low, medium, and high groups, respectively, and the only death from bleeding was in the high-dose group (pulmonary hemorrhage). In this study, the percentage of patients with grade 2 or higher bleeding was significantly greater among those undergoing chemotherapy (73%) or allogeneic stem cell transplant (SCT) (79%) compared to those undergoing autologous or syngeneic SCT (57%). However, platelet dose did not demonstrate an effect on bleeding in any of these groups. There was no difference in grade 4 bleeding among these different treatment groups [103]. Among these three dose groups, the low dose significantly reduced the quantity of platelets transfused, although with more transfusions given. Equivalent numbers of transfusions were given in the medium- and high-dose groups. This study suggests that a strategy of low-medium dose per BSA of platelets could reduce the number of platelets transfused, and preserve the resource that is increasingly being utilized, and maintain safe management of patients undergoing treatment for hematologic malignancies and HSCT [103].

Two studies were reported evaluating the timing of platelet transfusions for patients with therapy-induced hypoproliferative thrombocytopenia [104, 105]. These studies compared the incidence of World Health Organization (WHO) grade 2 or higher bleeding (Table 54.5) between groups of patients who received transfusions either prophylactically at the prespecified morning platelet count of 10×10^9 per liter, or therapeutically for clinical evidence of bleeding, or before invasive procedures or as decided by the treating physician. Patients who had prestudy episodes or evidence of bleeding were

Table 54.5 World Health Organization bleeding scale grade 2–4

Site of bleeding	Grade 2 Evidence of bleeding
Oral/Nasal	Epistaxis or oral bleeding >30 min per 24 h period
Skin/soft tissue	Purpura >1 in.
Musculoskeletal	Spontaneous hematoma in deeper tissues
	Joint bleeding
Gastrointestinal	Melanotic stool; Hematochezia—visible blood
	Hematemesis—visible blood
Genitourinary	Gross (visible) hematuria
	Abnormal, excessive vaginal bleeding
Pulmonary	Hemoptysis—visible blood
CNS	Retinal bleeding without visual impairment
	Microscopic RBC on lumbar puncture—nontraumatic tap
Invasive sites	Bleeding—i.e., venipuncture; IV site >1 h per 24 h
Grade 3	Any bleeding requiring RBC transfusion over routine transfusion needs
	Any bleeding associated with moderate hemodynamic instability and requiring RBC transfusion
Grade 4	Any bleeding associated with severe hemodynamic instability; fatal bleeding; CNS bleeding on imaging study; retinal hemorrhage with visual impairment; CNS symptoms with nontraumatic lumbar puncture

Ref. [106]

excluded, as were patients with promyelocytic leukemia. In the Wandt et al. study, more than 50% of patients were undergoing autologous SCT, and in the Stanworth study, 70% were undergoing autologous SCT [104, 105]. As can be seen in Table 54.5, Grade 2 bleeding is clinically evident bleeding and the distinction between grade 2 and grade 3 is that grade 3 bleeding initiates RBC transfusion specifically for bleeding above and beyond routine red blood cell support for hemoglobin level [106]. As stated in an editorial analysis by Slichter, in both studies, bleeding rates were higher in the no-prophylaxis groups, and the time to onset of bleeding was shorter, and the number of days of bleeding was longer in the no-prophylaxis groups than in the prophylaxis groups [107]. Also of concern, in the Stanworth study there were 6 episodes of central nervous system bleeding among the no-prophylaxis AML patients, 2 of which were fatal [105].

Subsequent subset analyses of the Stanworth study have compared the risk and degree of bleeding among the patients undergoing autologous SCT with those with de novo AML or undergoing allogeneic SCT, and have found a significantly shorter time to first bleeding episode, and increased duration of grade 2–4 bleeding among those with AML/alloHSCT compared to those undergoing autologous SCT [108, 109]. A large number of patients in the autologous SCT group in this study required no platelet transfusions [108, 109]. Wandt et al. have also reported the option of only therapeutic platelet transfusions in the setting of autologous SCT, however, they still report a greater incidence and degree of bleeding in the no-prophylaxis group [110, 111]. Campbell et al. reported a cost analysis of the Stanworth trial and concluded that it was unclear whether a no-prophylaxis policy saves costs overall, since platelets are a small percentage of the total cost of the treatment of de novo AML or of transplant patients [109, 112]. Similarly, Slichter addressed the issue of reducing transfusion exposure, and noted that even with increased platelet transfusions in the prophylactic transfusion group, there were fewer RBC transfusions, therefore producing equivalent donor exposures to those receiving less platelets but more RBC transfusions [107, 113]. In summary, the prophylactic approach to platelet transfusion remains the standard of care in the treatment of patients with therapy-induced hypoproliferative thrombocytopenia and is recommended by guidelines from the AABB and ASCO [17, 85].

Other important data regarding bleeding risk even in the setting of prophylactic platelet transfusion has come from subset analysis of the PLADO trial, which reported that bleeding risks are higher in children included in that study, compared to adults, and significantly high in those undergoing autologous SCT [114]. This was observed at a wide range of morning platelet counts [114]. This may in part reflect the intensity of chemotherapy regimens utilized in children, but may also be evidence of differing vascular physiology in children and suggests that studies of adults may not be generalizable to pediatric patients [107, 114, 115].

Assessment of Transfusion Response

The goal of therapeutic platelet transfusions is to stop active bleeding, which is usually easily assessed clinically. The effectiveness of prophylactic platelet transfusions is more difficult to evaluate, although as noted decreased episodes of bleeding are measurable. Bleeding times, although accurately reflecting platelet function in vivo, are not usually done in granulocytopenic patients because of the risk of infection and because achievement of a platelet count of 100,000/μL is required to normalize the bleeding time [83]. Therefore, response to transfusion is monitored by observing the increase in platelet count shortly after transfusion (i.e., platelet recovery). The increment achieved depends on the size of the recipient and on the number of platelets given. As stated above, the PLADO trial evaluated 3 levels of platelets, $1.1 \times 10^{11}/m^2$, $2.2 \times 10^{11}/m^2$, and $4.4 \times 10^{11}/m^2$ and observed good control [103].

The survival (duration of time circulating) of transfused platelets can be followed by obtaining daily platelet counts following a platelet transfusion. In a patient who is truly aplastic and not producing platelets, the half-life of the transfused platelets can be calculated. Platelet survival will be

shortened by a number of clinical factors, which, in turn, increase the requirement for platelets. These factors are similar to those that increase the risk of bleeding, and include active bleeding, fever, infection, coagulopathy, and hepatosplenomegaly. Platelet survival is also shortened by the development of alloimmunization to histocompatibility antigens, producing immunologic destruction of the transfused platelets. To differentiate alloimmunization from other forms of platelet destruction, platelet recovery after a transfusion (which is diminished by alloimmunization) may be helpful in stable patients. The posttransfusion recovery is assessed by calculating the corrected count increment:

$$\text{Corrected count increment}\left(\text{CCI}\right)=\frac{\text{Observed increment }\left(\text{count}/\mu L\right)\times\text{ body surface area }\left(\text{m}^2\right)}{\text{Number of platelets transfused }\times 10^{11}}.$$

For example, an improvement in count from 20,000 to 60,000/μL after 4×10^{11} platelets when given to a 2.0 m^2 individual produces a corrected count increment of 20,000/μL.

After the transfusion of fresh or properly stored random donor platelets to a clinically stable adult patient of average size, the absolute count increment at 1 h should be 6000–8000/μL/U of platelet transfused, with a CCI of 10,000–20,000/μL. The hallmark of the clinical diagnosis of alloimmunization is a failure to achieve an adequate platelet count increment at 1 h posttransfusion [90] (for practical purposes, a 10-min posttransfusion count may be equally helpful) [116]. Other clinical factors may contribute to the rapid utilization of platelets, however, and may reduce the posttransfusion count (Tables 54.3 and 54.4).

Bishop et al. [91, 117] performed a multivariate analysis of clinical factors influencing the efficacy of pooled platelet transfusion as determined by the 1-h posttransfusion platelet CCI. This study identified six major clinical factors that affected 1-h posttransfusion platelet counts. Whereas splenectomy resulted in improved increments, several factors had a negative effect on transfusion outcome: palpable splenomegaly, bone marrow transplantation, disseminated intravascular coagulation, amphotericin B therapy (which may reflect the degree of illness of a given patient, who may have fever and infection), and anti-HLA antigen-directed antibodies [91, 117]. This group performed a similar evaluation of the effect of clinical factors on the 20-h platelet count (platelet survival) and again found that the clinical situation had a significant impact [117]. The combination of all these factors makes confirmation of the diagnosis of alloimmunization difficult in rather complex clinical cases, and refractoriness to transfusion without development of antibodies appears to reflect the multitude of clinical factors impinging on posttransfusion platelet counts [91, 117–119].

In addition, Hanson and Slichter [120] demonstrated a reduced platelet life span in severely thrombocytopenic patients, presumably due to utilization of platelets for support of vascular integrity. In this study using autologous platelets, platelet life span was only modestly shortened when patients with platelet counts in the 50,000/μL to 100,000/μL range (7.0 ± 1.5 days, 9.6 ± 0.6 days, respectively) were transfused, but was markedly shortened in severely thrombocytopenic patients (less than 50,000/μL) (5.1 ± 1.9 days) [120]. Recovery of autologous platelets was also diminished in patients with platelet counts less than 50,000/μL (50 ± 22%) compared with that in patients who had counts more than 50,000/μL (74 ± 15%).

The controversy regarding the effectiveness of platelet transfusion mismatched for ABO continues to be discussed. An early study indicated decreased platelet survival with ABO-mismatched platelet transfusions [121]. This study evaluated paired ABO-matched and ABO-mismatched random donor platelet transfusions and demonstrated a detrimental effect of ABO mismatch on platelet transfusion outcome [121]. Although the initial platelet transfusion was not always affected by ABH incompatibility, results of subsequent mismatched transfusions deteriorated, perhaps because of an increase in ABH antibody titers [121].

Nevertheless, platelets can successfully be transfused across ABH groups. Clinical complications or transfusion reactions are only rarely associated with ABH-mismatched platelet transfusions. A retrospective systematic review of the literature on transfusion of ABO-identical vs. nonidentical platelets evaluated both transfusion and patient outcome [122]. There was a consistently higher platelet increment with the use of ABO-identical platelet transfusions, but there was no consistent pattern of negative clinical impact on patient survival, bleeding, or transfusion reaction reported [122]. In a secondary analysis of platelet transfusion characteristics in the PLADO dose study, generally higher platelet increments were obtained with ABO-identical platelets and the interval between transfusions was longer with ABO-matched platelets, but there was no demonstrable negative effect on incidence of bleeding from utilization of ABO-mismatched platelet transfusion [123]. In contrast, Julmy et al. have presented data in children which demonstrate considerably poorer efficacy of ABO major-mismatched platelets compared to ABO identical platelets [124]. This is particularly apparent in platelets of subgroup A_1 significantly expressing A antigen, and these were rapidly removed from circulation in recipients who were group O or group B. Those donor platelets that were subgroup A_2, expressing no detectible antigen, were successfully transfused. Therefore, it is still a consideration to evaluate ABO-identical platelet

transfusions in patients who have become refractory and who have received ABH-mismatched platelets.

Sensitive techniques have demonstrated the presence of intrinsic H substance on platelet membranes with expression of ABH antigens corresponding to the RBC phenotype, suggesting the presence of intrinsic and extrinsic antigenic substance residing on platelets [125, 126]. The report by Julmy et al. demonstrates the potential clinical impact [124]. Additionally, DeLelys et al. have demonstrated wide variability of expression of blood group A and H on platelets, but in a predictable pattern, related to genotype [127].

Alloimmunization

Alloimmunization is the presence or development of antibodies (primarily to histocompatibility [HLA] antigens) which may lead to immune-mediated refractoriness to platelet transfusions. Patients with exposure to blood products prior to therapy for their hematologic malignancy or women who have had prior pregnancies are the most likely to have preexisting alloimmunization. Prior to the routine use of leukodepleted blood products in the supportive care of hematologic malignancy patients, acquired alloimmunization was a major factor in the development of refractoriness to platelet transfusions and led to hemorrhagic deaths. However, with the frequent use of leukodepleted blood products, the new development of allo-antibodies is much less frequent, as demonstrated in the TRAP study [92]. Whereas patients with preexisting immunization may have persistent allo-antibodies, requiring specialized HLA-matched or crossmatched platelet support, those with treatment-associated acquired antibodies may not have persistent antibodies [128, 129]. In the TRAP study, factors associated with development of antibodies were prior pregnancies and a broad spectrum of antigen reactivity in a lymphocytotoxicity panel [129]. In the PLADO trial, prior pregnancy, chemotherapy only compared to progenitor cell transplant, and low platelet dose were all associated with higher rates of alloimmunization [130].

Additionally there is a substantial group of patients who do not become alloimmunized during remission induction therapy, perhaps a result of therapy/disease mediated immunosuppression [92, 131–133]. These data are derived from an era prior to significant leukodepletion of blood products, and contemporary studies demonstrate an even lower rate of alloimmunization [129, 130]. Most importantly, there was no evidence of a dose response between the numbers of lymphocyte-containing platelet transfusions and the development of alloimmunization [132, 133].

Specifically, in the study of patients with acute myeloid leukemia (AML) by Dutcher et al. [132], nonalloimmunized patients were evaluated during remission induction therapy (the first 8 weeks of treatment) for the development of alloimmunization, assessed by response to random donor platelet transfusion and the development of lymphocytotoxic antibodies. All patients received non-leukoreduced random donor platelet transfusion (mean, seven transfusions; range, two to more than ten), given prophylactically and therapeutically. Of the patients not previously alloimmunized, 40% became alloimmunized, some after as few as two transfusions (Fig. 54.2). By contrast, 60% of the patients did not become alloimmunized, even after multiple platelet transfusions. Except for previous pregnancies and blood transfusions, no predisposing factors were predictive of the

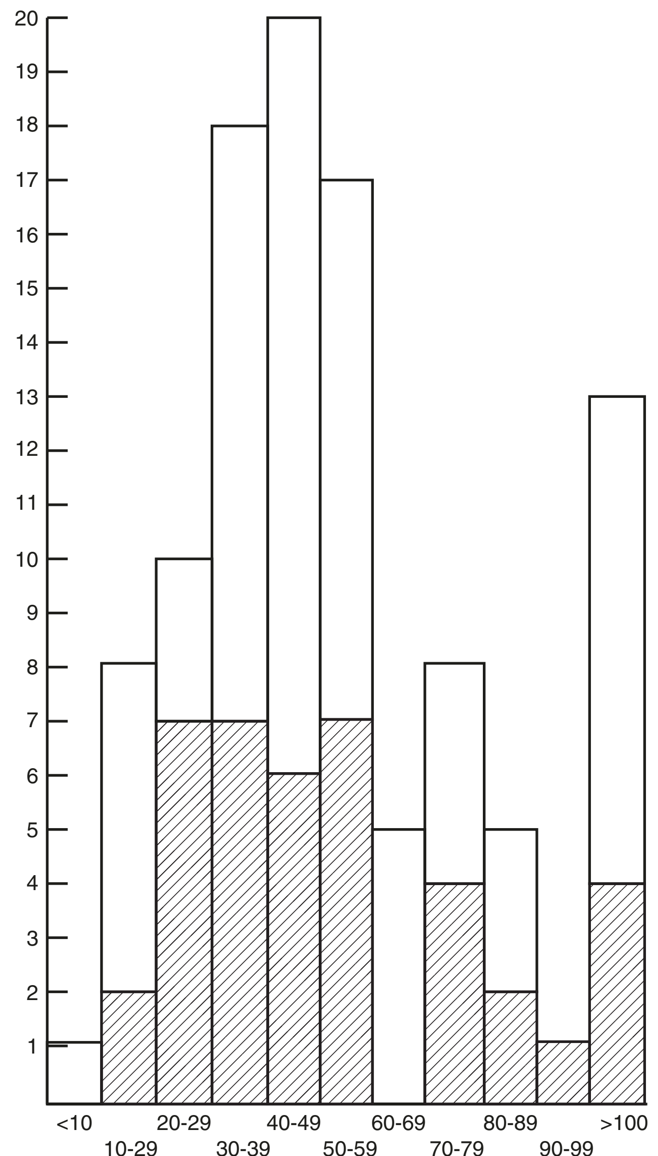

Fig. 54.2 Number of units of platelets administered per patient during induction therapy in patients with acute leukemia. There is no relationship between the number of units given and the rate of alloimmunization. *Cross-hatching*: patients who became alloimmunized (Reproduced with permission from Dutcher et al. [132])

development of alloimmunization. Since a minimum of two platelet transfusions (and usually more) is needed for support through the remission induction phase of AML treatment, no rationale exists for restricting the number of platelet transfusions specifically to prevent alloimmunization [132]. No dose–response phenomenon occurs at a clinically manageable level, and the development of alloimmunization appears to depend on the immunologic responsiveness of the recipient. Long-term follow-up showed that those who did not develop antibodies during initial anti-leukemic therapy were unlikely to develop antibodies during subsequent consolidation or maintenance therapy [131].

Much of the body of work evaluating the impact of anti-HLA antibodies on platelet transfusion results utilized panels of lymphocytes expressing known antigens and assessed the percentages of antibodies to the panel (lymphocytotoxic antibodies) in the sera of recipients [90, 134–136]. Several studies demonstrated correlation of the presence of these antibodies with lower posttransfusion count increments [90, 134–136]. Platelet transfusion support was then achieved utilizing selection from large pools of HLA-typed donors and matched at HLA-A and HLA-B loci [137]. The demonstration of limited expression of certain HLA antigens on platelets, as well as cross-reactive groups facilitated donor effectiveness even when not perfectly matched [138–140]. This is demonstrated in Fig. 54.3 in which a patient and donors are mismatched for HLA-B7, HLA-B12, and HLA-B44 and yet there are successful transfusion outcomes (transfusion #2,# 4, #6, # 7) similar to the perfectly matched donor (#3). In contrast, when mismatched at a strongly expressed antigen (#5), the poor result is similar to that of random donor platelets (#1). These cross-reactive antigen groups reflect differences in public and private epitopes and the use of this strategy is described as utilizing cross-reactive groups (CREGs) [141]. Further discussion of newer strategies for matching of platelets for alloimmunized patients will be presented subsequently.

If appropriately matched donors cannot be located for refractory alloimmunized patients, it is inadvisable to continue to administer random donor platelets prophylactically because the risks and discomforts of such transfusions outweigh the benefits. However, significant bleeding in these patients can sometimes be managed by infusions of massive amounts of unmatched platelets [119], although heavily sensitized patients even then do not obtain count increments and continue to bleed. The possible mechanisms leading to response with this approach may include the accidental inclusion of partially matched platelets in the random pooled platelets or a temporary reduction in antibody titer by the large amount of infused antigen, enabling some of the transfused platelets to survive.

As noted above, it has been demonstrated that some patients lose their allo-antibodies over time, particularly those who develop these antibodies while on treatment [128, 129, 131]. In certain cases, no recent antigenic challenge has occurred, which would explain the decline in lymphocytotoxic antibody levels, and a rapid, anamnestic response to rechallenge is often seen. However, in an early study of 234 patients who had developed lymphocytotoxic antibodies at some time in their clinical course, 70 (30%) had significant declines in antibody level [128]. Among 35 evaluable patients, previously alloimmunized, who then lost their antibodies and were rechallenged with random donor platelets, 34 patients when rechallenged responded with good transfusion outcomes to random platelets for 2 weeks to 36 months [128]. Twenty-one patients failed to regenerate lymphocytotoxic antibodies despite repeated transfusions [128]. Again, in the TRAP study, 145 patients became antibody positive, and 81 (56%) subsequently became antibody negative [129].

Over the past decade, technology has evolved to identify the numerous epitopes or alleles that are components of the individual HLA antigens (see Chapter 56). This information has been particularly important in advancing the field of mismatched stem cell transplantation, but is also being utilized

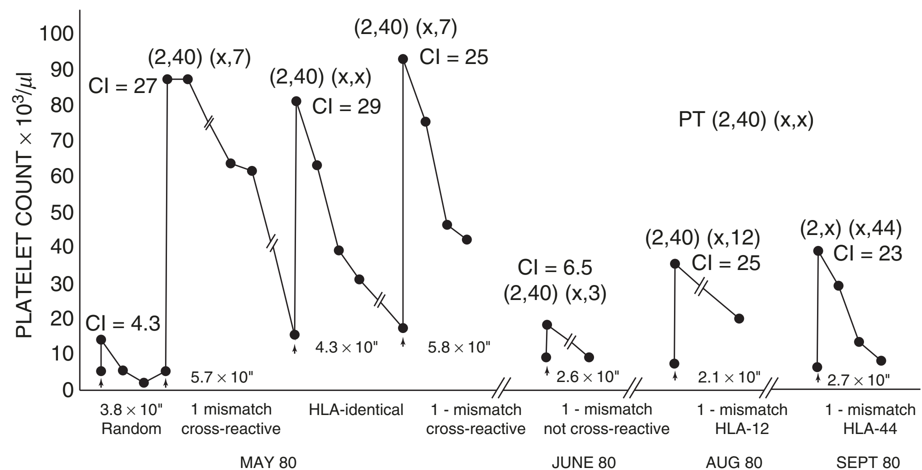

Fig. 54.3 Clinical course of this alloimmunized patient demonstrates the value of selectively mismatched platelets when the antigens are cross-reactive with recipient antigens (transfusions #2 and 4). Platelets mismatched at HLA-44 were also clinically effective (transfusion #7). *Parentheses*, HLA phenotypes; *CI* corrected increment

to define optimal platelet donor/recipient matches. Duquesnoy et al. have developed a structurally based matching algorithm based on amino acid triplets and subsequently epitopes called eplets to further define the HLA phenotypes [142]. This HLA-matchmaker program has been utilized and reported on, and a prospective trial is underway [142–144]. Additionally, the refined exposition of the HLA structure has led to an understanding that allo-antibodies have different specificities among these epitopes, with differing impact on transfusion outcome. Petz et al. recommended identifying donors based on recipient antibody profile [145]. Technology has been developed to provide more sensitive anti-HLA antibody detection, with techniques such as enzyme-linked immunosorbent assays (ELISA) and mini-flow bead platform binding (Luminex Corp) [146–150]. The latter was initially directed toward solid organ transplantation, but more centers with solid and stem cell transplant programs are using antibody profiles to help direct platelet transfusions for alloimmunized recipients [148, 149]. The sensitivity of these approaches are relevant to organ transplantation, but may be overly sensitive in the setting of platelet transfusion, and Jackman et al. has reported that low level HLA-antibodies, as determined by modern bead-based technology, did not predict platelet transfusion failure in the TRAP study [151]. Antibody cutoffs continue to be defined and likely have different implications in transplantation and transfusion.

There is continued interest in utilizing cross-matching tests with the platelet as the target cell. The original approach was to use stored donor platelets from potential donors, to be cross-matched with recipient serum prior to transfusion [152, 153]. Moroff et al. [152] evaluated comparative transfusion data in patients known to be refractory to random donor platelets, choosing donors by HLA matching or by platelet cross-matching using three different methods. They found comparable percentages of successful transfusions using either HLA-selected or cross-matched-compatible donor selection. In another early study, both HLA-compatible and cross-match-compatible methods were effective in providing single-donor platelets and the authors concluded that these were independently important selection methodologies [153].

More contemporary reports of cross-match-compatible platelet transfusions for refractory patients, utilizing newer methodology, provide interesting insights [154–157]. In one report, cross-match was effective in providing successful transfusions except in patients with broad reactivity, and this group suggests utilizing broad reactivity to trigger a workup for HLA-matched platelets [154]. Another report utilizing a modified antigen capture ELISA cross-matching technique appeared to be quite successful in selecting transfusions [155], and similarly, reports utilizing a solid-phase red cell adherence technique was reported to be successful [156, 157]. However, Rioux-Masse et al. compared utilization of cross-matched or HLA-matched platelets from a blood center, and found unsatisfactory results with both approaches [158]. Other clinical factors affecting platelet transfusion outcome were suspected, but not identified, and the numbers of transfusions and patients were small [158].

All methods of donor selection have their proponents in the blood bank and transplantation community, based on technology available, patient needs, donor availability, and cost in time and expense.

Table 54.6 provides an algorithm for managing platelet transfusion support throughout the course of a patient's treatment for leukemia.

Prevention of Alloimmunization

The contaminating lymphocytes in earlier preparations of platelet transfusions served as the major antigen-presenting component leading to alloimmunization to HLA antigens [159]. Animal studies document this, in that in murine studies, repeated administration of pure preparations of platelet suspensions was incapable of inducing an antibody response, but when the preparation also contained lymphocytes, an antibody response was induced [159]. Lymphocytes carry class II histocompatibility antigens that are necessary for invoking a recipient immune response against class I HLA antigens. Although class II antigens are not found on platelets, the presence of lymphocytes in the transfusion leads to activation of an immune response that is subsequently directed toward both lymphocytes and platelets (which carry class I antigens) and thus produces the development of alloimmunization and transfusion refractoriness [159, 160].

It appears that different levels of leukocyte depletion yield specific results. For example, a reduction to less than 10^7 leukocytes/transfusion will reduce the rate of transfusion reactions. However, it requires a reduction to less than 10^6 leukocytes to prevent transmission of cytomegalovirus (CMV) and to reduce the development of alloimmunization [92, 161, 162].

The TRAP study has demonstrated that this level of leukocyte depletion can be accomplished utilizing both modern apheresis techniques and modern filtration techniques, most with polyester, leukoadherent filters (all provide reduction of greater than 3 logs, to $<10^7$ leukocytes) [16, 28, 92, 161, 162]. These data are supported by other smaller studies that in fact provided the stimulus to engage in this randomized trial to test the hypothesis of leukodepletion and the prevention of alloimmunization [16, 28, 163–165]. In addition, in the TRAP study, a method of lymphocyte inactivation, utilizing ultraviolet B (UVB) irradiation, was administered to the transfusion products, to inactivate lymphocytes and antigen-presenting cells, such that they became incapable of generating an alloresponse [92, 166–168]. In animal studies, data

Table 54.6 Algorithm of platelet transfusion management

1. Preparation of a new leukemia or other patient requiring multiple transfusions
(a) Obtain HLA typing from patient and family and maintain record
(b) Transfusion history: prior pregnancies, transfusions, viral infections
2. Transfusion products
(a) RBCs: filtered or leukodepleted at blood center
(b) Platelets: Leukodepleted, random donor
• Pooled single units
• Apheresis
(c) Irradiated if potential transplant candidate or severely immunosuppressed
3. Reactions to platelets or poor 24-h increment
(a) Obtain 1 h or 10 min posttransfusion count
(b) Assess other clinical factors that may contribute to refractoriness
(c) Assess storage duration of platelets prior to transfusion
(d) Evaluate ABH compatibility
(e) Assess for presence of lymphocytotoxic antibodies
(f) Reaction, but adequate posttransfusion increment
• Initiate leuko-poor or filtered platelets if not done previously
• Continue to monitor early posttransfusion platelet counts
(g) Poor immediate posttransfusion increment
• Nonmatched but fresh single-donor product—get early posttransfusion count
• Family donor—possibly more compatible—get early posttransfusion count
• Consider HLA-matched platelet transfusion—get early posttransfusion count
• Consider cross-matched, ASP-selected platelets—get early posttransfusion count
4. Subsequent courses of treatment
(a) Reevaluate transfusion history to determine previous response to platelet transfusions
(b) Obtain lymphocytotoxic antibody (LCTAb) screening level
(c) If alloimmunized, refractory, or with a history of reactions or with high-titer LCTAb
• Initiate autologous platelet cryopreservation
• Be prepared to provide HLA-compatible or cross-matched platelet products
• Monitor all transfusions with early posttransfusion counts
(d) If no history of alloimmunization or refractoriness
• Begin with pooled single units or random single-donor apheresis platelets
• Monitor early posttransfusion counts
– May develop anamnestic antibody response
– Likely to continue to respond to random donor platelets

demonstrated the ability to prevent alloimmunization and to perhaps induce immune tolerance using this technique [166, 167]. Initial studies in humans demonstrated the functional integrity of platelets subjected to UVB irradiation as evaluated by posttransfusion platelet count increments [166, 168], although storage time was somewhat diminished [169]. Therefore, this technique was felt to be appropriate for study in the TRAP trial, since it was not known at the initiation of the trial whether the current techniques would produce sufficient leukodepletion to actually prevent alloimmunization.

Subsequently, the TRAP study has demonstrated that this level of leukodepletion or leukocyte inactivation by UVB does in fact lead to a major reduction in the rate of alloimmunization among patients with leukemia who are transfused multiple units of platelets and RBCs [92]. All three approaches (filtration, apheresis, and UVB inactivation) significantly reduced the rate of alloimmunization compared to unmanipulated platelet products, and they were all equally effective. Among the subjects who received nonmanipulated platelets, the rate of development of lymphocytotoxic antibodies was 45% (somewhat lower than that in many previous reports), but the rate of development of lymphocytotoxic antibodies among the other three treatment groups was 17–21%. The rate of alloimmunization leading to refractoriness to platelet transfusion was 13% among those who received standard, nonmanipulated, pooled random donor platelets (again, lower than that in many reports) compared to 3–4% in the patients in the other three groups [92].

The overall rate of refractoriness was 27%. Thus, the current platelet transfusion product recommended for patients expected to receive multiple platelet transfusions, such as those being treated for leukemia or expected to undergo SCT, is to provide leukocyte depleted platelets. Irradiated products are recommended for those who will undergo SCT and those with severe immunodeficiency, such as Hodgkin's disease. This will be discussed further subsequently.

Hazards of Platelet Transfusion

Platelet transfusions are usually very safe, and the benefits outweigh the potential risks. Nevertheless, certain hazards of platelet transfusion therapy should be considered. Transfusion reactions occur most commonly during or shortly after infusion (although they may be delayed if the patient is premedicated with acetaminophen) and are usually mild, consisting of a sensation of chilliness (rarely shaking chills) or fever, with or without urticaria. Urticaria is most often associated with plasma-related components. Reactions due to leukoagglutinins (white cell antigen–antibody reactions) are febrile and nonhemolytic. Leukocyte-poor platelet products have been shown to reduce the incidence of platelet transfusion reactions due to leukocyte-specific antigens and even to anti-HLA alloimmunization [170]. Some advocate removing plasma as well, as an immunologically active medium, containing reactive substances than may contribute to reactions [34, 171]. Stored platelets, if not prefiltered, may accumulate

cytokines released from leukocytes during the storage process, such as interleukin-6 (IL-6) among others. These may lead to a febrile reaction upon transfusion [33, 170–172]. The presence of IL-6 in the transfusion may also induce what appears to be an allergic reaction with urticaria [172].

Although with modern platelet preparation, red cell contamination is reduced, there is still considerable plasma, particularly with apheresis platelet products, which may contain antibodies to ABH blood types. Therefore, ABH-mismatched platelet transfusion may rarely be associated with a hemolytic reaction if the donor has a high-titer hemagglutinin [173–176]. These have been reported over the years as case reports, but Larsson et al. suggests that this type of reaction may be underrecognized in a population receiving numerous blood products [174]. Additionally there has been a greater utilization of apheresis platelets with considerable plasma volume. Fontaine et al. implemented a risk mitigation protocol which includes volume reduction of ABH incompatible platelet units [175].

Circulatory congestion is a common, preventable problem in very ill patients receiving multiple infusions. This develops not only from the individual transfusions being administered, but also from the additive effects of administration of all blood products, multiple antibiotics, and other intravenous medications. If necessary, the volume of plasma in a platelet transfusion can be decreased immediately before infusion, using centrifugation and resuspension in a smaller volume of plasma. This is routinely done for transfusions to children.

Transfusion-related acute lung injury (TRALI) may be an unrecognized cause of non-cardiogenic pulmonary edema following platelet transfusion. This is usually a reaction from administration of anti-neutrophil and/or anti-HLA antibodies in the plasma of platelet units, and possibly other bioactive substances into susceptible recipients. In the past decade, TRALI-risk reduction policies for donor screening have been implemented in a number of countries and have been widely accepted [177, 178]. Essentially, female platelet donors with history of prior pregnancies trigger HLA-Ab testing and those who are positive are redirected to whole blood donation. There has been a dramatic reduction of TRALI by more than two-thirds in both the United States and United Kingdom with this approach, with fatalities similarly greatly reduced [178].

Bacterial contamination of platelets is rare, but it is a documented cause of platelet transfusion reaction from stored platelets. This must be considered in severe reactions, and the transfusion bag and patient should be cultured [179]. Because platelets are currently stored at room temperature, the risk of bacterial growth exists with storage [180, 181]. New methods of testing for bacterial contamination are being applied pre-transfusion [182, 183]. Trials of pathogen reduction storage systems are underway worldwide, including the use of UV irradiation with or without additives [64–66]. As noted in the section on platelet storage, 7-day storage has recently been approved when used with the Verax Platelet PGD test as a pre-infusion test for pathogen screening [47, 48]. Additionally a pathogen reduction system called Intercept has been approved for use in the United States for stored apheresis platelets which utilizes amotosalen and UVA illumination to irreversibly cross-line nucleic acids in potential pathogens [184]. A system called Theraflex UV is being studied in Australia for pathogen control of emerging viral infections [185].

Clearly, a major concern in transfusion support is the transmission of infectious diseases carried by donors. Serologic testing of donors for hepatitis viruses has markedly diminished transfusion-related transmission of hepatitis [182, 183]. As noted above, several of the systems undergoing investigation are directed at emerging, and often subclinical infections among donors [184, 185].

Leukocyte-associated viruses may also be transmitted by transfusion, and these include human T-cell leukemia virus types 1 and 2 (HTLV-1 and 2), CMV, and the Epstein–Barr virus (EBV). Systematic donor screening is routinely performed for HTLV-1 and -2 to eliminate donors carrying these viruses. It has also been shown that the incidence of CMV infections developing in CMV-negative recipients as a result of transfusion can be modulated by limiting the number of CMV-positive donors and by adding CMV-immune globulin [186]. However, the ubiquitous nature of the CMV carrier state makes it nearly impossible to completely supply blood product support to very ill patients with strictly CMV-negative donors. The use of leukocyte-depleted blood products also markedly reduces exposure to CMV by reducing the number of virus-carrying leukocytes and in many cases prevents the development of primary CMV infection in a CMV-negative recipient [186–190]. The AABB recently published a Committee Report on reducing transfusion-transmitted CMV, and this describes the variation in practice to control this entity [191].

Another recognized complication of transfusion that is receiving increased attention is transfusion-associated graft-vs.-host disease (TA-GvHD). This phenomenon is mediated by immunocompetent donor lymphocytes that activate against the foreign recipient. Although this has been a long-standing problem in bone marrow transplantation, this has also been described in the nontransplant setting and in infants [192]. In addition, immunocompetent recipients undergoing whole blood transfusion from haplotype-identical donors have developed this syndrome [193–195]. Because of the haplo-identity of the donor, usually a relative, the recipient recognizes the donor as self, but the donor cells react against the recipient's nonidentical haplotype.

The clinical syndrome is usually severe, with erythematous rash, fever, diarrhea, and abnormal liver function tests.

A skin biopsy is often diagnostic, with infiltration of lymphocytes along the dermal–epidermal junction, basal cell vacuolar degeneration, hyperkeratosis of the stratum corneum, and degenerative dyskeratotic cells that may be accompanied by lymphocytes, known as satellite dyskeratosis [195–198]. HLA typing of the donor and patient may also give an indication of the cause of the syndrome. TA-GvHD is often rapidly progressive and frequently fatal.

Patients with hematologic malignancies, particularly those undergoing intensive treatment, are considered to be at increased risk for TA-GvHD, although several studies have demonstrated that the reported incidence in the USA is much lower than would be expected by analysis and prediction from HLA-type frequencies [197, 198]. Clinical reports in the USA are also relatively rare considering the frequent use of family donors. Studies from Japan implicate the use of fresh whole blood and a homogeneous population in the development of this phenomenon [199]. Other studies have suggested that the degree of T-cell competence or T-cell depletion of the recipient, such as in Hodgkin's disease and perhaps non-Hodgkin's lymphoma, is important in the manifestation of this syndrome [196, 197]. Current standards recommend that blood products from directed donors that are first or second degree and to recipients who are significantly immunoincompetent be irradiated, such as transfusion to those with Hodgkin's disease [23, 196, 197]. Currently, most patients with hematologic malignancies who are in consideration of transplant or who are immunoincompetent are receiving irradiated blood products. Studies are under way to evaluate the effect of gamma irradiation and ultraviolet irradiation on both platelet function and leukocyte inactivation.

Granulocyte Transfusion Therapy

The concept of utilizing granulocyte transfusions for treatment of neutropenic sepsis arose out of the successful use of platelet transfusions in controlling bleeding. As a result of that success, patients undergoing treatment for leukemia were at much lower risk of mortality from severe bleeding; however, they frequently succumbed to infection. The development of technology capable of separating granulocytes from whole blood led to the evaluation of granulocyte transfusions in severely infected neutropenic patients. The ongoing limitation of this cellular support continues to be the ability to provide sufficient numbers of granulocytes to eradicate infection in severely infected, severely neutropenic patients. Providing donors that are ABO matched, at a minimum, on a daily basis, who are accepting of premedication including dexamethasone and/or granulocyte colony stimulating factor (G-CSF) all add to the complexity of supporting such a severely ill patient through what is expected to be a temporary situation. Nevertheless, the experience of many investigators and clinicians has shown efficacy in many cases, and this continues to stimulate research and innovation in providing this critical supportive cell therapy.

The initial investigations utilized granulocytes from patients with chronic myelogenous leukemia (CML), to take advantage of the elevated WBC count, which allowed collection of large numbers of granulocytes. This produced both an elevated posttransfusion WBC count in the recipient, and a clinical benefit [3, 200, 201]. Evaluation of the function of these cells showed responsiveness to bacterial infections [202]. These transfusions successfully eradicated infection, including gram-negative organisms [3, 200, 201]. Collections of granulocytes from patients with CML were in fact the first "peripheral blood stem cell transfusions." They included not only mature neutrophils, but myeloid precursors, primarily committed, leading to temporary engraftment with persistent production of myeloid cells and sustained neutrophil counts of more than 500/μL for 4 or more days after the transfusion [3, 201]. These initial investigations pointed out the principles necessary for success of granulocyte transfusion therapy: a sufficient dose (more than 10^{10} neutrophils) and the sustained presence of infection-fighting cells.

Despite the success of these early investigations, the use of CML donors was not practical in terms of donor availability as well as new, more effective treatments for patients with CML. However, it provided a proof of principle that with sufficient dose and duration, granulocyte transfusions could aid in eradicating severe infection in neutropenic patients. Therefore, granulocyte transfusion research has focused on optimizing granulocyte collection from normal donors, with improvements in apheresis technology and strategies to prestimulate donors to enhance collection numbers.

Granulocyte Collection and Storage

Granulocyte collection technology has followed steps similar to those of platelet collection and utilizes the same principles of differential centrifugation to obtain the selected blood component. Modern techniques utilize the apheresis technology described in Chap. 52, with the best yields obtained with continuous-flow leukapheresis. Granulocytes are difficult to separate from whole blood because they are essentially the same density as RBCs. Therefore, whether apheresis or gravity leukapheresis is utilized, additional techniques are necessary to induce the efficient separation of granulocytes from RBCs [6, 203, 204].

This involves the use of sedimenting agents that induce the formation of erythrocyte rouleaux so that "clumps" of RBCs become heavier than granulocytes and the two cell types can be centrifuged apart. Hydroxyethyl starch (HES) and low molecular weight dextran have been used for this purpose [205]. Both agents coat the red cell surface, induce

the formation of rouleaux, and allow efficient differential centrifugation, with sedimentation of the red cell clumps. Since granulocyte transfusions are collected from normal donors, the effect of starch exposure in donors has been evaluated. At 24 h, 50% of the HES remains in the blood of the donor, and traces of the substance have been found as long as 8–9 months after a leukapheresis procedure [206]. No long-term effects have ever been reported in either donors or recipients in more than 30 years of leuapheresis utilizing this substance. HES is also widely used as a volume expander in surgical and intensive care patients with no long-term ill effects reported.

Granulocytes, particularly for adult recipients, are almost exclusively collected using apheresis machines (see Chap. 52 for details) [6, 204]. Techniques of granulocyte collection of historical interest include a manual technique called gravity leukapheresis, in which 1 U of whole blood was removed and sedimented with HES; the granulocytes were then separated, and the red cells were reinfused. This cycle was repeated until an adequate number of granulocytes were collected, similar to the gravity method for platelet collection [5, 203]. Reports from Japan have utilized a “simple bag method” to obtain granulocytes from growth factor-stimulated donors without apheresis for pediatric recipients [207].

The major technical problem limiting granulocyte transfusion efficacy has been the inability to obtain a sufficient dose of granulocytes from normal donors to be effective in combating sepsis in neutropenic patients. Evolution of granulocyte collection from gravity methods to continuous flow apheresis improved yields [208, 209], as did the adoption of premedication with corticosteroids (dexamethasone 8 mg orally 12 h prior to the procedure, and 10 mg as a slow intravenous infusion immediately preceding the procedure) to induce marginalized granulocytes to enter the blood stream [210]. Even with all of these improvements, however, the yield of granulocytes ranged from 2.5 to 5×10^{10} granulocytes for each donation [208–210]. This is still 1/100th of the estimated intrinsic response to sepsis. Functional studies demonstrated normal antibacterial function of granulocytes collected using steroid premedication and HES sedimentation [211].

Several reports have demonstrated that premedicating normal donors with G-CSF with or without dexamethasone further enhanced the yield of granulocytes [212, 213]. Donors receive single or multiple doses of G-CSF and donor WBC counts reach as high as 50,000/μL, with mean granulocyte collection yields of 4×10^{10} (range, $1–14 \times 10^{10}$) [212]. Recipients in these initial studies demonstrated sustained circulation of transfused granulocytes and no significant ill effects were noted in the donors [212, 213]. Granulocyte function studies in these collections showed normal chemotaxis and phagocytosis, and possibly enhanced enzymatic activity, demonstrated by chemiluminescence and superoxide formation [212, 214–216]. Reports in pediatric oncology, where there is a high granulocyte dose to body surface area (BSA) ratio, suggest clinical benefit with increasing doses of cells per BSA [207, 217, 218].

Studies have evaluated the efficacy and tolerability of G-CSF alone, dexamethasone alone, or the combination, with reductions in doses of G-CSF and individual centers have their preferred granulocyte mobilization regimen [219–224]. The ability to premedicate donors and provide daily or every other day granulocytes is most efficiently achieved within the setting of a cancer center with apheresis capability and where patient—related donors are often highly motivated to provide products for a specific patient. Nevertheless, Price et al. have demonstrated the ability to provide maximally stimulated granulocytes in high yields utilizing community donors who are also highly motivated [225].

The ability to collect larger and potentially more therapeutically useful doses of granulocytes has stimulated interest in revisiting the issue of granulocyte storage. Historically, even short-term liquid storage of granulocytes has been extremely difficult due to the high metabolic activity of these cells. The number of morphologically normal granulocytes in standard storage conditions declines by 10–15% per day during the first 2 days of storage. Studies have shown rapid exhaustion of glucose in the storage media [226], with measurable decreases in functional parameters such as microbial killing, chemotaxis, and the ability to circulate within the first 24 h of storage [227, 228]. Alterations in expression of adhesion molecules have also been described, which may contribute to these functional deficiencies [229]. One study evaluated the storage potential of granulocytes mobilized with G-CSF [230]. Although the hypothesis was that these cells might be less metabolically active, in fact the pH was less than 7.4 at the time of collection, and was less than 6.0 after 24 h of storage. To maintain storage pH, mobilized granulocyte concentrates required dilutions by 1–8 or 1–16, neither of which is practical [230].

Other investigations of enhancing granulocyte storage have evaluated the addition of G-CSF to the storage medium [216, 231, 232], and some investigators have reported successful 24-h storage with this approach in conjunction with reduced temperature [232]. Further evaluation is needed, and no standard long-term storage practice currently exists.

Thus, current practice dictates that granulocytes be transfused as soon after collection as possible. Donors must be pretested so that the product can be transfused within hours of collection. Even for short-term storage (meaning hours), granulocytes should be placed in large-volume bags (1000–2000 mL) with a large volume of plasma to avoid loss of function. Storage should, however, be avoided if at all possible.

Criteria for and Evaluation of Normal Donor Granulocyte Transfusions

Although the use of granulocyte transfusions has diminished considerably since the late 1970s, the clinical indications remain the same [233–235] (Table 54.7). Granulocyte transfusions should be considered in patients who are severely neutropenic (neutrophil counts less than 500/μL), whose marrow is not expected to recover imminently but will eventually, and who have a severe infection such as pneumonia or septicemia that is not responding to appropriate antibiotics.

Fortunately, this clinical setting occurs less frequently than previously, at least for bacterial infections, due to more knowledgeable use of empirical antibiotic approaches, and better and more broad-spectrum antibiotics. The latter can lead to resistance, however, and therefore may yield another scenario in which granulocytes may be considered. Fungal infections remain a difficult therapeutic dilemma in granulocytopenic patients. Therefore, infections remain the major cause of morbidity and mortality in neutropenic patients. Mobilization of donor granulocytes with growth factor stimulation in addition to dexamethasone prior to collection has yielded larger numbers of granulocytes, which it is hoped will lead to improved efficacy, particularly in patients with sepsis or fungal infections [234–236].

Studies evaluating granulocyte transfusions in patients with fungal infection must be attentive to dose of granulocytes, and such transfusions must be considered early in the clinical course, preferably prior to positive blood cultures. Doses less than or equal to 1×10^{10} are unlikely to be particularly effective, as noted from prior studies with cells from CML patients and prior animal studies [3, 236–241]. Data from studies in animals and with CML donors suggest that more than 10^{10} neutrophils in a 70-kg person is the minimum requirement for efficacy (1.5×10^8/kg) [239–241], which is one-tenth of the daily production of neutrophils in a normal, noninfected adult. Two studies reported yields of $2–4 \times 10^{10}$ neutrophils/transfusion with growth factor-stimulated donors, and some investigators have recommended that amount as the new standard for granulocyte transfusion therapy [212, 242]. Evaluation of the potential clinical value of granulocyte transfusions in infected, neutropenic patients will require an optimal dose and duration of granulocyte transfusion therapy. Thus, when technical factors do not limit the modality, it can best be evaluated, in the context of the data from the older CML donor transfusions.

Table 54.7 Criteria for initiating granulocyte transfusions

Criteria
Severe neutropenia (neutrophils <500/μL)
Marrow shows no evidence of immediate recovery
Clinically significant infection such as pneumonia or septicemia
Failure or inadequate response to appropriate antibiotics
Fungal infection poorly responsive to appropriate antibiotics
Expectation of eventual marrow recovery

Contemporary single institution reports, utilizing growth factor stimulated donors, both retrospective and prospective, again report major clinical benefit in a proportion of patients [243–247]. The variable outcomes reflect the impact of clinical factors, donor availability, and technical issues. A Cochrane analysis of the few randomized trials including old studies of lower doses and even prophylactic transfusions describes data quality issues related to enrollment biases, technological issues, and granulocyte doses [248, 249]. Because granulocyte transfusions, even in studies, are given in clinically emergent situations, the ability to control variables is limited.

A recent report of a prospective, randomized trial, RING—Resolving Infection in Neutropenia and Granulocytes, demonstrates the complexities and difficulties of controlling variables and conducting studies in this modality [250, 251]. The trial randomized infected patients, using specific criteria, to either standard antimicrobial treatment or the addition of granulocytes, mobilized by G-CSF/dexamethasone. The goal was to evaluate the efficacy of transfusion of high doses of granulocytes in seriously infected patients. Even in the setting of this trial, the results cannot be interpreted due to major limitations: (a) only half the planned number of patients were accrued (114 of the planned 236 subjects, with 56 receiving granulocytes)—interpreted as patient/clinician sense of lack of equipoise, (b) patients eligible might not have been routinely selected for granulocytes, and (c) major dose issues, with more than 25% receiving less than the prespecified dose of granulocytes, some substantially less according to the report [250]. Of importance is that when a subset analysis was conducted, based on dose of granulocytes administered, there indeed was a statistically significant benefit to those who received the high dose of granulocytes [250]. Therefore, the ability to maximize dose of granulocytes, even with pretreatment mobilization, remains a technical challenge. Nevertheless, with optimal circumstances, as reported in numerous small studies, granulocyte transfusion appear to provide clinical benefit. Optimizing this approach will require further research.

A commentary in reference to this paper suggests that perhaps mature granulocytes are not the best source of cellular anti-infection therapy, given their short life-span after collection (10 h), the technical issues of pre-screening and premedicating donors, the continued issues with obtaining sufficient doses of granulocytes, and the emergent requirement of providing a product within 6 h of collection [251]. This concept is leading to new avenues of research (see future directions).

Histocompatibility Issues in Granulocyte Transfusions

Febrile reactions and subsequent pulmonary infiltrates have been observed following granulocyte transfusions [249]. Although not always detected after such reactions, alloimmunization is a potential cause of reactions and has been documented in several studies [252, 253]. Granulocytes have both HLA antigens and neutrophil-specific antigens (the latter not linked to HLA) on their surface.

Observations from early granulocyte transfusion studies suggested a rough correlation between the occurrence of transfusion reactions and recipient alloimmunization, with the presence of antibody directed against the donor leukocytes [254]. Clinical studies suggested that alloimmunization to platelet transfusion (antibodies to HLA antigens) also affected the clinical outcome of granulocyte transfusions [255–257]. Studies imaging the infusion of Indium-111-labeled granulocytes showed more definitively that documented alloimmunization prevented the migration of granulocytes to sites of infection [258, 259]. Studies of Indium-111-labeled granulocytes in alloimmunized patients also demonstrated prolonged uptake in the lungs, pointing to alloimmunization as a component of the pulmonary reactions sometimes noted with unmatched granulocyte transfusions [260, 261]. One study evaluated granulocytes obtained from colony-stimulating factor-mobilized granulocytes and also described an effect of leukocyte compatibility, evaluating lymphocytotoxicity as a major factor in granulocyte increment and survival after transfusion [262]. Another study of granulocyte transfusions given to patients with severe aplastic anemia and serious infections did not observe a difference in increment despite HLA antibody production [263].

Granulocyte donors are currently selected based on ABH compatibility. However, testing for leukocyte antibodies is variably performed [261, 262]. If no evidence of clinical alloimmunization exists, then ABH compatible granulocyte transfusions are given. In patients who are already alloimmunized to platelet transfusions, proceeding with granulocyte transfusions can be hazardous, as described earlier. To proceed, donors who are effective platelet donors for alloimmunized patients are the safest candidates for granulocyte donation. No standard compatibility approach has yet been established, in part due to the rarity of the use of this transfusion product and its often urgent request. In the RING trial, volunteer donors were not chosen by HLA or granulocyte compatibility [250].

Reactions and Risks of Granulocyte Transfusions

All of the commonly reported types of blood product reactions can occur with granulocyte transfusions. Nonspecific and possibly multifactorial reactions include fever, urticaria, and fluid overload. Other potential causes of severe pulmonary reactions include the appropriate migration of the neutrophils to the site of the pulmonary infection with or without the development of an infiltrate on a radiograph and, more seriously, acute pulmonary edema and adult respiratory distress syndrome. The latter may be a result of an immunologic reaction (i.e., alloimmunization) or infection and the release of inflammatory cytokines. Pulmonary decompensation has also been associated with the combined administration of granulocyte transfusions and amphotericin B in one series [264], but less definitively causal in several other reports [265–267]. Adverse reactions including pulmonary reactions have been documented with either granulocytes or amphotericin B alone so that either or both may be the causative factors in reactions when they are administered concurrently. However, although the risk of reactions appears to relate to each individual component, prudence dictates that whenever possible, granulocyte transfusions and amphotericin B be administered separately, and with several hours between administrations [266]. In the contemporary RING study, transfusion reactions within 6 h of granulocyte transfusion were recorded, and included grade 1–2 (mild/moderate) in 41% of recipients (fever, chills, mild change in blood pressure). More severe reactions (grade 3–4) occurred in 10 patients (20%), including hypoxia ($n = 7$), tachycardia (n − 1), hypotension ($n = 1$), and allergic reaction ($n = 1$). One patient had grade 4 hypoxia requiring temporary ventilator support [250]. As noted above, donors were matched by ABH only.

Again, as with other blood products, the potential for TA-GvHD exists, particularly since family donors are often utilized for granulocyte transfusions. The AABB has recommended irradiation of all cellular components donated by relatives. The potential effect on viability adds emphasis to the recommendation that granulocytes be transfused as soon as possible after collection to ensure a viable and effective blood product.

Finally, the transfusion of granulocytes increases the risk of transfusing cells containing CMV. Both donors and recipients should be screened prior to initiating granulocyte transfusions. Although a large majority of the population has already been exposed to CMV with antibody titers, and therefore do not require CMV-negative blood products, the occasional recipient may be negative and will therefore require CMV-negative granulocytes. If the clinical infection is so severe that granulocytes are a necessity, then weighing the risk/benefit ratio of CMV-positive products becomes a very difficult decision. An acute CMV infection due to transfusion is less likely to occur during standard induction therapy for leukemia, but could potentially be fatal in the allogeneic transplant setting.

Future Potential for Granulocyte Transfusion Therapy

Granulocyte transfusions are infrequently used today, even though infection is still the major cause of death in neutropenic leukemia and bone marrow transplant patients.

A resurgence of interest has occurred due to the ability to provide transfusions with enhanced numbers of granulocytes, and due to the frequency of either resistant bacteria or fungal infections [243–251]. Several investigators have commented that granulocyte transfusion was prematurely abandoned, and we must now relearn their use with safer, more effective technology for collection [233, 251].

Additional research is ongoing to develop related cellular products such as myeloid progenitor cells with the capability of differentiating and providing an ongoing but temporary source of granulocytes [268, 269]. Animal studies have demonstrated the ability to recover from lethal challenges of bacteria and fungus using co-transplantation of lineage-specific progenitors [268]. A phase I trial in neutropenic leukemia patients has been reported and a phase II trial is ongoing [270, NCT 02282215]. Other studies are exploring an approach to generate functionally mature granulocytes induced from pluripotent stem cells [271, 272]. The potential for granulocyte support clearly demonstrates a need, and innovative approaches are undergoing investigation to supply this need.

Conclusions

The development of successful transfusion supportive care has had a major impact on our ability to treat patients with hematologic malignancies and those undergoing bone marrow transplantation. Additionally, transfusion immunology has contributed to the overall understanding of allogeneic transplant immunology. We continue to advance technology to make blood component therapy and transfusion a safer modality. Both platelet and granulocyte transfusion will remain a part of our armamentarium in the treatment of hematologic malignancies, and further optimization of these lifesaving components will continue. They are critical to the current management of these patients.

Alternative Sources of Hematopoietic Stem Cells and Their Clinical Applications

Filippo Milano, Shelly Heimfeld, and H. Joachim Deeg

History

Reports on the therapeutic use of bone marrow for the treatment of anemia associated with leukemia or parasitic infections date back about one century (reviewed in [1]). However, it was not until the events at Alamogordo, New Mexico, and the observations in atomic bomb casualties at Hiroshima and Nagasaki that systematic research into hematopoietic stem cell transplantation (HSCT) got under way [2]. Studies on total body irradiation (TBI) in mice, rats, dogs, and nonhuman primates revealed three levels of TBI-related injury: a marrow (hematopoietic) syndrome at about 500–700 cGy, an intestinal syndrome at 1200–10,000 cGy, and a cerebral syndrome at even higher doses [3]. In mice, shielding of the spleen during TBI, implantation of a syngeneic spleen, or infusion of syngeneic spleen or marrow cells after TBI rescued animals from the marrow syndrome [4, 5]. Intravenous injection was the most effective way of transplanting hematopoietic cells, which "homed" to the marrow cavity and other hematopoietic organs. These studies also showed that hematopoietic stem cells (HSC) were present at sites other than the marrow and were viable in the circulation. While the infusion of autologous or syngeneic cells rescued animals without complications, animals given cells from allogeneic donors developed a "secondary disease," subsequently known as graft-vs.-host disease (GVHD) [3, 6].

The first modern clinical transplant attempts were undertaken in patients with end-stage leukemia beginning in 1957. Results were discouraging: patients transplanted from syngeneic twin donors had a smooth posttransplant course, but generally died from progressive leukemia. Patients transplanted from allogeneic donors, on the other hand, generally died with severe GVHD [7]. The development of GVHD was recognized to be due to histoincompatibility between donor and recipient first described by Gorer in mice [8] and then characterized in humans by Dausset and others [9, 10].

Characterization of Hematopoietic Stem Cells and Sites of Hematopoiesis

A stem cell is defined by the ability to generate progeny while maintaining this capacity by way of self-renewal. Hematopoiesis is a continuous developmental process in which stem cells make specific cell fate decisions to produce various blood cell lineages [11]. The consistent generation of appropriate numbers and types of mature cells, as well as the maintenance of the HSC pool, requires a regulatory network, which is progressively being characterized. Within the hematopoietic microenvironment a complex signaling network involving soluble and cell-bound cytokines, as well as interactions among hematopoietic cells and stromal elements, has evolved to appropriately regulate the differentiation and proliferation of HSC and progenitor cell populations [12]. Despite considerable experimental and laboratory progress, the molecular signals that mediate cell fate specification and the self-renewal of HSC remain incompletely understood and controversial [11–14]. Recent studies using refined phenotypic and genetic analysis have generated data that challenge the established model of precursor cells leading to common myeloid/lymphoid and erythroid/megakaryocytic branches [15, 16].

Hematopoiesis in vertebrates evolves through three embryological stages [17]: the mesoderm is formed near the primitive streak, and mesodermal cells begin to migrate along the amniotic wall and visceral endoderm to form the first visceral blood islands (mesodermal or yolk sac phase). These islands then become connected by blood vessels of the primitive circulatory system. Later in embryogenesis, the

spleen and liver become the primary sites of hematopoiesis (hepatosplenic phase) before eventually the bone marrow takes over (medullary phase). At the time of birth, the marrow has become the predominant site of hematopoiesis in humans; only under stress conditions—such as in disease states—will hematopoiesis occur in the spleen, liver, and other extramedullary sites during adult life. In other species, e.g., mice, the spleen remains a hematopoietic organ throughout life.

In 1951, Brecher and Cronkite showed that cross-circulation between normal rats and rats irradiated with marrow-ablative doses of TBI rescued the irradiated animals by way of engraftment of hematopoietic cells originating from the nonirradiated partner [18]. Similar results were obtained subsequently in mice, baboons, dogs, sheep, and other species, showing that precursor cells capable of long-term hematopoietic reconstitution were present in the circulation. HSC are also present at relatively high concentrations in umbilical cord blood (UCB) [19], an extracorporeal segment of the fetal circulation.

Studies with candidate human HSC have essentially been confined to in vitro or xenogeneic animal model assays since it is ethically unacceptable to experimentally test various cell populations in humans for their long-term repopulating ability. In vitro characterization has involved Dexter-type long-term cultures, blast cell assays, assays for long-term culture initiating cells, or high proliferative potential colony-forming cells (reviewed in [20]). Early progenitors have also been identified phenotypically [21], and have been transplanted and characterized in immunodeficient (SCID) or SCID/NOD (non-obese diabetic) mice as well as in NSG (NOD/SCID/gamma) mice or sheep and in some clinical trials [22, 23]. According to the most prevalent opinion, the earliest identifiable hematopoietic precursor in human adult marrow is $CD34^{+}$ $CD38^{-}$ $CD33^{-}$ $HLA\text{-}DR^{-}$ $Thy1^{lo}$ $c\text{-}kit^{lo}$ ($Rho123^{dim}$) and noncycling [24]. However, this view has been challenged, and recent data suggest the existence of $CD34^{-}$ precursors that are more primitive than $CD34^{+}$ cells [25, 26]. $CD34^{+}$ cells account for 1–2% of nucleated marrow cells, and about 1% of those are $CD38^{-}$ DR^{-}. In peripheral blood of healthy individuals cells with similar characteristics are present, albeit at 100-fold lower concentrations [27]. Primitive stem cells in umbilical cord blood appear to be DR^{+} [28]. HSC from all these sources are further characterized by the lack of expression of lineage-specific markers.

Rationale for Hematopoietic Stem Cell Transplantation

Depending on the disease being treated and the patient's characteristics, the rationale for HSCT, and consequently donor selection and preparative regimen, vary. HSCT is widely used to overcome dose-limiting hematopoietic toxicity of chemoradiotherapy, to mediate disease elimination via an allogeneic graft-vs.-tumor (GVT) effect, and to replace congenitally defective hematopoietic systems or repair congenital metabolic or immune disorders. Encouraging results are also obtained in the treatment of autoimmune diseases. Thus, congenital and acquired, malignant and nonmalignant diseases are being treated successfully with HSCT. The use of HSC as "vehicles" for gene therapy remains investigational. Lymphohematopoietic cells have also been used in conjunction with solid organ transplantation to induce tolerance [29, 30].

Dependent upon the indication, HSC may be collected from the patients themselves (autologous) or from donors other than the patient (allogeneic), or, in rare cases, from an identical twin (syngeneic).

Autologous HSCT is utilized primarily as treatment of several malignancies in which dose intensification of therapy to myeloablative levels is potentially curative or capable of delaying disease recurrence (see below). For patients undergoing autologous HSCT to treat autoimmune disorders, the rationale is that intensive conditioning eradicates autoimmune cells and may allow a new and healthy repertoire of immune cells to regenerate and selectively increase regulatory T cells [31]. Active investigation of gene therapy to treat primary immune deficiencies, hemoglobinopathies, and metabolic diseases is ongoing. Allogeneic HSCT, in addition to hematopoietic reconstitution, contributes a GVT effect with curative potential for various malignancies [32]. This effect, mediated by donor lymphocytes, results in destruction of residual disease cells in the patient. Recognition of the GVT effect has led investigators to develop minimally toxic yet adequately immunosuppressive preparative regimens that allow for engraftment of donor cells and development of the GVT effect. These regimens (see next section) can be administered even to older individuals or patients with comorbid conditions who cannot tolerate the toxicity that may be associated with high-intensity conditioning regimens. However, because a GVT effect may take time to develop and is unlikely to have the capacity to overcome a high disease burden, these regimens are most effective in patients with indolent diseases or in patients in complete remission (CR) at the time of transplantation [33–35]. For younger, fitter patients, and patients at higher risk of relapse, high-intensity conditioning is generally still desirable prior to allogeneic HSCT to minimize disease burden and decrease relapse risk [36].

Allogeneic HSCT is also used as a curative strategy for nonmalignant congenital or acquired conditions that result in ineffective hematopoiesis, immunodeficiencies, or certain metabolic disorders. The allograft corrects the

deficiency and reconstitutes a normal hematopoietic system. Here, the goal is to minimize regimen-related toxicity and avoid GVHD. Because these patients often have not been treated with cytotoxic, immunosuppressive therapies prior to HSCT, their immune systems are frequently more intact, and securing engraftment can be more challenging [37, 38].

Preparation for Transplantation

High-Intensity (Myeloablative) Regimens

These intensive regimens ablate the patient's marrow and if not salvaged with HSC infusion would result in aplasia or severely prolonged cytopenias. High-intensity preparative regimens generally include chemotherapeutic agents such as busulfan, etoposide, melphalan, thiotepa, cytarabine, carmustine, and are often combined with irradiation, either in the form of TBI, limited field irradiation, or targeted radioimmunotherapy.

Reduced-Intensity Conditioning (RIC) Regimens

These regimens are designed to be less toxic than high-intensity regimens. However, the separation of conditioning into two intensity groups is somewhat artificial as there is a broad spectrum. The least intense and minimally toxic regimens provide immunosuppression just sufficient to allow engraftment of donor cells. Mixed chimerism of donor and host cells frequently develops for a period following transplantation. For nonmalignant disorders, mixed chimerism may be sufficient to correct the underlying condition, but to treat malignancies, complete donor chimerism is generally desired as the persistence of host cells tends to be associated with a high probability of relapse.

Two gray (Gy) TBI ± 90 mg/m^2 of fludarabine is the paradigmatic low-intensity regimen for patients undergoing HSCT for malignant diseases [39]. However, for patients undergoing transplantation for nonmalignant conditions, or those who have not received significant prior therapy for their malignancies, additional immunosuppression may be required to secure sustained engraftment. Modest increases in radiation doses, or added T-cell-specific therapies such as antithymocyte globulin (ATG) or alemtuzumab (anti-CD52 antibody), may be incorporated into these regimens [40, 41].

Fludarabine combined with modest doses of busulfan, cyclophosphamide, melphalan, or TBI are frequently used, somewhat "intensified" regimens [42–45]. Treosulfan, a busulfan analogue with less liver toxicity and possibly greater antileukemic potential, is currently under investigation as a novel agent in various regimens [46, 47].

Radioimmunotherapy has also emerged as a strategy to intensify radiation therapy with minimal toxicity. Radiolabeled antibodies targeting receptors expressed on hematopoietic elements allow for high dose internal radiation exposure of disease tissue/cells with minimal exposure of other organs. Radiolabeled CD20 antibodies are well established in the treatment of lymphoma, and radiolabeled CD45 antibody is effective in the treatment of myeloid leukemia and myelodysplastic syndrome (MDS) [46, 48]. New strategies to pretarget radiolabeled antibodies directly to malignancy may lead to even greater specificity and efficacy of this strategy [49].

Selection of Hematopoietic Stem Cell Donors

Three major questions are addressed when deciding upon the HSC source. First, will the transplant be autologous or allogeneic? Second, for allogeneic transplantation, will the donor be related or unrelated? Third, will the stem cells be collected from the bone marrow or peripheral blood or will cord blood be used? Characteristics of these stem cell sources are summarized in Tables 55.1 and 55.2.

Table 55.1 Hematopoietic stem cell sources

Source	Indication
Marrow/peripheral blood	
HSC in peripheral blood originate from marrow and recirculate to the marrow. Their presence in peripheral blood makes them readily accessible. However, their differentiation status may differ from that of marrow HSC, and they are further modified by exposure to G-CSF, which "mobilizes" them from the marrow. PBSC lead to faster hematopoietic recovery posttransplant than cells aspirated from unmanipulated marrow. Also, PBSC can possibly be obtained even if aspiration from marrow is not possible.	
Allogeneic[a]	Acquired diseases with or without HSC involvement; congenital disorders
Syngeneic	Acquired malignant or nonmalignant diseases with or without HSC involvement
Autologous	Acquired, usually malignant disorders, generally without HSC involvement; autoimmune disorders; possibility of genetic correction of defect
Umbilical cord blood	
Allogeneic[a]	Lack of alternative stem cell source; acquired diseases with or without HSC involvement; congenital disorders
Autologous	Experimental; possibility of genetic correction of defect

[a]Includes related and unrelated donors

HSC hematopoietic stem cells, *G-CSF* granulocyte colony-stimulating factor, *PBSC* peripheral blood stem cells

Table 55.2 Characteristics of marrow, peripheral blood, and cord blood used for allogeneic HSCT

Characteristic	Marrow[b]	Peripheral blood	Cord blood
Harvest procedure	Anesthesia—Multiple marrow aspirates	Vascular access—Apheresis (≈4 h × 1–2)[a]	Extraction of cells from cord and placenta
Number of cells obtained (per kg patient weight)			
• Total mononuclear	$1–4 \times 10^8$	$2–100 \times 10^8$	$0.7–30 \times 10^7$
• CD34+	$1–5 \times 10^6$	$2–20 \times 10^6$	$<1–45 \times 10^5$
• T cells	$5–50 \times 10^6$	$2–10 \times 10^8$	$<5–>20 \times 10^6$
Cell subpopulations			
• CD34+		↑ #	↑ #
• T cells		↑ #; ↓ Reactivity	↓ Reactivity
• Monocytes		Increased IL-10	Reduced HLA-DR, CD86, ICAM1, IFN-γ production

[a]G-CSF mobilized
[b]Some results with marrow cells following G-CSF administration have been reported recently [50, 51]

Autologous vs. Allogeneic Transplantation

As described earlier, autologous transplantation is indicated for several diseases. While autologous HSC in principle should be available for every patient (except possibly heavily pretreated patients or patients with marrow failure states who are unable to mobilize sufficient stem cells for subsequent transplantation), autologous transplantation conveys no GVT effect, and there is always concern that some malignant cells are returned to the patient with the transplant inoculum. Until more effective gene transfer strategies are developed, autologous HSC are also not useful for genetically determined disorders. Given its inherent risks, allogeneic transplantation is generally reserved for diseases not amenable to treatment with autologous HSC. Allogeneic transplantation is basically always performed with curative intent.

Allogeneic Donor Selection

HLA matching has been the primary consideration when selecting an allogeneic donor [52]. The Class I molecules HLA-A, B, C and the Class II molecules HLA-DR ± DQ are considered in screening potential donors. In general, an HLA-matched sibling donor is considered the first choice. Because individuals inherit one set of HLA genes from each parent, any sibling has a 25% chance of being matched to the patient [53]. In addition, phenotypically matched related donors are identified for about 1% of patients, and somewhat less than 1% of patients will have an identical (syngeneic) twin donor [54]. Syngeneic donors, however, do not provide a GVT effect.

For patients lacking a matched sibling, an alternative donor must be identified. The typical second choice is an unrelated donor matched at high-resolution (DNA level) typing for at least 8 or 10 HLA antigens. Due to the efforts of organizations such as the Anthony Nolan Appeal in the UK, the National Marrow Donor Program in the United States, the DKMS in Germany, and other organizations worldwide, more than 25 million volunteer donors have been added to registries as potential HSCT donors [55]. Computer searches of those databases very quickly generate an idea as to the probability of finding an HLA-matched unrelated donor. However, the logistics of confirming eligibility and coordinating timing of an unrelated donor HSCT may take weeks to months, and this delay may be unacceptable for disease control in patients with aggressive malignancies [56]. The likelihood of finding an optimal donor differs between racial and ethnic groups, with the highest probability among whites of European descent, at 75%, and the lowest probability among blacks of South or Central American descent, at 16% [53, 57].

For patients lacking a matched unrelated donor, alternative donor options include mismatched unrelated donors, UCB, and HLA haploidentical donors. A rapidly increasing body of data supports the efficacy of UCB transplantation for patients lacking suitably matched related or unrelated donors. UCB units mismatched at one or two HLA loci and of sufficient size are available for almost all patients younger than 20 years of age and for more than 80% of patients 20 years of age or older, regardless of racial and ethnic background [57]. HLA-haploidentical donors—related donors who share only one haplotype (the maternal or paternal #6 chromosome) with the patient—are appealing, because nearly all patients will have a donor who is immediately available. HLA haploidentical donors are increasingly utilized as source of stem cells because of lower acquisition cost, availability regardless of race, fast procurement of stem cells, and the likely availability of the donors to collect additional cells if needed. Haploidentical transplantation outcomes have improved primarily because of the use of posttransplantation cyclophosphamide for GVHD prevention [58].

The Type of Hematopoietic Stem Cells

Once a donor is identified, a final consideration is whether to use HSC collected from bone marrow or peripheral blood; in some cases, cord blood might be the first choice.

Bone Marrow vs. Peripheral Blood

Bone marrow was the original source of HSC used for transplantation. Demonstration of the ability to mobilize HSC into the peripheral blood either with high-dose granulocyte colony-stimulating factor (G-CSF) or chemotherapy ± glucocorticoids made it possible to use peripheral blood stem cells (PBSC) for HSCT [59–61]. PBSC show a lower retention of rhodamine 123 (which is typical for noncycling cells), and may have a lower expression of CD38 as compared to bone marrow cells. Unless T cell depleted, PBSC contain significantly greater numbers of T cells than marrow.

PBSC sustain hematopoiesis as well as cells aspirated from the marrow. Many patients have now been followed for more than 15, 20, or even 25 years and show normal hematopoiesis [62, 63]. Given the ease of collecting PBSC, the proportion of PBSC transplants has increased significantly, and PBSC are currently used for basically all autologous transplants in patients with hematologic malignancies.

Numerous randomized trials have compared outcomes with bone marrow and PBSC. A recent phase III, multicenter, randomized trial of transplantation from unrelated donors showed no statistically significant difference in 2-year overall survival. The incidence of graft failure was significantly lower in the PBSC group, 3%, versus 9% in the bone marrow group ($p = 0.002$). The incidence of chronic GVHD at 2 years was significantly higher with PBSC, 53% versus 41% in the bone marrow group ($p = 0.01$). There were no significant between-group differences in the incidence of acute GVHD or relapse [64].

In patients prepared with RIC regimens, PBSC have been used almost exclusively as the source of HSC, in part because of the greater "engraftment potential" ascribed to those cells and in part related to the larger numbers of cells that are obtainable along with higher T-cell doses [65].

However, in patients undergoing HSCT for nonmalignant disorders, concern about the increased risk of GVHD associated with PBSC still favors the use of marrow [65]. Patients with nonmalignant diseases are unlikely to derive any gain from chronic GVHD.

Umbilical Cord Blood

Umbilical cord blood (UCB) has emerged as an important source of HSC. Since the first UCB transplant in 1988 using an HLA-identical sibling's UCB [66], there has been a steep increase in the use of UCB. The proliferative potential of UCB stem cells is greater than that of adult marrow or PBSC [67]. UCB contains proportionally higher numbers of progenitor cells than adult blood and possibly adult marrow [19, 68, 69]. Cord blood T cells are less immunocompetent than adult cells [66, 69]. Intracytoplasmatic signaling (following T-cell receptor engagement) in cord blood T cells differs from that in adult T cells [70]. Cord blood monocytes express lower levels of HLA-DR, CD86, and ICAM-1 than monocytes in adult blood, and produce lower levels of IL-10 and IFN-γ. IL-4 and IL-5 are basically absent [71]. These differences may contribute to the tolerability of greater HLA mismatching between donor and patient.

Additional advantages of cord blood include the ready availability (frozen off-the-shelf product), the absence of risk to the donor, and the minimal risk of transfer of viruses. Major challenges include the limited number of HSC and progenitors in a single cord unit, which can lead to delayed engraftment and graft failure—particularly in adults and large children—as well as possible delays in immune reconstitution. However, recent advances, including increased availability of units with a higher cellular content, the ability to use two units to increase cell dose, and various ex vivo expansion methods, have further increased the application potential of this cell source [72, 73].

Harvesting and Infusing HSC for Transplantation

Bone Marrow

Bone marrow is the primary organ of hematopoiesis in adults and the site from which stem cells for transplantation were traditionally harvested [74]. For that purpose, the donor (or patient) receives anesthesia, and under sterile conditions, multiple small volume aspirates (≈3 mL) of marrow are obtained from both posterior iliac crests [75]. Additional potential aspiration sites are the anterior iliac crests, the sternum, and, particularly in children, the tibia heads. Approximately 10–15 mL/kg donor weight is collected, usually yielding $1–4 \times 10^8$ cells/kg recipient weight (Table 55.3). The concentration of cells is generally higher in children than in adults and in first harvests than in subsequent aspirations if done within a short time interval after the first procedure [76–78]. The marrow is passed through filters, in closed systems, to break up cell aggregates and remove bone particles. If no ABO incompatibility exists and if the marrow is not to be subjected to any in vitro purging procedure or other manipulation, the resulting cell suspension is infused intravenously, generally via an indwelling intravenous catheter (e.g., Hickman line), and cells "home" through the peripheral blood circulation to the marrow cavity to reconstitute the hematopoietic system.

Table 55.3 Autologous and allogeneic peripheral blood stem cell (precursor) harvesting

	HSC source	
	Autologous	Allogeneic
Methods of mobilization	Chemotherapy, cytokines/growth factors (antibodies to adhesion molecules)	Cytokines/growth factors
Types of chemotherapy	Cyclophosphamide; etoposide; paclitaxel; epirubicin; ifosfamide; cisplatin; carboplatin (combinations)[a]	–
Cytokines/growth factors used	G-CSF (5–20 μg/kg/day)	G-CSF (2–20 μg/kg/day)
	GM-CSF (4–64 μg/kg; 125–250 μg/m²)	
	IL-3 (5–10 μg/kg)	
	TPO/MGDF (0.03–5 μg/kg)	
	SCF (10–25 μg/kg) (combinations)[b]	
Risk of tumor cell contamination	Yes (higher without chemotherapy)	No
Time course for harvest	Predictable for cytokines; variable for chemotherapy	Predictable

[a]Various schedules, generally disease-dependent, have been used; blood leukocyte and CD34+ counts are monitored for optimum timing of apheresis

[b]Various injection and infusion schedules are used. G-CSF, currently the most widely used regimen, is generally given once a day s.c. for 5 days with leukapheresis on day 5 (and day 6 if necessary) [79].

Abbreviations: *G-CSF* granulocyte colony-stimulating factor; *GM-CSF* granulocyte macrophage colony-stimulating factor; *HSC* hematopoietic stem cells; *SCF* stem cell factor; *TPO/MGDF* thrombopoietin/megakaryocyte growth and development factor

Peripheral Blood Stem Cells

At steady state, HSC circulate at very low concentrations in peripheral blood. Following cytotoxic therapy, however, the frequency of early hematopoietic precursors in the circulation increases dramatically, though transiently, during the recovery phase [59]. The same effect is achieved if cytotoxic agents such as cyclophosphamide, etoposide, or taxol are given for the very purpose of "mobilizing" cells from the marrow into the circulation (Table 55.3) [80]. The administration of recombinant hematopoietic growth factors, such as G-CSF, granulocyte-macrophage colony-stimulating factor (GM-CSF) or c-kit ligand alone or in combination, has similar effects (although presumably via different mechanisms [81]), and the timing of the maximum stem cell yield, around 4–6 days after initiation of treatment with growth factors, is more predictable than with chemotherapy [60, 61]. Furthermore, the absence of cytotoxicity and the associated side effects allows the application of this approach to healthy donors. The mechanism involved in dislodging cells from the marrow and forcing them into circulation is incompletely understood. HSC are normally anchored within the marrow environment, through specific receptor interactions with other cells and extracellular matrix. In agreement with that notion, plerixafor, an inhibitor of the stem cell homing receptor CXCR 4, has been shown to improve mobilization and do so within a shorter time interval [82].

PBSC (including cells at various stages of differentiation) are harvested from blood by leukapheresis. The best currently available marker of the cells required for a successful transplant (stem cells; long-term repopulating cells) is the surface glycoprotein, CD34. For autologous procedures the goal is to harvest approximately 3–5 × 10^6 $CD34^+$ cells/kg recipient weights [83]. Higher cell numbers are targeted if the cells are to be processed in vitro or if cells for a "back-up" infusion or second transplant are desired. The yield of $CD34^+$ cells per apheresis (usually 10–16 L over 2–4 h) for autologous transplants varies considerably, largely dependent on the intensity of prior therapy given to the patients. Lenalidomide-treated patients, for example, are difficult to mobilize, and a "lenalidomide-free" interval should be allowed before attempting cell collection.

The most reliable indicator of the likely success of apheresis is the concentration of $CD34^+$ cells in blood [84]. In many patients, one single harvest will suffice; in others, several sessions are required. However, after 2 (or 3) days of apheresis, generally the incremental cell yield of $CD34^+$ cells from additional aphereses is small. Large-volume apheresis may be useful in some patients. Usually autologous cells need to be cryopreserved until completion of the patient's conditioning regimen. Mobilization of PBSC by G-CSF in healthy allogeneic donors results in more consistent cell yields than in pretreated patients. By and large, 2–20 × 10^6 $CD34^+$ cells/kg are obtained with a single harvest [62, 63]. As the harvest can be timed such that it coincides with completion of the transplant conditioning regimen in the patient, allogeneic PBSC are usually transplanted fresh. Cryopreservation is possible, however, and has been used, for example, to accommodate donor preferences.

Cord Blood Cells

Cord blood is collected either by venipuncture in the third stage of labor while the placenta remains in utero or by gravity drainage of the ligated umbilical vein once the

placenta has been delivered [85]. Collected cord blood must be shipped to a bank for further processing and cryopreservation. Units are screened for size, and appropriate units are processed. A minimum size threshold for further processing is approximately 0.9×10^9 total nucleated cells. Processing strategies include directly freezing the unit in 10% DMSO vs. various approaches involving red blood cell and plasma depletion. Units may be manually depleted using hydroxy ethyl starch or PrepaCyte-CB or by automated systems including Sepax (Biosafe, Eysins, Switzerland) and AutoExpress (AXP; Thermogenesis). Though direct freezing results in the smallest loss of total nucleated cells, the large product volumes occupy significant storage space, can cause hemodynamic complications upon infusion in small patients, and result in potentially larger DMSO exposure of patients. RBC and plasma-depleted products reduce these concerns, but some cell loss is inevitable during processing [86].

The thaw and wash technique developed by Rubinstein et al. is most commonly used in preparation for infusion [87]. A thaw and dilute procedure may increase efficiency and potentially improve infused cell doses [88].

More than 600,000 UCB units have been stored for transplantation worldwide, and more than 30,000 UCB transplants have been performed. Cord blood is generally donated to a public cord blood bank, but private biobanks are expanding rapidly both in size (ViaCord, which in 2000 stored only a few thousand UCB units, held over 300,000 units in 2013) and in number. In 2011, approximately 1 million UCB units were stored in more than 130 private UCB banks worldwide [89]. Private biobanks are prohibited in some countries, such as Italy [90]. Given current indications for cord blood transplantation, uses of privately banked cord blood are extremely limited. Additionally, private banks are not currently regulated, and the quality of units collected is not guaranteed. Expert opinion does not currently encourage private cord blood banking [91].

Fetal Liver Cells

Fetal liver, if obtained at the optimum time of gestation, provides a rich source of HSC [92]. However, this stem cell source has become obsolete.

Clinical Data

Currently more than 40.000 transplants are carried out annually worldwide (57% autologous and 43% allogeneic). Transplant activity is increasing, more so in Eastern European countries than in the West, and there is a progressive increase in the use of HLA haploidentical family donors (by 25%), while the growth of unrelated donor HSCT has slowed, as has the use of CB. The main indications for HSCT are leukemias (33%; 96% allogeneic); lymphoid neoplasias (57%; 11% allogeneic); solid tumors (4%; 3% allogeneic); and nonmalignant disorders (6%; 88% allogeneic).

Autologous Transplantation

Malignancies

Multiple myeloma (MM) remains the leading indication for high-dose chemotherapy and autologous stem cell transplantation (ASCT) worldwide [93] and the International Guidelines recommend that ASCT be offered at some point during the treatment program for all medically fit patients [94, 95]. High-dose melphalan at 200 mg/m^2 is the standard conditioning for autologous transplantation (ASCT) with very low transplant-related mortality (TRM) [96, 97].

ASCT is also a standard treatment for patients with chemosensitive relapsed or refractory aggressive B-cell Non-Hodgkin Lymphoma, including diffuse large B-cell lymphoma (DLBCL), occurring de novo or via transformation of indolent disease. ASCT is also widely employed in patients with relapsed follicular lymphoma and forms part of primary therapy in those with mantle cell lymphoma [98]. Second-line salvage high-dose chemotherapy and ASCT are established therapy for refractory/relapsed Hodgkin lymphomas, leading to durable responses in approximately 50% of relapsed patients and a minority of refractory patients [99].

In acute leukemia, in contrast to MM or lymphomas, ASCT occupies more controversial place [100]. In fact, the optimal post-remission treatment for acute myeloid leukemia in first complete remission remains uncertain. Controlled prospective trials comparing consolidation chemotherapy with ASCT [101–103] and biological randomization to HLA-identical matched sibling donor myeloablative transplantation conducted in the mid-1990s favored the allogeneic bone marrow strategy because of a lower probability of relapse, despite the high incidence of treatment-related mortality. With improved conditioning regimens and the broad availability of allogeneic donors, ASCT does not play a significant role in the treatment of leukemia [104–107].

Autoimmune Disorders

While not part of the "Neoplastic Diseases," several autoimmune disorders, including multiple sclerosis, scleroderma, rheumatoid arthritis, and others have been treated successfully by HSCT, generally using autologous cells [108, 109].

CAR-T Cell Therapy

Strategies of ex vivo transfer a therapeutic gene (via a viral vector) into autologous HSC are now being integrated into

clinical trials. The ability to engineer T cells to recognize tumor cells through genetic modification with a synthetic chimeric antigen receptor (CARs) has ushered in a new era in cancer immunotherapy. The most advanced clinical applications are in targeting CD19 on B cell malignancies. This has become possible by the introduction of genes that encode high affinity tumor-targeting T cell receptors (TCRs) or synthetic chimeric CARs, respectively [110, 111].

The most impressive clinical results have been achieved in patients with refractory B cell malignancies including acute lymphoblastic leukemia, chronic lymphocytic leukemia, and lymphoma who have been induced into complete remissions after infusion of autologous T cells modified with a CD19-specific CAR [112–116]. The group from the Children's Hospital of Philadelphia and the University of Pennsylvania reported treatment of 53 children and young adults (≤24 years) with B-ALL who received $1.0–17.4 \times 10^6$ CAR-T cells/kg after lymphodepletion chemotherapy. Forty-five of 53 patients (85%) achieved marrow CR by flow cytometry at 1 month and 2 additional patients were in CR by 3 months without further therapy [116, 117]. They reported CD19 CAR-T cells effectively eliminated disease even in the CSF. Of the 45 patients in CR at 1 month, 20 subsequently relapsed, 13 with CD19-negative disease, and relapse-free survival was 44% at 12 months. However, CD19 CAR-T cell infusion may be associated with significant toxicities, including a cytokine release syndrome (CRS, with fever, hypotension, capillary leak, coagulopathy, and neurotoxicity). Seizures and stroke like phenomena have occurred. Interleukin-6 plays a major role in the development of toxicity, and the anti-IL-6 receptor (IL-6R) antibody, tocilizumab, and corticosteroids have been used therapeutically and pre-emptively. In most patients CRS and neurotoxicity are transient. The optimal approaches are still being determined.

While effective in many patients with B-ALL, NHL, and CLL, for unknown reasons other patients do not respond, even though they experience the same toxicities. Thus, major challenges remain.

Allogeneic Transplantation

Complications associated with allogeneic HSCT include graft failure, delayed engraftment, regimen-related toxicity, GVHD, infection, and relapse. Clinical data regarding each of these issues as well as general outcomes with respect to donor source are discussed later and summarized in Table 55.4.

Table 55.4 Complications of transplantation by transplant type

Donor source/ conditioning regimen	Graft failure	GVHD	Infection	Relapse
Autologous	[b]	N/A	[b]	[b]
Allogeneic	↑		↑	↓
MRD	[b]	[b]	[b]	[b]
MURD	[b]	↑	↑	↓
MMURD	↑	↑↑	↑↑	↓↓
Cord	↑↑	[b]	↑↑	? ↓↓↓[a]
Haploidentical	↑↑	↑	↑↑	↑
High-intensity	[b]	[b]	[b]	[b]
Reduced-intensity	↑	Similar (later onset)	? ↓	↑

[a]Double unit cord blood transplantation may be associated with particularly low relapse rates
[b]Reference value
GVHD graft-vs.-host disease, *N/A* not applicable, *MRD* matched related donor, *MURD/MMURD* matched/mismatched unrelated donor

Transplantations from HLA-Matched Related and Unrelated Donors

While HLA-matched sibling donors have inherited the same genes, HLA-typing at the *allele level* is required to determine true HLA identity in unrelated patient/donor pairs since the same serologically defined *antigen* can be shared by an entire family of alleles. In a large retrospective study, Lee et al. investigated the impact of HLA mismatching detected by low- or high-resolution DNA testing at HLA-A,-B,-C-DRB1 on outcome of unrelated allo-SCT. They concluded that 8/8 matching was the minimal level of matching required for transplant since matching for only 7/8 or 6/8 was associated with a 10%–15% decrease in 1-year survival with each incremental mismatch [118].

The CIBMTR retrospectively investigated the outcome of adult patients who received a myeloablative allo-SCT from either an 8/8 matched unrelated donor ($n = 941$) or an HLA-matched related donor ($n = 3158$) [119]. Unrelated transplant recipients showed a higher incidence of or treatment-related mortality (TRM) and relapse in cases of acute myeloid leukemia (AML), but not in those with acute lymphoblastic leukemia (ALL) or chronic myeloid leukemia (CML). In addition, leukemia-free survival (LFS) was lower for patients with AML who received 8/8 matched unrelated donor compared to the ones receiving grafts from related donors. This was not the case for patients with ALL or CML.

A prospective study from the French Society of Bone Marrow Transplantation and Cellular Therapy (SFGM-TC) investigated the outcome of 236 consecutive patients with standard-risk malignancy. The study included 55 recipients, less than 55 years of age with an unrelated donor matched for 10/10 alleles and 181 recipients with HLA-matched related donors.

Diagnoses included acute leukemia (*n* = 175), chronic myeloid leukemia (*n* = 43), and myelodysplastic syndrome (MDS; *n* = 18). All patients were required to receive the same myeloablative conditioning regimen and GVHD prophylaxis. The use of antithymocyte globulin (ATG) was not allowed. In multivariable analysis, overall survival and transplantation-related mortality were adversely influenced by recipient cytomegalovirus-positive serology, age of donor older than 37 years, and the occurrence of acute grade ≥ II GVHD. The effect of donor type was nonsignificant for OS, EFS, and relapse [120].

In patients with high-risk or advanced hematologic malignancies the Seattle team observed no significant differences between recipients of HLA-matched related and 10/10 matched unrelated donors, while in patients with intermediate risk disease TRM was higher and survival lower with transplants from 10/10 matched unrelated donors after myeloablative conditioning and PBSC transplantation [121]. If no 10/10 matched donor is available, transplant physicians have to select between mismatched donors. Petersdorf et al. reported an outcome analysis in 4796 unrelated donor transplants receiving myeloablative conditioning. Of those, 61% were 10/10 matched and 39% were mismatched for a single allele or antigen. After adjusting for disease stage, age, and ethnicity, the hazard of mortality conferred by a single HLA mismatch (any locus) was significantly higher than the hazard observed after matched unrelated transplants [122]. Fürst et al. reported on 2646 patients. All were high-resolution–typed for HLA-A,-B,-C,-DRB1, and -DQB1. The highest mortality was seen for HLA-A,-B, and -DRB1 mismatches. HLA-DQB1–antigen mismatched cases showed a nonsignificant trend toward higher mortality [123].

HLA Haploidentical Transplantation

Although high transplant-related mortality, mostly due to delayed immune reconstitution, has been a barrier to success in HLA haploidentical transplantation, outcomes have significantly improved with the advent of high-dose posttransplantation cyclophosphamide (PTCy) [124, 125]. PTCy has been now incorporated in several myeloablative and non-myeloablative conditioning regimens, including Flu with busulfan and thiotepa [126], Flu with melphalan and thiotepa or TBI [127], and Flu with ablative TBI doses [128]. Using these approaches relapse rates for patients with myeloid malignancies have varied from 20% to 40% at 1 year. In some studies, outcomes of haploidentical transplants performed with PTCy have been similar to those with HLA-matched transplants (related and unrelated) [129, 130]. These findings were recently confirmed in a large retrospective analysis of the Center for International Bone Marrow Transplant Research (CIBMTR). This study compared outcomes in patients with AML transplanted from an HLA haploidentical donor or an 8/8 HLA matched unrelated donor and showed comparable survival at 3 years for patients after myeloablative (41% vs. 42%, *P* = 0.87) or RIC/non-myeloablative conditioning (35% vs. 37%, *P* = 0.89) [131]. Haploidentical transplantation is an area of active investigation with novel approaches focused on better controlling alloreactivity, elimination of posttransplantation immunosuppression, prevention of disease relapse, and improvements in immunologic reconstitution.

Cord Blood Transplantation (CBT)

UCB transplantation has made HCT available to many more patients, and novel strategies such as ex vivo stem cell expansion have yielded encouraging results [72, 73]. Improved survival in adult CBT followed the observation that cell dose was critical for engraftment and survival, leading to studies on double CBT [132]. However, recent results have questioned the benefit of double as opposed to single CBT. In adults, a Eurocord retrospective analysis reported improved DFS for leukemia patients in CR1 receiving a double as opposed to single CBT but no advantage for patients in CR2 [133]. These data suggest that single CBTs may be appropriate for most children while the data for adults requires further investigation [134].

Investigators at the Fred Hutchinson Cancer Research Center and the University of Minnesota compared outcomes in 128 patients who received myeloablative conditioning and double CBT with the outcome of patients who received transplants from HLA matched related (*n* = 204), matched unrelated (*n* = 152), or mismatched unrelated donors (*n* = 52) [135]. Disease-free survival at 5 years was similar for the three groups, whereas the risk of relapse was lower in recipients of double CBT. Similar findings were observed in two subsequent smaller studies [136, 137].

Major obstacles to greater success of CBT include delays in engraftment and immune reconstitution that lead to increased mortality [138, 139]. Several methods to improve the speed of engraftment and decrease transplant related mortality are under investigation, including ex vivo expansion with cytokine cocktails, modification of homing, and the concurrent use of mesenchymal stem/stromal cells [72, 73, 140, 141].

Summary and Outlook

The field of HSCT has expanded exponentially in recent years. During the last decade, RIC transplant approaches have emerged as an effective strategy to treat older and more

infirm patients who could not previously benefit from HSCT. The use of "alternative" sources of HSC has facilitated clinical applications of this modality and has made it widely available. Recognition of then immunotherapeutic aspect of HSCT has led to exciting new developments such as the use of CAR T cells and other genetically modified donor cells.

56 HLA Typing in Support of Hematopoietic Cell Transplantation from Unrelated Donors

Effie W. Petersdorf, Claudio Anasetti, Paul J. Martin, and John A. Hansen

Introduction

Advances in the field of immunogenetics of the human leukocyte antigen (HLA) system have changed the landscape of unrelated hematopoietic cell transplantation (HCT). The advent of molecular tissue typing methods provided an unprecedented level of accuracy in the characterization of the class I and II genes and the much needed tools for querying the genetic diversity and implications of human genetic variation on clinical outcome after unrelated donor HCT. Clinical application of DNA-based typing methods for registry donors, together with the growth of international donor registries, has greatly increased the chances that any given patient may identify a suitable donor and benefit from a life-saving transplant.

The HLA System

The HLA system was first described by Jean Dausset in 1952 after the discovery of agglutination reactions in recipients of blood products from multiparous female donors or blood donors who themselves were sensitized from previous blood transfusions [1]. HLA alloantigens were defined by serological methods in a complement-dependent microcytotoxicity assay using panels of alloantisera containing HLA antibodies that demonstrated the polymorphic nature of the HLA system [2–4]. Nomenclature was formalized starting in 1964 by the establishment of collaborative workshops [5]. The term "antigen" in HLA tissue typing describes epitopes that are recognized by antibodies, to be distinguished from epitopes that can be recognized by T cells. Transplantation responses involve both humoral (B cell) and cellular (T cell) immunity; although the link between HLA antigens and humoral responses is strong, the link between HLA alleles and cellular (T cell) responses is still an area of intense investigation, since not all allelic polymorphisms result in a T-cell response.

The HLA genes are located within a 4 Mb region at p21 on chromosome 6 within the major histocompatibility complex (MHC) and consists of three regions termed class I, class III, and class II. Genes within the class I and class II regions are structurally and functionally related; genes within the class III region, including tumor necrosis factor and heat shock protein, do not directly function as major transplantation genes but participate in the immune response through inflammatory reactions.

HLA Class I Genes

The class I HLA-A, B, and C genes lie within a 2 megabase region comprising the telomeric half of the MHC. Each class I gene is composed of 8 exons that encode specific domains of the class I molecule: exon 1, leader peptide; exon 2, α1 domain; exon 3, α2 domain; exon 4, α3 domain; exon 5, transmembrane

domain; and exons 6, 7, and 8, cytoplasmic domain. The lengths of the exons are known to be the same for each serologically defined antigen. Polymorphism is most extensive in exons 2, 3, and 4, which form the basis for defining the HLA-A, HLA-B, and HLA-C alleles currently recognized [6]. Of the three extracellular domains of the class I molecule, the α1 and α2 domains fold to bind peptide in a groove between two α helices on a platform of a β-pleated sheet. The membrane-proximal α3 domain encodes the main binding site for CD8 and contact residues for β2 microglobulin [7, 8]. The extraordinary polymorphism of class I genes modulates the range of bound peptides and the T-cell repertoire expressed by CD8 T cells, the response to natural killer (NK) cells, and interactions of HLA-A, B, and C with peptide transporters (TAP) and chaperones [9–15]. The allele and locus-specific patterns of polymorphism of class I genes are thought to reflect distinct selective pressures exerted on the class I loci due to both specific antigenic challenge and the need for heterozygosity as a way of maximizing the range of antigenic responses.

HLA Class II Genes

Nine HLA genes reside in the class II region and share structural and functional similarity. The HLA-DR region encompasses five loci: HLA-DRA, DRB1, DRB3, DRB4, and DRB5. The HLA-DQ and DP regions encompass two loci each: DQA1, DQB1 and DPA1, DPB1, respectively. The class II molecule is a heterodimer of an α chain product of the A gene and a β chain product of the B gene. Within the HLA-DR gene, DRA and DRB1 products form the heterodimer that defines the HLA-DR1-DR18 serological phenotype. HLA-DRB3, DRB4, and DRB5 encode supratypic specificities that are expressed with DRB1 on only three haplotypes: DRB3 (DR3, DR11, DR12, DR13, DR14), DRB4 (DR4, DR7, DR9), and DRB5 (DR15, DR16). Haplotypes that are DR1, DR10, or DR8-positive contain only the DRA and the DRB1 genes. The DRA, DQA1, and DPA1 genes show limited diversity, whereas the DRB1, DQB1, and DPB1 genes are highly polymorphic [6].

HLA Typing Methodology

Definition of HLA class I and class II alleles has been made possible by the development of DNA-based typing methods over the last three decades. These techniques have had a significant impact on the ability to match potential stem cell donor and recipients with precision. The birth of the DNA typing era came in 1987 when the 10th International Histocompatibility Workshop demonstrated the utility of restriction fragment length polymorphism (RFLP) techniques to uncover polymorphism within serologically defined HLA-DR antigen families [16].

The advent of polymerase chain reaction (PCR) in the late 1980s revolutionized the HLA typing world, providing a new generation of powerful methods for allele typing [17, 18]. The major technological advances stemming from this prolific period of research include sequence-specific primers (SSP), sequence-specific oligonucleotide probes (SSOP), sequence-based typing (SBT), reference-strand conformational analysis (RSCA), oligonucleotide arrays, and, most recently, next-generation sequencing (NGS).

Sequence-Specific Primers

Complete sequence homology of the template DNA with the PCR primers allows maximal efficiency and specificity of the PCR amplification reaction; mismatching of the DNA template and primer for one or more nucleotide bases causes inefficient amplification. SSP methodology utilizes panels of PCR primers that are descriptive of known HLA polymorphisms [19–25]. Panels of primers can be informative for DNA substitutions that distinguish families of HLA antigens ("group specific") or that are unique for specific alleles ("allele specific"). After the test DNA is amplified using the entire panel of PCR primer pairs, the product(s) is electrophoresed in a gel. The presence of an amplified product is indicative that the test DNA encoded the same sequence as the PCR primer (Fig. 56.1). The HLA genotype is determined by evaluating the pattern of positive and negative amplifications to the entire primer panel. The SSP method is a cost-effective technique whose main advantage is simplicity and rapidity for typing at the equivalent level of the HLA antigen family ("low resolution" or "intermediate resolution" level typing). Definition of the allele ("high resolution") generally necessitates large panels of primer pairs; hence, SSP methods for high-resolution typing are more labor intensive and less cost effective than the probe-based technologies described in the next sections.

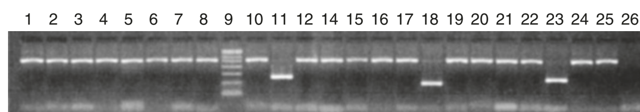

Fig. 56.1 Sequence-specific primer (SSP) technique demonstrating positive PCR amplication for HLA-C*07 in lane 11 and for HLA-C*12 in lanes 18 and 23. Lanes containing a single PCR-amplified band are controls; molecular weight marker was loaded in lane 9. Methodology was previously described by Bunce and Welsh [21]

Sequence-Specific Oligonucleotide Probes

Sequence-specific oligonucleotide probe (SSOP) methods were among the earliest tools developed for typing polymorphic positions of HLA alleles [26–30]. The first protocols were designed using radiolabeled probes and hybridization of each probe to the target DNA. Several generations of SSOP methods were subsequently developed that incorporated strips of probes and nonradioactive labels. The newest platforms use bead technology and chemoluminescence for detection of hybridization (http://www.onelambda.com). The basic principle of SSOP relies on the design of oligonucleotide probes to specific regions within the polymorphic exons of class I genes (exons 2, 3, and 4) and of class II genes (DRB, DQA1, DQB1, DPA1, DPB1). After the test DNA is amplified by PCR, the amplified product is allowed to hybridize to the SSOPs. Only those probes having complementary sequence with the test DNA will hybridize; SSOP that are mismatched will fail to hybridize. The presence of hybridized SSOP to DNA is signaled by the label (Fig. 56.2). The HLA sequence of the template DNA is deduced by the pattern of positive and negative hybridization. Panels of SSOP can be descriptive of every nucleotide position of the exon; alternatively, SSOP panels may be informative for only certain positions that are known to be polymorphic. The use of the latter, while informative for known alleles, would not detect novel alleles encoding substitutions outside of the probed regions. SSOP techniques are well suited for high-resolution typing and are especially efficient for large-scale analysis.

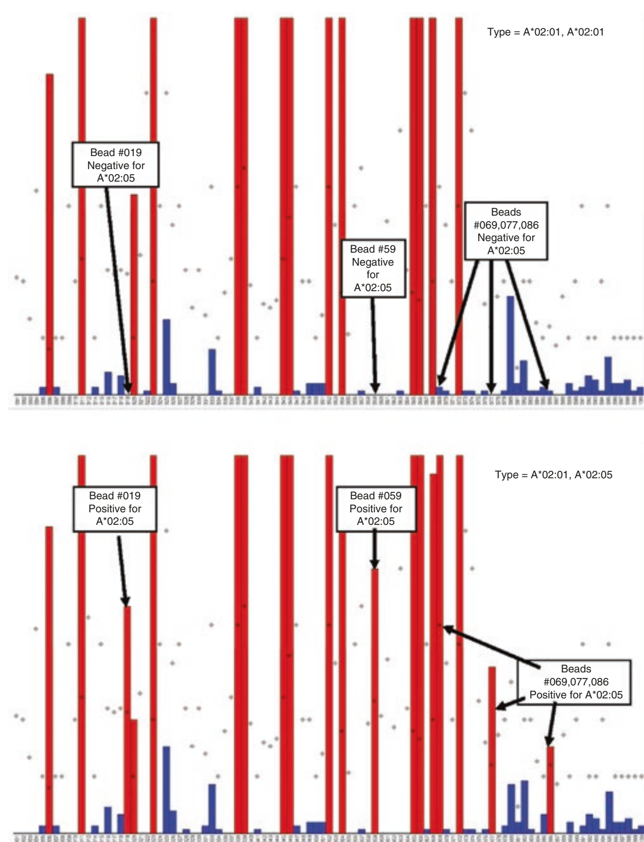

Fig. 56.2 Representative typing using the Luminex® bead-based technology (http://www.onelambda.com). *Top panel* shows the reactivity pattern of HLA-A*02 beads for a homozygous A*02:01, 02:01 sample. Each *bar* represents the reaction of a bead to the template DNA, with the *blue bars* indicating no reactivity (A*02:05) and the *red bars* indicating positive reactivity (A*02:01). *Bottom panel* shows the results for an A*02:01, 02:05 heterozygous sample (Samples courtesy of Dr. Shalini Pereira)

Array Technology

Oligonucleotide array technology has revolutionized the study of molecular biology. Its applications have been far-reaching including large-scale gene discovery, gene expression monitoring, detection of mutations and polymorphisms, and mapping. The HLA system represents an ideal application of this particular technology because of the highly polymorphic nature of the class I and II genes [31]. Array methods allow parallel analysis of simultaneous HLA gene polymorphisms. It is a flexible method in which the addition of new probes descriptive of novel substitutions may be easily configured onto the array. The use of fluorescent labels allows ease in the application of this method to a high-throughput clinical laboratory. Finally, the results of the hybridization can be quantified. An approach for sequence analysis of HLA-B has been recently described [31]. This system utilizes a panel of oligonucleotide probes designed for all known polymorphisms in exons 2 and 3 of the gene. The presynthesized probes are arrayed onto glass slides. Following PCR amplification of HLA-B using fluorescent-labeled primers, the PCR product is allowed to hybridize with the array; stringent conditions are required to discriminate perfectly matched duplexes and detect a single nucleotide difference between the template DNA and the probe (Fig. 56.3). The array is scanned using an automated fluorescent scanner, and the HLA-B sequence is determined by quantitative analysis of the hybridization pattern. Oligonucleotide array technology has its greatest potential in the scalability and reduced cost for assaying large numbers of samples.

Sequence-Based Typing

Sequence-based typing (SBT) methods provide information on the nucleotide sequence of the template DNA and permit detection of single base differences to enable discrimination of unique HLA alleles. Its power lies in it being a highly robust, accurate, and definitive technique for uncovering novel variation [32–36]. Many approaches for SBT have

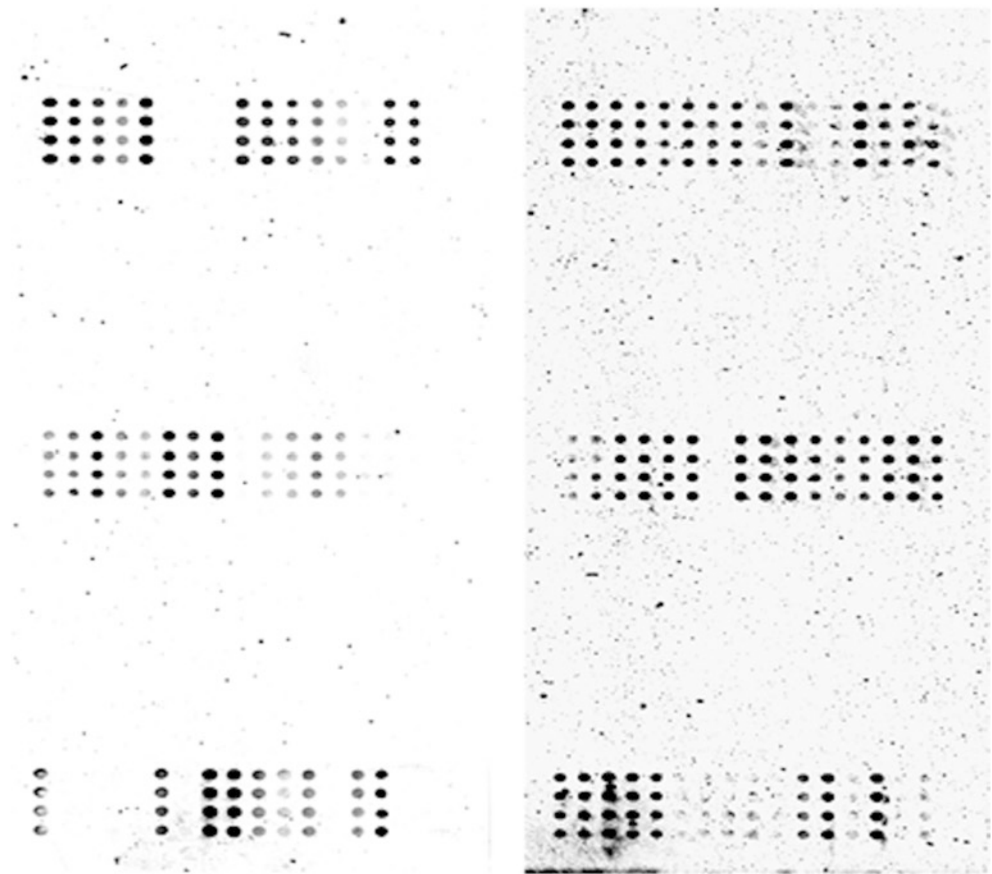

Fig. 56.3 Oligonucleotide array for HLA-B. Actual hybridization of array using probes for HLA-B, reviewed in Guo et al. [31]

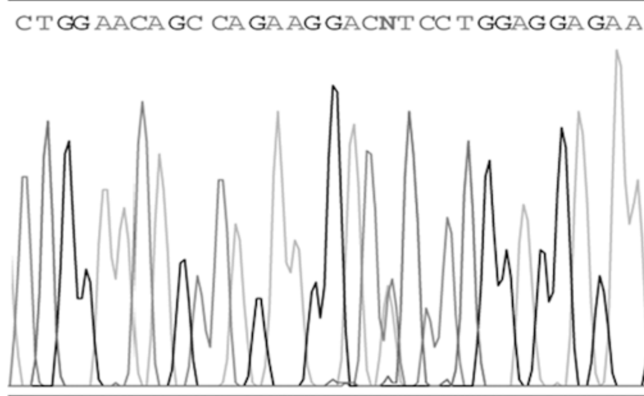

Fig. 56.4 Sequence-based typing (SBT) method demonstrating chromatogram for HLA-DPB1*03:01, 04:01-positive sample using methodology published by Rozemuller et al. [34] and Verslius et al. [36]. Chromatogram demonstrates incorporation at "N" of both C and A at position 182 of exon 2 corresponding to DPB1*03:01 and DPB1*04:01, respectively

been developed including direct sequencing from PCR-amplified genomic DNA or from cDNA. Among the most widely used methods is automated fluorescent sequencing. In this method, after the HLA allele(s) is PCR amplified, cycle sequencing is performed using fluorescent-labeled primers. Alternatively, sequencing can use fluorescent-labeled dideoxynucleotides. The sequenced templates are electrophoresed in a polyacrylamide gel in an automated sequencer. The fluorescent signals emitted from either the labeled primers or the labeled dideoxynucleotides are detected by a laser within the sequencing apparatus and interpreted by software (Fig. 56.4). Automated allele identification using software simplifies and automates the data analysis.

The physical linkage of markers on the same chromosome, also known as phase, is an essential feature of unambiguous assignment of alleles, particularly when an individual expresses two different HLA alleles ("heterozygous") [37, 38]. Using HLA class I proteins as an example, HLA-A, B, and C are defined by sequence polymorphisms in exons 2, 3, and 4, which span 1.7 kilobases inclusive of introns. When both alleles are co-amplified together, the inability to phase across multiple exons and introns will generate a mixture of sequences that could be represented by more than 1 combination of alleles. For traditional Sanger sequencing-based methods, the phase of polymorphisms can be achieved by designing amplified templates that overlap at each end so that the full-length phased sequence can be assembled.

New methods surmount not only the need for long template reads that can be sequenced, but also the phase across extremely long distances. Known as "next-generation sequencing" or NGS, these automated sequencing platforms permit phasing of complex sequence polymorphisms across

long stretches of HLA genes. The ability to assay multiple regions of genes at the same time, and in many samples simultaneously ("sequencing in parallel") offers an entirely new level of DNA sequence ascertainment. Because of its ability to define phased sequences, NGS is also known as "clonal sequencing."

One of the earliest NGS platforms was "454" sequencing by Roche, in which clonal amplification is combined with on-phase sequencing [39]. This technology used long-range PCR amplification of the entire class I gene, and fragmented the template for sequencing, followed by assembly of the sequences for definitive allele assignments. The use of beads to capture single-stranded DNA molecules was a revolutionary strategy that offered a powerful approach for phasing complex variation in HLA genes. After the advent of the prototype 454 sequencing method, several other platforms have been developed. For example, the "MiSeq" protocol by Illumina is based on dye terminator chemistry and uses primers that are immobilized on a chip [40]. Ion Torrent is bead-based and uses hydrogen emission for detection. The PacBio "SMRT" (single molecule real-time sequencing) system uses clonal sequencing of single molecules and can sequence up to 10–15 kilobases of template [41]. Another variation of SBT is represented by whole exome sequencing where the entire genome or exome sequence spanning 4–5 million basepairs and multiple HLA genes is targeted [42]. Current protocols may provide typing for HLA-A, C, B, DRB1, DRB3, DRB4, DRB5, DQA1, DQB1, DPA1, and DPB1 genes in a single sequencing run. A clear advantage of NGS methods over traditional sequencing is that millions of single DNA molecules are sequenced in parallel at a significantly lower cost than conventional sequencing, and as such, these methods are highly amendable for typing large numbers of registry donors at recruitment [43]. Regardless of the specific sequencing platform, throughput and phasing capabilities, NGS strategies all require informatics to facilitate data analysis (please refer to the section below entitled "Information Technology in Support of Unrelated Donor Identification").

Imputation of HLA Genotype with Single Nucleotide Polymorphisms (SNPs)

The imputation of HLA genotypes from SNPs has been an invaluable tool for ascertaining the most probable HLA tissue type in samples that have been characterized with dense SNP arrays for the HLA region [44]. Imputation is the inference of HLA types from SNP genotype data. The SNPs used for imputation do not typically reside within the HLA genes themselves. Rather, the SNPs are located inter-genically. Imputation relies on positive linkage disequilibrium (LD) between SNPs and the nucleotide substitutions in exons that define the HLA type. HLA imputation is most commonly used for SNP genotyped research samples that have never been HLA typed. Recent studies have also shown that imputed KIR alleles correlate with sequenced KIR alleles [45].

HLA Nomenclature

The origins of HLA nomenclature date back to the third workshop when the designation "HLA" was introduced: *H* referring to the Hu1 system described by Dausset, and *LA*, the designation given by Payne and Bodmer for the same antigen system, discovered independently in the two laboratories [1, 46]. "HLA" emerged as an acronym for "human leukocyte antigen." The naming of new HLA alleles is the responsibility of the World Health Organization Nomenclature Committee for Factors of the HLA System (http://www.ebi.ac.uk/imgt/hla/). With the universal application of molecular-based tissue typing methods, novel HLA sequences are being discovered at a rapid rate. Beginning on April 1, 2010, a new nomenclature was adopted to permit unlimited numbers of new alleles to be named. Following the term HLA, the locus is specified as -A, -B, -C, -DRB1, -DQB1, etc. An asterisk (*) signifies that the name is derived from DNA. Following the asterisk, the serologic equivalent of the antigen, the allele number, silent substitutions, and differences outside of coding regions are given in order, each delimited by a colon (:). The name is completed by information as to the level of expression, if known. For example, the name HLA-A*24:02:01:02L refers to the A24 serologic antigen equivalent (24), the second allele of the A24 family (02), the first silent substitution (01), intron polymorphism (02), and low-expression variant (L). As of June, 2016, over 3399 HLA-A, 4242 HLA-B, 2950 HLA-C, 1883 DRB1, 911 DQB1, and 644 DPB1 alleles are officially recognized (www.imgt/hla).

Information Technology in Support of Unrelated Donor Identification

With the growth of unrelated stem cell donor registries worldwide, and the increasing complexity of the HLA system, there has been a worldwide effort to develop the necessary information technology to aid clinicians and patients identify the most suitable donor for transplantation and support the coordination of the procurement of donor stem cells between registries and transplant centers [47]. These efforts represent a multidisciplinary approach by experts in the fields of HLA immunogenetics, bioinformatics, programming, clinical transplantation, and registry operations. The availability of powerful NGS typing strategies now in place in many clinical HLA laboratories has in particular demanded a new level of data management and tools for the exchange of HLA information within the clinical community. MIRIN is a recently organized consortium intended to facilitate downstream analysis and data management of HLA data. Included among the research and

development activities are the development of a checklist that enables the content of NGS genotyping results to be evaluated and compared across genotyping platforms. The ability to reanalyze historic HLA typing data in the context of sequencing data generated by NGS methods with modern nomenclature is a major goal of the consortium. This goal has immediate utility in bridging legacy HLA typing with primary sequenced data generated by NGS methods [48].

Tissue Typing in Support of Unrelated Donor HCT

The Early Years

Experience with the use of volunteer unrelated donor HCT began in the early 1970s. The preliminary results demonstrated the high-risk nature of these transplants, especially with respect to graft failure and GVHD [49–59]. In addition to the medical needs and complications faced by recipients of unrelated donor transplants, the practical issues of identifying suitable donors dominated the early experience, and lengthy, expensive donor searches limited its application more broadly.

Major progress was made in the 1980s and 1990s in allogeneic transplantation with respect to improved supportive care of transplant patients, particularly the development of effective antiviral agents to prevent and treat cytomegalovirus (CMV) infection and the development of immunosuppressive regimens for the prophylaxis of GvHD [60–62].

Recognition of the importance of HLA compatibility between the donor and recipient in mediating host-versus-graft and graft-versus-host reactions, together with the growth of unrelated donor registries worldwide, contributed to successful use of unrelated volunteer donors for HCT [63–68]. The first volunteer donor registry was organized in London at the Anthony Nolan Research Centre, clearly demonstrating public interest in volunteer donation as well as the financial feasibility of performing registry HLA typing [69]. In the United States, the National Marrow Donor Program (NMDP) was established in 1986 [70] and was followed soon thereafter by Bone Marrow Donors Worldwide [71]. The network of international donor registries is coordinated by the World Marrow Donor Association (WMDA) [72] and includes donor registries and 350 donor centers representing 52 countries. This collaborative effort represents over 28 million volunteer donors (www.worldmarrow.org).

The DNA Era

The advent of DNA-based typing methods has provided powerful tools for understanding the biological relevance of allele disparity in unrelated donor HCT. The elucidation that a single HLA antigen can be encoded by many unique alleles has had enormous clinical implications for the typing and selection of appropriate donors for transplantation. It is clear that DNA-based methods, when applied to the analysis of serologically matched patients and donors, can uncover allelic disparity [73–79] and are also more reliable than alloantisera [28, 29, 80]. Increased sensitivity and specificity of DNA-based methods compared to serologic reagents were validated in a quality control study by the National Marrow Donor Program (NMDP) [29]. In a single center analysis of 300 CML unrelated donor transplants, sequence-based typing (SBT) methods for HLA-A, B, and C genes and SSOP methods for HLA-DRB1 and DQB1 were used to define alleles; 47% of these pairs were matched for all five genes, and 53% were mismatched for at least one class I or class II allele [81]. A large retrospective analysis by the NMDP evaluated the rate of undetected HLA disparity in 1259 patients who had received HCT from unrelated donors identified by the NMDP [75]. This study utilized SSOP and SBT methods to analyze DRB, DQA1, DPA1, and DPB1. Only 9.4% of the 1259 pairs were found to be matched at all loci tested. Noteworthy were the findings that 79.4% were matched for DRB1, but only 13.2% for DPB1. Sixty-six percent of the study population encoded mismatches for two or more class II alleles. Worldwide experience has confirmed the power of DNA methods to uncover donor–recipient allele disparity among putative well-matched pairs. DNA-based methods should therefore be used as the gold standard for identifying HLA class I and class II alleles in support of donor selection for unrelated donor HCT. Continued refinements in methodology including the use of filter paper spots as a robust source of high-quality DNA permitted the application of large-scale HLA typing for registry typing [82].

Today, the integration of NGS technologies for donor registry typing has provided laboratories with an unprecedented level of throughput as well as a vast new body of sequence data for both coding and noncoding regions of HLA genes [43]. As described below in the section entitled “HLA Expression,” the clinical significance of noncoding regions has only just begun to be elucidated. The emergence of technologies that readily capture the complete sequence of HLA genes provides investigators with the much needed tools for investigating the functional impact of noncoding regions.

Clinical Impact of Donor HLA Incompatibility

The probability of identifying an HLA-compatible donor depends on many factors including the patient’s ethnicity and the size and composition of donor registries [83]. When only mismatched donors are available, clinicians can be better equipped to avoid donors whose HLA mismatch may

increase risks to the patient. Today, the tools available to clinicians and search specialists are based on the level of resolution of the HLA mismatch (allele or antigen), the presence of mismatching for specific amino acid residues, and the level of expression of the patient's and the donor's mismatched HLA allotypes.

The Vector of Incompatibility

The early haploidentical related HCT experience served as an important platform for understanding the role of HLA in unrelated HCT and provided the clinical and immunogenetic basis for the definition of the vector or direction of HLA mismatches [63]. Nonshared HLA antigens of the donor could provoke host-versus-graft (also known as the "HVG" or "rejection vector") allorecognition leading to significantly increased risk of graft failure [84]; furthermore, graft failure was compounded by the presence of a positive pretransplant cross-match [63]. HLA mismatching with graft-versus-host allorecognition (also known as the "GVH vector") was also shown to influence risk of clinically severe acute GVHD after haploidentical donor HCT [85–87].

The original observations in the early haploidentical transplant experience have subsequently been validated in several large independent studies. In a recent analysis by the Center for International Blood and Marrow Transplant Research (CIBMTR), patients transplanted from unrelated donors with a single HLA-A, B, C, or DRB1 mismatch in the HVG vector had a lower risk of GVHD than patients receiving transplants from donors with a single HLA disparity in the GVH vector [88]. These results confirm that HVG vector mismatches are well-tolerated with respect to GVHD, and that the direction of incompatibility has biological consequences.

The Effect of the Number and Nature of HLA Mismatches

The early studies directed at understanding donor HLA mismatching analyzed patient–donor pairs who were variably typed at HLA-A, C, B, DR, and/or DQ, using a combination of serological and DNA-based typing methods [89–94]. Hence, interpretation of the data requires knowledge of the limitation of the typing technologies that were available at the time of each study. The first locus for which outcomes data were available was HLA-DRB1 followed soon thereafter by HLA-DPB1, and later HLA-DQB1. Information on the importance of class I was feasible once SSP, SSOP, and sequencing methods were designed and optimized; tools for HLA-A and B preceded those for HLA-C [76, 79, 81, 93, 95–100]. Despite these technological limitations, the early literature clearly established the concept that (1) DNA-based methods could detect allele mismatches among serologically matched transplant pairs, (2) allelic differences were functional, and (3) increasing numbers of allele mismatches correlated with increased risks.

The availability of DNA methods for all six classical HLA loci, together with an expanded unrelated donor clinical transplant experience, led to the current recommendations for donor typing and matching for HLA-A, C, B, DRB1, DQB1 alleles, the "10/10" matched donor [73, 76, 96, 99–106]. Today, transplantation from a 10/10 allele-matched donor yields outcomes comparable to HLA identical sibling transplantation for certain patient groups [107].

Most recently, the CIBMTR has shown the deleterious effect of additive donor–recipient disparities at the supratypic class II loci termed HLA-DRB3, DRB4, and DRB5 [108]. HLA-DRB1 is in strong positive LD with each of these supratypic genes when DRB3/4/5 are present according to the DRB1 haplotype as described in the preceding section entitled "HLA Class II Genes." When a patient and donor are mismatched at HLA-DRB1, there is a high likelihood that the pair is also mismatched at DRB3/4/5. In the retrospective CIBMTR analysis [108], as the number of mismatches at DRB1/DRB3/DRB4/DRB5 increased, the risk of mortality increased. From a donor selection standpoint, when an HLA-DRB1-mismatched donor is considered, typing of DRB3/DRB4/DRB5 (where relevant) is indicated to define risks to the patient.

Recently, the Japan Marrow Donor Program (JMDP) evaluated the incidence of acute GVHD according to the number of mismatches at HLA-A, B, C, DRB1, DQB1, DPB1 as defined by high-resolution molecular methods [109]. Higher risks of acute GVHD and overall mortality were observed as the number of donor–recipient mismatches increased from 1 to 5, compared to no HLA mismatching. Interestingly, not all HLA mismatches conferred the same risks. A single HLA-DRB1 or HLA-DQB1 mismatch was not associated with higher risks of GVHD or mortality, but when patients and donors were mismatched at both HLA-DRB1 and DQB1, risks increased significantly. These data suggest that HLA-DRB1 and DQB1 could be defined as a "super-gene" complex. When the study population was reanalyzed according to DRB1/DQB1 mismatches, the total number of HLA-A, B, C, DPB1, and DR/DQ mismatches was associated with increased risks of grades III-IV acute GVHD and overall mortality.

The tally effect of multi-locus HLA mismatches has recently been evaluated by the CIBMTR [110]. In a series of over 10,000 unrelated donor transplants, increasing numbers of HLA mismatches correlated with worse outcome. Non-HLA factors were also identified as risk factors. Survival was better for patients with younger age donors (aged 18–32 years). For every 10-year increment in donor age, the

hazard of mortality increased by 5.5%. Sex, parity, and CMV serostatus were not associated with survival. The JMDP and CIBMTR studies support the selection of a young donor with the fewest HLA mismatches when a fully compatible donor is not available.

The sixth HLA locus, HLA-DPB1, also functions as a classical transplantation gene, because donor HLA-DPB1 mismatching is associated with higher risks of graft failure and GVHD [96, 99, 105, 111–117] and a lower risk of disease recurrence after HCT, suggesting a potential beneficial effect of graft-versus-leukemia ("GVL") activity [111, 113, 117, 118]. Although the clinical importance of donor matching for HLA-DP was shown after the effects of other classical class I and II genes were already integrated into routine clinical HLA testing of unrelated donors, new information on the importance of this locus has enabled further refinements in donor selection to be made, as described in more detail in the sections below entitled "Donor Mismatching for Class II Residues" and "HLA Expression."

Donor Mismatching: Alleles Versus Antigens

The molecular typing methods described earlier in this chapter provide the means to detect single nucleotide differences between the patient and donor. Differences detectable only by molecular tools discriminate between two unique alleles ("allele" mismatches). When differences between the patient and donor HLA molecules can be detected by alloantisera (i.e., serological methods), the mismatches are referred to as "antigen" mismatches, as they define epitopes of the expressed HLA molecule that can be recognized by the humoral immune system.

Are allele and antigen mismatches functionally different? Historical studies suggested that antigen mismatches are more immunogenic than allele mismatches [73] particularly for HLA-C [98]. These data suggested that when HLA-matched donors are not available, prioritization of allele mismatched over antigen-mismatched donors may decrease the risk of posttransplant complications. Whether these concepts could be applied equally to each HLA gene has been an important area of investigation, not only for donor selection but also for understanding the characteristics of HLA molecules that are immunogenic. In an early study by the CIBMTR, antigen and allele mismatches conferred similarly high risks with one important exception, HLA-C [103]. When compared to transplants from HLA-A, B, C, DRB1 allele-matched donors ("8/8"), HLA-C allele mismatches ("7/8") were not associated with statistically significantly higher mortality, TRM, or acute GVHD; however, transplantation from donors mismatched for HLA-C antigens conferred increased risk for mortality and acute GVHD. These data suggested that selection of an HLA-C allele-mismatched donor should be prioritized over an HLA-C antigen-mismatched donor, when HLA-matched donors or single DQB1-mismatched donors are not available.

New information has become available on the most common HLA-C mismatch observed among unrelated donor–recipient pairs, the HLA-C*03:03/03:04 combination [119]. This particular mismatch does not elicit in vitro cytotoxic T cell responses. Patients mismatched for the C*03:03/03:04 allele combination had similar outcomes as HLA 8/8-matched recipients [119]. A possible basis for the lower risks associated with this particular mismatch compared to other HLA-C mismatches, has recently been elucidated and is described below in the section entitled "HLA Expression."

The immunogenicity of HLA class I mismatches may depend on the locus that is mismatched. An analysis by the NMDP [120] found no correlation of the specific combinations of HLA-A allele mismatches with engraftment, acute or chronic GVHD, relapse, TRM, or survival. It was estimated that over 11,000 donor–recipient pairs would be required to fully address whether specific HLA-A allele mismatch combinations are more or less deleterious.

Most of the information regarding the clinical significance of donor HLA mismatching and outcomes has come from marrow grafts. In 2008, over 19,481 adult stem cell donations were provided to patients worldwide, and of these, 7260 were peripheral blood stem cell (PBSC) products [72]. The increasing use of mobilized peripheral blood stem cell (PBSC) products for transplantation motivated a new analysis of these data by the CIBMTR [121, 122]. An increased step-up in risks associated with allele and antigen mismatching was observed compared to the historical bone marrow transplant experience. Furthermore, only HLA-C antigen mismatches were significantly associated with mortality [122]. This study suggests that the effect of donor HLA may depend on the manipulation of the stem cell product. With the vast majority of patients now receiving peripheral blood stem cell grafts [123], more information is needed to clarify the difference of locus-specific effects after PBSC compared to bone marrow transplantation.

HLA-Mismatched Transplantation Today: Reduced-Intensity Conditioning

Although the concepts of HLA matching in unrelated donor transplantation grew out of the clinical experience with traditional ablative conditioning regimens, data also support the importance of donor–recipient HLA mismatching with reduced intensity conditioning regimens. In a study of patients receiving reduced-intensity conditioning for unrelated donor transplants, patients with an HLA 8/8-matched donor had improved 1 and 3 year survival rates compared to HLA 7/8-matched transplants [124]. Transplantation from a

7/8-matched donor was associated with higher risks of grades II-IV acute GVHD and transplant-related mortality, and lower probabilities of disease-free survival and overall survival. No differences in risks of chronic GVHD or relapse were appreciated. These data are consistent with those from experience with ablative conditioning regimens and suggest that additive effects of HLA mismatching should be avoided where possible.

Donor Mismatching for Key Residues of Class I Molecules

Molecular HLA typing methods can discriminate single nucleotide substitutions that permit unique HLA alleles to be identified and distinguished from closely related allele sequences. These DNA sequences in turn represent amino acid sequences of the mature HLA protein. Most substitutions in HLA molecules are located within the peptide binding groove and/or at positions involved in contact with the T-cell receptor. In unrelated donor HCT, the earliest report of HLA mismatching and outcomes demonstrated that even a single amino acid difference between the recipient and donor HLA-B genotype could increase risk of graft failure [125]. This initial observation of class I disparity and graft failure was later borne out by a single center study that demonstrated the role of HLA-A, C, and B allele-level mismatches on graft failure and suggested that the location of putative high-risk amino acid residues might define patients at highest risk for graft failure [98].

The importance of mismatching at specific residues for different amino acids has been explored in different models. The cytotoxic T lymphocyte precursor (CTLp) assay has been employed to test the hypothesis that alloreactivity arises from donor recognition of recipient sequence polymorphisms encoded in the α1 and α2 domains of class I molecules [126]. Lower CTLp frequencies are associated with a lower probability of GVHD [127]. CTLp reactivity is a measure of the number of mismatches encoded within the α helix and β-pleated sheet of single class I locus mismatches [128]. The presence of 5α/5β mismatches in addition to a negative CTLp was a strong predictor of favorable outcome compared to any other mismatch, suggesting that both the number of mismatched epitopes and the ability of these epitopes to elicit a CTLp provide additional information than either variable alone in assessing whether a given HLA class I mismatch may be permissible.

Comparative sequence analysis has provided novel information on putative residues important in GVH allorecognition. The earliest study to correlate transplant outcome with mismatching for specific class I residues identified mismatching at positions 114 and 116 in HLA-B-mismatched transplants to be predictive of severe GVHD and high TRM [129]. The observations from this Italian analysis were extended in a large-scale study by the Japan Marrow Donor Program (JMDP) [130]. A total of four HLA-A, one HLA-B, and seven HLA-C mismatch combinations (along with two HLA-DR/DQ haplotypes and two HLA-DP nonpermissive mismatch combinations) were significantly associated with transplant outcomes. Risks increased with increasing numbers of nonpermissive mismatches. Donor–recipient mismatching at seven specific positions correlated most strongly with GVHD risk: Tyr9–Phe9 of HLA-A and Tyr9–Ser9, Asn77–Ser77, Lys80–Asn80, Tyr99–Phe99, Leu116–Ser116, and Arg156–Leu156 of HLA-C. These early data suggested that HLA-A and HLA-C locus mismatches that do not involve the high-risk amino acid disparities may be permissible.

A role for donor mismatching for residues 116 and 99 of HLA-C, and residue 9 of HLA-B has recently been validated by the CIBMTR [131]. Donor mismatching for amino acids at residue 99 of HLA-C was associated with higher risk of transplant-related mortality, and mismatching at residue 116 was associated with a significantly higher risk of acute GVHD compared to matching at these residues. Donor mismatching at residue 9 of HLA-B was associated with higher risk of chronic GVHD compared to matching at residue 9. These recent data confirm the importance of high-resolution typing and matching at key residues that influence the repertoire of peptide antigens that bind in the groove between the alpha helices of class I molecules, thereby influencing outcomes after HCT.

Donor Mismatching for Class II Residues

HLA-DP has served as a model locus for understanding the importance of donor matching for class II residues. Site-specific mutagenesis has been used to elucidate HLA-DP motifs that define alloreactive T-cell epitopes (TCEs) [112, 116]. Presence of the 8LFQG11 motif in the HLA-DP β chain was found to correlate most strongly with T-cell responses. As many as 75% of donor–recipient pairs are not mismatched for this TCE disparity in the host-versus-graft direction, and use of such donors would be predicted to decrease the risk of graft failure, especially in the setting of HCT for thalassemia [116].

The concept of permissible HLA-DP epitopes has been explored recently by the International Histocompatibility Working Group (IHWG) in HCT [117]. This study tested the hypothesis that (mis)matching for immunogenic TCEs encoded by particular HLA-DPB1 alleles may be relevant to outcome after unrelated HCT. In this model, mismatching in both the graft-versus-host (GVH) and host-versus-graft (HVG) vectors was analyzed. HVG mismatching may include the potential for the mismatched donor antigen presenting

cells to cross-present allogens of the patient to donor T cells, thereby increasing the risk of GVHD. Mismatches associated with higher risks are called “nonpermissive,” to be distinguished from mismatches associated with low cytotoxicity (“permissive mismatches”). In a population of 5838 HLA-A, C, B, DRB1, DQB1 matched transplants, 4490 were DPB1 mismatched and 1348 were DPB1 matched (“12/12”). The HLA-DP-mismatched pairs were defined as TCE-matched or TCE-mismatched. Compared to the DP-mismatched TCE-matched group, the DP-mismatched TCE-mismatched group had higher risks of grades III–IV acute GVHD, TRM, and mortality, but lower relapse (see section below entitled “Beneficial Consequences of HLA Mismatching”). The 12/12 transplants had lower TRM and severe acute GVHD, but higher relapse. The IIHWG observations were confirmed in an independent cohort of patients by the CIBMTR [132]. These results suggest that mismatches involving DPB1 alleles carrying the same TCE might be well tolerated, whereas mismatches involving a TCE disparity confer risk. A tool to score patient and donor DPB1 alleles according to TCE permissive and nonpermissive mismatches can be found at www.imgt.hla.

Beneficial Consequences of HLA Mismatching

Early clinical experience described an overall lower risk of posttransplant disease recurrence among patients who had experienced clinical acute GVHD [133]. Many studies have subsequently confirmed a relationship between GVHD and a reduced risk of relapse, a phenomenon known as the graft-versus-leukemia (GVL) effect. Historical data from the JMDP identified four HLA-C and six HLA-DPB1 allele mismatch combinations associated with lower risk of relapse, eight of which were allele combinations that differed from those previously identified for GVHD [111].

More recent studies have identified strong GVL effects associated with HLA-DPB1 mismatching [117, 134]. In the setting of T-cell depleted transplantation, concurrent mismatching for HLA-DP with other HLA loci was associated with better outcomes in patients with more advanced disease [134]. A new JMDP analysis of HLA-A, B, C, DRB1, DQB1, and DPB1 mismatched transplants [109] uncovered only HLA-C and HLA-DPB1 mismatches to be associated with a lower risk of relapse. Taken together, these observations suggest that patients with HLA-DP-mismatched donors might derive some benefit from GVL effects of the mismatch. Elucidation of the underlying mechanisms responsible for GVL involving T cell or natural killer cell-mediated effects remain an important area for research.

HLA Expression

Noncoding sequences can affect expression levels, and the information gleaned from regulatory regions of HLA genes may be leveraged to define permissive HLA mismatches. Outside of transplantation, HLA-C and HLA-DP expression each play an important role in the control of infection, HIV-AIDs for HLA-C and hepatitis B for HLA-DP [135, 136]. In addition, the level of HLA-DP expression correlates with the risk of Crohn’s disease [135], suggesting a potential role for HLA expression in autoimmunity. The theory behind HLA expression in disease relates to the presentation of foreign antigens, which may be more robust when larger numbers HLA molecules are expressed at the cell surface, resulting in improved immune surveillance. By the same token, high HLA expression may provide the target needed to elicit a strong autoimmune attack on host tissues leading to autoimmunity.

The recent observation made by the CIBMTR for cumulative effects of HLA-DRB1/DRB3/DRB5 mismatching described above may implicate a tally effect of several low-expression gene products on clinical outcome [108]. The level of expression of HLA-DRB3, DRB4, DRB5, DQB1 genes is generally lower than that of HLA-A, B, C and DRB1. Among HLA 8/8-matched transplants, a donor–recipient mismatch involving a single low-expression allele was not associated with higher risks compared to matching, but the presence of 3 or more low-expression mismatches at HLA-DRB1/3/4/5/DQ in addition to a mismatch at HLA-A, B, C or DRB1, was associated with higher overall mortality and transplant-related mortality.

The clinical significance of HLA-C and HLA-DP expression in outcome after unrelated donor hematopoietic cell transplantation has recently been investigated. Using the median fluorescent intensity value for each HLA-C allotype, each HLA-C mismatch in a population of HLA 9/10-matched donor–recipient pairs with a single HLA-C mismatch was used to measure the hazards of mortality and odds of GVHD [137]. As the level of expression of the patient’s mismatched HLA-C allotype increased, the risks of acute GVHD and non-relapse mortality also increased. HLA-C*03 and C*07 molecules have the lowest levels of expression, and C*01 and C*14 the highest levels of all HLA-C gene products [135]. Risks depended not only on the level of HLA-C expression, but also on residue 116 and KIR ligand epitope mismatching. Patients with low-expression HLA-C*03 and 07 mismatches that were also residue 116 and KIR ligand-mismatched, had similar clinical outcome as HLA-C-matched transplants. However, patients with high-expression HLA-C*01 or 14 mismatches that were also residue 116 and KIR ligand-mismatched had higher risks. These data strongly support a role for the level of HLA-C expression in immunogenicity related to graft-versus-host alloresponses.

In contrast to the allotype-specific expression patterns exhibited by HLA-C molecules, low or high level expression of HLA-DP gene products appears to be regulated by a polymorphism within the noncoding region, the 3′ untranslated region (UTR), of HLA-DPB1 [136, 138]. A recent retrospective analysis of HLA 10/10-matched patient–donor pairs found higher GVHD rates when the patient's mismatched DPB1 allele was a high-expression allotype, compared to patients with low-expression HLA-DPB1 mismatches [138]. These observations are consistent with the hypothesis that highly expressed mismatched patient HLA-DP allotypes may be potent targets for donor-anti-host recognition. The data furthermore illustrate the clinical importance of understanding diversity of regulatory regions of HLA genes, as a means to facilitate the selection of mismatched unrelated donors.

HLA Allele-Specific Risks in Transplantation

A rich history of clinical research in disease associations has elucidated a major role for HLA alleles in the susceptibility to a wide range of diseases [139]. In transplantation, the vast majority of information on HLA is founded on a mismatch model where the patient and donor encode different HLA alleles; however, recent information suggests that risks may also arise from the presence of specific alleles carried by either the patient or the donor. In an analysis of T-replete unrelated donor bone marrow transplants facilitated by the JMDP, patients and/or donors who possessed HLA-B*51:01 had significantly higher posttransplant risks than patients and donors who were B*51:01-negative [140]. Possession of certain HLA-C alleles also influenced the risk of GVHD and mortality in the mismatch model. Compared to HLA-C-matched patients, HLA-C-mismatched patients with an HLA-C*14:02 allele had the highest risk of severe acute GVHD transplant-related mortality of all patients in the series. These results suggest that feature(s) specific to the HLA-B*51:01 and HLA-C*14:02 allotypes may be involved in transplant-associated risks, including those that arise from donor recognition of these molecules by recipient cells.

The Role of the Noninherited Maternal Antigen

In Transplant Outcome

Noninherited maternal antigens (NIMAs) are those antigens of the nonshared haplotype among haploidentical siblings. For example, for an HLA-A1, A2-positive patient, an HLA-A1, A3-positive donor (mismatch is between recipient A2 and donor A3), and an HLA-A2, A3-positive mother of the donor, the noninherited maternal A2 antigen is matched to the patient's A2 ("NIMA matched"). The impact of NIMAs on the donor's immune system (and hence, the recipient) may be significant. The tolerizing effect of NIMAs has been observed in haploidentical related donor HCT under a variety of transplant regimens [141–143]. These studies have demonstrated that transplantation from mother to child is associated with low risk of both acute and chronic GVHD and mortality, indicating that there is donor-specific suppression of T-cell responses against NIMAs. In contrast, transplantation from father to child is associated with higher risk of GVHD, indicative of an immunizing effect of paternal antigens.

Proof of principle has recently been established with the demonstration of NIMA-associated protective effects in cord blood transplantation [144]. This retrospective study included 1121 patients who had received a single unit cord blood transplant for whom HLA typing of the recipient, the unit, and the mother of the baby was available. HLA typing at three loci—HLA-A, B, and DRB1—was evaluated. For each transplant pair, the number of mismatches in the patient that were identical to the noninherited maternal haplotype of the cord blood unit was scored. Of the 1121 total pairs, 1059 pairs were mismatched for one or two antigens at HLA-A and/or B and/or DRB1. Of these mismatches, the mismatched antigen(s) were shared between the transplant recipient and the mother of the cord blood unit in 79 (7%). Of these, 25 patients had one mismatch and 54 had two mismatches. Outcome after transplantation for patients whose mismatched antigen was shared with the NIMA of mother of the cord blood unit ("NIMA match") was compared to that for patients who did not share the NIMA of the mother of the cord blood unit ("NIMA mismatch"). Lower transplant-related mortality (TRM) was observed with NIMA-matched transplant compared to those who shared no NIMAs.

These data suggest that, in utero, the cord blood is exposed to the NIMAs, and this two-way trafficking of cells or soluble HLA antigens promotes tolerance of noninherited maternal histocompatibility antigens by the immune system of the fetus. When the transplant is performed with cord blood stem cells that have been tolerized to the NIMA, which happens to be the same antigen in the transplant recipient that is mismatched, there is less graft-versus-host allorecognition, leading to lower GVHD, lower TRM, and improved survival. These data have potential implications to the selection of potential cord blood units. If maternal HLA typing were available for cord blood units, further consideration to select the unit whose NIMA is the same as the HLA mismatch between the recipient and the cord blood unit might be envisioned. More data will be needed to ascertain the size of available cord blood registries that will optimally support the integration of NIMA information into cord blood selection. The relative risks associated with transplantation using a unit

with fewer HLA mismatches but without NIMA matching, compared to a lesser matched unit with NIMA matching, remain research questions of great interest.

Typing for the Human Platelet Alloantigen System

The technical developments made for typing the human platelet alloantigens (HPA) and glycoproteins parallel those that have been achieved for the HLA gene complex. Serological methods dominated the early history of platelet typing, with the first alloantigen, Zw[a], having been discovered using agglutination methods [145]. Between the 1950s and the 1980s, serologically based methods were refined and immunochemical techniques were introduced [146–151]. Representative techniques that have been widely used in the discovery of new HPA and in clinical testing include the platelet suspension immunofluorescence test (PSIFT) [151], the mixed passive hemagglutination test (MPHA) [150], the modified antigen-capture enzyme-linked assay (MACE) [147], and the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) [148, 152].

The modern era of HPA typing has witnessed the development of PCR-based DNA typing methods that share similarity with those described previously for the HLA class I and II genes. The earliest application of molecular technology to HPA typing came in 1989 with the use of RFLP analysis for HPA-1 [153]. RFLP techniques were subsequently applied to investigate the polymorphism of HPA-2, 3, 4, and 5 [145, 154]. The development of SSP approaches [155, 156] and SSOP methods [157–159] was instrumental in uncovering the allelic diversity of the HPA system.

Large-scale HPA typing is currently feasible with high-throughput tools: oligonucleotide ligation assay (OLA), preferential homoduplex formation assay (PHFA), allele-specific PCR, melting curve analysis, and 5′-nuclease assays [160–164]. One of the most technically facile approaches for rapid cost-effective HPA genotyping is based on the TaqMan® oligonucleotide hybridization method relying on the 5′-endonuclease activity of *Taq* polymerase to cleave a dye fluorophore from the oligonucleotide probe. The genotypes are defined by the clustering of fluorescence for the different dye fluorophores. This simple read-out enables the user to rapidly identify samples that have homozygous or heterozygous genotypes.

The most challenging clinical scenario remains transfusion support of alloimmunized platelet-refractory patients. Approaches to facilitate the selection of HLA-matched platelet products are available, in addition to screening for anti-HLA antibodies [165]. Current and future research are addressing the benefits of HLA-matched or cross-matched compatible platelet components, and the utility of class I residue matching.

Conclusions

The success of unrelated donor HCT as a curative modality for hematologic malignancies is due in part to a better understanding of the immunogenetics of the HLA system and to the development and application of robust DNA typing technologies for donor matching. The extensive diversity in both the coding and noncoding regions of HLA genes has important biological implications in unrelated donor HCT. Whereas complete genotypic identity between a donor and recipient is associated with optimal transplant outcome, at least with respect to engraftment and risk of GVHD, it is clear that not every disparity is functionally relevant. Future clinical research will be required to define the acceptable limits of HLA disparity and to identify mismatches that are well tolerated so that life-saving transplants can be made available to patients lacking matched unrelated donors.

57 Special Care of Blood and Marrow Hematopoietic Cell Transplant Recipient

Syed A. Abutalib and Hillard M. Lazarus

Introduction

Hematopoietic cell transplantation (HCT) has evolved into one of the most effective therapeutic modalities for the treatment of neoplastic, immunologic, and genetic disorders in pediatric and adult populations [1]. Careful preclinical scientific studies in the late 1940s and 1950s set the stage for the triumph of clinical HCT [2–4]. In the late 1960s and early 1970s, E. Donnall Thomas and his colleagues at the Fred Hutchinson Cancer Research Center refined clinical allogeneic bone marrow transplantation techniques sufficiently that cures could be obtained in far-advanced leukemia and aplastic anemia subjects [5]. By the 1980s, autologous bone marrow transplantation was demonstrated to provide long-term survival in acute myeloid leukemia and relapsed adult lymphoma subjects [6, 7]. These successful experiences helped move HCT to use earlier in the disease course, including patients in first complete remission but thought to be at high risk for subsequent relapse, and led to exploration in a variety of disorders.

HCT is a life-saving art and more than one million subjects have undergone the procedure [8]. It is estimated that more than 65,000 persons per year undergo HCT, with a 3% growth rate per year. Due to a greater understanding of human histocompatibility, advances in transfusion medicine, improved antibiotics, more effective anticancer drugs, and the development and implementation of recombinant hematopoietic growth factors, overall- and disease-free survival rates dramatically have improved. Alternative sources of hematopoietic grafts have been expanded and include, in addition to the use of autologous grafts, HLA-mismatched related and unrelated, HLA matched unrelated adult volunteers, HLA haploidentical and umbilical cord blood (UCB) cells. The use of UCB as a graft source is unique for its low number of hematopoietic progenitor cell content due to small volume yet highly proliferative and novel immunologic properties. UCB is an important graft source, especially in pediatric diseases [9–11]. Culture-expanded bone marrow stromal cells, termed multipotent mesenchymal stromal cells (MSCs), are being utilized in conjunction with hematopoietic cells to enhance engraftment, reduce the incidence and severity of graft-versus-host disease (GvHD), and facilitate organ repair [12–15].

The potential for serious morbidity and mortality of the myeloablative preparative regimen may preclude a number of patients from undergoing allogeneic transplant. These patients, however, could benefit from a HCT procedure and now may benefit from a “nonmyeloablative” or “reduced-intensity conditioning” regimen (Table 57.1). These approaches depend more upon cellular therapy via the allogeneic effect to eliminate neoplastic cells rather than the potential cytotoxic effect of chemoradiation on neoplastic cells. The phenomenon of donor cells eradicating tumor often is referred to as the graft-*versus*-cancer effect and appears to be driven by donor alloreactive T-cells [16–19]. Certain hematologic maliganancies are more vulnerable to this graft-versus-cancer effect than others [19]; the explanation for such variability is not clearly understood. Older patients and those with significant comorbid illnesses now are potential candidates for HCT whereas in the past these subjects would not be considered for conventional myeloablative HCT procedures due to the unacceptably high treatment-related mortality (TRM) [18]. The pioneering work of E. Donnall Thomas and his colleagues ultimately was recognized with the 1990 awarding of the Nobel Prize in Medicine/Physiology to Professor Thomas. Today, bone marrow transplantation has continued to undergo significant technological and clinical transformation. HCT, a term which encompasses autologous or allogeneic transplantation of hematopoietic progenitor cells from bone marrow, blood,

Table 57.1 Definition of conditioning regimens for hematopoietic cell transplantation according to the intensity of chemotherapy

Intensity of conditioning regimen	Definition	Mechanism of effect
Myeloablative conditioning (MAC)	Regimen destroys the hematopoietic cells in recipient bone marrow with resulting long-lasting pancytopenia, usually irreversible. Fatal in most instances unless hematopoiesis is restored by infusion of HPCs	Potent cytotoxic agents and the allogeneic ("graft-versus-tumor") effect combine to eliminate malignancy and facilitate donor cell engraftment
Reduced-intensity conditioning (RIC)	Regimen intermediate in intensity between MAC and NMA. Results in pancytopenia that may be prolonged and requires HPC rescue	Modest intensity cytotoxic agents and the allogeneic ("graft-versus-tumor") effect combine to eliminate malignancy and facilitate donor cell engraftment
Nonmyeloablative (NMA)	Regimen results in minimal cytopenias but significant lymphopenia and does not require HPC rescue	Limited effect of cytotoxic agents; relies predominately on the allogeneic ("graft-versus-tumor") effect to eliminate malignancy and facilitate donor cell engraftment

or UCB, is an effective modality for the treatment of variety of neoplastic and nonneoplastic conditions. Presently, essentially all patients now have the possibility of undergoing either an autologous HCT or an allogeneic HCT, the latter using a related, histocompatible or partially mismatched donor; matched unrelated adult donor; an umbilical cord blood graft; or a HLA-haploidentical donor graft. Further, regimen intensity can be adjusted per patient tolerance, e.g., myeloablative conditioning; reduced-intensity conditioning; and nonmyeloablative conditioning. The age of recipients steadily has increased as well. As a result of continued improvements and sophistication of supportive care, an increasing number of transplants also are being undertaken in the ambulatory, rather than the inpatient, setting. In the US, the number of allogeneic transplants recently surpassed 8,000 per year, with a cumulative total of 320,000 transplants [20] (Fig. 57.1). Currently, more than 30,000 transplant recipients are surviving beyond 5 years. Should transplant survival rates remain unchanged, by 2030 there may be over half a million long-term survivors in the US, and up to one million worldwide [20, 21] (Fig. 57.2). The use of this modality, however, requires extremely sophisticated medical, financial, and psychological supportive care for a successful outcome [22, 23]. This review describes the medical aspects of HCT recipients in a detailed fashion.

Recipient Suitability

The effectiveness of myeloablative therapy and HCT must be tempered by the potential for significant morbidity and mortality [24]. The decision to proceed with HCT must take into consideration disease- (type and state of disease) and patient- (comorbid conditions) related factors since these variables influence all aspects (pre-, peri-, and post-) of transplant [25–31] (Table 57.2). Armand and Coworkers [25] developed the Disease Risk Index (DRI) after analyzing the outcomes of 13,131 patients reported to the Center for International Blood and Marrow Transplant Research (CIBMTR) who underwent HCT between 2008 and 2010. The DRI stratified patients into four risk groups (Table 57.2) with 2-year overall survival (OS) ranging from 64 to 24% and is the strongest prognostic factor, regardless of age, conditioning regimen intensity, graft source, or donor type. With

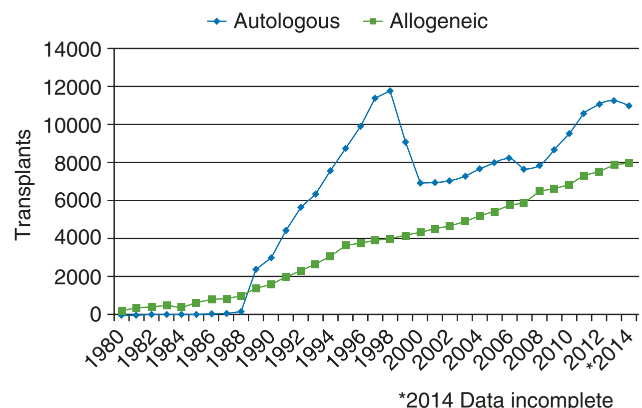

Fig. 57.1 Estimated annual numbers of transplant recipients in the U.S. were compiled according to the number first transplants registered with CIBMTR [20]

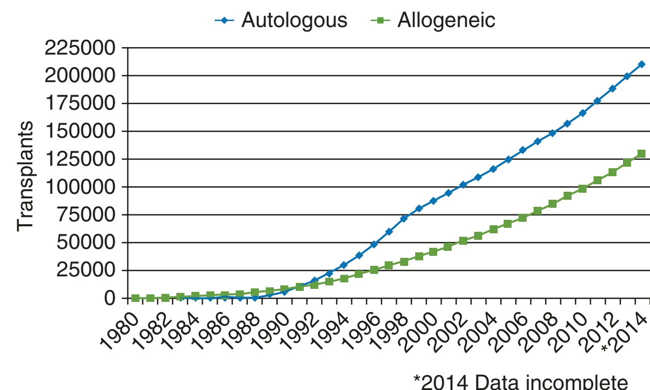

Fig. 57.2 Cumulative number of transplant recipients in the U.S. reached 340,000 in 2014 (CIBMTR data) [20]

Table 57.2 Disease risk index for allogeneic hematopoietic cell transplantation [25]

Disease risk group	2-year overall survival (%)	Disease risk category
Low	**66**	• Chronic lymphocytic leukemia or small lymphocytic lymphoma in complete or partial remission
		• Chronic myeloid leukemia in chronic phase
		• Acute myeloid leukemia[a] with favorable risk cytogenetics in complete remission
		• Hodgkin lymphoma in complete remission
		• Mantle cell lymphoma in complete remission
		• Clinically indolent B-cell non-Hodgkin lymphoma in complete or partial remission
Intermediate	**51**	• Chronic lymphocytic leukemia or small lymphocytic lymphoma in stable condition or progressive disease
		• Chronic myeloid leukemia in accelerated phase
		• Acute myeloid leukemia[a] with intermediate risk cytogenetics in complete remission
		• Acute lymphoblastic leukemia in first complete remission
		• Low-risk myelodysplastic syndrome[b] (<5% blasts and intermediate cytogenetics) in any disease stage
		• Low-risk myelodysplastic syndrome[b] (<5% blasts and adverse cytogenetics) in early disease stage
		• High-risk myelodysplastic syndrome[b] (≥5% blasts and intermediate cytogenetics) in early disease stage disease
		• Mantle cell lymphoma in partial remission
		• Clinically aggressive B-cell non-Hodgkin lymphoma in complete or partial remission
		• T-cell non-Hodgkin lymphoma in complete or partial remission
		• Multiple myeloma in complete or partial remission
High	**33**	• Acute myeloid leukemia[a] with favorable risk cytogenetics AND induction failure or active relapse
		• Acute myeloid leukemia[a] with intermediate risk cytogenetics AND induction failure or active relapse
		• Acute myeloid leukemia[a] with adverse risk cytogenetics AND complete remission
		• Acute lymphocytic leukemia in second or third complete remission
		• Low-risk myelodysplastic syndrome[b] (<5% blasts and adverse cytogenetics) with induction failure or active relapse
		• High-risk myelodysplastic syndrome[b] (≥5% blasts and intermediate cytogenetics) with induction failure or active relapse
		• High-risk myelodysplastic syndrome[b] (≥5% blasts and adverse cytogenetics) at any stage
		• Mantle cell lymphoma with induction failure or active relapse
		• Burkitt lymphoma in complete remission
		• T-cell non-Hodgkin lymphoma with induction failure or active relapse
		• Multiple myeloma- relapsed or refractory
Very-high	**23**	• Chronic myeloid leukemia in blast crisis
		• Acute lymphocytic leukemia with induction failure or active relapse
		• Aggressive B cell non-Hodgkin lymphoma with induction failure or active relapse
		• Burkitt lymphoma with induction failure or active relapse or partial response to therapy
		• Acute myeloid leukemia[a] with adverse cytogenetics AND induction failure or active relapse
Examples of risk assessment score systems for allogeneic hematopoietic cell transplantation		
	Attributes and caveats	**Score assessment**
EBMT [26] **(2009)**	Mainly for chronic myeloid leukemia patients.	Overall survival and treatment related mortality calculated based on assessment of 5 factors;
	Limited utility in current era	1. Donor type
		2. Stage of chronic myeloid leukemia
		3. Age of the patient
		4. Donor/recipient gender matching
		5. Time to transplant from diagnosis

(continued)

Table 57.2 (continued)

PAM [27] **(2006)**	Only useful for predicting the risk for death within the first 2 years after hematopoietic cell transplantation	The risk for death within 2 years for patients with PAM scores in the highest category was significantly higher than for those with scores in the lowest category
		Eight pretransplantation clinical variables:
		1. Patient age
		2. Donor type
		3. Disease risk
		4. Conditioning regimen
		5. FEV1
		6. Carbon monoxide diffusion capacity (DLCO)
		7. Serum creatinine concentration
		8. Serum alanine aminotransferase (ALT) concentration
HCT-CI [28] **(2005)**	Assessment of patients who have a variety of hematologic neoplasms	HCT-CI score weighs 17 different categories of organ dysfunction to calculate a score ranging from 0 to 29 for overall survival and nonrelapse mortality assessment
	Prospectively validated	Online web-based calculator available at www.hctci.org
	Age added to the index [32]	
	Most widely used	

[a]Acute myeloid leukemia t(8;21), inv(16), and t(15;17) were classified as favorable cytogenetics, complex karyotype ($>$4 cytogenetic abnormalities) as adverse cytogenetics, and all others as intermediate
[b]myelodysplastic syndromes, abnormal chromosome 7 and complex karyotype (≥4 abnormalities) were classified as adverse cytogenetics, and all others as intermediate.
Modified from Ref [25]
EBMT European Group for Blood and Marrow Transplantation, *PAM* Pretransplantation Assessment of Mortality, *HCT-CI* hematopoietic cell transplantation-specific comorbidity index

regard to patient-related factors and transplant outcomes, a number of composite scoring systems are available that may assist estimating mortality risk in patients considering HCT [26–31]. Of these, the three most commonly used assessments are the European Group for Blood and Marrow Transplantation (EBMT) risk assessment score; the Pretransplant Assessment of Mortality (PAM) score; and the Hematopoietic Cell Transplantation-specific Comorbidity Index (HCT-CI) (Table 57.2) [26–28, 32]. Advances in supportive care have not only improved short-term outcomes but have also resulted in many more long-term survivors and the need for continuing follow-up on this groups to prevent or intervene early for problems that may develop [31]. Additionally, the expanded use of reduced-intensity conditioning (RIC) regimens has allowed more patients formerly excluded from this procedure due to organ dysfunction to undergo successful allogeneic HCT. Defining the ideal conditioning regimen for more vulnerable patients, especially those who are considered "elderly" or with compromised organ function, remains a challenge. Recently, Sorror and coworkers proposed the integration of age into the comorbidities index for clinical decision-making and comparative effectiveness in the setting of allogeneic HCT [32]. Data from 3033 consecutive recipients of HLA-matched grafts from five institutions contributed to this analysis. The patients whose composite comorbidity-age index were low (scores 0 or 1–2) had comparable mortality risk regardless of conditioning regimen used; these subjects should be offered higher-intensity regimens. On the contrary, patients with higher scores (≥ 3) had statistically significant higher mortality risk and are more suitable for lower-intensity regimens. Although many investigators have examined the role of pretransplant evaluation in predicting organ-specific, treatment-related morbidity, few have focused on identification of pretransplant factors associated with mortality in older adults undergoing RIC-based HCT. McClune and colleagues [33] published a retrospective analysis of over 1000 patients age 40 years or older who underwent RIC allogeneic HCT. They examined the influence of age-group on several outcome measures including marrow recovery, acute and chronic GvHD and nonrelapse survival. Age had no significant impact on any outcomes using RIC regimens.

Optimal Donor for Allogeneic Hematopoietic Cell Transplant

Prospective allogeneic HCT candidates undergo histocompatible testing to identify HLA suitable hematopoietic cell donor [34, 35]. The HLA donor searches begin with family members; if a full HLA-match sibling is not identified, then the process is extended. Options include searches with

unrelated registries such as the National Marrow Donor Program for an HLA-match unrelated donor (MUD); or, institutional preference, for HLA-partially matched donors or HLA- haploidentical mismatched donors; or UCB grafts. Optimal donor characteristics include HLA identity at the A, B, C, and DRB1 loci, same gender for donor and recipient, younger donor age, same ABO red blood cell (RBC) type, and CMV concordance. Rarely are all such characteristics met. Priority is given to HLA- matching over other parameters. Often a family member donor is not identified as fully HLA- match and alternative types of grafts are sought. Allogeneic HCT performed using unrelated donors are associated with higher rates of graft failure, increased incidence and severity of GvHD, and increased susceptibility to infection when compared to HLA- matched sibling-donor transplants [36]. The development and application of DNA-based typing techniques for class I and II molecules for identifying histocompatibility between donor and recipient at the A, B, C, DR, and DQB1 loci (10/10 preferred allele match in unrelated donor setting) is a substantial improvement over serologic methods [34, 35, 37–40]. These sophisticated techniques have enabled selection of a more congruent graft resulting in fewer cases of graft rejection and has lowered the incidence and severity of GvHD. Inherited minor histocompatibility antigen mismatches, deriving from polymorphic peptides encoded elsewhere than chromosome 6 in the genome, are key molecules in the development of graft-versus-tumor and GvHD effect, especially in the HLA-matched transplant setting [41–43].

In addition, greater emphasis during donor selection now is being placed on specific NK cell alloreactivity [44] and DP locus status for improvement in transplant outcomes [45–51]. Recent data suggest that an HLA-DPB1 mismatch is associated with increased risk of graft failure and GvHD. The observation that the risks of GvHD may be offset by a beneficial effect of graft-versus-leukemia (GvL), leading to lower disease recurrence, provides a potential therapeutic avenue for patients with high-risk malignancies. Attempts to refine graft selection within the realm of 7 out of 8 HLA-match unrelated donor transplant setting has brought forth few intriguing concepts [52–56]. First, the transplant outcomes were not adversely affected if mismatch antigen (7 out of 8 HLA matched setting) was in the host-versus graft-direction (unidirectional HvG vector, i.e., the host immune system identifies the donor allele and mounts a reaction) [52, 53]. Second, adverse transplant-related outcomes were seen if ≥3 mismatches are present within DRB 3/4/5, DP, and DQ in GvH direction [54]. Third, the mismatch combination HLA-C*03:03–03:04 is shown to be clinically well tolerated due to lower risk associations with GvHD and mortality compared to other HLA-C mismatches; this effect was not accompanied by increased hazard of relapse [55]. Finally, mismatches involving high expression HLA-C alleles were shown to be associated with significantly higher risks of severe acute GvHD but not of relapse compared to low expression HLA-C mismatches [56]. These observations suggest that HLA-C*03:03-03:04 and low-expression HLA-C mismatches might allow for at least partial separation between GvL and GvHD. Few similar concepts appear to apply to HLA-DPB1 mismatches [49]. The process of locating a HLA-matched unrelated donor and securing a graft, however, may take up to many months, on average about 3 months. Depending on the ethnicity of the potential recipient, a HLA matched donor may not be located. A recent study from the NMDP showed that the likelihood of finding an optimally matched (8/8 match at HLA-A, -B, -C and -DRB1) donor ranged from 75% for patients of European descent down to 16% for Blacks of South or Central American descent [57]. Alternative donor sources also include HLA-haploidentical family members and UCB units (discussed later in text) providing a donor for almost 100% of the patients in need of allogeneic transplant [58]. The former are a ready source of hematopoietic cells, while the latter can be procured via the National Marrow Donor Program or via UCB banks such as the New York Blood Center. The incidence and severity rates of GvHD are lower with UCB units than with other hematopoietic cell sources, in part, due to the low numbers and immaturity of lymphocytes contained in the product [59, 60]. Specifically, recipients of UCB obtained from HLA-identical siblings had a lower risk of acute and chronic GvHD when compared to patients given bone marrow grafts obtained from HLA-identical siblings [61]. Other data demonstrate a lower risk of GvHD in recipients of unrelated donor UCB versus HLA-matched unrelated bone marrow [62]. On the other hand, UCB transplants, especially in adults, are hampered by a smaller number of cells in the graft (per recipient weight), longer duration of severe neutropenia, a higher graft failure rate, and the potential for increased treatment-related morbidity and mortality [60, 63]. In children, nonrelapse mortality is lower in allele level matched single UCB vs. mismatched units at 1, 2, 3, 4, or 5 alleles considering HLA-A, -B, -C, and -DRB1 loci and the myeloablative conditioning setting [64]. Transplantation of more than one unit and the recently developed expansion of UCB cells ex vivo may ameliorate these limitations [65]. Further, use of double UCB grafts may be associated with a lower malignancy relapse rate due to an enhanced GvL effect [66, 67]. The use of UCB grafts is discussed in greater detail elsewhere in this text.

Graft Source: Peripheral Blood versus Marrow

First utilized in the late 1980s, blood rather than marrow has become the preferred source of support for autograft and allograft patients alike. Many trials [68–87] have demonstrated that the use of mobilized blood grafts is associated

with faster time to return of neutrophil and platelet counts, fewer infections, fewer transfusions, shorter hospital stays, reduced antibiotic use, and often lower costs than its bone marrow counterpart. Also, the rates of acute GvHD appear similar between the two graft sources. Such data, however, indicate that chronic GvHD rates are higher with mobilized blood than with the use of marrow graft. There does not appear to be a survival advantage for one graft source over another, especially with longer follow-up data except in patient with high-risk leukemias where blood is the preferred source with matched-sibling donors [84–86]. It is important to recognize that myeloablative conditioning predominantly was used in most studies and HCT is a multifactorial process; hence, the results should be interpreted cautiously and cannot be generalized. However, there is firm consensus to avoid mobilized blood grafts in nonmalignant disorders and in children with malignant disorders [88].

Conditioning Regimen Intensity

Over the past several years, investigators increasingly utilize "nonmyeloablative" (NMA) or "reduced-intensity conditioning" (RIC) regimens in the allograft setting, i.e., less toxic preparative regimens that maintain reliable donor engraftment [89–91]. Successful exploitation of this approach allows patients thought to be ineligible for a full myeloablative transplant due to older age, organ function impairment, prior myeloablative transplantation, or other risk factors such as hepatitis B seropositivity, to undergo allogeneic HCT [92–96]. Conventional allografts rely upon both high-dose chemoradiation therapy for cell kill and the donor immune system to induce a graft-versus-tumor effect whereas RIC and NMA conditioning rely more on donor cell mediated immune effects and less on the cytotoxic effects [92, 93]. NMA transplants utilize regimens sufficiently immunosuppressive to facilitate donor cell engraftment, but are less toxic to both marrow and non-marrow organs (Table 57.1). These reduced-conditioning preparative regimens generally involve the use of nucleoside analogs, low-dose total body irradiation (TBI), and often antithymocyte globulin (ATG) [97–100]. One group has reported striking results when photopheresis therapy is added to the preparative regimen, although this approach has not gained wide acceptance [101]. Extracorporeal photopheresis (ECP) is a form of apheresis in which patients are given drugs such as 8-methoxypsoralen that are photoactivated. During the apheresis process, recipient blood is exposed to ultraviolet light that activates the drug. The 8-methoxypsoralen irreversibly binds covalently to both strands of the DNA of nucleated cells after photoactivation. It is theorized that the photochemically damaged T-cells, returned to the patient, do not induce GvHD, although there may be other explanations for the observed clinical efficacy of ECP. The use of ECP grafts is discussed in greater detail elsewhere in this text.

NMA approaches rely predominantly on the immunotherapeutic effect of donor cells and may be associated with higher relapse rates than those observed with ablative conditioning. To address this finding, investigators have truncated the posttransplant GvHD prophylaxis in order to induce a graft-versus-tumor effect. Donor lymphocyte infusion (DLI) is another strategy utilized to improve RIC and NMA transplant [102–104]. Lymphocytes are collected from the hematopoietic cell donor via apheresis and are infused intravenously at various intervals and doses. This modality has been demonstrated to be an effective treatment for patients who have early or impending relapse after allograft. This maneuver can provide antitumor effect and result in prolonged disease-free survival, particularly in chronic myeloid leukemia (CML) and lymphoid malignancy patients; the results of DLI are less impressive in other malignant disorders [102–106]. Although tyrosine kinase inhibitors (TKIs) have never been compared with DLI in a prospective trial for relapsed CML after allogeneic HCT, there is continued interest in utilizing TKIs posttransplant instead of DLI due to the more favorable toxicity profile [107]. Some investigators have addressed the higher relapse rates by combining an initial autotransplant followed soon thereafter by a RIC allograft [108]. Although this double transplant approach initially was initiated in lymphoid malignancies, the greater use of these so-called tandem autologous-allogeneic-transplant has been in multiple myeloma patients [109, 110]. GvHD, with or without DLI, may complicate the RIC procedure and may negate the benefit of this approach. Caution is urged for this newer modality, which will require controlled trials to define its role.

Alternative Hematopoietic Progenitor Cell Donors

HLA-Haploidentical and Cord Blood Transplants

In patients in whom an autograft is not an appropriate consideration, and in whom a HLA-sibling matched donor or HLA-MUD are not available, strategies may include the use of HLA-haploidentical donor or an UCB graft [60, 111] (see section "Selection of an Allogeneic Donor"). These approaches are considerably more complicated and are associated with significantly more supportive care needs [112]. Although a randomized trial comparing these diverse donor sources is ongoing (Blood and Marrow Transplant Clinical Trial Network protocol BMTCTN 1101), currently available comparisons rely on observational data and small phase II trials [111]. Table 57.3 illustrates the results of two concurrent, phase II BMT CTN trials that essentially demonstrated equipoise and

Table 57.3 Haploidentical marrow transplant versus unrelated double cord blood transplant with [a]reduced intensity conditioning [111]

	BMT CTN 0603	BMT CTN 0604
	Haploidentical marrow transplant	Unrelated double cord blood transplant
Total number of patients	50	50
Age	Median 48 (7–70) year	Median 58 (16–69) year
GvHD prophylaxis	Tacrolimus + mycophenolate mofetil + cyclophosphamide (days 3, 4 after transplant)	Cyclosporine + mycophenolate mofetil
Neutrophil engraftment	16 days	15 days
Platelet engraftment	24 days	43 days
Primary graft failure	1 patient	5 patients
Acute GvHD (grade II-IV) at day + 100	32%	40%
Acute GvHD (grade III-IV) at day + 100	No reported cases	21%
Chronic GvHD till 1-year	13%	25%
Progression-free survival at 1-year	48%	46%
Treatment-related mortality at 1-year	7%	24%
Non-relapsed mortality at 1-year	7%	24%
Overall survival at 6-months[b]	84%	74%
Overall survival at 1-year	62%	54%
Most common cause of death	Relapse	Relapse

[a]Cyclophosphamide, fludarabine, 200 cGy total-body irradiation
[b]Primary end point of both studies; GvHD-graft-versus-host disease; Adapted from Kekre N, Antin JH. Semin Hematol. 2016;53:98–102

provided justification to pursue the ongoing head-to-head comparison. For UCB grafts, the GvHD incidence and severity appear reduced; on the other hand, recovery of the myeloid compartment in UCB transplant recipients in adults is significantly slower than with other hematopoietic graft cell sources, i.e., a median time to neutrophil recovery >500/μL of 27 days [113]. The slow immune system recovery leads to a significant risk of opportunistic infection and treatment-related morbidity and mortality [111, 113]. Many investigations are ongoing to address these and other issues, including the infusion of two UCB units and ex vivo expansion of cells [114].

Use of HLA-haploidentical graft for transplant conversely reconstitute the recipient myeloid function rapidly but is associated with an increased risk for severe GvHD. This limitation can be attenuated by use of posttransplant cyclophosphamide (see below). Nonetheless, other problems may plague this approach, including opportunistic infection and tumor relapse [111, 115, 116]. This graft source may be more readily available and at a lower graft acquisition cost.

Supportive Care

Central Venous and Hemapheresis Catheters

Central venous catheters (CVC) are indispensable for the transplant procedure. Typically, a dedicated expert inserts a long-term, silastic, multilumen, small-bore, flexible catheter that remains in situ for many weeks to months. Such an approach requires vigilant care by a team of heath care professionals to prevent complications [117, 118]. These devices are used for: chemotherapy administration; collection of hematopoietic cells in autograft candidates undergoing the hematopoietic progenitor cell mobilization process; infusion of hematopoietic cells; supportive care management including frequent blood sampling, intravenous antibiotics, analgesics, antiemetics, blood component transfusions, electrolyte replacement, parenteral nutrition, and even performing ECP procedures [119]. Complications associated with use of central venous catheters range from pain, infection, and bleeding at the local insertion and exit sites, to bloodstream infections, venous thromboembolism, arrhythmias, mechanical obstruction, and catheter migration. Over the past 10 years, antiseptic-impregnated catheters have been developed to reduce the risk of infections in immunocompromised hosts [120]. Some centers have reported decreased rates of infectious complications with their use. Other infection control measures that have been shown to decrease catheter-associated blood stream infections include education of patients and staff regarding catheter care, good hand hygiene, aseptic technique during insertion and when accessing the device, and standard catheter dressing care guidelines [117, 121]. Additionally, catheters should be removed when they are no longer necessary. There are no data to suggest that systemic prophylactic antibiotics or routine catheter replacement decreases the risk of infectious complications.

Prevention of Nausea and Vomiting - An Important Aspect of Transplant Care

Nausea and vomiting are among the most common acute adverse events arising from high-dose chemotherapy and radiation therapy in the HCT setting [122]. Dopamine-blocking agents such as prochlorperazine previously were the mainstay in the treatment of nausea and vomiting in cancer

chemotherapy. The introduction and use of 5-HT3 receptor antagonists, i.e., serotonin antagonists, revolutionized the treatment of this malady. The first series describing this approach in HCT recipients appeared over 20 years ago [123]. Subsequently, the combination of a serotonin blocker with dexamethasone is the most frequently prescribed prophylactic agent combination to prevent emesis associated with high-dose cytotoxic therapy [124–126]. The neurokinin-1 receptor antagonists aprepitant, fosaprepitant, rolapitant, and casopitant recently have been added successfully to the armamentarium [127, 128]. “Complimentary therapy” such as acupuncture also has been used but, unlike results in the non-HCT setting, has been not found to be advantageous [129].

There are obvious differences in planning an antiemetic strategy in the HCT patient. The American Society of Clinical Oncology guidelines suggest use of the three-drug approach consisting of dexamethasone, a serotonin antagonist, and a neurokinin-1 antagonist for subjects receiving highly emetogenic chemoradiation therapy. This position is based on factors that include the recognition that TBI often is a component of therapy, the cytotoxic treatments are given for a number of consecutive days, and most HCT patients are not chemotherapy naïve [130].

Although several publications describe the use of the various 5-HT3 blockers in the HCT setting, there appear to be few differences between the various serotonin blockers as they relate to side effects, efficacy, or the combination. Palonosetron is an exception to this finding as its receptor half-life is substantially longer than the other agents and this property permits less frequent dosing [125, 126, 130]. Four important statements can be gleaned from antiemetic guidelines as such pertain to HCT. First, a serotonin blocker always should be used in conjunction with dexamethasone. Second, the minimally effective biologic (antiemetic) agent dose should be used. Third, as it appears that all current 5-HT3-blocking medications are therapeutically equivalent, the choice of agent should be determined by economic factors at each institution. Fourth, patients receiving highly emetogenic regimens may derive benefit from up front addition of neurokinin-1 receptor antagonists. Supplementary benefit from use of adjunctive agents such as dopamine blockers (haloperidol and prochlorperazine) also may be advantageous on an as needed basis.

Transfusion Support in the Hematopoietic Transplant Setting

Nearly all HCT recipients develop anemia, neutropenia, and thrombocytopenia. All cellular blood products, including red blood cells (RBCs) and platelets, contain small numbers of leukocytes. These “passenger leukocytes” are important in immunization of the recipient to HLA antigens present in the donor. Hence, transfusions from blood relatives *must* be avoided when possible for all potential allogeneic transplant candidates, and blood banks at most centers utilize a formal protocol to prevent such occurrences. Such strategy minimizes the risk of graft rejection and refractoriness to platelet transfusions [131]. The “passenger leukocytes” also may be responsible for transmission of cytomegalovirus (CMV) infection (see below) and febrile transfusion reactions (cytokine-mediated). Further, recipient immunocompromised status is a risk factor for transfusion-associated GvHD, a condition that is nearly always fatal and for which currently there is no effective therapy [132, 133]. To prevent CMV transmission and inadvertent lymphoid engraftment and proliferation, all blood components are irradiated routinely (1200–3000 cGy) prior to infusion. Irradiation of blood products usually is continued until 6–9 months after transplant, at which time, it is believed that full immunologic reconstitution has been restored. In recent years, leukocyte reduction filters have been employed before and after collection and storage of blood components, which significantly reduces the incidence of refractoriness to platelet transfusion, HLA alloimmunization, and transmission of CMV infection. These filters, however, are not able to provide adequate protection against transfusion-associated GvHD; therefore, irradiation remains the preferred method in HCT recipients [134–136].

Transplant-related nonhemolytic anemia, due, in part, to a relative endogenous erythropoietin deficiency, plagues allogeneic and autologous HCT. Red blood cell transfusions should be undertaken if Hb < 8 g/dL or Hct < 25%. A higher transfusion threshold should be considered if the patient is elderly or has symptoms of severe fatigue, headache, tachycardia, cardiac ischemia, or hypotension. In a prospective randomized trial examining administration of exogenous erythropoietin (500 U/kg per week), erythroid recovery was hastened and transfusion requirements decreased if started 1 month after allogeneic HCT. The proportion of complete correctors (i.e., Hb ≥13 g/dL) before 126 days after HCT was 8.1% in the control arm (median not reached) and 63.1% in the erythropoietin arm (median, 90 days) ($P < .001$). Hb values were higher and transfusion requirements lower ($P < .001$) in the erythropoietin arm. Of note, when erythropoietin therapy was started 28 days after transplant, only 5 patients had a Hb level higher than 11 g/dL (mean 9 g/dL), in keeping with current guidelines for initiation of erythropoietin therapy [137]. Despite these data, most transplant centers do not employ this approach.

Spontaneous bleeding, the most frequent complication of severe thrombocytopenia, is greatest at platelet counts of 20,000/μL or less. A number of investigators have advocated lower threshold levels for prophylactic transfusion in view of heightened concerns about transfusion costs and risks of infection and alloimmunization [134, 135]. Few studies have

addressed this issue prospectively and many of the trials were undertaken in leukemia patients who were not receiving HCT. Some centers administer platelet transfusions only if the count drops below 5000/μL while others maintain a 10,000 or 20,000/μL threshold. In patients with active bleeding or those scheduled to receive an invasive procedure, most physicians target a platelet count of 50,000/μL (higher in those with suspected or documented CNS hemorrhage).

Granulocyte Transfusions

For more than five decades, granulocyte transfusions have been used for treating infections in neutropenic patients; infusion of low numbers of transfused cells, however, hampered effectiveness [138]. With the advent of recombinant hematopoietic growth factors, the yield from volunteer donors given G-CSF and corticosteroids (dexamethasone) significantly increased cell dose [139]. A clinician may anticipate a rise in blood absolute neutrophil count to approximately 1,000 cells/μL if the recipient is given a collection containing 5–8 × 10^{10} granulocytes. The posttransfusion neutrophil increment may persist for more than 24 h after transfusion. This cellular product is plagued by difficulty identifying donors, high procurement costs, and short shelf life. Further, both the volunteer donor and the recipient are subject to risks in this endeavor. Donors given repeated dexamethasone doses are at increased risk for the development of subcapsular cataracts [140]. Fever, chills, and respiratory compromise due to new infiltrates or exacerbation of preexisting infiltrates may accompany a granulocyte transfusion, especially if a recipient has preexisting HLA alloantibodies [141]. The latter reaction (alloimmunization) also may be induced by the large number of lymphocytes that are contained within the product. Investigators usually screen for class I and class II HLA and anti-neutrophil antibodies before initiating a course of granulocyte transfusions in order to identify compatible donors; if not, these subjects may have subtherapeutic responses or a greater likelihood of adverse events [142]. As noted above, CMV disease also can result by transmission of this virus contained within the granulocytes. Despite these drawbacks, some clinicians advocate granulocyte transfusions for treatment of severe, progressive infections in neutropenic patients who fail to respond to antimicrobial agents and recombinant hematopoietic growth factors [143, 144]. The decisions to initiate and to continue transfusions can be difficult and a clinician carefully must consider the benefits versus the risks of granulocyte transfusions. Daily administration should be continued until control of the infection, neutrophil recovery, or development of significant toxicity. Sometimes it is unclear whether to continue this approach as patients initially may have worsening of symptoms (i.e., pulmonary, as above) due to trafficking of granulocytes to sites of infection. Such patients ultimately may experience clinical and radiologic evidence of improvement.

In an attempt to bring clarity, the National Heart, Lung and Blood Institute (NHLBI) of the United States undertook a randomized, controlled prospective, 14 center trial to evaluate the efficacy of granulocytes to treat infection in neutropenic patients. The Resolving Infection in Neutropenica with Granulocytes (RING) Study enrolled 56 patients who were given granulocytes compared to 58 control. No benefit of granulocyte transfusion was observed, but the power of the study was reduced due to low accrual [145–147]. In a post hoc secondary analysis, however, patients given higher granulocyte doses tended to have better outcomes than those receiving lower doses. These data suggest that if a clinician decides to administer granulocyte transfusions, it is important to collect and infuse at least 0.6 × 10^9 neutrophils/kg recipient weight. Newer products are being developed to help meet this target.

Cytomegalovirus (CMV) Detection and Disease

CMV is one of the leading causes of infectious morbidity and mortality in the allogeneic HCT population [148, 149]. CMV infection and disease are significantly less common in the autologous HCT setting, the exception being patients who are receiving CD34$^+$ -enriched grafts [150]. Some multiple myeloma and lymphoma CMV-seropositive patients appear to be at increased risk for CMV reactivation during autotransplant [151]. CMV infection is indicated by isolation of CMV from any body site, or the seroconversion of a patient in the absence of any clinical signs or symptoms of disease. CMV disease is defined as a positive culture from a deep tissue or clinical or histologic evidence of active viral infection. While a number of organs can be involved in the course of an allograft, CMV interstitial pneumonitis is the most severe infection.

Despite nearly eliminating CMV disease during the first 3 months after transplantation, CMV still remains an important pathogen in HCT recipients in the current era of antiviral prophylaxis and preemptive therapy [148, 149]. Transfusion-transmitted CMV infection can be reduced by the use of blood products obtained from seronegative donors. Filtered, leukocyte-depleted blood products and more recently, photochemical treatment using a combination of the psoralen amotosalen HCl and long-wavelength UV light also are extremely effective [152]. There remains, however, a 1–2% risk of transmitting CMV disease. There are no controlled studies that have investigated whether there is added benefit from the use of both seronegative and filtered blood products. CMV-seronegative patients, if possible, should receive

grafts from a CMV-seronegative donor. When using an unrelated donor, an HLA-A, -B, -C, -DR match but CMV-seropositive donor most likely will be preferred to a CMV seronegative donor of lesser match. For a lesser degree of mismatch, such as allele mismatches or mismatches on HLA-DQ, or -DP, a CMV-negative donor could be considered even if the match was worse. UCB grafts are a special situation and as such can be considered as CMV negative.

Several cohort studies show that CMV-seropositive transplant recipients and seronegative recipients of a CMV-positive graft have a persistent mortality disadvantage when compared with seronegative recipients receiving a seronegative donor graft, especially in the setting of highly immunodeficient patients, e.g., recipients of ex vivo or in vivo T-cell depletion transplants from unrelated or HLA-mismatched donors. If the only donor available for a CMV-seronegative patient is CMV seropositive, the risk of CMV transmission by the hematopoietic cell product is 20–30%; there currently are no strategies to eliminate the risk of primary CMV infection.

As discussed in the next section, immunoglobulin preparations have not been shown to improve outcome. Chemoprophylaxis with antiviral agents remains the mainstay of prevention, although this strategy results in unnecessary treatment of many patients who will not develop CMV infection or disease. Ganciclovir prophylaxis, in general, appears to be the most effective agent for CMV disease prevention but is plagued by myelotoxicity. Foscarnet clearly is efficacious but renal failure and electrolyte disturbances are significant and generally use is reserved for CMV resistance. Acyclovir and valacyclovir are not recommended to prevent CMV disease due to lesser efficacy. Because of such drawbacks, some institutions do not use prophylaxis routinely and employ preemptive strategies upon (quantitative) detection of CMV DNA in blood. The preemptive approach of treating infection, i.e., when blood titers become positive but before active disease is present, has become a standard of care at many centers. As patients may be treated in the outpatient setting when this situation occurs, valganciclovir has become an important and successful treatment option in selected patients [153].

Late onset CMV disease in high-risk populations and the immunomodulatory/immunosuppressive effects of CMV disease leading to invasive bacterial and fungal infections also contribute to the poor outcome in HCT. On the other hand, the risk of antiviral resistance in most patients remains low, except in the setting of intense immunosuppression as observed in HLA-haploidentical donor and T-cell depleted transplants. If drug resistance is suspected, genotypic testing and switching to an alternative drug is recommended as first-line approach [154]. Ganciclovir has been the mainstay of antiviral therapy but its use is associated with marrow suppression. When cytopenias are significant, foscarnet is a reasonable alternative. Viral load can be used to monitor the response to treatment. CMV gastrointestinal disease often can be treated with an antiviral drug alone. Recommendations for treating CMV pneumonia include the addition of intravenous immunoglobulin [155]. The impact of new drugs such as conventional dose maribavir has been disappointing. Few phase II, dose-ranging trials are examining higher doses of maribavir treatment of refractory or resistant CMV disease and as preemptive therapy. One investigational agent, brincidofovir (CMX001; lipid formulation of cidofovir), is an orally administered cidofovir compound conjugated to a lipid. The design is to release parent compound intracellularly and permit higher intracellular concentrations and lower plasma concentrations. One recent phase II dose-escalation study [156] showed a reduction of CMV infection or disease in patients receiving brincidofovir at doses of 200 mg/week for prophylaxis started at engraftment. The most common side effect was diarrhea in patients receiving at brincidofovir doses of 200 mg/week or higher and was dose-limiting at 200 mg twice weekly. There was no difference in renal or hematologic adverse effects between brincidofovir and placebo recipients [156]. A phase III randomized multicenter trial (SUPPRESS trial) of brincidofovir at a dose of 100 mg twice weekly is in progress using a similar trial design as the phase II trial (NCT01769170). Other agents under investigation include letermovir (AIC-246), BAY 38-4766 (nonnucleoside inhibitor), leflunomide, and artesunate (anti-malaria drug). Immunologic strategies such as adoptive transfer of CMV-specific T-cells and vaccination of the donor/recipient are labor-intensive; specialized efforts that have not yet been able to be extended on a widespread basis [148, 149]. Efforts are in development to better define the subgroups of patients who may benefit from intensified, prophylaxis strategies.

Intravenous Immunoglobulin in Hematopoietic Cell Transplant Setting

HCT recipients as well as patients with lymphoproliferative disorders have a higher incidence of infections due to secondary hypogammaglobulinemia. Intravenous immunoglobulin (IVIG) replacement has been one approach to prevent infection [157, 158]. Randomized controlled trials, however, have demonstrated conflicting results with respect to preparation type, schedule, and dose. Polyvalent immunoglobulin or hyperimmune CMV-IVIG are not superior to control for all-cause mortality. Although IVIG significantly reduced the risk for interstitial pneumonitis, the likelihood of hepatic SOS and other adverse events such as allergic reactions, fluid overload, and venous thrombosis was increased [158, 159]. Routine prophylaxis with IVIG is not supported for HCT and may be associated with impaired recovery of humoral immunity

during the period of GvHD prevention as well as thromboembolic phenomenon in hematologic malignancy patients [159]. Some investigators, however, still utilize IVIG therapy for very low serum immunoglobulin concentration within the first 3 months after HCT. Given the success in treating primary immunodeficiencies and polyneuropathies as well as in some hematologic malignancies, new initiatives in this area include the use of subcutaneous immunoglobulin as replacement therapy [160].

ABO- and Rh-Incompatible Transplants

The red blood cell (RBC) ABO system is inherited independently of the HLA system. Approximately 40% of all allogeneic HCT are performed successfully across either major or minor ABO-incompatible barriers between donor and recipient; these HCTs are not usually associated with an increase in grade II–IV acute GvHD or graft rejection [161, 162]. RBC antigen types may present obstacles if the donor has antibodies (isoagglutinins) against recipient RBCs (minor ABO mismatch), or if the recipient has antibodies against RBCs to donor (major ABO mismatch) antigens. Additionally, if there is a state of incompatibility in the Rh and other red cell antigen systems, significant adverse events may result [161–164]. In contrast to routine blood transfusion, the risk of hemolysis occurs not only at the time of infusion, but also may manifest weeks later if viable lymphocytes contained within the graft produce isohemagglutinins directed against recipient RBC antigens. This condition is termed the so-called *passenger lymphocyte syndrome* (see below) [161, 162].

Major ABO incompatibility presents a clinically significant risk of hemolysis against the RBCs in the graft as a result of host isohemagglutinins directed against donor cells [162]. Peripheral blood HCT grafts are collected via apheresis and contain low RBC numbers. As a result, hemolysis risk is much lower with this graft source compared to a marrow graft that contains a larger volume of RBCs. The risk of clinically relevant hemolysis is reduced by removal of RBCs from the graft using any of a variety of separation or sedimentation techniques, or reduction of isoagglutinin titer from the recipient by an apheresis approach. Isohemagglutinin titers can be depleted by large volume plasma exchange performed on the day of graft infusion and on additional days for patients with higher titers. Major ABO-incompatible HCT recipients, however, may experience delayed RBC recovery and prolonged transfusion up to 1 year later after transplantation because of immune-mediated delayed erythropoiesis with reticulocytopenia as well as slightly slower neutrophil recovery. Various strategies, including extracorpeal immunoadsorption columns, DLI, and rituximab, have been used [162] (Table 57.4).

Table 57.4 Immunologic consequences and standard prevention methods to avoid complication in major and minor ABO incompatible transplants

ABO major mismatch		
Consequences	*Etiology*	*Standard prevention methods*
Acute hemolysis	Infusion-incompatible RBCs	• Monitor for acute hemolytic reaction
Delayed neutrophil and platelet engraftment	Expression ABO antigens on granulocytes and platelets	• If recipient anti-donor titer ≥1:32 and graft contains >20 mL of RBC, deplete graft of RBC, or deplete isoagglutinin in recipient
Delayed RBC engraftment	Host anti-donor isoagglutinins	• If ≥1:32 but graft with <20 mL RBC, OR ≤1:16, infuse graft without modification
Pure RBC aplasia	Persistence of anti-donor isoagglutinins	
ABO minor mismatch		
Consequences	*Etiology*	*Standard prevention methods*
Acute hemolysis	Donor plasma with high isoagglutinin titers	• Monitor for delayed hemolytic transfusion reaction
		• If donor anti-recipient titer ≥ 1:256, plasma depletion of graft
		• If donor anti-recipient titer ≤1:128, infuse without modification
Delayed hemolytic (DAT positive) anemia	Passenger lymphocytes producing anti-host isoagglutinins	

Patients who undergo HCT using minor ABO-incompatible grafts, in contrast to major ABO-incompatible transplants, face two risks: immediate hemolysis from the infusion of incompatible plasma (that can be avoided by plasma removal prior to infusion), as well as delayed, but life-threatening hemolysis mediated by viable donor lymphocytes, i.e., "passenger lymphocytes" [162]. These cells may transiently produce sufficient concentrations of isohemagglutinins which result in potentially life-threatening hemolysis of recipient RBCs 7–14 days after transplantation, sometimes requiring hemodialysis. This situation is distinguished from transplantation-associated thrombotic microangiopathy by a positive direct antiglobulin test (DAT) (Table 57.4). Recipients at greatest risk are those who receive mobilized blood rather than marrow grafts (due to greater numbers of blood T cells infused in the graft), blood group A recipients whose donors have hemolytic anti-A isohemagglutinins in high titers, and omission of the anti-lymphocyte agents methotrexate or mycophenolate mofetil (MMF) as part of GvHD prophylaxis. Some centers advocate an aggressive preventative approach to all

ABO-incompatible transplants using RBC exchange, while others utilize aggressive interventions only for symptomatic management [162]. It is of note that donor isohemagglutinins are not produced in patients undergoing ABO-incompatible UCB transplants, an advantage of this graft source [165].

Non-ABO red cell alloantibodies can develop after HCT [161–164]. Rh incompatibility is usually not a major concern except if an Rh negative recipient is alloimmunized and receives an Rh positive graft. In that case, acute hemolysis may occur upon infusion of the graft. Transfusion of Rh positive (D positive) RBCs into Rh negative (D negative) persons frequently can result in alloimmunization and the development of anti-D antibodies. In the immunosuppressed Rh negative subject given a hematopoietic graft from an Rh positive donor, however, the likelihood of such an occurrence is low, i.e., < 10%; the higher rates are recorded in subjects given RIC or nonmyeloablative conditioning compared to myeloablative conditioning recipients [163]. In contrast, Rh positive patients who receive a graft from an Rh negative donor should be given Rh negative (D negative) blood products in the posttransplant period due to the risk of developing anti-D antibodies. To decrease the risk of alloimmunization, the use of RhIg (Rh immune globulin) is a reasonable and safe alternative [166]. In the setting of severe thrombocytopenia (or neutropenia) in which intramuscular injection of Rh Ig (RhoGam®, Kedrion Biopharma, Ft. Lee, NJ) may be associated with significant risks, IV RhIg (WinRho®, Cangene, Winnipeg, Canada) should be considered. In the latter setting, a dose of WinRho® 1500 IU or 300 mcg IV will neutralize 15 mL of Rh positive RBC. The practitioner should be mindful that use of WinRho may be associated with severe hemolysis [167]. Additionally, infusion of platelet concentrates for transfusion and granulocytes transfusions may contain RBC and consultation with a blood bank colleague or expert in transfusion medicine should be undertaken.

Prevention and Treatment of Mucositis

Mucositis is a frequent and significant complication in patients undergoing HCT, contributing to local as well as systemic complications [168–170]. Mucositis of the oral cavity causes pain, barrier disruption leading to an increased risk of infection, and sometimes septicemia (often with *Streptococcus* sp.), especially in the neutropenic host. From the patient's point of view, mucositis may be the most debilitating complication of transplant. Reactivation of HSV can exacerbate preparative regimen-induced mucositis and HSV prophylaxis is important. Mucositis increases the financial cost of care and it may extend the length of hospitalization and even increase mortality; a retrospective study showed a fourfold increase in mortality in subjects with severe oral mucositis [171]. A thorough evaluation of the patient's oral cavity by a dental specialist is essential and should include imaging such as panorex before initiating the preparative regimen. A dental cleaning and removal of diseased teeth is strongly recommended. Monitoring of oral mucositis during HCT is difficult due to lack of a reliable, objective, and valid scale, especially given the high subjectivity of pain severity that significantly influences the evaluation. In an effort to improve research in this area, the Oral Mucositis Index (OMI) assesses the severity of oral mucositis in terms of erythema, ulceration, atrophy, and edema (each graded on a scale of 0–3, where 0 = none and 3 = severe). This approach is internally consistent with high test–retest and inter-rater reliability and exhibits strong evidence of construct validity but is cumbersome to apply in routine practice [172]. The most commonly used, the National Cancer Institute Common Terminology Criteria for Adverse Events (NCI CTCAE), grades the severity of mucositis on a scale from 1 to 5, (Table 57.5) based upon symptomatology, clinical findings, and interventions required [173]. During HCT, it is permissible to allow removable dentures to remain in place while eating but otherwise this appliance should be removed and placed in appropriate antimicrobial/antifungal solutions during storage. Cryotherapy prophylaxis (ice chips or iced medications) historically has been a useful adjunct by decreasing blood flow to the mucus membranes but is useful only with chemotherapy agents that have a very short half-life, i.e., single agent melphalan. Amifostine is a parenterally administered organic thiophosphate prodrug which is hydrolyzed in vivo by alkaline phosphatase to the active cytoprotective thiol metabolite. This agent has been shown not only to reduce the incidence of mucositis in HCT patients but also decrease the use of parenteral nutrition and narcotic use directly related to degree of mucositis [174]. Anticholinergics such as propantheline are thought by some to be useful as these agents may decrease the excretion of parenterally administered drugs into saliva. Medicated rinses also have been used but alteration of pH by some agents such as hydrogen peroxide

Table 57.5 Oral mucositis grading: National Cancer Institute common terminology criteria for adverse events

	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
Oral mucositis	Asymptomatic or mild symptoms; intervention not indicated	Moderate pain; not interfering with oral intake; modified diet indicated	Severe pain; interfering with oral intake	Life-threatening consequences; urgent intervention indicated	Death

Reproduced from: Common Terminology Criteria for Adverse Events (CTCAE), Version 4.0, June 2010, National Institutes of Health, National Cancer Institute. Available at: http://evs.nci.nih.gov/ftp1/CTCAE/CTCAE_4.03_2010-06-14_QuickReference_5x7.pdf (Accessed June 8, 2017)

can retard healing of injured areas. Topical analgesics have been utilized including morphine and ketamine rinses but both need to be used cautiously [175, 176]. Other potentially beneficial agents include povidone–iodine, chlorhexidine, and topical granulocyte-macrophage colony-stimulating factor (GM-CSF). Nystatin and clotrimazole troches are useful to prevent oral fungal infections; topical tetracyclines in combination with diphenhydramine and glucocorticoids may avert bacterial infections in the oral cavity. Laser therapy has been used for both prevention as well as treatment of oral mucositis [177, 178].

Recombinant human keratinocyte growth factor (KGF; palifermin), a heparin-binding member of the fibroblast growth factor family, represents another effective approach for management of acute reactions in oral, gastrointestinal, and cutaneous epithelia after radiation exposure [179, 180]. Animal and human models indicated that this agent causes thickening of the nonkeratinocyte layers of the oral mucosa and digestive tract [181]. For conditioning regimens that utilize TBI during autologous HCT, palifermin has been somewhat effective in reducing the duration of mucositis of parenteral nutrition and increasing quality of life scores [179, 180]. The effect on hematopoietic cell engraftment as well as GvHD and overall morbidity is yet to be fully defined. Newer therapeutic approaches still in early development include gamma-D-glutamyl-1-tryptophan and D-methionine [182]. The published guidelines outline the foundation for management of mucositis related to chemoradiotherapy management [183, 184].

Sinusoidal Obstructive Syndrome

Significant hepatic injury in the course of a myeloablative HCT may affect as many as half of transplant recipients. Etiologies include infections, high-dose chemoradiation therapy, malignancy, antibiotics, parenteral alimentation, immunosuppressive agents, hematopoietic growth factors, and GvHD; overlapping clinical and laboratory features are present with many of these conditions [185–187]. Hepatic sinusoidal obstructive syndrome (SOS), formerly referred to as hepatic veno-occlusive disease (VOD), is an often fatal syndrome characterized by jaundice, fluid retention, and painful hepatomegaly. This condition may range in severity from mild and reversible to one associated with fatal multi-organ failure (MOF), hepato-renal syndrome, and mortality. The diagnostic criteria [186–188] have limitations (Table 57.6), often leading to misdiagnosis and at times, late diagnosis. In adults, the so-called Baltimore criteria [187] may be preferred over the so-called Seattle criteria [186]. Neither criterion considers the case of late-onset SOS typically appearing more than 21 days ("late-onset") after HCT [189]. Few studies highlight the role of monitoring specific

Table 57.6 Routinely employed diagnostic SOS criterias and their limitations in HCT.

HCT-related SOS criteria		Limitations
Modified Seattle criteria [186] (1984)	Presence of at least two of the following within 20 days of HCT:	• Cannot reliably predict natural course of disease
	1. Serum total bilirubin concentration >2 mg/dL	• Cannot realibily predict severity of disease
	2. Hepatomegaly or right upper quadrant pain	• Do not consider "late-onset" disease
	3. Sudden weight gain (>2% of baseline body weight) due to fluid accumulation	• Additional testing may be required for correct diagnosis
Baltimore criteria [187] (1987)	Serum bilirubin >2 mg/dL within 21 days of HCT plus at least two of the following	
	1. Hepatomegaly	
	2. Ascites	
	3. Weight gain >5% from pre-HCT weight	

serum biomarkers, i.e., procollagen type III, protein C, plasminogen activator inhibitor type 1, with the aim to diagnose and classify the severity of SOS [190–193]. At present, the presence of multi-organ failure (MOF) in which the kidneys, lungs, or central nervous system are injured appear to be the best clinical marker of severe SOS [194]. The area and role of imaging for diagnosis [195] remain of interest and active investigation. Fortunately, in most patients (75–80%), SOS progressively resolves over a 2–3-week period. Nevertheless, severe SOS is a potentially life-threatening complication associated with a high mortality rate (> 80%), and methods or models to prevent or attenuate poor prognostic disease are warranted. The rate of rise in serum bilirubin (especially in adults) and weight gain may be more rapid for patients whose illness is likely to be severe versus those who are likely to have self-limited disease.

The pathogenesis of SOS is believed to reside at the level of venous hepatic endothelial cell. Histologically, development of hepatic SOS demonstrates damaged sinusoidal endothelial cells with venular obstruction and centrilobular hemorrhagic necrosis in zone 3 of the liver acinus. Sinusoidal obstruction is prominent and has led to use of the term SOS, although this designation has not been adopted universally. Continued injury causes deposition of collagen, sclerosis and fibrosis of hepatic venules and sinusoidal occlusion which ultimately lead to liver failure and death [196–199].

Hepatic SOS is much more common in allogeneic rather than autologous HCT recipients. The current incidence of SOS varies between studies and is approximately 10–15% after allogeneic HCT using myeloablative conditioning regimens and is <5% after RIC or autologous HCT [196, 200,

201]. Risk factors for the development of hepatic SOS include a history of previous hepatocellular disease, evidence of active liver injury (elevated AST levels) at time of initiating the preparative regimen, use of busulfan-containing preparative regimens, exposure to the monoclonal antibody gemtuzumab ozogamicin, children age < 7 years, older age adults, female gender, donor–recipient HLA disparity, advanced malignancy, prior abdominal radiation, second myeloablative conditioning transplant, reduced corrected pulmonary diffusion capacity (DLCO), recent fungal infection, and poor performance status at start of transplant (Table 57.7) [185, 186, 188, 198, 200–206].

A number of interventions have been associated with variable success as prophylaxis and as therapy. These strategies include use of tissue plasminogen activator, antithrombin III and prostaglandin E1, low-dose heparin, and low molecular weight heparins as well as non-pharmacologic interventions (transjugular intrahepatic portosystemic shunts [TIPS], and charcoal hemofiltration). Ursodeoxycholic acid, a hydrophilic nonhepatotoxic bile acid, appears to be useful as an agent that if begun many weeks in advance of HCT can prevent hepatic SOS and other hepatic complications of HCT [207, 208]. One of the most promising agents appears to be defibrotide, a single-stranded polydeoxyribonucleotide that possesses anti-ischemic, anti-thrombotic, and thrombolytic activity but without significant anticoagulant effects [201, 202, 209, 210]. Multiple studies have demonstrated 30–60% complete remission rates with defibrotide, even among patients with severe SOS and MOF. Defibrotide has been approved by the US Food and Drug Administration and European Medicines Agency for the treatment of adults and children affected by SOS with renal or pulmonary dysfunction after HCT. Recommendations regarding use of defibrotide in the prophylactic setting await the results of randomized, prospective trials. Guidelines from the British Society for Blood and Marrow Transplantation [201], however, recommend its use in children (IA) and adults (IIA) at high risk of SOS: preexisting hepatic disease, second myeloablative conditioning HCT, allogeneic HCT for leukemia beyond second relapse, conditioning with busulfan (Bu)-containing regimens, prior treatment with gemtuzumab ozogamicin, or a diagnosis of primary hemophagocytic lymphohistiocytosis, adrenoleucodystrophy or osteopetrosis. The use of IV busulfan and dose adjustment based on plasma drug concentration profoundly have decreased the incidence of SOS.

Table 57.7 Potentially modifiable risk factors associated with SOS in HCT

HLA disparity
Higher dose of gemtuzumab ozogamicin prior to HCT (Newer FDA approved dose may be safer)
High serum ferritin concentrations
Myeloablative regimen in subjects who have pre-existing liver disease
Avoidance of hepatotoxic drugs
Avoidance of HCT in subjects who have a corrected DLCO <70%
Use of certain myeloablative regimen (Bu/Cy>Bu/Flu)
Myeloablative TBI containing regimens (single dose > fractionated doses)
Oral busulfan (as opposed to intravenous busulfan)
Drug sequence of conditioning regimen (Cy/Bu instead of Bu/Cy)
Sirolimus plus methotrexate as GvHD prophylaxis in myeloablative setting

Bu/Cy busulfan/cyclophosphamide, *Bu/Flu* busulfan/fludarabine, *Cy/Bu* cyclophosphamide/busulfan, *GvHD* graft-versus-host disease

Transplant-Associated Thrombotic Microangiopathy: A Distinct Entity

Transplant-associated thrombotic microangiopathy (TA-TMA) refers to inflammatory and thrombotic diseases of the microvasculature characterized by Coombs-negative hemolytic anemia, presence of schistocytes and thrombocytopenia on peripheral blood smear, elevated serum LDH, decreased serum haptoglobulin concentrations, and evidence of organ damage, particularly acute renal failure [211–215] (Table 57.8). Increasing evidence suggests that TA-TMA is a multifactorial disorder that is distinct from thrombotic thrombocytopenic purpura (TTP), and likely represents the final common pathway of a number of endothelial cell insults [214–216]. This syndrome is estimated to occur in up to 10–20% of patients who undergo allogeneic HCT [211–216]. True estimates of the rate at which TA-TMA occurs in the allogeneic HCT setting, however, are difficult to make because of inconsistencies in the diagnostic criteria applied and because of the overlap of clinical signs and laboratory abnormalities with posttransplant complications that mimic TA-TMA. In an attempt to standardize the diagnosis, two groups developed separate guidelines [217, 218]. A validation study published by Cho and coworkers, [216] noted limitations and expanded the guidelines to include the concept of “probable-TMA,” which does not require renal or neurologic findings. This condition is more frequently seen when calcineurin inhibitors are combined with sirolimus and in patients with acute GvHD.

TA-TMA presents diagnostic challenges because the syndrome may not clearly fall into one of the categories of two major conditions similar in scope and presentation: atypical hemolytic uremic syndrome (aHUS) and TTP. In addition, complications of the transplant itself, including infection, GvHD, and disseminated intravascular coagulation, as well as the side effects of immunosuppressive drugs, can mimic TMA. To highlight the diagnostic challenge of TA-TMA, Inamoto and coworkers reported that 92% of transplant recipients undergoing colonoscopy for severe diarrhea thought to be secondary to GvHD had histologic evidence of TA-TMA, while only 30% had concomitant histologic evidence of

Table 57.8 Different diagnostic criterias for TA-TMA

Blood and Marrow Transplant Clinical Trials Network (BMT CTN) toxicity committee consensus definition for TMA [217]
1. RBC fragmentation and x 2 schistocytes per high-power field on peripheral blood film
2. Concurrent increased serum LDH above institutional baseline
3. Concurrent renal and/or neurologic dysfunction without other explanations
4. Negative direct and indirect Coombs test results
International Working Group Definition for TMA [218]
All of the following are present:
1. Increased percentage (44%) of schistocytes in the blood
2. De novo, prolonged or progressive thrombocytopenia (platelet count less than 5×10^9/L or a 50% or greater decrease from previous counts)
3. Sudden and persistent increase in serum LDH
4. Decrease in hemoglobin concentration or increased red blood cell transfusion requirement
5. Decrease in serum haptoglobin concentration
Probable TMA as defined by validation study by Cho and coworkers [216]
1. RBC fragmentation and × 2 schistocytes per high-power field on peripheral blood film
2. Increase in serum LDH
3. Thrombocytopenia: $\leq 50 \times 10^9$/L or a $\geq$ 50% decrease in platelet count
4. Decrease in hemoglobin
5. Decrease in serum haptoglobin concentration
6. Negative Coombs test results
7. Absence of coagulopathy

GvHD [219]. The low blood concentration of ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) helps establish the diagnosis of other conditions including non-transplant associated TTP/HUS. Activity above 5–10% is found in most patients with TA-TMA. The pathophysiology of TA-TMA is poorly understood but includes loss of endothelial cell integrity induced by intensive conditioning regimens, immunosuppressive therapy, irradiation, infections, and GvHD. Interestingly, a recent study suggested that the presence of the HLA-DRB1*11 antigen may contribute to the development of TA-TMA [220]. Unfortunately, the treatment outcomes of TA-TMA remain suboptimal. Therapy should include cessation or dose reduction of calcineurin inhibitors and sirolimus. While often utilized, plasma exchange should be discouraged as morbidity and mortality are quite high due to the introduction of infection and complications of venous access devices. The anticoagulant defibrotide, the humanized monoclonal antibody eculizumab directed against complement protein C5, and rituximab have been used with some success [211–215, 221, 222]. Future research should emphasize the discovery of "early" markers as the successful treatment of TA-TMA may depend on early initiation of therapy.

Prevention and Treatment of Hemorrhagic Cystitis: An Emerging Concern

Hemorrhagic cystitis can be seen early or late in the HCT setting, and results from bladder mucosal injury as a result of chemotherapy, radiation, or viral infection [223–225]. The condition rarely is fatal, but the morbidity can be considerable and can be associated with infection, multi-system organ failure and ultimately death; as a result, some centers employ very aggressive strategies or prophylaxis. Patients may develop microscopic or gross hematuria, dysuria, and bladder pain, usually within 3 weeks of HCT, or as late as several months after transplant. This condition may lead to major urinary obstruction, sepsis, renal failure, or the need to undertake surgical or chemical bladder cauterization. Some high-dose chemotherapeutic agents, eliminated, in part, via the urinary tract such as cyclophosphamide, thiotepa, busulfan, ifosphamide, and etoposide, can initiate injury that is exacerbated by the development of neutropenia, thrombocytopenia, or the combination. Most investigators recommend platelet transfusions to keep the platelet count at least 50,000/μL once the injury occurs. Reactivation of Bk virus is the other major cause of hemorrhagic cystitis, although CMV and other virus infections have been reported [224]. Asymptomatic Bk virus infection occurs during childhood and 90% of adults are seropositive; reactivation risk factors and associated hemorrhagic cystitis include myeloablative conditioning, allogeneic HCT, HLA-haploidentical transplants, use of unrelated donors, and development of GvHD [224, 225]. Interestingly, use of busulfan was shown to be associated with significantly greater Bk virus-associated hemorrhagic cystitis compared to myeloablative HLA-haploidentical transplant using a TBI based regimen [226]. The finding of Bk virus in the urine usually precedes the occurrence of hematuria. Urine polymerase chain reaction (PCR) usually can detect the virus but if clinical suspicion is high and urine testing negative, cystoscopy and biopsy of the bladder epithelium should be undertaken. If indicated, immunosuppressive medications should be decreased. Ciprofloxacin therapy, given for prolonged periods, often is the treatment of choice. Cidofovir given either systemically or via the intravesical route has been effective [227, 228]. Aggressive intravenous hydration (100–150 mL/m^2/h), liberal use of diuretics, and frequent voiding have been reported as effective preventative measures. Intravenous mesna therapy, a uroprotectant with a free sulfhydryl group, inactivates acrolein and the active alkylating metabolites of cyclophosphamide and ifosphamide and usually is effective as prevention.

Treatments for hemorrhagic cystitis range from simple measures to invasive approaches. Insertion of a three-way Foley urinary bladder catheter with saline lavage is the mainstay

of treatment. A variety of other approaches have been used in patients who have refractory bleeding and include ganciclovir, instillation of alum (an astringent), prostaglandins, hyperbaric oxygen, epsilon-aminocaproic acid, conjugated estrogen formalin, hyaluronic acid, recombinant human GM-CSF, and palifermin [229–232]. Finally, one group has reported that IV MSC therapy may be useful [233].

Graft Failure and Rejection

HCT requires infusion of an adequate hematopoietic progenitor cell dose after administering high-dose chemoradiation therapy. Quantifying $CD34^+$ cell surface antigen expression has been demonstrated to be a reliable predictor of sustained hematopoietic recovery after transplant. In the autologous HCT setting, data suggest a dose–response relationship between the number of $CD34^+$ cells infused and engraftment kinetics [234]. It is estimated that delayed hematopoietic engraftment is observed in 10–20% of non-Hodgkin lymphoma patients undergoing autotransplant [235]. Although multiple studies have attempted to define the required $CD34^+$ cell dosage for a successful HCT, the results are not uniform and many physicians consider a cell dose of $2.0–2.5 \times 10^6$ $CD34^+$ cells/kg of body weight as a minimum for achieving hematopoietic reconstitution (usually recovery of neutrophils) within a reasonable timeframe. Infusion of a cell dose about 5.0×10^6 $CD34^+$ cells/kg of body weight, however, seems to be optimal. Enhanced engraftment kinetics translate into fewer RBC and platelet transfusions, diminished antibiotic usage, shorter hospital stay, and decreased overall costs.

In some patients, despite what are considered effective stimuli, an insufficient number of $CD34^+$ cells are mobilized. This group of patients may otherwise be acceptable candidates for autotransplant, but are precluded from the procedure due to insufficient cells for infusion. If autologous HCT is attempted, these subjects are at significantly increased risk for infections, bleeding, and other complications associated with slow or incomplete engraftment. This "hard-to-mobilize" group usually can be identified by a number of factors, including exposure to hematopoietic stem cell toxins such as fludarabine, nitrogen mustard, melphalan, BCNU (carmustine), extensive prior chemotherapy or radiation therapy, advanced age, or tumorous involvement of bone marrow [236, 237].

Plerixafor (Mozobil™, Genzyme Corp.), in combination with hematopoietic growth factors, has been shown to be effective for mobilization of hematopoietic progenitor cells in NHL and multiple myeloma patients [236, 237]. This agent acts as an antagonist for the CXCR4 chemokine receptor and blocks homing of hematopoietic stem cells to the bone marrow stroma. In combination with hematopoietic growth factors, plerixafor increases $CD34^+$ cell collection, decreases the number of apheresis sessions, and allows more patients to proceed to autologous HCT. Side effects are minimal and include gastrointestinal distress, injection site reactions, headache, and fatigue. Studies using other mobilizing agents in patients and use of plerixafor in volunteer hematopoietic cell donors for allogeneic HCT are ongoing [238].

Failure of donor cells to fully engraft after myeloablative therapy in the allogeneic transplant setting may reflect infusion of insufficient numbers of donor hematopoietic progenitor cells, splenomegaly, a damaged marrow microenvironment, anti-HLA antibodies, viral infection, and inadequate GvHD prophylaxis [239–241]. This problem is more common with use of UCB grafts, haploidentical grafts, T-cell depletion of the graft, increased donor:recipient HLA disparity, use of RIC, insufficient preparative regimen immunosuppression, or infection due to CMV, HHV6, HHV8, or parvovirus [242–245].

Whatever the etiology, graft failure or rejection is a life-threatening process requiring immediate intervention [245]. Various solutions include withdrawal of potentially marrow-suppressive agents such as antibiotics, administration of recombinant hematopoietic growth factors, infusions of additional hematopoietic progenitor cells (if available), and in the case of a failed allograft, the decision to perform a second transplant [246]. The outcome for patients experiencing this problem generally is poor and has led some investigators to utilize other grafts for salvage [246–252]. Early recognition and institution of back up grafts can rescue some patients [253].

Acute Graft-versus-Host Disease

Allogeneic HCT in humans is hampered by the development of both acute and chronic GvHD resulting in significant morbidity and mortality, even when grafts from HLA-identical (10 of 10 matched) siblings are used [43, 254–256]. This syndrome results when genotypically disparate, alloreactive donor-derived T-cells recognize and react to host histoincompatible antigens in a host incapable of rejecting such cells. Other mechanisms, however, have been implicated including massive disequilibrium in tissue specific immunoregulation [257] and imbalance in the $CD4^+$ $CD25^+$ regulatory T-cells (T_{regs}); these cells are generated in the thymus and are thought to play a key role in the maintenance of immunologic self-tolerance. In preclinical studies, these Tregs have been shown to prevent GvHD by suppressing alloreactive donor T-cells, while preserving graft-versus-leukemia (GvL) effect [258]. Patients noted to have a higher relative frequency of Tregs after allo-HCT had a lower rate and severity of GvHD, lower rate of nonrelapse mortality, and equivalent relapse mortality [259].

When donor and recipient are not HLA identical, differing by even a single antigen, severe GvHD can ensue with an increase in mortality [260]. If a transplant is performed between HLA-identical siblings, GvHD appears to be mediated via the minor histocompatibility antigens. Both animal and human studies have demonstrated that B cells are involved in the immunopathophysiology of acute and chronic GvHD [261, 262]. Some preliminary clinical trials have shown that B-cell depletion using the monoclonal antibody rituximab may result in a beneficial effect on both acute and chronic GvHD [262, 263]. These data have implications for the clinical management of patients undergoing allogeneic HCT.

Acute GvHD is a consequence of complex interactions between donor and host innate and adaptive immune responses and multiple inflammatory molecules and cell types are involved [261]. Cytotoxic chemo- or chemoradiation therapy that comprises the conditioning or preparative regimen damages recipient tissues such as skin, gastrointestinal tract mucosa, liver, and other organs. This damage triggers release of multiple inflammatory cytokines and stimulates the preexisting antigen disparities between host and graft tissue. Other factors involve the cellular sensors that detect these triggers and present alloantigens. The process is escalated via mediators such as various T-cell subsets including naive, memory, regulatory, Th17, and natural killer T-cells that interact with effectors and amplifiers; this interaction results in damage of target organs.

A lack of understanding of the molecular mechanisms involved in the initiation phase of GvHD has been one obstacle in addressing effective prophylaxis. Recently, important mechanisms have been identified regarding the induction of GvHD through the interplay of microbial-associated molecules and innate immunity such as Toll-like receptors. This new information has opened a new area, i.e., microbiome, for future therapeutic approaches [264–266].

GvHD traditionally has been divided into acute and chronic GvHD phases, predominantly based on time of onset and clinical presentation. Acute GvHD occurs within the first 100 days after allograft, usually within the first 2–6 weeks. A hyperacute, fulminant form can occur within the first week of transplant but is rare unless patients do not receive GvHD prophylaxis [267]. The target organs for this syndrome usually are the skin, gastrointestinal mucosa, and liver; sometimes the lung, lymph nodes, and bone marrow become involved. Formerly, if the onset of a syndrome with clinical manifestations of acute GvHD occurred beyond 100 days after HCT, it was called chronic GvHD. In 2009, the National Institutes of Health (NIH) established that clinical manifestations, not time after transplantation, distinguish chronic GvHD from late onset acute GvHD [268]. The latter condition appears to be more common in patients who have undergone RIC or nonmyeloablative allogeneic HCT and it also includes persistent, recurrent, or late-onset acute GvHD. While acute GvHD is a clinical syndrome that can be diagnosed in the absence of a tissue diagnosis, it is preferred to obtain biopsies of affected tissues to firmly secure the diagnosis.

Several investigators have used a panel of serum biomarker proteins (interleukin-2-receptor-alpha, tumor-necrosis-factor-receptor-1, interleukin-8, and hepatocyte growth factor) to confirm the diagnosis of acute GvHD at onset of clinical symptoms [269–273]. This testing may provide prognostic information independent of GvHD severity and is an area of active investigation

Risk factors for developing acute GvHD include donor–recipient genetic disparity, full myeloablative compared to RIC regimens, advanced patient and donor age, gender mismatch (female donor to male recipient), use of T-replete bone marrow and blood grafts (blood > marrow grafts) compared to T cell-deplete grafts, or UCB units and prior splenectomy [274]. Another factor contributing to the increased frequency of acute GvHD is use of donor lymphocyte infusion (DLI), often administered for patients in relapse after allogeneic HCT as discussed earlier [102–107].

Acute GvHD traditionally has been quantified as grade I, II, III, or IV using clinical criteria, although the reproducibility for diagnosis and grading is problematic (Table 57.9) [275, 276]. Several groups have offered modifications of this grading system to improve the correlation between extent of GvHD and outcome; these systems are not in widespread use [277–279]. Clinically significant acute GvHD (grade II–IV) usually occurs in 10–50% of HLA-identical sibling-matched recipients compared to rates as high as 70–90% in unrelated HLA-matched and related HLA-haploidentical transplants [274–279]. The usual strategy is prophylaxis with drugs to partially suppress the graft by preventing or attenuating GvHD while maintaining an allogeneic or graft-versus-tumor effect. Immunosuppression with combinations of agents such as cyclosporine, tacrolimus, methotrexate, and corticosteroids are more effective at reducing the incidence and severity of acute GvHD and improving overall survival (OS) compared to single agents [280–282]. The regimens used most frequently include either cyclosporine or tacrolimus, in combination with methotrexate, the latter agent given usually for short periods [281, 282]. A recent survey involving 79 centers from the European group for Blood and Marrow Transplantation (EBMT) highlighted that there is no currently agreed upon standard regimen, and clinical practice varies by institution [283].

A number of newer agents are being used to prevent development of acute GvHD [280–284]. Sirolimus, in combination with other agents such as tacrolimus, appears to be an interesting and potentially more effective drug [284]. Sirolimus, however, is associated with significant adverse drug interactions and is associated with higher risk of hepatic SOS [206]. A recent, open label phase 3 study assessed the

Table 57.9 Staging of Acute GvHD

Organ	Skin	Liver	Gastrointestinal
Individual organ staging			
Stage	**Body Surface Area**	**Bilirubin (mg/dL)**	**Diarrhea (mL/day)**
1	Rash <25%	2–2.9	500–1000 or biopsy-proven upper GI involvement
2	Rash 25–50%	3–6	1000–1500
3	Rash >50%	6.1–15	1500–2000
4	Generalized erythroderma with bullae	> 15	> 2000 or severe abdominal pain with or without ileus
Revised Glucksberg grading [275]			
I	Stage 1–2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	–	Stage 2–3 or	Stage 2–4
IV	Stage 4 or	Stage 4	–
International bone marrow transplant registry grading [276]			
A	Stage 1	None	None
B	Stage 2	Stage 1 or 2	Stage 1 or 2
C	Stage 3	Stage 3	Stage 3
D	Stage 4	Stage 4	Stage 4

For bilirubin in μmol/L: Stage 1 = 34–50, stage 2 = 51–102, stage 3 = 103–255, stage 4 > 255

combination of tacrolimus and sirolimus compared to methotrexate and tacrolimus after HLA matched related donor blood cell transplantation [285]. The combination of tacrolimus and sirolimus had equivalent efficacy with regard to GvHD prevention but showed marked improvement in hematopoietic engraftment over the other combination. Use of the sirolimus-containing regimen did not impact mortality. Mycophenolate mofetil (MMF), an antibiotic with strong immunosuppressant properties, also has become a commonly used drug in GvHD prophylaxis [286, 287]. A less common approach to prevent acute GvHD is ex vivo T cell depletion (TCD) of the graft. This maneuver can be performed by a variety of means including physical separation, density gradient, flow cytometry, lectin depletion, cytotoxic agents, monoclonal antibodies, immunoconjugates, and magnetic beads [288]. Although TCD reduces the incidence of acute GvHD, to date this strategy is associated with an increase in engraftment failure, tumor relapse, opportunistic infection, and secondary cancers. T-cell depletion trials have not demonstrated an improvement in OS [289]. Anti-T-cell globulin (antithymocyte globulin) when used in the preparative regimen has been shown to reduce the incidence of acute GvHD without significant impact on survival [290–292]. Low-dose alemtuzumab combined with cyclosporine also has shown some early promise [293]. High-dose cyclophosphamide (50 mg/kg/day IV on the third and fourth days after transplant) is given as an innovative approach and has been successful in reducing the incidence of acute GvHD in the haploidentical setting [294, 295]. Pre-clinical models demonstrate that the cyclophosphamide eradicates the proliferating alloreactive T cells. Although this strategy has been employed successfully in the HLA-matched setting, more data are required before recommending incorporation into routine practice [296].

The treatment of acute GvHD has been summarized in recommendations by expert panels in recent years [283, 297]. For patients who have predominantly GvHD confined to the skin that is not fully responsive to corticosteroids, ECP may be an effective, less toxic therapeutic approach [298, 299]. More intensive treatment, however, is necessary for grade II–IV acute GvHD. The initial approach consists of continuing the original immunosuppressive prophylaxis and the addition of corticosteroids. Acting via lympholysis, corticosteroids (alone or in combination with immunosuppressives) remain the most effective agent. Methylprednisolone at a dose usually of at least 2 mg/kg/day is initiated as primary therapy; overall grade of acute GvHD and graft source (HLA-sibling-match versus unrelated donor, etc.) may influence initial dosing decisions and subsequent response to therapy.

Patients who develop acute GvHD after allogeneic HCT and do not respond to primary therapy, usually with corticosteroids, often experience considerable morbidity and mortality [283, 297–299]. In a recent survey from the Swiss-Austrian-German GvHD consortium, the heterogeneity of second-line approaches used in different centers reflects this lack of standardization. The approaches to steroid-refractory (SR) acute GvHD range from increasing the dose of glucocorticoid therapy (if less than 2 mg/kg/day) to the addition of monoclonal antibodies such as alemtuzumab or polyclonal antibodies (antithymocyte globulin), including immunoconjugate toxins, additional immunosuppressive medications, and ECP [283, 297–300] (Table 57.10). Most such interventions that have shown success have been pilot studies that have not been corroborated in larger, randomized, controlled trials. For second-line treatment, randomized trials are missing. MMF has been studied in several trials but has not been demonstrated to significantly enhance overall patient outcomes. The addition of MMF to corticosteroids as initial therapy for acute GvHD does not improve GvHD-free survival compared with corticosteroids alone [301]. Failure during acute GvHD therapy often is due to the high incidence of opportunistic infections from bacterial, invasive fungal, and viral infections. As a result, all patients receiving systemic therapy for acute GvHD should receive intensive prophylaxis against infectious agents.

Chronic Graft-versus-Host Disease

Chronic GvHD, a significant cause of morbidity and mortality, occurs in about two-thirds of long-term survivors of allogeneic HCT [302–305]. As a result of greater availability

Table 57.10 Variety of second-line drugs/strategies utilized in acute G*v*HD treatment [300]

Drug	Mechanism of action	Toxicity
Mycophenolate Mofetil (CellCept®, Myfortic®)	Non-competitive inhibitor of IMPDH, the rate limiting step for de novo purine synthesis on which lymphocytes depend	Dose related cytopenia and gastrointestinal toxicity. Enteric-coated mycophenolic acid (Myfortic®) may be better tolerated.
Denileukin diftitox (Ontak®)	Recombinant fusion molecule of human IL-2 and diphtheria toxin that binds to the IL-2R-α and triggers apoptosis in activated T cells	Dose limiting toxicity -elevation of hepatic transaminases
Sirolimus (Rapamune®)	Binds to FK-binding protein complex and blocks mTOR, ultimately causing cell cycle arrest in G1.	Reversible cytopenia, hypertriglyceridemia, nephrotoxicity (HUS/TMA) and neurotoxicity (TTP). Less common are transaminitis, edema, arthralgias, and non-infectious pneumonitis
Infliximab (Remicade®)	Chimeric murine/human monoclonal antibody that binds with high affinity to soluble and membrane-bound TNFα, resulting in clearance of TNFα and T cells.	Anaphylaxis is uncommon, but can occur.
Etanercept (Enbrel®)	Soluble dimeric fusion protein that competes for TNF-α binding and renders it inactive	Generally well tolerated
Pentostatin (Nipent®)	Nucleoside analog that potently inhibits adenosine deaminase, reducing CD4 and CD8 T-cells and B-cells and lowering of IgG levels	Myelosuppression, should reduce dose by 50% if ANC <1000 per μL and discontinue if ANC < 500 μL. Reversible transaminitis, renal insufficiency and neurotoxicity can occur.
Daclizumab (Zenepax®)	Humanized monoclonal antibody against CD25 (IL-2 receptor) which prevents T cell proliferation	Well tolerated, anaphylaxis has not been observed.
Basiliximab	Chimeric (murine/human) monoclonal antibody against CD25 (IL-2 receptor) which prevents T cell proliferation	Anaphylaxis and hypersensitivity reactions have been reported but are not common.
Horse antithymocyte globulin (ATGAM®)	Antilymphocytic, primarily monomeric IgG, from hyperimmune serum of horses immunized with human thymus lymphocytes.	Anaphylaxis is uncommon but skin testing prior to first dose is recommended. Fever and chills common, also thrombocytopenia, leukopenia, and rash. Less common are serum sickness, dyspnea/apnea, arthralgia, chest, back, or flank pain; diarrhea and nausea and/or vomiting.
Rabbit antithymocyte globulin (thymoglobulin®)	Antilymphocytic globulin from hyperimmune serum of rabbits immunized with human thymus lymphocytes.	Skin testing is not considered necessary but must monitor closely for anaphylaxis or cytokine release syndrome. Thrombocytopenia and opportunistic infections are common.
Alemtuzumab (Campath®)	Humanized IgG1monoclonal antibody against CD52 on normal and malignant T- and B-cells, NK cells, monocytes, macrophages and some granulocytes.	Cytopenias including hemolytic anemia. Most common reactions are rigors and fever and nausea and vomiting. Less common are rash, fatigue, hypotension, urticaria, dyspnea, pruritus, headache, and diarrhea.
Ruxolitinib (Jakafi®)	Kinase inhibitor which selectively inhibits Janus Associated Kinases (JAKs), JAK mediated signaling involves recruitment of STATs (signal transducers and activators of transcription) to cytokine receptors which leads to modulation of gene expression	Cytopenia and cytomegalovirus-reactivation
Extracorporeal photopheresis (ECP)	Direct apoptosis of mainly lymphocytes and reinfusion interferes with dendritic cell maturation, cytokine modulation, and expansion of regulatory T cells	Limited, but includes blood loss from the extracorporeal circuit, hypocalcemia due to anticoagulant, and mild cytopenia.

Ho VT, Kekre N: Diagnosis and treatment of acute graft-versus-host disease. In: Abutalib SA, Hari. P (eds): Clinical Manual of Blood and Marrow Transplantation, Hoboken, NJ, Wiley-Blackwell, 2017 [300]

and use of alternative donors, increase in early posttransplant survival, inclusion of older recipients, and increasing use of nonmyeloablative conditioning regimens, the incidence of this syndrome appears to be rising [303]. Approximately 30–70% of subjects surviving >1 year after allogeneic HCT are affected and have a 5-year mortality rate of 30–50% [304, 305]. This syndrome is heterogeneous with respect to time of onset, affected organ sites, and response to treatment [306]. The variation in clinical presentation has made classification difficult. In contrast to acute GvHD that affects predominantly epithelial surfaces (skin, gastrointestinal tract, biliary radicals of the liver), chronic GvHD can affect both epithelial and mesenchymal tissues such as nerve and muscle as well as organs such as the buccal mucosa, lung,

and eye. The diagnosis of chronic GvHD often is challenging due to frequent coexistence of acute GvHD, polymorphic presentation, and lack of adequate biomarkers. Historically, chronic GvHD has been classified as subclinical (proven by histology but no clinical symptoms); limited extent (localized skin involvement, hepatic dysfunction due to chronic GvHD, or both); and extensive (generalized skin involvement, or limited extent plus involvement of a target organ such as liver histology showing chronic aggressive hepatitis, bridging necrosis, or cirrhosis, eye involvement, minor salivary gland, or oral mucosal involvement). Additionally, chronic GvHD has been classified according to the pattern of onset of clinical disease: de novo, quiescent, and progressive disease.

Newer classification systems have moved away from time of onset as a delineating feature of acute versus chronic GvHD and moved toward signs and symptoms at presentation [304, 305]. In addition, the conventional grading of chronic GvHD as limited versus extensive has been challenged. The newer NIH criteria for scoring of chronic GvHD provide meaningful information on disease severity and functional impairment of key organ systems in patients with chronic GvHD and are the current standard [304]. This scoring system can be applied *only after* the diagnosis of chronic GvHD has been established. While chronic GvHD is thought to result from immune dysregulation, the exact mechanisms remain unknown. There is evidence of the role of B-cell dysregulation, with production of autoreactive antibodies [307–310]. It has been suggested that B-cell activation may result from high levels of B-cell activating factor (BAFF) in the lymphoid microenvironment [307]. These observations may explain occasional responses of chronic GvHD to therapy with rituximab [311, 312].

The likelihood of developing chronic GvHD appears to be associated with increasing HLA disparity between recipient and donor (especially unrelated donor recipients), prior diagnosis of acute GvHD and corticosteroid use by 100 days after allograft, use of non-T-cell depleted bone marrow (compared to T-repleted bone marrow), male recipients of multiparous female donors, older age of recipient or donor, and use of blood rather than bone marrow grafts (Table 57.11) [86, 304, 313–316]. According to CIBMTR analysis the 1-year probability of chronic GvHD was approximately 30% after HLA-identical sibling HCT, 25–46% after one-antigen HLA-mismatched sibling HCT, and approximately 44–51% after HLA-matched unrelated HCT [317]. In addition, minor HLA antigen mismatches also may play a role in the development of chronic GvHD, particularly the H-Y antigen. Symptoms of chronic GvHD usually occur gradually, starting on average between 3 months and 2 years after HCT. Clinical manifestations of chronic GvHD are similar to autoimmune collagen vascular diseases including oral ulcerations (lichen planus),

Table 57.11 Risk factors for the development of chronic GvHD [322]

Most important risk factor	Prior acute GvHD
Frequently reported risk factors	Greater donor: recipient HLA disparity
	Increased donor and recipient age
	Use of female donors (especially multiparous) for male recipients
	Use of mobilized blood as a graft source
	Use of donor lymphocyte infusion
Less frequently reported risk factors	Higher infused $CD34^{+}$ cell dose in mobilized blood cell transplantation
	Lower infused $CD34^{+}$ cell dose when bone marrow is graft source
	Faster achievement of complete hematopoietic chimerism
	Corticosteroids in GvHD prophylaxis
	Transplantation for chronic myeloid leukemia and aplastic anemia
	Cytomegalovirus seropositivity in recipient

GvHD Graft-versus-Host Disease, *HLA* Human Leukocyte Antigen, *HPSC* hematopoietic progenitor and stem cells. Adapted from Pusic I and Pavletic SZ. Chronic Graft-versus-Host Disease- Updates, Challenges and Controversies. In: Lazarus HM et al. (eds) (2017) *Hematopoietic Cell Transplants: Concepts, Controversies and Future Directions*. Cambridge University Press, United Kingdom

keratoconjunctivitis sicca, xerostomia, polyserositis, esophagitis and stricture, vaginal ulceration and stricture, intrahepatic obstructive liver disease, obstructive pulmonary disease, scleroderma, morphea, fasciitis, and myositis [305]. Chronic GvHD diagnosis is primarily clinical and histologic confirmation is not mandatory if the patient has at least one diagnostic sign. Further testing is recommended to confirm chronic GvHD in situations where distinctive but non diagnostic signs are present or alternative diagnoses are considered. A detailed color-atlas and classification of the skin and oral chronic GvHD is available at http://www.asbmt.org/?page=MeasureCGvHD [305]. In the absence of histologic or clinical signs characteristic of chronic GvHD, persistence, recurrence or new onset of maculopapular erythematous rash, gastrointestinal symptoms or cholestatic hepatitis should be classified as acute GvHD, regardless of the time after transplantation. The 2014 NIH consensus criteria have defined the *overlap* category as the presence of acute GvHD manifestations in a patient diagnosed as being affected with chronic GvHD. The *overlap* syndrome is often transient and depends on degree of immunosuppression. In those patients who present with the *overlap* syndrome, acute GvHD features can resolve with treatment while chronic GvHD symptoms and signs may persist. Likewise, acute GvHD may flare in patient with chronic features when immunosuppression is tapered.

Currently, there are no preventive strategies shown to improve overall survival in patients with chronic GvHD. Only antithymocyte globulin appears to decrease incidence of

chronic GvHD and chronic lung dysfunction without providing a survival benefit [316, 318, 319]. While decreasing the incidence of acute GvHD, T-cell depletion of the graft has not been shown to lower the incidence of chronic GvHD as demonstrated in a randomized, multicenter trial [319].

Effective treatment for chronic GvHD has evolved little over the past several years [320–322]. Immunosuppressive therapy, initially with corticosteroids, with the addition of cyclosporine or tacrolimus, is a generally accepted regimen for those patients needing therapy. A study examining the addition of MMF failed to demonstrate any benefit [323]. About 50% of patients with chronic GvHD will fail to achieve complete or partial response to steroid therapy by 1 year after diagnosis. As there is no standard of care for second-line therapy for chronic GvHD, when possible, patients should be treated on clinical trials. Second-line therapy is indicated for patients who fail to respond or progress through steroid-based therapy (Table 57.12) [321, 322]. A number of small phase II studies have been published, most of them showing incomplete and brief responses. Although the mechanism of action is unknown, there are recent, promising results using rituximab [311, 312], ECP [281], imatinib [324, 325], and ruxolitinib [326] for treatment of sclerotic chronic GvHD. Preliminary results presented in abstract form of a phase II trial with ibrutinib (n = 42) demonstrated multiorgan responses in two-thirds of the patients [Blood. 2016;128(22)]. Based on these data, Ibrutinib was approved by the US Food and Drug Administration (FDA) for treatment of chronic GvHD and is an acceptable alternative to calcineurin inhibitors.

Organ dysfunction and opportunistic infection may accompany chronic GvHD [327]. Hence, ancillary therapy

Table 57.12 Second-line therapies for chronic GvHD [322]

Agent	Mechanism of action	Common and serious side effects	Comments
Pentostatin	Nucleoside analog	Nausea, vomiting, infections, renal	Activity in treatment of both acute and chronic GvHD
Low-dose methotrexate	Antimetabolite, anti-inflammatory	Myelosuppression, liver toxicity	Cannot be used in renal failure
Imatinib	Multi-kinase inhibitor targeting PDGFR and TGF-β	Myelosuppression, hepatitis	Best responses in skin and pulmonary GvHD
Psoralen and ultraviolet A	8-Methoxypsolaren and ultraviolet A irradiation	Nausea, photosensitivity, skin cancers	No systemic effect, best for skin lichen-planus lesions
Hydroxychloroquine	Anti-malarial agent	Gastrointestinal, renal polyneuropathy	Best results in mucocutaneous and liver GvHD
Montelukast	Leukotriene antagonist	Headache, nausea	Lung GvHD
Acitretin	Retinoid	Skin dryness, alopecia, night blindness, pancreatitis, hyperlipidemia	Skin GvHD
Pulse cyclophosphamide	Alkylating agent	Myelosuppression, hemorrhagic cystitis	Effective for skin, liver, oral GvHD; toxicity profile acceptable
Clofazimine	Antimycobacterial	GI symptoms, hyperpigmentation	Best responses in mucocutaneous GvHD
Total lymphoid irradiation	Low-dose 100 cGy ionizing irradiation	Leukopenia, infections	Best responses in fasciitis and oral GvHD; rarely used today
Bortezomib	Proteasome inhibitor	Diarrhea, neuropathy	Small studies, responses in GI and skin GvHD
Daclizumab	Humanized anti-IL-2 receptor monoclonal antibody	GI symptoms, headache, insomnia, fatigue, infections	Limited reports, responses in skin GvHD
Infliximab	Chimeric anti-TNF-a monoclonal antibody	Hypersensitivity, infections	Limited reports
Etanercept	Recombinant human soluble TNF receptor fusion protein	Infections	Small studies, use in overlap syndrome with GI and skin GvHD
Low-dose IL2	Cytokine; induces Treg expansion	Constitutional symptoms, thrombotic microangiopathy	Best responses in skin and joint GvHD
Thalidomide	Anti-inflammatory, immunomodulatory	Neuropathy, somnolence, constipation, neutropenia, teratogenic, DVT	Disappointing as primary therapy; toxicity is a limitation
Alefacept	Dimeric anti-CD2 LFA-3 fusion protein	Infectious risk	Limited reports, last resort
Alemtuzumab	Unconjugated IgG1 monoclonal antibody	Infectious risk	Limited reports, last resort

GvHD Graft-versus-Host Disease, *GI* gastrointestinal, *DVT* deep venous thrombosis, *Treg* regulatory T-cell. Adapted from: Pusic I, Pavletic SZ. Table 57.13 Ancillary therapy and supportive care interventions in chronic GvHD [327]

Organ system	Organ-specific intervention
Skin and appendages	Photoprotection, sunscreens, avoidance of sun exposure; surveillance for malignancy
	For intact skin: topical emollients (ointments and creams are better than lotions), corticosteroids (Triamcinolone cream 0.1% tid to body; Hydrocortisone cream 1.0% bid to face, axila and groin), antipruritic agents, PUVA, calcineurin inhibitors
	For erosions/ulcerations: topical antimicrobials, protective films or other dressings, debridement, hyperbaric oxygen, wound care specialist consultation
Mouth and oral cavity	Maintain good oral/dental hygiene. Routine dental cleaning and endocarditis prophylaxis. Surveillance for infection and malignancy. Nutritional counseling.
	Topical high and ultra-high potency corticosteroids (fluocinonide gel 0.05%, triamcinolone 0.1%), analgesics (mouthwash- 1 part dexamethasone +2 parts viscous lidocaine, follow by tap water rinse), topical tacrolimus ointment 0.1%. Therapy for xerostomia (fluoride, saliva substitutes, cevimeline, pilocarpine)
Eyes	Photoprotection, regular ophthalmology exams by eye specialist
	Artificial tears and ointments, topical corticosteroids or cyclosporine, punctal occlusion, humidified environment, occlusive eye wear, moisture chamber glasses, tarsorrhaphy, gas-permeable scleral contact lens, autologous serum, topical antimicrobials, doxycycline.
Musculo-skeletal	Surveillance for decreased range of motion, yearly bone densitometry, calcium levels and 25-OH Vitamin D
	Physical therapy, calcium, vitamin D, bisphosphonates
Gastrointestinal tract and liver	Surveillance for infection (viral, fungal)
	Eliminate other etiologies. Dietary modification, enzyme supplementation for malabsorption, gastroesophageal reflux management, esophageal dilatation, pancreatic enzyme replacement for pancreatic insufficiency, topical corticosteroids, bile salts resins
Lungs	Surveillance for infection
	Eliminate other etiologies. Inhaled glucocorticoids, bronchodilators, supplementary oxygen. Pulmonary rehabilitation. Consider lung transplantation for appropriate candidates
Hematopoietic	Eliminate other etiologies, surveillance for infection
	Hematopoietic growth factors, immunoglobulin
Neurologic	Calcineurin drug level monitoring. Seizure prophylaxis including blood pressure control, electrolyte replacement, anticonvulsants
	Occupational and physical therapy, treatment of neuropathic syndromes with tricyclic antidepressants, selective serotonin reuptake inhibitors, or anticonvulsants
Vulva and vagina	Surveillance for estrogen deficiency, infection and malignancy
	Water-based lubricants, topical estrogens, topical corticosteroids or calcineurin inhibitors, dilators, surgery for extensive synechiae or obliteration
Immunologic and infectious disease	Immunizations and prophylaxis against PCP, VZV and encapsulated bacteria. Consider immunoglobulin replacement. Surveillance for infection.
	Organism-specific antimicrobials and empiric broad-spectrum antibiotics for fever

Modified from Carpenter PA, et al. NIH Consensus Development Project on Criteria for Clinical Trials in Chronic Graft-versus-Host Disease: V. The 2014 Ancillary Therapy and Supportive Care Working Group Report. Biol Blood Marrow Transplant. 2015; 21: 1167–1187 [327]

and supportive care are the central components in the long-term multidisciplinary management of affected patients (Table 57.13). Immunodeficiency, leading to a variety of opportunistic infections and often to death, is the most important associated complication of chronic GvHD [327]. *Pneumocystis cariini*, *Streptococcus pneumoniae*, and CMV are the pathogens most likely to cause serious and fatal infection, and prophylaxis strategies against these pathogens should be undertaken. Comprehensive guidelines for infectious prophylaxis in HCT recipients, including patients with chronic GvHD, have been published [327]. Patients experiencing chronic GvHD, with or without attendant immunosuppression, likely may not have an optimal response to anti-infective vaccination (see below).

Late Complications

As a result of many biologic and technologic advances, tens of thousands of HCT recipients are alive today [31, 328–333]. The HCT procedure is associated with considerable early morbidity and mortality but those who attain long-term survival generally enjoy good health. Many of these individuals no longer are under the care of the physicians at the transplant center and are followed by health care providers in the community who are not necessarily familiar with late complications. Such conditions after transplant include those due to the preparative regimen, late infections, chronic GvHD, recurrence of malignancy, and secondary malignancy. Such complications include dental defects/caries, cataracts and other ophthalmic complications, osteoporosis/osteopenia,

avascular bone necrosis, late neurologic conditions such as leukoencephalopathy and cognitive function impairment, retardation of growth and development in children, endocrine disturbances such as hypothyroidism, infertility, hypogonadism, restrictive lung disease, chronic obstructive pulmonary disease, bronchiolitis obliterans organizing pneumonia (cryptogenic organizing pneumonia), iron overload, hepatitis B and C infection, and psychologic and sexual dysfunction [31, 333, 334]. Infertility, which can be devastating to young patients, is almost universal when using myeloablative regimens. This can be addressed with sperm cryopreservation for male patients, assuming they have adequate sperm number and function. Embryo or oocyte cryopreservation in female patients can also be attempted, with generally less favorable results [331].

In an effort to provide a uniform and thorough approach, a consensus panel formulated screening and preventative practices [31, 332, 333]. Major areas include addressing visceral organ (pulmonary, cardiovascular, renal) complications, secondary malignancy, and anti-infective vaccinations. Some investigators have subcategorized late complications into (a) delayed (onset at 3 months to 2 years and often affecting lung due to chronic GvHD); (b) late (onset at 2–10 years, often calcineurin-induced renal injury); and (c) very late events (onset at >10 years, frequently cardiac dysfunction due to anthracycline exposure) [31, 334]. In most instances, these recommendations are not based on randomized or controlled clinical trials. Nonetheless, these approaches represent a sensible practice for optimizing long-term outcome. Patients should be evaluated at least once or twice a year for conditions common in the general population including essential hypertension, hypercholesterolemia, diabetes mellitus, sexually transmitted diseases and depression, as well as other conditions [31]. When indicated, sophisticated diagnostic testing should be undertaken, including invasive studies/biopsies, if necessary.

Quality of Life After Hematopoietic Cell Transplant

Over the past three decades, the primary focus of autologous and allogeneic HCT has been to improve overall survival by eliminating the underlying disorder and reduce the immediate and early complications. Greater success of this modality has produced many more survivors and correspondingly, health care personnel have placed an increasing emphasis on the patient's quality of life (QoL) after the transplant. In fact, cancer survivors routinely cite QoL as among their greatest concerns [335, 336]. QoL is a dynamic, multifaceted concept related to physical, cognitive, emotional, and social and financial functioning and well-being [335, 336]. Several factors, including the continued risk of relapse, however, negatively may affect a transplant survivor's ability to function fully and normally in important areas of everyday life, including employment, relationships with others, and sexuality.

A number of publications have addressed QoL evaluation after transplant [337–340]. These and other studies show the most significant issues interfering with QoL are altered body image, sexual difficulties, fatigue, lack of physical strength, inability to work at their chosen employment, and financial problems. The psychosocial literature that examines patients longitudinally indicates faster return to baseline for autograft compared to allograft recipients. Subjects with moderate impairment after transplant generally return to baseline function by 100 days after HCT and that more than half of patients report good to excellent QoL with no major functional limitation when queried 1–2 years after transplant. On the other hand, approximately one-quarter of patients still have ongoing, significant, or bothersome symptomatology. Many of the physical and psychosocial deficits perceived as problems by the patient were, in fact, present prior to transplant. A lower QoL persists more often in older patients, those with less formal education, subjects with a more advanced disease state at transplant, and those in whom there is evidence of active chronic GvHD or chronic visceral organ dysfunction. Progress in this area is hampered by lack of standardized instruments that would facilitate comparisons within HCT groups and with non-HCT groups. Further, transplant physicians need to better understand patients' symptoms and QoL issues in order to facilitate progress [341, 342].

Second Malignancies After Hematopoietic Cell Transplants

All patients undergoing HCT should be informed of the potential risk of developing a second cancer and should be monitored on a continuous basis [31, 332]. The trend toward an increase in risk over time after transplantation and the greater risk among younger patients, particularly those who received autologous transplant, indicates the need for lifelong surveillance. HCT survivors, however, had similar health behaviors as matched controls and comparable to those reported by cancer survivors who did not undergo HCT despite higher levels of engagement with health care providers [334]. Several groups have reported their experiences to determine the incidence and risk factors for the development of new malignancies occurring after HCT. Baker and coworkers [343] noted 147 posttransplant malignancies in 137 patients (including myelodysplasia, acute leukemia, lymphoproliferative disorders, and solid tumors) from a population of 3372 who underwent HCT during the period 1974–2001. This figure represented an eightfold increased

risk and a 6.9% cumulative incidence for the development of any post-HCT malignancy at 20 years. The cumulative incidence plateaued at 1.4% by 10 years for both posttransplant lymphoproliferative disorders, myelodysplasia and acute myeloid leukemia. Solid tumor incidence, on the other, continued to increase (3.8% at 20 years), necessitating long-term, close follow-up.

In one of the largest studies, Rizzo and colleagues from the CIBMTR retrospectively studied 28,874 allogeneic transplant recipients and noted 189 solid tumor malignancies, twice the expected rate [344]. The risk for non-squamous cell cancers was increased substantially in patients younger than age 30 years who received radiation as part of conditioning while chronic GvHD and male gender were the main determinants for risk of squamous cell carcinomas. These data underscore the need to develop strategies to promote lifelong surveillance among these patients.

Risk factors for secondary malignancy include radiation therapy, length/severity of immunosuppression, and chronic GvHD [31, 345, 346]. Recommendations for screening include skin and breast self-examination, avoidance of tobacco and UV exposure. Further, general health maintenance testing should be performed as in the general population, including screening for essential hypertension, hypercholesterolemia, colorectal cancer, diabetes mellitus, depression, sexually transmitted diseases, prostate cancer in men, and breast and cervical cancer in women [31].

Infection Prevention and Posttransplant Vaccination

Patients undergoing both autologous as well as allogeneic HCT are exposed to cytotoxic and immunosuppressive agents. Further, the hematopoietic grafts are in the process of regeneration and often the patients have GvHD or are receiving treatment for this syndrome. These factors, alone or in combination, contribute to a heightened and prolonged risk for the development of many opportunistic infections by bacteria, fungi, viruses, and even protozoa [347, 348]. In addition, HCT often is associated with a loss or diminution of previously acquired host protective immunity against pathogens targeted by childhood immunizations such as tetanus, mumps, rubella, and poliovirus [349, 350]. Vaccine efficacy in HCT recipients has not generally been studied in large multicenter trials and previously published surveys in Europe and the United States varied considerably in the posttransplant vaccination practice guidelines. The current guidelines now are more uniform. Vaccination recommendations include consideration of initiating anti-infective vaccinations as early as 6 months after HCT, predominantly in patients no longer receiving immunosuppressants. Anti-infective vaccines include use of protein-conjugated pneumococcal vaccine (in contrast to the less immunogenic polysaccharide vaccine), tetanus, diphtheria, acellular pertussis vaccine, *Hemophilus influenza* type b conjugate, meningococcal conjugate, inactivated poliovirus, inactivated influenza, and recombinant hepatitis B vaccine. Human papillomavirus (HPV) is causally linked to squamous cell carcinoma of the genital tract and head and neck; the cancer incidence is higher among HPV infected and immunosuppressed individuals. Several groups recognize the value of vaccination against HPV and recommend use in HCT recipients [351, 352].

Most anti-infective vaccine preparations are devoid of live organisms, the previous exception being a live, attenuated mumps-measles-rubella vaccine. More recently, the recommendations have been expanded to permit use of a dose-attenuated, live, varicella-zoster virus vaccine (Varivax®) in patients beyond 2 years after HCT who are not receiving immunosuppressives [353]. The robust-dose varicella-zoster virus vaccine Zostavax®, however, is contraindicated. Other vaccinations not in routine use, to be given only under special circumstances, include hepatitis A, yellow fever (live, for use in endemic areas), rabies (occupational exposure), tick-borne encephalitis, and Japanese B encephalitis, both for endemic areas. Those vaccines that should be avoided include Bacillus Calmette-Guérin (live), oral poliovirus (live), intranasal influenza (live), cholera, typhoid (both oral, live and intramuscular), and rotavirus. Testing after vaccination is indicated to determine response and the need for additional or boost vaccination. For the vaccine to be relevant clinically, a protective immune response in the form of at least a fourfold rise in specific antibody titers, or T- and B-cell adaptive immunity must be partially reconstituted. In some instances, vaccination using tetanus toxoid, pneumococcal conjugate vaccine, and *H. influenza* type-b conjugate vaccine of the potential hematopoietic cell donor has been shown to improve the posttransplant immunity of the graft recipient. The logistics for this approach, however, are quite complex and no specific recommendations can be made.

Summary

HCT has become a frequently used tool to provide potentially curative therapy for a variety of neoplastic, immunologic, and genetic disorders in both adults and children. As a result of previous and ongoing clinical and translational work, many of the hurdles that formerly plagued this approach have been lowered or removed and treatments can be individualized for each potential recipient. Vigorous supportive care with blood component transfusions, broad-spectrum antibiotics, and immunosuppressives to prevent or treat GvHD remain an essential component of this life-saving art. While many thousands of patients have achieved cure or

significant prolongation of survival, work still remains and participation in clinical trials is strongly encouraged to continue the dramatic progress.

58 Hematopoietic Growth Factors in the Supportive Care and Treatment of Patients with Hematologic Neoplasms

Ryan W. Jacobs, Omotayo Fasan, Edward A. Copelan, and Belinda R. Avalos

Introduction

The hematopoietic growth factors (HGFs) are naturally occurring glycoproteins required for the survival, proliferation, and differentiation of hematopoietic cells. Their effects are mediated by high-affinity binding to specific receptors on their hematopoietic target cells. The isolation, purification, cloning, and manufacture of HGFs have permitted their clinical use, originally to correct cytopenias caused by deficiency of specific growth factors, and subsequently in additional settings. Recombinant HGFs are used in the treatment of patients with hematologic malignancies to improve disease and treatment-related cytopenias and to mobilize hematopoietic stem cells from the marrow into the peripheral blood from where they can be harvested for autologous and allogeneic hematopoietic cell transplantation. This chapter will focus on the biology and use of the clinically important recombinant HGFs in patients with hematologic malignancies. Those HGFs which are employed clinically will be individually discussed, including a description of their application in specific clinical settings.

Clinically Important Hematopoietic Growth Factors

Granulocyte Colony-Stimulating Factor

Granulocyte colony-stimulating factor (G-CSF), also called CSF3, is a naturally occurring glycoprotein. The gene that encodes it is located at chromosome 17q21-22 and the transcribed molecule exists in two forms, 174 and 177 amino acids long. G-CSF is responsible for the regulation of granulopoiesis promoting the maturation of myeloid progenitor cells along the polymorphonuclear neutrophil (PMN) lineage [1].

G-CSF supports the survival, proliferation, and differentiation of neutrophil precursors and the survival and activity of mature neutrophils. In particular, it upregulates the expression of C3b receptors, increases the binding of the chemotactic agent N-formyl-Met-Leu-Phe (fMLP) to PMNs, enhances generation of superoxide anions, and promotes antibody-dependent cellular cytotoxicity (ADCC) and the release of arachidonic acid (a source of proinflammatory and anti-inflammatory eicosanoids) [2–6]. G-CSF null mice demonstrate chronic neutropenia and severely impaired responses to infection [6].

The biological activities of G-CSF are mediated by the GCSF receptor (CSF3R), a transmembrane protein expressed on the surface of cells of the neutrophil lineage [7, 8]. Like other cytokine receptors, the extracellular portion of CSF3R binds ligand and the cytoplasmic tail transduces intracellular signals [3, 4, 7]. Distinct regions in the cytoplasmic domain mediate specific activities. The membrane-proximal domain of CSF3R mediates proliferative signals, while the distal region transduces differentiation signals. Studies of mice with CSF3R knock-out or knock-in mutations indicate the CSF3R generates unique signals to maintain circulating PMN levels during basal and stress granulopoiesis [9–12]. CSF3R null mice demonstrate chronic neutropenia, decreased numbers of myeloid cells in the bone marrow, and defects in PMN activation [6, 10]. A total of five different CSF3R isoforms differing in their transmembrane or cytoplasmic sequences and arising from alternative splicing have been isolated in humans. Most notable is the Type IV isoform that replaces the 87 carboxy-terminal amino acids of the full-length Type I CSF3R with a unique sequence and is defective in differentiation signaling [13–17].

In 1991, recombinant human G-CSF became the first CSF to receive FDA approval in the United States. G-CSF (filgrastim, Neupogen) was initially approved for prevention of febrile neutropenia in patients with cancer receiving myelosuppressive

chemotherapy after a Phase III placebo-controlled trial demonstrated a reduction in the incidence of febrile neutropenia (57% vs. 28% in cycle 1), the duration of neutropenia, days of hospitalization, and days of intravenous antibiotic use [18]. Additional studies have consistently shown a significantly shorter duration of neutropenia with G-CSF than in controls. The labeled indications for G-CSF were subsequently expanded to include use for accelerating neutrophil recovery after bone marrow transplantation, mobilizing progenitor cells into the peripheral blood for collection and hematopoietic cell transplantation, and shortening the duration of neutropenia in patients receiving induction and consolidation chemotherapy for acute)myelogenous leukemia (AML). G-CSF is also approved to reduce the incidence and sequelae of neutropenia in symptomatic patients with congenital, cyclic, or idiopathic neutropenia and in treating patients acutely exposed to myelosuppressive doses of radiation.

Concerns regarding the appropriate use of high-cost CSFs prompted the American Society of Clinical Oncology (ASCO) to convene a panel of experts to review data evaluating the effectiveness of CSFs and develop practice guidelines for the use of CSFs in patients not enrolled in clinical trials, which were published in 1994 [19] and updated in 1996 [20], 2000 [21], 2006 [22], and 2015 [23]. The 2015 guidelines support primary prophylaxis with G-CSF starting with the first cycle and continuing with subsequent cycles of use of myelotoxic chemotherapy when the risk of febrile neutropenia is estimated to be 20% or higher. The recommended dose in this setting is 5 μg/kg/day subcutaneously beginning 1–3 days after administration of chemotherapy. If G-CSF is administered after high dose chemotherapy and autologous stem cell rescue it can be started 1–5 days after chemotherapy. G-CSF should generally be continued until the ANC is greater than $2–3 \times 10^9$/L. In patients who do not receive primary prophylaxis, secondary prophylaxis with G-CSF should be considered if they experience neutropenic fever in the preceding cycle, especially if delayed treatment or dose reduction may adversely affect survival. The routine administration of G-CSF to patients with neutropenia following chemotherapy should be avoided in the absence of fever. Febrile neutropenic patients in high-risk situations such as those with severe neutropenia, i.e., ANC < 0.1 × 109/L with expected duration of neutropenia of 10 days or more, elderly (age > 65 years) or critically ill patients with pneumonia, invasive fungal infection or multiorgan failure and sepsis syndrome should receive G-CSF at a dose of 5 μg/kg daily.

G-CSF is utilized for peripheral blood progenitor cell mobilization either alone, in combination with plerixafor, a CXCR4 antagonist, or after chemotherapy. The usual dose is 10 μg/kg daily for at least 4 days before apheresis and continuing daily until the target progenitor cell dose is reached. Some mobilization algorithms administer an extra dose of filgrastim on the evening of day 4 while some employ twice daily dosing at 8 μg/kg twice daily.

The utilization of G-CSF in patients with acute myelogenous leukemia has been controversial, because G-CSF stimulates the proliferation of leukemic blasts in vitro. However, G-CSF has not demonstrated an adverse effect on complete remission duration or on survival of AML patients who receive it compared to those that do not where the leukemic burden has been reduced by cytotoxic chemotherapy. In fact G-CSF significantly accelerates the recovery of neutrophils after chemotherapy variably resulting in a decrease in the incidence of infections, the number of days of febrile neutropenia, duration of infection, and antibiotic use. Some studies, however, failed to show a decreased incidence of infection. There is some evidence that the resurgence of leukemic blast cells may occur in patients whose blast cells have fewer numbers of G-CSF receptors with a high affinity [24–26].

In acute lymphocytic leukemia (ALL), use of CSFs is recommended after the first few days of initial induction therapy or following the first post-remission course. The use of G-CSF in)children with ALL, however, should be carefully considered due to their excellent prognosis and the potential risk of secondary myeloid leukemia and myelodysplasia (MDS).

Pegylated G-CSF (pegfilgrastim, Neulasta) [it is a long-acting FDA-approved G-CSF] is a modified filgrastim in which a 20 kDa polyethylene glycol (peg) moiety is covalently added to the N-terminus of G-CSF. The addition of the peg moiety decreases clearance, particularly by the kidneys, resulting in sustained drug levels. Pegfilgrastim and filgrastim have an identical mechanism of action, but because pegfilgrastim has a longer half-life, it can be dosed once per chemotherapy cycle to prevent neutropenia. The recommended dose of pegfilgrastim in adults is 6 mg once to be given more than 24 h after the completion of chemotherapy. Pegfilgrastim has also been utilized for peripheral blood progenitor cell mobilization. In a cohort of 52 patients with hematologic malignancies single dose pegfilgrastim 6 mg ($n = 2$) or 12 mg ($n = 20$) was compared to filgrastim (G-CSF) 10 μg/kg daily from day 1 with apheresis beginning when the peripheral blood CD34 (PBCD34) reached a threshold of >5/μL on day 4 or day 5. The median PBCD34 count was 26/μL in the pegfilgrastim group compared to 16.2/μL in the filgrastim group. The target CD34 yield ($>2 \times 10^6$ per kg) was reached in 91% vs 80% in the pegfilgrastim and filgrastim arms, respectively, within a similar median of 3 days of apheresis in both arms [27].

Following the expiration of Amgen's patent on filgrastim (Neupogen), numerous G-CSF biosimilars have become available for clinical use worldwide. The approval of biosimilars occurs by an abbreviated process for biologics shown to be interchangeable or "biosimilar" to a reference standard. In March 2015 the FDA approved Sandoz's Zarxio (filgrastim-sndz) a biosimilar to Amgen's Neupogen, the reference standard. Zarxio is approved for similar indications to Neupogen (patients with cancer receiving myelosuppressive chemotherapy, patients with acute myeloid leukemia receiving induction or consolidation chemotherapy,

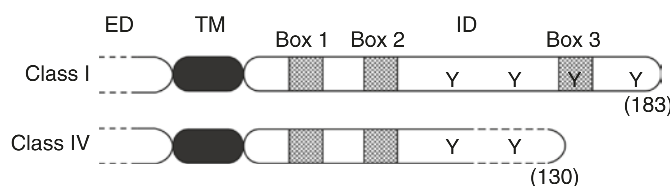

Fig. 58.1 Schematic diagram of Class I (wild-type) and Class IV CSF3R isoforms. The extracellular domain (ED), transmembrane domain (TM), and intracellular domain (ID) are indicated. The length of the intracellular domain is indicated by the number in parentheses at the bottom right. The locations of the cytoplasmic tyrosine (Y) residues at positions 704, 729, 744, and 764 are indicated. The dotted line represents the alternative carboxyl tail in the Class IV G-CSFR within which lies a unique tyrosine residue at position 734 (modified with permission from Avalos BR. Molecular analysis of the granulocyte colony-stimulating factor receptor. Blood 1996;88:761–77)

patients undergoing bone marrow transplantation, patients undergoing peripheral blood progenitor cell mobilization and collection, and patients with severe chronic neutropenia).

Common adverse events due to filgrastim and pegfilgrastim include nausea, headaches, mild to severe bone pain, and myalgias. Notable severe adverse events include anaphylaxis, splenic rupture, sickle cell crisis (when administered to patients with sickle cell disease), capillary leak syndrome, and acute respiratory distress syndrome. More recently the FDA highlighted the occurrence of a reversible glomerulonephritis with hematuria, proteinuria, and azotemia. A dose reduction or cessation of G-CSF should be considered if this develops.

Acquired point mutations in the CSF3R gene resulting in truncation of the carboxy-terminal maturation-inducing region of the CSF3R have been reported in patients with AML with preceding severe congenital neutropenia (SCN), an inborn disorder of granulopoiesis frequently associated with mutations in the gene encoding neutrophil elastase [28]. SCN has a marked propensity for transformation to MDS/AML with a cumulative transformation rate that exceeds 20%. Despite the relatively high frequency (30%) of mutations in tyrosine kinase genes such as FLT3, JAK2, and KIT in patients with de novo AML, these mutations have not been detected in patients with SCN transforming to AML [29]. Instead, mutations of the CSF3R gene are common and reported in up to 78% of patients with SCN and monosomy 7, MDS, or AML in one series [30]. There is evidence that the truncation mutations of CSF3R observed in patients with SCN are activating. Expression of the mutant CSF3R forms in myeloid cell lines results in defective ligand internalization and enhanced proliferative and survival signals in response to G-CSF [31, 32]. Transgenic mice carrying truncating mutations of CSF3R also display a hyperproliferative response to G-CSF [9, 11]. Since the CSF3R and tyrosine kinases share many signaling pathways, these observations along with the rarity of tyrosine kinase mutations in SCN/AML suggest the mutant CSF3R may provide the missing activated tyrosine kinase signal for malignant transformation. Notably, in patients with SCN less responsive to even high doses of G-CSF (≥8 μg/kg/day) there is a significantly increased risk of transformation to AML/MDS compared to SCN patients responsive to lower doses of G-CSF [33] (40% vs. 11% after 10 years).

The use of G-CSF with immunosuppressive therapy in severe aplastic anemia (SAA) remains under study and is currently not standard treatment. Previous studies by several groups have suggested a link between the use of G-CSF and an increased risk of MDS/AML after immunosuppressive therapy in patients with SAA. In the largest survey published, the European Group for Blood and Marrow Transplantation (EBMT) reported that the incidences of MDS/AML in 840 patients with SAA receiving immunosuppressive therapy who did or did not receive G-CSF were 10.9% and 5.8%, respectively. A significantly higher hazard (1.9) of MDS/AML was associated with the use of G-CSF, and the use of G-CSF did not improve overall survival [34]. Whether G-CSF provides a survival advantage to an abnormal hematopoietic stem/progenitor cell clone in the subset of patients developing MDS/AML remains unknown (Fig. 58.1).

Granulocyte–Macrophage Colony-Stimulating Factor

Granulocyte–macrophage colony-stimulating factor (GM-CSF) is a pleiotropic cytokine secreted by T cells, macrophages, mast cells, endothelial cells, and fibroblasts in response to inflammatory stimuli and cytokines. Recombinant human GM-CSF supports the growth of progenitors of multiple lineages including granulocytes, monocytes, eosinophils, and megakaryocytes [35–37]. The predominant effect of GM-CSF is increased production of neutrophils and macrophages, but GM-CSF is also a potent chemoattractant for neutrophils and eosinophils and enhances the effector functions of neutrophils and macrophages [38]. More recently, GM-CSF has been shown to function as a dendritic cell growth factor and to stimulate effector functions of dendritic cells [39, 40]. The broad spectrum of GM-CSF's activities likely explains its toxicity profile, which includes fever, chills, hypersensitivity reactions, and manifestations of capillary leak syndrome with generalized edema, weight gain, and pleural and pericardial effusions.

GM-CSF exerts its biological activities by binding to specific receptors on the surface of responsive cells. Unlike the receptor for G-CSF which is a single chain that dimerizes upon ligand binding, the GM-CSF receptor is more complex

and composed of a ligand-specific α chain subunit and a common signal-transducing beta subunit that is shared with the receptors for interleukins-3 and -5 (IL-3 and IL-5). The complexity of the GM-CSF receptor contributes to its diverse biological activities [41].

Recombinant human GM-CSF (sargramostim) is a glycoprotein made from a Saccharomyces cerevisiae expression system. It is 127 amino acids long and the sequence differs from the naturally occurring molecule at position 23 where an arginine molecule takes the place of leucine. It initially received FDA approval in March 1991 for use following autologous bone marrow transplantation, following a placebo-controlled multicenter trial of high dose chemotherapy and autologous transplantation for lymphoid malignancies in which patients randomized to receive GM-CSF 250 μg/m^2/day experienced neutrophil recovery 7 days earlier than those not receiving G-CSF (19 days vs. 26 days) [42]. GM-CSF use was associated with fewer days of hospitalization and antibiotic administration, and a lower incidence of infection. GM-CSF was subsequently approved for use in patients experiencing graft failure or delayed engraftment in both the autologous and allogeneic settings as well as for AML, mobilization of peripheral blood stem cells, and following peripheral blood progenitor cell transplantation.

Erythropoietin

Erythropoietin is a glycoprotein that promotes the proliferation of erythroid progenitors and supports the survival of erythroid cells. The existence of erythropoietin was first suspected when investigators injected serum from anemic rabbits into normal animals and noted an increase in the number of reticulocytes which peaked at about 5 days [43]. It is produced predominantly by the juxtatubular interstitial cells of the renal cortex where an oxygen-dependent hydrolase regulates the stability of hypoxia-inducible factor 1α (HIF-1α), the primary transcription factor for erythropoietin [44]. Low oxygen levels maintain inactive hydrolase and stable, unhydroxylated HIF-1α, which drives production of erythropoietin [44, 45]. Blood levels, which are normally approximately 20 mU/mL, increase with declining tissue oxygenation accompanying anemia or hypoxia to levels as high as 200,000 mU/mL [46].

Exogenously administered erythropoietin increases the number of erythroid progenitor cells in the marrow, where it promotes red blood cell (RBC) production and exit into the bloodstream. It was initially approved for treatment of anemia due to chronic renal failure, which is associated with erythropoietin deficiency. It has been subsequently applied in anemias of multiple etiologies. Recombinant preparations are as potent as naturally occurring erythropoietin. The addition of an N-linked carbohydrate (darbepoetin) prolongs its half-life [47]. The American Society of Clinical Oncology/American Society of Hematology clinical practice guideline update consider the effectiveness and safety of these agents to be equivalent [48].

Anemia is common in patients with hematologic malignancies as a consequence of disease and therapy-related suppression of hematopoiesis. Anemia of chronic inflammation, blood loss related to thrombocytopenia and/or frequent blood draws, immune mechanisms, and other factors may contribute as well. Patients with anemia and malignancy often do not produce amounts of erythropoietin appropriate for their degree of anemia [49]. Those whose blood level exceeds 500 mU/mL are less likely to benefit from exogenous administration than patients whose levels are low [50], but, aside from myelodysplastic syndromes (MDSs), levels are not considered sufficiently predictive to guide treatment. Controlled trials demonstrate that patients with cancer and hemoglobin <10 g/dL require fewer blood transfusions and feel better with erythropoietin therapy [47, 48].

ASCO and ASH initially published evidence-based practice guidelines for the use of erythropoietin in 2002 [51] and subsequently updated them [48, 52]. These guidelines emphasize consideration of other correctable causes of anemia before initiating therapy with erythropoiesis-stimulating agents (ESAs). Appropriate clinical evaluation for correctable causes include a history, physical examination, and diagnostic tests [52]. The use of epoetin or darbepoetin is recommended as a treatment option in individuals with anemia associated with chemotherapy whose hemoglobin concentration is less than 10 g/dL in order to reduce the transfusion of red blood cells. Clinical judgment should determine when to implement treatment in individuals with Hb < 12 with angina, limited cardiopulmonary reserve, or other circumstances limiting their ability to carry out activities of daily living. Systematic reviews of randomized clinical trials have demonstrated an increase in thromboembolism in patients receiving these agents [53, 54]. They should be used with particular caution in patients with a previous history of thrombosis, those who have prolonged immobilization and patients with multiple myeloma who are receiving lenalidomide or thalidomide [55]. The US Food and Drug Administration (FDA) has approved a starting dose for erythropoietin of 150 U/kg three times per week or 40,000 U weekly subcutaneously, and for darbepoetin of 2.25 μg/kg weekly or 500 μg every 3 weeks administered subcutaneously [47]. US Food and Drug Administration approved labeling should be followed for dose escalation and doses should be withheld when the hemoglobin exceeds 12 g/dL until it reaches 11 g/dL where it should be restarted at a lower dose [48]. Dose reduction should occur when the hemoglobin exceeds 11 g/dL or increases 1 g/dL in a 2 week period. It is important to note that the use of ESAs in cancer patients with anemia not receiving myelosuppressive chemotherapy is not recommended. The one exception to this is the

use of ESAs to treat anemia due to low-risk myelodysplastic syndrome.

The use of ESAs in cancer patients has been implicated in both preclinical and clinical studies as a cause of tumor progression and increased mortality [56]. Given the reported risk of cancer progression and thrombosis, the safety of ESAs including Epogen, Procrit, and Aranesp are now closely monitored. The FDA requires all ESAs to be prescribed under a risk evaluation and mitigation strategy (REMS). Patients must now be told of the risks and benefits and provided with a medication guide that explains these to them. Prior to starting ESAs patients are required to sign an acknowledgement form indicating that they have been counseled on the risks and benefits of ESAs. Healthcare professionals that prescribe ESAs must complete training under the ESA APPRISE (Assisting Providers and Cancer Patients with Risk Information for the Safe use of ESAs).

Thrombopoietin Receptor Agonists

Thrombopoietin supports the proliferation and survival of megakaryocytes. More than 50% is normally produced in the liver but thrombopoietin is also produced in the kidney, skeletal muscle, and marrow stroma [57]. Receptors (c-Mpl) on megakaryocytes and platelets bind it and remove it from the circulation [58]. Elimination of the genes for thrombopoietin or for its receptor reduces platelet numbers by 90% [59]. Thrombopoietin also primes platelets to aggregate by activating the phosphoinositol 3-kinase signaling pathway [60] and supports the proliferation of hematopoietic stem cells [61].

When truncated recombinant thrombopoietin (megakaryocyte growth and development factor) modified with polyethylene glycol was administered subcutaneously to platelet donors, it stimulated antibody production which cross-reacted with endogenous thrombopoietin in some donors, resulting in severe thrombocytopenia [62]. This adverse occurrence led to a search for molecules which would bind and stimulate the thrombopoietin receptor without stimulating potentially dangerous antibodies to thrombopoietin [45]. Although such molecules are not true HGFs, such agents are included here because of their potential clinical impact.

Romiplostim (NPlate) is a peptibody with four copies of a thrombopoietin receptor-binding peptide on an immunoglobulin scaffold [45]. It increases platelet counts in healthy individuals and in those with refractory ITP [63, 64] where it has been approved for treatment. Its safety and effectiveness have been demonstrated in patients with lower-risk MDS [65, 66]. However the manufacturer clearly states that it is not indicated for the treatment of thrombocytopenia due to MDS or other causes other than chronic ITP. There are reports of an increase in blast cell counts and progression to AML with the use of romiplostim in patients with MDS. The starting dose is 1 mcg/kg once weekly subcutaneously. The dose should be adjusted in weekly increments of 1 mcg/kg to achieve and maintain a platelet count >50 K/μL. The maximum weekly dose is 10 mcg/kg. If counts do not increase 4 weeks after the maximum dose then further doses should be withheld.

Eltrombopag (Promacta) is a small molecule agonist of the thrombopoietin receptor c-mpl [67]. It is approved for the treatment of chronic ITP in patients who have not had an adequate response to treatment with steroids, intravenous immunoglobulin, and splenectomy. The starting dose is 50 mg daily orally. Care should be taken in patients with hepatic dysfunction where the dose should be lowered to 25 mg daily. Eltrombopag carries a boxed warning for hepatotoxicity and transaminase levels must be measured prior to starting and closely thereafter. Eltrombopag is also effective in improving hematopoiesis in patients with aplastic anemia [68]. In a phase 2 study of 25 patients with severe aplastic anemia, eltrombopag at a starting dose of 50 mg daily for 12 weeks (the dose could be escalated to a maximum of 150 mg daily to achieve a response), 44% of patients had a hematologic response with 36% achieving platelet transfusion independence.

Non-Hodgkin and Hodgkin Lymphoma

Use of Myeloid Growth Factors in Patients with Febrile Neutropenia

Factors associated with an increased risk of mortality in conjunction with neutropenic infection are listed in Table 58.1. Older patients clearly have an increased risk of mortality from neutropenic infection [69–71]. A Spanish study which included patients with lymphoma (and solid tumors) showed that among patients with febrile neutropenia following chemotherapy who had one or more high-risk factors, those randomized to receive G-CSF (5 μg/kg daily) had a shorter duration of grade 4 neutropenia and antibiotics (median 1 day) and a 2 day shorter hospital stay [72]. These data, along with ASCO and NCCN guidelines [22, 23], support

Table 58.1 High-risk factors in patients with neutropenic fever

1.Expected neutropenia $<0.1 \times 10^9$/L
2.Age > 65
3.Poorly controlled lymphoma
4.Pneumonia or other clinically documented infections
5. Hypotension with multiorgan dysfunction
6.Invasive fungal infection
7.Hospitalization at time of fever development
8.Neutropenia expected to last >10 days
9.Prior episode of febrile neutropenia

the use of myeloid growth factors in patients with Hodgkin or non-Hodgkin lymphoma (NHL) and risk factors for excess mortality who develop neutropenic fever.

Prophylactic Use of Myeloid Growth Factors

In individuals with lymphoma, the risk of neutropenia following chemotherapy increases with age [73–75]. A retrospective study in patients with NHL reported a 34% incidence of neutropenic fever in those over 65 compared to 21% in younger patients. The duration of neutropenia was a median of 4 days longer in the older patients [76].

The 2006 Update Committee of the American Society of Clinical Oncology agreed unanimously that prophylactic administration of myeloid growth factors is justified following chemotherapy whenever the expected rate of febrile neutropenia is 20% [22]. This recommendation was based on the inclusion of reduced toxicity and improvement in quality of life among clinical outcomes that may justify the use of a drug. The committee recommended the use of prophylactic CSF for patients with diffuse aggressive lymphoma 65 years and older treated with CHOP or more aggressive regimens to reduce the risk of febrile neutropenia and infection.

Select regimens for treating high grade lymphomas have utilized neutropenia as a biomarker to inform proper dose adjustment for subsequent cycles. Dose adjusted rituxan, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (dose adjusted REPOCH), a regimen being more widely utilized in NHL, utilizes standard prophylactic CSFs following chemotherapy administration with subsequent monitoring of resultant neutropenia [77]. The degree of neutropenia that occurs following each cycle dictates the dosing of chemotherapy for the following cycle. With the support of CSFs, chemotherapy dosing can be maintained or increased in patients who do not develop severe neutropenia.

In many clinical settings, the usefulness of prophylactic CSFs is uncertain. A meta-analysis of 12 randomized trials, including 1823 patients with NHL and Hodgkins disease, found a significantly reduced risk of febrile neutropenia with prophylactic myeloid growth factors but no reduction in the number of patients requiring intravenous antibiotics, infection-related mortality, or survival [78]. Furthermore, although the CSFs are effective in reducing the risk of febrile neutropenia when its risk is 20% [79, 80], questions over cost-effectiveness are largely responsible for wide variations in clinical practice. Although cost-effectiveness is difficult to precisely determine, inclusion of indirect costs of febrile neutropenia, e.g., loss of productivity, may make their administration cost-neutral in some settings where more direct calculations are less favorable [81].

Table 58.2 High-risk factors for development of neutropenic fever

1.Prior chemotherapy or radiation therapy
2.Persistent neutropenia
3.Bone marrow involvement by tumor
4.Recent surgery and/or open wounds or other clinically documented infections
5.Liver dysfunction (bilirubin >2.0)
6.Renal dysfunction (creatinine clearance <50)
7.HIV positive

Aside from elderly patients with NHL receiving aggressive chemotherapy, the use of prophylactic CSFs in patients with Hodgkin or NHL should be based on individual patient risk factors. Patients with Hodgkin or NHL who experience neutropenic fever with chemotherapy not accompanied by growth factor prophylaxis should receive prophylaxis with subsequent doses [22]. In patients who do not receive prophylactic CSFs who develop fever, growth factors should be administered to patients at high risk for complications or who exhibit other characteristics predictive of poor clinical outcome. These characteristics, based on the NCCN guidelines, are summarized in Table 58.2 [82].

Myelodysplastic Syndromes

MDS is associated with varying degrees of anemia, neutropenia, and thrombocytopenia. HGFs have been effective in improving cytopenias and quality of life, but most trials of their effectiveness have been small, non-randomized, and included heterogeneous patient populations. The studies also used disparate definitions of response. Standardization of disease classification and response to therapy is required to define the usefulness of growth factors in MDS.

A pooled analysis of more than 2500 patients with low-risk MDS (defined as less than 5% marrow blasts or an International Prognostic Scoring System (IPSS) score ≤ 1) from 162 different reports compared patients with similar baseline characteristics who received therapy with growth factors versus other therapies [83]. Almost all had one or more cytopenias prior to treatment. Patients treated with HGFs had significantly higher response rates (39.5% vs. 31.4%, $P = 0.016$) than those receiving other therapies. Responses were predominantly erythroid. Those receiving erythropoietin with or without G or GM-CSF had the highest response rates. Significant advantages in survival and progression-free survival were experienced by the growth factor group, even when controlling for all known predictors of outcome.

These data support the usefulness of erythropoietin in patients with low-risk MDS. Some studies have indicated that the combination of erythropoietin plus G-CSF may

improve erythroid response and survival in patients receiving minimal or no RBC transfusions [84], but other data do not support the value of adding a CSF to erythropoietin [83].

Once they begin to require red cell transfusions, it is reasonable to initiate erythropoietin or darbepoetin in low-risk patients. Patients with pre-transfusion erythropoietin levels below 100 mU/L and whose transfusion needs are minimal are most likely to respond [85]. Approximately 40% of patients respond, but eventually develop resistance. Treatment should be limited to patients whose hemoglobin is less than 10 g/dL and stopped once the hemoglobin reaches 12 g/dL. G or GM-CSF should be considered in patients with neutropenia who develop recurrent infections; however, their routine long-term use in neutropenic MDS patients is not recommended.

Thrombocytopenia is an independent adverse prognostic factor in MDS [86] and clinically significant thrombocytopenia occurs in more than 40% of patients [87, 88]. The only effective treatment of severe thrombocytopenia is platelet transfusion, which may be associated with acute adverse effects including febrile transfusion reactions, transfusion-related acute lung injury, and alloimmunization, which results in loss of platelet transfusion effectiveness. Multicenter studies found that weekly subcutaneous doses of the Fc-fusion protein romiplostim were well tolerated in patients with lower-risk MDS and thrombocytopenia and that 57% of patients had a complete response [65, 66]. A systematic review and meta-analysis of the use of TPO-receptor agonists in MDS suggests that Romiplastem can decrease bleeding events and platelet transfusion, but that most of the bleeding events were not clinically important and platelet transfusion reduction was relevant mainly for those receiving prophylactic transfusions. While the risk of AML progression was not increased, these data were not adequate to dismiss this risk [89].

Acute Myeloid Leukemia

Myeloid Growth Factors Following Induction

The capacity of myeloid growth factors to shorten the duration of neutropenia following induction therapy in acute myeloid leukemia (AML has been extensively studied for three decades. In order to achieve cure of AML, induction, and post-remission chemotherapy must eradicate leukemia-initiating cells as well as the bulk of leukemia cells [90, 91]. Toxicity to normal hematopoietic stem and progenitor cells, which closely resemble leukemia-initiating cells, as well as to more mature hematopoietic cells, results in prolonged marrow aplasia and frequent infections with bacteria and fungi. Approximately 10% of adult patients less than 60 and 20% of patients older than 60 die from infections after receiving standard induction therapy [22, 92], however treatment related mortality has been more recently reduced to less than 5% [93]. By reducing the duration of neutropenia, myeloid growth factors could decrease the incidence and severity of bacterial and fungal infections and mortality in patients with AML.

Numerous prospective randomized studies using G- [26, 94–98] or GM-CSF [99–103] following induction chemotherapy have demonstrated a significant reduction in the duration of neutropenia (by as much as 1 week), a shorter duration of infection, less use of antibiotics, and, in some, shorter hospitalization. Cost analyses have demonstrated conflicting results [104, 105]. Although some studies demonstrated higher rates of complete remission (CR) in patients given myeloid growth factors, a significant benefit in survival was achieved only in the Eastern Cooperative Oncology Group trial of patients aged 55–70 [102]. The lower than usual median survival of the placebo control group in that trial (4.8 months) has limited its persuasiveness [93].

Myeloid Growth Factors Following Intensive Post-remission Chemotherapy

Results similar to those following induction therapy have been reported in a randomized trial of G-CSF following post-remission therapy in patients with AML, with shortened durations of neutropenia (by 1 week), antibiotics, and hospitalization [106]. The incidence of documented infections, toxic death, disease-free, and overall survival, however, was not affected.

Growth Factor Priming

Demonstration that myeloid leukemia cells express myeloid growth factor receptors on their surface and that growth factors could stimulate differentiation of leukemic progenitors led to generally unsuccessful attempts to induce differentiation of leukemic cells in selected patients. Greater interest was generated by the demonstration that GM and G-CSF increased the proportion of leukemia cells in S phase [107–109] and that their use in combination with cytarabine increased incorporation of cytarabine into leukemia cell DNA and improved cytotoxicity [107–109]. Despite this evidence that growth factors recruit leukemic cells into S-phase and improvement in DFS in some studies of growth factor priming, randomized trials have not shown a significant benefit in survival [110–115]. The lack of clinical benefit may result from the modest increase in blasts recruited into S phase (6.0–10.7% in one study [109]).

Lowenberg et al. reported results of a trial of 640 adults ≤60 years of age randomized to receive or not receive G-CSF

starting the day before cytarabine administration in each of two induction courses [113]. Although CR rates were not significantly different, the group receiving growth factors experienced a significantly lower relapse rate and better DFS, but without improved survival. Patients with standard risk cytogenetics who received growth factor priming showed improved survival due to reduced relapse rates. A French trial in young adults (<50 years), which administered GM-CSF with induction and post-remission chemotherapy, demonstrated significantly higher CR rates and a strong, but not significant, trend toward better EFS in growth factor primed patients [114]. Patients with intermediate risk AML had significantly better EFS using growth factor. Despite the tantalizing suggestion that priming might improve the effectiveness of induction chemotherapy, the entirety of results does not support its usefulness.

The chemokine receptor CXCR4 is expressed on leukemia blasts, as it is on normal hematopoietic stem cells and is essential for homing to the marrow. Plerixafor blocks CXCR 4/CXCL12 interactions and stromal HSC and stromal leukemia cell interactions, leading to "mobilization" of HSCs and leukemic cells from the marrow [116] into the bloodstream where they are more susceptible to chemotherapy. Combining plerixafor with chemotherapy appears to sensitize patients with relapsed or refractory AML [117]. G-CSF and plerixafor have been used to sensitize leukemic cells prior to allogeneic transplantation with preferential mobilization of leukemic cells compared to normal white blood cells, but without improving relapse rates [118]. Better mechanisms of mobilization of leukemia cells could be translated into meaningful therapeutic advances.

Potential of Myeloid Growth Factors to Cause Adverse Effects on Leukemia

In addition to recruiting leukemia cells into S phase, myeloid growth factors can also result in leukemia cell expansion [109]. This has raised concern that growth factor administration might adversely affect remission and relapse rates. Many studies in AML thus delayed growth factor administration until a marrow examination performed 10 or more days after induction demonstrated aplasia. No specific clinical evidence is available to support this approach and the virtual certainty of relapse if additional chemotherapy is not given provides compelling evidence that residual leukemic cells are present in patients with "aplastic" marrows.

In general the fear of an adverse effect on leukemia cells has not been supported by clinical trials; however, one recent study has raised concerns. Increased expression of the Type IV CSF3R isoform leading to an imbalanced ratio of Type IV to Type I expression has been reported in some patients with AML. Recent results from the prospective multicenter Acute Myeloid Leukemia Berlin–Frankfurt–Muenster (AML-BFM) 98 study randomly testing the ability of G-CSF to reduce infectious complications and outcomes in children and adolescents with AML reported a trend toward an increased incidence of relapse in the standard-risk group after G-CSF treatment. Patients overexpressing CSF3R isoform IV randomly assigned to receive G-CSF after induction showed a 5-year cumulative incidence of relapse of 50% ± 13% compared to 14% ± 10% with low level isoform IV expression ($P = 0.04$). The level of isoform IV expression had no significant effect in patients not receiving G-CSF [119].

While some guidelines have approved CSF use following induction therapy, most experts do not advocate their routine use in that setting [93]. They are used by some clinicians in older patients. The use of prophylactic growth factors is not recommended in refractory or relapsed AML.

Although their administration during intensive post-remission chemotherapy has not been demonstrated to improve survival, their use is recommended by the Update Committee for their potential to derail infections and hospitalizations. These benefits must be balanced with the absence of improvement in other significant outcomes, questionable cost-effectiveness, and potential for leukemic cell expansion. For patients in whom myeloid growth factors are not given prophylactically, they may be useful in the setting of severe neutropenia and life-threatening infection.

Acute Lymphocytic Leukemia

Several studies of myeloid growth factor support have demonstrated a reduced duration of neutropenia following remission induction and post-remission chemotherapy in ALL [120–126]. A CALGB trial demonstrated shorter duration of neutropenia following induction (by a median of 6 days), significantly shorter hospitalizations, fewer deaths with induction, and a higher, though not significantly, rate of CR in patients receiving myeloid growth factors. Although growth factors were associated with faster neutrophil recovery following each of two post-remission treatments (by 9 and 6 days respectively), patients did not complete the first three rounds of therapy more quickly. Survival and DFS were not improved [120].

Dose and timing have been analyzed in this setting. A dose of 5 mcg/kg/day of G-CSF during induction significantly shortened the neutropenic period compared to a dose of 2 mcg/kg/day [125]. Administration of growth factors early (within 1 week) after initiation of chemotherapy, compared to late (10–12 days after initiation of therapy) results in faster neutrophil recovery [121], less antibiotic and antifungal use [127], and earlier discharge (by a median of 2 days) [121], but more growth factor administered and an

uncertain impact on cost. Concerns regarding expansion of leukemic clones exist, but less so than in AML. Based on evidence indicating neutropenic days and hospitalization are shortened and that severe infections and induction deaths can be decreased, growth factors are used routinely following intensive induction and post-remission therapy in ALL.

Use of HGFs in Other Hematologic Malignancies

The ASCO guidelines for myeloid growth factors and erythropoietin apply to patients with multiple myeloma, chronic lymphocytic leukemia (CLL), and low-grade lymphomas. The committee now cautions against the use of erythropoiesis-stimulating agents (ESAs) under any circumstances given established increased risks associated with ESAs, including increased venous thromboembolism, stroke, tumor progression, and mortality [128]. In both chronic myeloid leukemia and CLL, severe neutropenia in patients receiving tyrosine kinase inhibitors is generally best handled by withholding drug, rather than with the use of myeloid growth factors. In contrast, patients with CLL receiving aggressive fludarabine containing regimens associated with a high incidence of neutropenia appear to benefit from G-CSF prophylaxis [129].

Growth Factors in Autologous Transplantation

Autologous hematopoietic stem-cell transplantation is an effective therapy for many hematologic malignancies, particularly Hodgkin and NHL and multiple myeloma. It requires collection of hematopoietic stem cells which rapidly produce mature hematologic cells following transplantation. Although unstimulated marrow or blood can serve as a source of these cells, "mobilized" peripheral blood is a much better source and is standard.

Animal studies indicate that hematopoietic stem cells, rather than more differentiated progenitors, give rise to early hematopoietic reconstitution following transplantation [130]. Quantification of CD34+ cells in the collected product serves as a surrogate of stem cell number and the number of CD34+ cells infused reliably predicts the speed of hematologic recovery after transplantation [131–133]. The number of CD34+ cells in the bloodstream is increased several-fold by the myeloid growth factors [134–136]. G-CSF is significantly more effective than GM-CSF in mobilization of CD34+ cells [135–138], and has been utilized alone, or in combination with non-stem-cell-toxic chemotherapeutic agents (e.g., cyclophosphamide [136] or etoposide [132]), combination chemotherapy, e.g., ifosfamide, cisplatin, etoposide (ICE) [139], or more recently with plerixafor [140, 141], a novel small molecule which inhibits the marrow binding of stromal derived factor 1 α (SDF-1α) to the CXCR4 chemokine receptor expressed on CD34+ cells.

Most centers target a dose of 4–5 × 10^6 CD34+ cells/kg, but doses ≥2 × 10^6 are generally adequate for transplantation [142]. Lower doses often result in delayed or inadequate hematopoietic recovery [143]. CD34+ cells are collected by aphereses. Collection within one or two procedures minimizes machine and personnel time, expense and inconvenience [144, 145], but in a large multi-institute study, only 20% of patients with NHL receiving G-CSF alone achieved CD34+ cell doses ≥5 × 10^6/kg within 4 apheresis days [140]. More that 20% of patients are poor mobilizers, defined by the need for more than four aphereses or additional mobilization attempts [143–145]. Extensive previous chemotherapy, particularly with stem-cell-toxic agents, prior radiation, female sex, high body mass index, marrow involvement with malignancy, and thrombocytopenia preceding mobilization are associated with poor mobilization [142, 143]. Poor mobilization is associated with poor survival [143]. In contrast, patients who are supermobilizers, i.e., collect ≥8 × 10^6 CD34+ cells/kg, have improved survival [146]. It is unclear whether the prognostic value of cell dose may be a surrogate for better general health and other good risk factors, although it was found to an independent favorable prognostic factor in multivariate analysis which included known prognostic factors [146].

When G-CSF, the most commonly used mobilization agent, is administered alone, it is generally given at a dose of 10 μg/kg subcutaneous daily for 4 days prior to and then throughout the duration of apheresis. Similar doses can be given following chemotherapy. Although chemotherapy combined with G-CSF is more effective in mobilizing CD34+ cells [136], this is balanced by a 20–30% incidence of neutropenic fever and other chemotherapy toxicities [132, 136]. Further, the appropriate day for starting apheresis is unpredictable after chemotherapy-based mobilization, complicating scheduling. Chemotherapy should be utilized for mobilization only when it is integrated appropriately into the treatment plan, e.g., a planned course of ICE in Hodgkin and NHL. Similarly, high dose etoposide appears to be as effective as standard salvage combination therapy regimens in obtaining objective response in Hodgkin and NHL [132]. In individuals who have achieved a CR to combination therapy, additional chemotherapy may not be beneficial and its use solely for efficient mobilization is not justified. In patients who undergo chemotherapy plus G-CSF, once the WBC rises from its nadir, peripheral blood CD34+ counts are useful in determining when apheresis should be initiated [133, 147, 148].

Because only a small proportion of lymphoma patients procure targeted CD34+ cell numbers with four aphereses, and because of the disadvantages of chemotherapy, plerixafor use in combination with G-CSF has grown tremendously. Its effectiveness was demonstrated in placebo-controlled,

randomized trials in myeloma [141] and NHL [136]. In NHL, its addition to plerixafor improved the percentage of patients procuring ≥5 × 10^6 CD34+ cells within four apheresis days from 20 to 59% [140]. In myeloma, procurement of ≥6 × 10^6 CD34+ cells with 2 days was improved from 34.4 to 71.6% [130]. The combination should be routinely utilized in patients considered at high risk of failure to collect adequate numbers of CD34+ cells. The considerable expense of plerixafor is balanced, at least in part, by the need for fewer aphereses and the associated expense, risk, and inconvenience of numerous aphereses and remobilization attempts [144, 145]. G-CSF is also administered at most centers following autologous transplantation where it modestly accelerates neutrophil recovery and shortens hospitalization [149]. A G-CSF regimen identical to that used for autologous stem-cell mobilization is also the standard mobilization method for peripheral blood donors for allogeneic transplantation. Aside from bone-pain, it is associated with few side effects and a vast majority of healthy donors mobilize adequate numbers of cells within two apheresis procedures.

The use of mobilized peripheral blood cells for allotransplantation is associated with an increased incidence and duration of chronic graft-versus-host disease compared to bone marrow (presumably because of a higher number of T cells) but with accelerated neutrophil and platelet recovery [150, 151]. Allogeneic recipients of bone marrow who receive G-CSF following transplant appear to experience higher incidences of acute and chronic graft-versus-host disease [152].

Delayed erythroid recovery occurs commonly following transplantation. Some patients require red cell transfusions for up to a year. While multiple factors contribute, prolonged anemia following both allogeneic and autologous transplantation is associated with an inadequate erythropoietin response [153]. Administration of erythropoietin appears to modestly decrease the transfusion requirement after allogeneic, but not autologous transplantation [154], although conflicting results have been reported [155]. Most centers do not routinely use erythropoietin following transplantation, but it may be beneficial in selected patients with delayed erythroid recovery.

Eltrombag has proven effective in elevating platelet counts in patients with persistent thrombocytopenia following autologous and allogeneic transplantation [156]. Its use is reasonable in selected patients.

Can Growth Factors Cause Leukemia?

There has been considerable concern over the potential of myeloid growth factors to accelerate leukemic expansion in patients with AML, as has been discussed, or to cause leukemia in some individuals. Two separate studies of over 5000 individuals failed to detect any increase in AML in peripheral blood stem-cell donors receiving G-CSF [157, 158]. A review of 25 randomized trials of patients receiving chemotherapy for solid tumors or lymphoma with or without G-CSF demonstrated a doubling of the incidence of MDS/AML, although all cause mortality was decreased among patients receiving G-CSF [159]. The increased risk of MDS/AML may be attributable to the increased dose intensity of leukemogenic agents which was delivered in those receiving G-CSF.

In addition to the increased incidence of AML in SCN associated with G-CSF use, a significantly increased incidence of MDS/AML was reported in Aplastic Anemia patients receiving immunosuppressive therapy and G-CSF compared to those not receiving G-CSF [34], as described earlier. A Japanese study demonstrated a strong leukemia risk in children with aplastic anemia receiving G-CSF, particularly those resistant to immunosuppressive therapy [160]. Interestingly, this group of patients had a high incidence of 7q− and monosomy 7. Fluorescence in situ hybridization (FISH) identifies monosomy 7 in many patients with marrow failure and normal cytogenetics by conventional metaphase analysis and in those in whom metaphase analysis could not be performed. Basic studies demonstrate that high concentrations of G-CSF increase the proportion of monosomy 7 cells in vitro and that CD34+ cells in MDS with monosomy 7 express increased proportions of G-CSFR isoform IV mRNA [161]. These data strongly suggest that pharmacologic doses of G-CSF increase the proportion of preexisiting monosomy 7 cells, rather than promote the malignant transformation of normal hematopoietic cells.

It is not yet clear whether G-CSF can directly contribute to the development of AML, but it has been suggested that the anti-apoptotic effect of G-CSF could rescue hematopoietic stem or progenitor cells which develop otherwise lethal mutations from chemotherapy. Rescue of these cells, which would otherwise die, might allow such cells to develop into myeloid malignancies [45].

The Future

The full benefits of HGFs have not yet been realized. Despite carefully crafted recommendations on their use, considerable variation in clinical practice exists. Concerns include their expense, inconvenience, and adverse effects. These concerns may be alleviated should ongoing basic work lead to the development of oral agents which stimulate hematopoiesis.

Bleeding and Thrombosis in Hematologic Neoplasia

59

Joseph J. Shatzel, Robyn Scherber, and Thomas G. DeLoughery

Leukemia and the Myelodysplastic Syndromes

Coagulation Defects

While both bleeding and thrombosis are associated with multiple types of leukemia and their treatment, acute promyelocytic leukemia (APL) is the leukemia classically associated with coagulation defects with evidence of disseminated intravascular coagulation (DIC) occurring in a majority of patients. The pathogenesis and therapy of coagulation defects are discussed separately in Chap. 23.

APL aside, clinically overt DIC is evident in up to a third of patients with other forms of acute leukemia, which may be present at diagnosis or manifest shortly after beginning treatment [1]. Patients with myeloid leukemia who present with higher peripheral blast counts appear to be at higher risk perhaps because of the propensity of myelomonocyte and monocytic leukemia to present in this manner [2–4]. Within the various subtypes of myeloid leukemia, the monocytic phenotype (M5 in the FAB classification) appears to have the highest incidence of DIC, with about 25% of patients having intravascular coagulation during their care [5–7], and about 50% having evidence of coagulopathy including increased D-dimer, thrombin-antithrombin III-complexes, low fibrinogen, low α2-PI plasma complex levels, or elevated elastase-α1 antitrypsin complexes [5, 7, 8]. DIC has also been reported in chronic myelocytic leukemia (CML), both with and without blast crisis [9–11] and in acute lymphocytic leukemia, especially of the T-cell type; however, it occurs far less commonly than in acute myeloid leukemia (AML) and its variants [9, 12, 13]. Biochemical markers of DIC have been found in many patients with acute lymphoid leukemia (ALL) including elastase-α1-antitrypsin complexes and rapid fibrinogen turnover [14]. When studied prospectively, DIC was seen in 12% of patients with ALL before chemotherapy, which rose to as high as 78% during chemotherapy [15].

A study evaluating the expression of markers of coagulation in AML patients has suggested that exaggerated tissue factor expression and circulating plasma microparticles may be the triggering source of DIC once sufficient levels are achieved [16, 17]. Additional non-tissue factor pathways including the shedding of cell free DNA likely contribute as well [16, 17] in APL specifically, a combination of tissue factor, cancer procoagulant, and microparticles are all produced by the malignant clone [18]. Thrombin generation is augmented in vitro as APL cancer cell lines cells undergo apoptosis, correlating with the clinical experience that DIC initially worsens with treatment of the leukemia [15, 18, 19]. APL cells also express aberrant levels of annexin II, which greatly augments the generation of plasmin by nearly 60-fold [20]. It is unknown if these mechanisms are important in coagulopathies of other forms of leukemia.

Life-threatening hemorrhage does occasionally occur in acute leukemia. Thrombocytopenia, anemia, DIC, and other coagulation defects common to acute leukemia likely contribute to the significant incidence of bleeding. A high incidence of subdural hematomas specifically has been reported in patients with monocytic leukemia, perhaps reflective of the incidence of intravascular coagulation and leukostasis [21, 22] large series of leukemia patients as a whole report that up to 7% will develop clinically significant hemorrhage [23]. Series specific to APL note a 5% incidence of fatal hemorrhage [24]. Hemorrhagic death in APL is most often attributed to cerebral (65%) or pulmonary (35%) hemorrhage [18, 25]. APL patients with a high blast count at diagnosis are more likely to have significant bleeding [26].

Clinically, thrombosis is also a common complication in leukemic patients during their initial hospitalization after diagnosis. A large observational study analyzing the incidence of thromboembolic disease in leukemic patients found a cumulative incidence of 19% in the first 3 months after diagnosis [27]. The risk significantly dissipates after the first 3 months. A similar pattern was found in ALL patients, but with a much lower incidence of 11% in the first 3 months. Certain chemotherapeutic protocols substantially increase the risk of thrombosis as outlined later in this chapter [15].

Subclinical intravascular clotting may be common in acute leukemia. Increased levels of fibrinopeptide A or D-dimer levels reflect activation of thrombin which promote fibrin generation and consumption of coagulations factors, while decreased levels of alpha 2-antiplasmin reflect heighten fibrinolysis which can lead to bleeding. These findings are often encountered in patients with acute leukemia without overt DIC before treatment, and can promptly rise after institution of cytotoxic chemotherapy [28–30]. Decreased levels of protein C and antithrombin III and elevated levels of thrombin-antithrombin complexes have been reported as well in patients with newly diagnosed myeloid leukemia [30]. These markers of coagulation often return to normal with achievement of remission, and in a few instances, rising levels predicted relapse [31].

Several other coagulation abnormalities have been reported in leukemia, including low factor V levels in Philadelphia chromosome-positive CML in children [32], and a decrease in the thrombin-sensitive subunit of factor XIII in a patient with acute leukemia and DIC [32, 33]. One report documented the secretion of two types of plasminogen activators by human myeloid leukemia cells in vitro [34]. The quantity or type of plasminogen activator that was secreted by these leukemic cells could not be correlated with either bleeding or the clinical severity of the disease. Another study suggested that leukemic cells that lacked cell-associated procoagulant activity can still incite a coagulopathy via the release of IL-1, a potent stimulator of endothelial tissue factor synthesis and inhibitor of thrombomodulin, an essential cofactor for the activation of protein C [35].

The most effective method to treat DIC is to treat the underlying leukemia but one must be prepared for an exacerbation of the DIC when tumor lysis occurs. The basic tests of coagulation should be obtained at least daily and more often if potentially clinically significant coagulation defects develop, using the results of these test guides one in replacement therapy of DIC (Table 59.1). Past concerns about “feeding the fires” have not been shown to be clinically valid and one should strive to maintain hemostatic competence to avoid severe bleeding [36–38]. Keeping the fibrinogen level over 150 mg/dL via the use of cryoprecipitate transfusions is reasonable in the leukemic patient with DIC [39]. Plasma replacement may be needed to correct multiple factor deficiencies [40]. A practical goal is to decrease the aPTT to less than 1.5 times normal if possible [39]. Heparin therapy is rarely used for the leukemia patient with DIC, and there is little evidence suggesting it offers a benefit. In APL specifically, early initiation of all trans retinoic acid (ATRA) is imperative to decrease bleeding risks, and should be considered even before molecular confirmation if APL is suspected [41]. Many authors advocate for platelet transfusion early in APL to increase levels >50,000/μL to prevent bleeding [39]. Some have suggested recombinant human soluble thrombomodulin as a potential treatment option, although current studies are limited to in vitro analysis [18].

Table 59.1 Management of disseminated intravascular coagulation

Tests to perform to assess hemostasis
1. Hematocrit
2. Platelet count
3. Prothrombin time
4. Activated partial thromboplastin time
5. Fibrinogen level
Therapy based on test results
(a) Platelets <50–75,000/μL—Give platelet concentrates or 6–8 pack of single donor platelets
(b) Fibrinogen <150mg/dL—Give 10 units of cryoprecipitate
(c) Hematocrit below 30%—Give red cells
(d) Protime >INR 2.0 and aPTT abnormal give 2–4 units of FFP

Platelet Defects

Studies of platelet function in patients with acute leukemia have been difficult because severe thrombocytopenia is often present. However, platelets from patients with acute myelocytic leukemia show abnormalities in size and granulation on light microscopy, as well as marked variations in granular content, disturbances of microtubule function, and striking dilatation of the open canalicular system by electron microscopy [42, 43]. Flow cytometry studies can show a population of platelets with loss of platelet activation markers [44]. Some investigators believe that they can distinguish two populations of cells—a normal population and a second “leukemic” population, showing marked variations in size, shape and granular structure [43].

Platelet function in acute leukemia has been shown to be abnormal, with defects of platelet aggregation in response to epinephrine, ADP, and collagen, as well as a lack of storage granules and impaired platelet factor III release [42, 45–47]. Patients with AML have significantly less in vivo platelet activation than patients with immune thrombocytopenic purpura (ITP) for instance [48]. Platelet function and morphology usually return to normal after a complete remission has been attained. The etiology of the platelet dysfunction has not been clearly defined but is most likely attributable to disease-induced abnormalities in the megakaryocyte. Alternatively, some platelets may undergo the release reaction within the circulation and thereby have deficient storage pool ADP and other morphologic changes [42].

Studies of platelet morphology and function in the various myelodysplastic syndromes (MDS) have found abnormalities similar to those reported in acute leukemia and the chronic myeloproliferative diseases. In many cases, megakaryocytes are normal to moderately increased in number in the marrow, are quite small, and have decreased nuclear "ploidy" with abnormal cytoplasmic granulation [43, 49]. As in acute leukemia, the platelets show numerous changes on electron microscopy, including unusual giant granules, lack of microtubules, and a dilated open canalicular system [42, 50]. A variety of platelet function defects have been described, but impaired platelet aggregation and a variably increased bleeding time are most prevalent [51, 52]. In one study 75% of MDS patients demonstrated reduced platelet aggregation with epinephrine, followed by decreased PA with arachidonic acid (54%), ADP (46%), collagen (43%), and ristocetin (22%) [53]. Abnormalities of platelet function occur in acute megakaryocytic leukemia including defects in platelet aggregation ex vivo but these are poorly related to clinical bleeding [54–58]. Platelet dysfunction and thrombocytosis has also been reported in refractory anemias or MDS associated with deletion of chromosome 5q or chromosome 3 [59–61].

Hairy Cell Leukemia

Hairy cell leukemia can lead to both quantitative and qualitative platelet defects. The platelet count in hairy cell leukemia is usually low, due to marrow infiltration with lymphocytes, or hypersplenism and the platelets often show abnormal aggregation to epinephrine, ADP, and sometimes collagen [62–64]. Furthermore, the granular content of ADP and serotonin is decreased, the release of ADP may be impaired, and prostaglandin synthesis may be inhibited [65]. On electron microscopy, the platelets are virtually agranular and show a dilated open canalicular system [65]. Several reports indicate that most of the platelet function defects and abnormal morphology return to normal after splenectomy [63, 65]. The mechanisms for these changes are unknown, but it has been postulated that these platelets undergo activation in the spleen and then recirculate with an acquired storage pool deficiency (i.e., "exhausted" platelets) [65]. While rates of bleeding associated with these platelet defects are not well described, spontaneous splenic ruptures have been rarely reported [66, 67].

Myeloproliferative Neoplasms

The myeloproliferative neoplasms (MPNs) which includes essential thrombocythemia (ET), polycythemia vera (PV), primary myelofibrosis (PMF), (previously known as agnogenic myeloid metaplasia or chronic idiopathic myelofibrosis), and chronic myelocytic leukemia (CML) are clonal disorders characterized by an expansion of the myeloid precursors in the marrow and blood, along with splenomegaly. All of these disorders are associated with thrombocytosis, and, with the notable exception of CML, commonly provoke bleeding or thrombosis. The diagnosis of PV and many cases of ET can now be made much earlier with the advent of the testing for common genetic mutations including JAK2, Calreticulin (CALR) and of the thrombopoietin receptor (myeloproliferative leukemia, MPL). The most common JAK2 mutation is *JAK2*V617F, which leads to the deregulated and constitutive activation of a tyrosine kinase that promotes myeloid precursor proliferation. This mutation is present in approximately 98% of PV patients, 50% of ET patients, and 60% of MF patients. CALR is a calcium binding protein which has been found to induce thrombopoietin-independent growth when mutated and induce downstream *JAK2* pathway activation [68]. CALR is present in approximately 30% of ET and MF patients and *MPL* in 3–7% of ET and MF patients, respectively. The diagnosis of PV and ET was previously made via endogenous erythroid colony assays, but now can be readily secured via peripheral blood or bone marrow genetic testing [69–71]. For patients who do not have a clonal marker of their MPN ("triple negative" MPN), there are clinical criteria that allow for diagnosis [72].

Bleeding and Thrombosis

Excessive bleeding occurs frequently in patients with PV, ET, and PMF and is usually due to both qualitative and quantitative abnormalities in platelet function and number [73, 74]. The incidence of hemorrhage is difficult to quantitate because the frequency can vary relative to the underlying disease process, stage of disease, age, and the presence of comorbid conditions. Hemorrhage is more common in PMF, which is felt to be a result of the thrombocytopenia, qualitative platelet defects, or even DIC [75]. Overall, about 25–30% of patients will have bleeding, in 5% it will be severe, but it will be fatal in less than 1% [76–84]. Symptoms are usually limited to easy bruisability or epistaxis, but gastrointestinal bleeding seems particularly common in PV.

Thrombosis occurs more frequently in PV and ET than in CML, and is a major cause of morbidity and mortality in patients with myeloproliferative neoplasm. Accordingly, reducing thrombotic complications associated with disease remains central therapeutic goal when considering treatment. A recent report highlights that thrombosis is present in 12% of ET patients evaluated, which included arterial (79/109) and venous (37/109) thrombosis [85]. As demonstrated in this and previous studies, arterial occlusion tends to be most common, followed by venous thromboembolism, and then microvascular thrombosis (digital skin necrosis, or

erythromelalgia) [73, 77, 79, 85–95]. The mechanism of underlying thrombophilia is diverse among these patients, consisting of a milieu of inflammatory cytokines, hyperviscosity, upregulation of endothelial adhesion receptors, acquired activated protein C (APC) resistance, overexpression of circulating procoagulant microparticles (MPs), and overall coagulopathic activity of the vascular endothelium. Platelets have been shown to have increased P-selectin and tissue factor [96].

The overall frequency of thrombosis is difficult to calculate, and underappreciated but it is more common than bleeding, and causes greater morbidity and mortality [74, 82]. At initial presentation, the reported incidence of thrombosis and bleeding in ET varied from 11–25% to 3.6–37%, respectively. The corresponding figures for PV were 12–39% and 1.7–20%. Factors that could have accounted for the relatively wide range of values include patient selection, definitions of events, accuracy in data reporting, and the effect of therapy. Cross-sectional studies suggest that approximately 30–40% of patients have thrombosis, and several large studies indicated that thrombotic complications occurred at approximately 3.4–8%/year [90, 94, 95, 97, 98]. The most common thromboses are cerebral vascular occlusion, deep venous thrombosis of the lower extremities, vascular occlusion of the digits, and particularly central abdominal thromboses (portal, hepatic, mesenteric vein). Increasing age, previous thrombosis, smoking, and a previous history of thrombosis predispose to thromboembolism in ET or PV [74, 99–103]. Splenomegaly has also been found to accompany a higher risk of thrombosis in ET [104]. Phlebotomy and elevated hematocrit add to thrombotic risk in PV. Guidelines now recommend a goal hematocrit less than 45% as this results in significantly lower mortality due to reduced thromboembolic events [105]. This correlation between thrombosis and elevated blood counts is not as clear for platelets. Overall, the elevated platelet count does not correlate with the risk of thrombosis for PV or ET [106, 107]. For example, some patients with very early MPN documented by molecular assays who have normal or near normal platelet counts can have repeated severe thromboses [107–110]. Others, for example, young women with platelet counts of more than 2,000,000/μL, often remain free of symptoms for many years. Several studies have showed that the majority of thrombotic complications occurred in individuals with platelet counts of less than 600,-800,000/μL suggesting factors other than platelet number account for the thrombosis risk [77, 107, 111, 112]. The role of leukocytosis as a risk factor for thrombosis remains controversial. Several studies suggest a WBC greater than 10,-15,000/μL may be a risk factor for thrombosis [99, 102] while other studies do not support this [113] or suggest it is not a risk factor for low risk patients [114].

The association between genetic mutations and thrombosis in the MPNs is still under investigation. CALR mutations, which are found almost exclusively in ET and PMF, tend on average result in lower thrombotic risk, although this correlation is most noticeable in type I (52-bp deletion) CALR mutations than in type II (5-bp TTGTC insertion) mutations [115]. ET patients with the JAK2 mutations have a double risk of thrombosis compared to non-carriers [116] and being homozygous for JAK2 mutations may further increase this risk [117–119]. The function of JAK2V617F in thrombotic risk is still under investigation, but can be attributed in part to changes in platelet function (i.e., elevated expression of p-selectin, increased platelet migratory ability, elevated erythropoietin signaling) and due to a direct effect on some non-hematopoietic cells such as liver endothelial cells in patients with Budd-Chiari [120–122].. MPL does not appear to be a risk factor for thrombosis [85]. Patients negative for mutations in JAK2, CALR, or MPL tended to have lower thrombotic risk [115].

MPN patients also have increased symptom burden compared to age-matched controls [123, 124]. Although MPNs have been found to have significant cytokine deregulation which contributes to symptom development, many symptoms can be a consequence of microvascular and large vessel thrombosis [125]. Erythromelalgia is a syndrome of painful toes and fingers associated with MPN. It is characterized by thrombocytosis and biopsy evidence of microvascular subendothelial vascular proliferation. In some cases, symptomatic platelet-mediated thromboses occur in the digits which can produce tissue ischemia and even gangrene [126, 127]. Erythromelalgia secondary to MPN often responds dramatically to low doses of aspirin [127, 128]. Headache is another common symptom that has been associated with platelet dysfunction, anemia, increased nitric oxide production, and microcirculatory disturbances. A trial of aspirin is recommended as first line treatment in MPN-associated headache. If the headache persists despite aspirin therapy, a combination of cytoreduction and aspirin is recommended [129]. Alternative symptoms that could be contributed to thrombosis include abdominal pain or discomfort (splanchnic vein thrombosis), sexual difficulties, cough, bone pain, and pruritus.

Mechanisms of Platelet Dysfunction

Sensitive tests of platelet function are frequently abnormal in chronic MPN, particularly PV, ET, and PMF. Tests of platelet reactivity correlate poorly with elevations of the platelet count or with syndromes of bleeding and thrombosis [130–133]. However, a rough relationship exists between a high circulating platelet count, impaired platelet function, and bleeding [76, 131, 134–137]. High platelet counts are also associated with increased platelet reactivity and vascular thrombosis, erythromelalgia, and peripheral gangrene [127, 128, 132, 138, 139]. Studies determining clonal status of patients with ET have demonstrated that there is a great deal

of heterogeneity in the presence of clonal disease [140]. Notably, there is clear evidence that clonal disease portends a higher risk of thrombosis [141–143].

Decreased Platelet Function

Platelet function has been examined in several series of patients with chronic MPN [51, 137, 144–152] (Table 59.2). Although abnormalities in tests of platelet function are quite common in vitro, the bleeding time is usually normal or, in about 20% of patients, mildly prolonged [137, 145, 146, 149, 151]. Rarely, the presenting clinical scenario is excessive bleeding and a markedly prolonged bleeding time, which is most often seen in patients with PMF [33]. The most common platelet function defect is abnormal platelet aggregation following the addition of collagen, ADP, or particularly epinephrine, to platelet rich plasma [137, 145, 146, 149, 151, 153, 154]. In most reports however, little correlations have been found between changes in platelet function, prolongation of the bleeding time, and clinically evident bleeding [51, 130, 147]. It should be noted that platelet aggregation testing is usually normal in patients with a reactive thrombocytosis, even if the platelet count exceeds 1,000,000/cmm [146].

A myriad of platelet function disorders have been discovered in patients with MPN. These include specific defects in the platelet membrane, the release of platelet coagulant activity, abnormal prostaglandin synthesis, and disordered platelet-dense granule composition and/or function. Platelet membrane abnormalities include the deficiency of several glycoproteins important for normal platelet aggregation [155, 156], increased numbers of platelet Fc receptors for immune complexes, or aggregated IgG [157], and prostaglandin D_2 or thromboxane A_2 receptor numbers and/or function [158].

Platelet prostaglandin synthesis has been shown to be inhibited, with decreased production of thromboxane A_2 after stimulation of the arachidonic acid pathway [155, 159]. Defects in lipoxygenase activity has been reported [160] as well as reduced platelet generation of lipoxin [161]. Finally, patients have been reported with decreased numbers of dense granules in their platelets, as visualized by electron microscopy. A reduction in dense granule content has been correlated with prolongation of the bleeding time [148, 162, 163]. Decreased alpha granule content has also been described [164, 165]. Other defects include the inability of stimulated platelets to expose procoagulant phospholipid despite normal membrane phospholipid composition [73, 137, 166].

Finally, patients with very high platelet counts (greater than one million) can have acquired von Willebrand's disease demonstrated by reduced ristocetin cofactor activity despite normal plasma levels of von Willebrand antigen and factor VIII coagulant activity [167–169]. The decreased plasma von Willebrand factor activity may be due to accelerated proteolysis of von Willebrand factor after its release from endothelial cells or uptake of the high molecular weight multimers by the increased number of platelets.

Table 59.2 Abnormalities in myeloproliferative neoplasms leading to thrombosis

Acquired activated protein C resistance
Hyperviscosity
Increase circulating microparticles
Increased platelet P-selectin and tissue factor expression
Inflammatory cytokines
Prothrombotic endothelium
Upregulation of adhesion proteins

Increased Platelet Activity

Several studies have identified platelet "hyperreactivity" in patients with MPN [138, 145, 149–151, 154, 170–173] (Table 59.3). A variety of tests to assess platelet reactivity has been used including the spontaneous platelet aggregation during ex vivo testing, increased plasma level of the platelet specific protein β-thromboglobulin, decreased circulating platelet aggregate ratios, platelet phospholipid-dependent thrombin generation, and increased platelet responsiveness to inhibitory prostaglandins. Although in some reports there appeared to be a correlation between increased platelet function and vascular thrombosis, it is not possible to predict clinical thrombotic events with the use of these assays.

Several investigators have measured levels of platelet specific proteins (platelet factor 4, β-thromboglobulin, or platelet derived growth factor) in patients with MPN. Platelet concentrations of these proteins were reduced, whereas plasma and urinary levels were increased [103, 174–177].

Table 59.3 Platelet abnormalities in myeloproliferative neoplasms

Decrease platelet function
Abnormal platelet aggregation
Abnormal prostaglandin synthesis
Decrease number and function of prostaglandin D_2 and thromboxane A_2 receptors
Decreased platelet procoagulant activity
Impaired platelet function
Increased platelet Fc receptors
Platelet dense granule function and composition
Platelet membrane defects
Increased platelet function
Increase platelet β-thromboglobulin
Increased expression of platelet activation markers
Increased platelet thrombin generation
Spontaneous platelet aggregation

These findings suggest that intravascular platelet activation occurred, which could explain platelet-mediated thrombosis or marrow fibrosis [96, 103, 175, 178]. Consistent with this idea is the findings that patients with increase expression of platelet activation markers have increased risk of thrombosis [173, 179, 180].

Other Laboratory Tests of Thrombophilia

Increase levels of homocystine have been reported in patients with MPN but have not correlated with thrombosis [181–183]. A thrombin generation assay to assess parameters of hypercoagulability in MPN patients indicates the presence of acquired APC resistance in ET and PV patients, which is likely a result of a reduction in free PS levels and that the APC-resistant phenotype is influenced by the JAK2 mutational load [184].

Given that MPN are clonal diseases it may be that other cell lines are contributing to the thrombophilia. Multiple studies have demonstrated the following parameters of blood cell and coagulation activation associated with thrombosis in the myeloproliferative neoplasms: increased percentage of platelets that expressed P-selectin, overexpression of the CD11b antigen on monocytes and neutrophils, increased platelet-neutrophil complexes, increased tissue factor after polysaccharide activation in monocytes, and increased reticulated platelets [179, 184–186]. One study demonstrated increased monocyte generation of tissue factor that was linked with elevated levels of prothrombin F1.2 fragment [187]. Another study suggested that neutrophil activation is abnormally high in MPN and is associated with signs of increase coagulation [188]. An intriguing study showed that endothelial cells from patients with visceral vein thrombosis have the JAK2 mutation which may be altering their antithrombotic properties [189]. Thus, it may be an interplay between multiple cell lines that leads to the thrombosis seen in MPN.

Clinical Laboratory Tests

Laboratory tests such as the CBC, platelet count, bleeding time, and platelet aggregation studies are frequently abnormal in patients with MPN, but unfortunately they often fail to predict bleeding or thrombosis in individual patients. However, patients with PV and markedly elevated hematocrits are at substantial risk of thrombosis, and patients with PMF or others with very high platelet counts (more than 1,000,000/cmm) and markedly prolonged bleeding times are likely to have an increased risk of bleeding [190]. Aspirin and non-COX selective nonsteroidal anti-inflammatory drugs should be used with caution in the latter instance.

The JAK2 mutation can be positive in patients with normal or near normal peripheral blood counts and bone marrow morphology, particularly those with a history of arterial or venous thrombosis of unknown cause [88, 108, 191, 192]. The assay should be considered as part of a laboratory evaluation in patients with recurrent thrombosis (particularly arterial and central abdominal venous thrombosis) who don't have other hereditary or acquired hypercoagulable states. For example, in several studies over 30–50% of patients presenting with portal vein thrombosis were found to be JAK2 positive or have other markers of MPN [108, 191–193].

Therapeutic Considerations

Hemorrhage

Major bleeding complicating MPN can usually be managed with platelet transfusions to overcome disease-induced platelet function defects. In a few patients, particularly those with very high platelet counts, platelet transfusions will be ineffective. In these instances, therapeutic platelet apheresis with acute lowering of the platelet count followed by transfusion of normal platelets may temporarily improve hemostasis. Platelet reduction on a long-term basis with hydroxyurea or other therapeutic agents may decrease symptoms of bleeding. Finally, phlebotomy in patients with PV has been reported to improve platelet function tests and to decrease bleeding in some instances [164, 165].

Venous Thrombosis

Intravenous heparin followed by warfarin is indicated for most patients with acute venous thromboembolism complicating the myeloproliferative disorders. Thrombolytic therapy should be considered in patients who have acute occlusion of the hepatic or portal veins. Long-term oral anticoagulants (INR 2–3) are usually recommended for prevention of recurrent thromboses. In a few instances, liver transplantation has been successful in treating liver failure due to Budd-Chiari syndrome [194, 195]. A key to long-term success is aggressive anticoagulation posttransplantation.

Arterial and Microvascular Thrombosis

Antiplatelet therapy, usually with aspirin, is recommended for treatment of patients with cerebral, coronary artery, or peripheral vascular thrombosis. Platelet inhibitors usually suppress the platelet hyperreactivity associated with MPN and can increase the usually shortened mean platelet survival time [196]. Low doses of aspirin (80–360 mg/day) are preferable in patients with MPN because the risk of bleeding with aspirin is dose-related.

One study using 100 mg/day appeared to be effective for preventing thrombosis without excessive bleeding as long as the platelet count was kept at under 1,000,000/μL [197]. Another study randomized 518 asymptomatic, low thrombotic risk, PV patients to treatment with low-dose aspirin (100 mg daily) versus placebo and found that aspirin significantly lowered the risk of cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, and major venous thromboembolism (relative risk 0.4 [95% CI 0.18–0.91]; $P = 0.028$). Total and cardiovascular mortality were also reduced by 46% and 59%, respectively. Major bleeding was only slightly increased by aspirin (relative risk 1.6, 95% CI 0.27–9.71). However, some large population trials have indicated no increased bleeding risk with aspirin use [85]. Given these results, low-dose aspirin (75–100 mg daily) is recommended in all PV patients without history of major bleeding or gastric intolerance [198, 199]. Patients with very high platelet counts should have Von Willebrant testing before starting aspirin [200].

Microvascular disease such as erythromelalgia or digital gangrene often responds dramatically to antiplatelet therapy [197]. In addition to its antithrombotic effects, aspirin may also inhibit platelet secretion of vascular growth factors and thereby reduce chronic vascular damage [201]. There is currently no data concerning the use of newer agents such as clopidogrel but these may be worth trying if the patient is aspirin intolerant.

A few patients will develop serious recurrent thromboembolic events despite treatment with aspirin. In such cases, combined anticoagulation (INR 2–3) and antiplatelet therapy should be considered [202]. The likelihood of bleeding will be increased, but the risks might be warranted in some patients. Careful monitoring will be required, particularly in patients known to have platelet dysfunction or a history of bleeding.

An even more difficult problem is whether to lower platelet counts or to give aspirin to patients with MPN who do not have a history of thrombosis. The evidence from the literature is conflicting; some studies suggest that young patients can tolerate very high platelet counts without major thrombosis, whereas others indicate that young as well as older patients remain at risk of thrombosis and bleeding [89, 203, 204]. Platelet reduction with hydroxyurea should be considered in asymptomatic older subjects with platelet counts over 1,000,000/μL, particularly if they have atherosclerosis, risk factors for arterial disease, or symptoms of vascular ischemia [205]. Also important is controlling reversible risk factors such as smoking or elevated cholesterol [206].

In addition to pharmacologic antithrombotic measures, lowering of elevated platelet counts should be considered in patients with MPN and a history of thrombosis. Hydroxyurea (1 g daily to start) is preferable to radioactive phosphorous or alkylating agents because of a lesser risk of leukemogenesis. A platelet count of 250–450,000/μL is an appropriate target. A randomized trial of high-risk patients (age over 60 or history of thrombosis) demonstrated that using hydroxyurea to maintain the platelet count less than 600,000 μL was associated with significantly less thrombosis (3.6 vs. 24%) [207]. Reduced thrombosis is felt to possibly be due to increased production of nitric oxide in vascular cells treated with hydroxyurea [208].

Anagrelide has also been used to lower platelet counts in MPN patients [209–211]. Unlike hydroxyurea clinical trial data exists to cast doubt on the efficacy of anagrelide in preventing thrombosis in high-risk patients. One long-term study of patients did demonstrate a 20% thrombosis rate in patients taking anagrelide [212]. However, platelet counts were above 400,000/μL in all patients who had thrombosis leaving unclear whether the agent would have been more successful at preventing thrombosis if the platelet counts were lower [213]. A more recent study compared hydroxyurea plus low-dose aspirin (100 mg daily) with anagrelide plus low-dose aspirin in 809 high-risk patients. Patients randomized to hydroxyurea and aspirin less likely experience major arterial or venous thrombosis, major hemorrhage, or death from a vascular cause ($P = 0.03$) [214].Additionally, anagrelide has also been associated with cardiovascular side effects and is not recommend for patients with a history of heart disease [212, 213]. Thus, hydroxyurea remains the first choice for lower platelet counts in high-risk patients.

Phase II studies have demonstrated that α-Interferon is effective in thrombophilic states, but its antithrombotic effect is unknown; moreover, its attendant side effect profile renders it difficult to utilize in the majority of patients [215–218].

Lastly, JAK2 inhibitors are progressively becoming a mainstay of therapy in the MPNs. Ruxolitinib, a JAK1/2 inhibitor, is currently FDA approved in the United States for the treatment of intermediate-2 and high-risk MF and PV patients who are intolerant or resistant to hydroxyurea [199, 219]. In a landmark study of ruxolitinib among PV patients, patients receiving ruxolitinib were noted to have fewer thrombotic events [220]. Further meta-analyses among MF and PV patients have indicated that there is indeed reduced thrombotic risk among ruxolitinib treated patients compared to patients receiving standard therapy [risk ratio 0.45, 95% confidence interval (CI) 0.23–0.88] [221]. One month following JAK2 inhibitors treatment, changes in thrombotic markers have been observed including decreased monocyte tissue factor expression, platelet monocyte aggregates, and neutrophil activation as well as increased monocyte count [222]. JAK2 inhibitors also have been found to reduce splenomegaly, which may also convey a reduction in MPN-associated SVT with portal hypertension along with the related sequelae of GI bleeding and thrombotic events.

Pregnancy

Although PV is rare to arise in pregnancy, an increasing challenge is the increase in number of young women with ET who become pregnant as they do tend to have a higher risk of

pregnancy-related complications, especially if they harbor the JAK2 mutation [223]. Interestingly, the platelet count often decreases during pregnancy, often to near normal levels lessening the need for cytoreductive therapy [224, 225]. The most common adverse event is an increase in miscarriages due to placental infarction [225–227]. Additionally, ET and PV are associated with increased risk of preeclampsia, fetal growth restriction, and maternal thrombosis and bleeding [228]. Due to the physiologic decrease in platelet count during pregnancy and concerns about fetal health, cytoreduction therapy should be avoided if possible. Most data now supports the use of aspirin throughout the pregnancy to prevent miscarriages and thrombosis. Women with a previous history of thrombosis should be therapeutically anticoagulated with low molecular weight heparin to prevent recurrence. If platelet lowering is required, interferon is the safest option but there is increasing data from sickle cell patients that hydroxyurea can be safely use starting in the second trimester [225, 229–232].

Paroxysmal Nocturnal Hemoglobinuria (PNH)

PNH is a clonal hematopoietic disorder characterized by complement mediated hemolysis and often some degree of bone marrow dysfunction [233]. The leading cause of morbidity and mortality in PNH is thrombosis, which some have described as the most vicious acquired thrombotic state in medicine [234–236]. Thrombosis accounts for 40–67% of the mortality in PNH [236]. 29 to 44% of patient will have a thrombosis during the course of their therapy [236]. Patients can present with thrombosis at any site (both venous and arterial), with a predilection for unusual sites. Up to 19% of patient may have a visceral vein thrombosis at the time of diagnosis [237]. Budd Chiari is rare, but has a strong association with PNH with up to 19% of Budd Chiari patients eventually diagnosed with PNH [238]. Thrombosis risk correlates with the size of the aberrant clone, but even patients with small clones <10% still have a significantly increased risk of thrombosis [236, 239]. The cause of the hypercoagulable state is not fully understood, but complement activated platelets are the likely driver, along with complement activated neutrophils [240–242]. Other likely causes include hemolysis driven events including toxicity from free hemoglobin, decreased nitric oxide, and release of procoagulant red cell microparticles, all of which may contribute to prothrombotic endothelial dysfunction [236].

A treatment for PNH is the complement inhibitor eculizumab, a humanized monoclonal antibody which targets complement protein C5, thereby preventing assembly of the terminal complement complex during complement activation. In studies, treatment with eculizumab has been shown to reduce hemolysis, as well as improve anemia, fatigue, and quality of life in patients with PNH [243]. Additionally, eculizumab has demonstrated efficacy in reducing thrombosis. In an aggregate review of rates of thromboembolism in three major clinical trials, the event rate with eculizumab treatment was 1.07 events/100 patient-years compared with 7.37 events/100 patient-years ($P < .001$) prior to eculizumab treatment (relative reduction, 85%; absolute reduction, 6.3 TE events/100 patient-years) [244].

Patients presenting with acute thrombosis should receive immediate anticoagulation, and this should be continued indefinitely. If not already on eculizumab, this agent should be started. Studies are underway to see if use of eculizumab therapy may allow cession of anticoagulation. In the past breakthrough thrombosis does occur even in patients on anticoagulation but as noted above this is rarely seen in the eculizumab era [239, 245].

Abnormal Proteins

Dysproteinemias

Although uncommon, defects in coagulation and platelet function may pose serious problems in the management of patients with dysproteinemias secondary to multiple myeloma, lymphoplasmacytic lymphoma, and rarely other B-cell disorders which can produce paraproteins [246, 247]. Paraproteinemia at high enough levels can cause pathologic interactions with coagulation factors, platelets and vascular endothelium which can lead to abnormal hemostasis test results, and rarely both bleeding diathesis and thrombosis [248].

Bleeding symptoms seem to be more frequent with IgM and IgA paraproteins, in dysproteinemias associated with κ rather than λ light chains, and in patients with total protein concentrations greater than 8 g/dL or serum viscosities greater than 5 [249, 250]. These correlations may reflect larger size or amount of paraproteins disrupting coagulation factor and platelet function. Patients with prolonged bleeding times and decreased platelet adhesiveness also are at a higher risk of hemorrhage than those with normal platelet function [250]. While rates of bleeding are lower with myeloma, at presentation up to 17% of patients with lymphoplasmacytic lymphoma may have bleeding complications [251, 252].

Multiple hemostatic abnormalities have been described in patients with dysproteinemias (Table 59.4). First, the physical structure of the fibrin clot may be abnormal, owing to increased serum globulins. Electron microscopy often shows an amorphous collection of proteins covering the fibrin strands, producing clots more gelatinous and susceptible to local fibrinolytic enzymes than normal [253]. Clot retraction is absent in some patients with a dysproteinemia because the abnormal protein prevents the attachment of platelet pseudopods to one another or to fibrin strands [253].

Table 59.4 Abnormalities of coagulation in myeloma and amyloid

Abnormally low clot retraction
Abnormally low and weak fibrin clot
Anti-glycoprotein IIb/IIIa antibodies leading to platelet dysfunction
Factor VIII inhibitor leading to low factor VIII levels
Factor X deficiency (amyloid)
Heparin-like anticoagulant
Impaired fibrin polymerization leading to poor thrombus formation
Inhibition of thrombin time indicative of impaired fibrin formation
Systemic fibrinolysis (amyloid)

Polymerization of fibrin is also impaired in some patients with circulating λ light chains, which is suggested by prolonged thrombin and reptilase times [254]. Myeloma proteins have also been shown to inhibit the thrombin time of normal plasma [254, 255]. More detailed studies have demonstrated that the antibody-binding portion of the myeloma protein, rather than the heavy chain, is involved in the inhibition of α-chain polymerization of fibrinogen [254]. The receptor for factor XIIIa (Also known as fibrin stabilizing factor) on fibrin strands can be blocked by an abnormal paraproteins leading to increased circulating level of factor XIII [256, 257]. Lastly, some patients with plasma cell leukemia have a potent heparin-like anticoagulant that produces very severe and often fatal bleeding (as discussed later in this chapter) [258].

Platelet abnormalities are less well defined in patients with myeloma and macroglobulinemia, although prolonged bleeding times and abnormal platelet adhesiveness have been described [250, 259]. The proposed mechanism is coating of platelets by immunoglobulins in a nonspecific fashion [252]. In one instance, a purified IgG_1-κ paraprotein was shown to bind to platelet glycoprotein IIIa inhibiting platelet aggregation and provoking a severe bleeding disorder [260].

An often overlooked and rare cause of bleeding is an acquired von Willebrand disease (VWD) which can occur with paraproteinemia [252, 261]. Over 450 cases of acquired VWD have been reported, likely being generated through a variety of different mechanisms, with a majority associated with paraproteinemia from a malignancy or monoclonal gammopathy of unknown significance (MGUS) [262]. Patients often present with laboratory findings similar to type 2A VWD including abnormal bleeding times, markedly reduced von Willebrand factor (VWF) activity, decreased VWF activity-antigen ratio, absence of large multimers, and normal plasma concentrations of VWF propeptide [263, 264]. VWF autoantibodies can rarely be detected with mixing studies, although laboratory analysis of these antibodies ifs difficult and it is unclear if this is the paraprotein itself or an associated secondary antibody [252, 265]. Acquired VWD is discussed more in detail later in this chapter.

Therapy for the hemostatic defects in the dysproteinemic syndromes include removal of the offending protein, either by reducing synthesis by treating the plasma cell dyscrasia or by intensive plasmapheresis. In several patients, return of normal hemostasis correlated with a substantial reduction in the paraprotein spike in the serum [250, 266].

Increasingly there is evidence that dysproteinemia are associated with an increased risk for thromboses as well. There are scattered case reports of paraproteins with lupus anticoagulant activity associated leading to deep venous thrombosis [267]. Inhibitors leading to acquired protein S and protein C deficiency have been reported [268, 269]. Acquired protein C resistance may be relatively common in multiple myeloma, and has been correlated to thrombotic risk [270]. Observational studies suggest that dysproteinemias irrespective of malignancy may be a common risk factor for thrombosis. Several studies have indicated that MGUS can be associated with a 2–3-fold risk of thrombosis, both arterial and venous [271, 272].

Amyloidosis

Patients with systemic amyloidosis, either primary or associated with myeloma show a marked increase in easy bruisability and other bleeding symptoms [273]. Abnormal coagulation testing is common in patients with amyloidosis with an elevated in thrombin time seen in 30–80% of cases, increased prothrombin time (PT) in 17–24%, and an increased partial thromboplastin time (aPTT) in 70% [274, 275]. Factor X deficiency was first reported to be associated with amyloidosis in 1962; subsequent studies have shown that the clotting factor is adsorbed onto amyloid proteins [247, 276, 277]. Splenectomy, plasmapheresis, and treatment with high-dose chemotherapy and auto stem cell transplant have all been reported to reduce the amyloid burden and to increase the levels of factor X [277–279]. Many of the bleeding symptoms from amyloidosis are also due to amyloid infiltration of blood vessels, rather than to coagulation or platelet defects [273]. Consistent with this idea is a study of 60 patients with factor X levels <50%, only line placement was associated with bleeding [280]. An observation study of 368 individuals with systemic AL amyloidosis found that 8.7% had factor X levels below 50% [277]. Another large case series at another institute reported a 14% incidence of low factor X with 5% of patients having levels below 20% [274].

Two other hemostatic defects have been reported to complicate primary amyloidosis. In one instance, circulating Bence-Jones protein formed complexes with plasma fibrinogen and interfered with the polymerization of fibrin monomer as evidenced by a prolonged thrombin time [281]. This, along with similar mechanisms as outlined in the section on dysproteinemia, may explain why abnormal thrombin and reptilase times are found in up to 30% of patients [274]. In another report, a circulating inhibitor to factor VIII was found to be an IgA-κ monoclonal protein similar in structure to the amyloid subunit protein [282].

Yet another cause of bleeding in patients with systemic amyloidosis is systemic fibrino(geno)lysis [283–286]. The euglobulin clot lysis time is shortened with striking decreases in α_2-PI, plasminogen, and circulating plasmin-antiplasmin complexes. Some patients have also been reported to have elevated plasma levels of tissue-type plasminogen activator, which can normalize with treatment of the amyloidosis [285, 287–289]. One small study found that more than 90% of bone marrow plasma cells from five different AL-amyloidosis patients were positive for a urokinase type-plasminogen activator by immunohistochemical staining [286]. The complete mechanisms responsible for the fibrinolytic state are not known is likely due to increased release of plasminogen activators or decreased plasminogen activator inhibitors from blood vessels infiltrated with amyloid, decreased α_2-PI because of its adsorption onto amyloid fibrils, or perhaps amyloid associated liver disease. The use of fibrinolytic inhibitors such as EACA or tranexamic acid have both corrected laboratory tests of fibrinolysis and reduced bleeding symptoms [289].

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) is not commonly associated with hematologic neoplasms, but has been reported in 2–4% chronic lymphocytic leukemia, and in approximately 2% of patients with Hodgkin's disease, but are less commonly seen as a complication of non-Hodgkin's lymphoma. ITP is known to predate the onset of Hodgkin's disease, to occur at the time of diagnosis, to indicate a recurrence (within the spleen), or to develop in disease-free individuals long after they have been considered cured [290–294].

The presentation of ITP in patients with lymphoproliferative diseases is usually not different than sporadic cases of ITP and is associated with decreased platelet survival and elevated levels of platelet associated IgG [294–297]. Why ITP occurs concurrently with some lymphoproliferative disorders is not well understood, although a disturbed immune system could possibly predispose patients both to the lymphoproliferative disorder and to thrombocytopenia [298, 299]. Rare cases of acquired Glanzmann thrombasthenia have been reported with Hodgkin's disease and other lymphoproliferative disorders [300, 301]. Acquired thrombasthenia should be considered when bleeding appears to be out of proportion to the decrease in platelet count.

Therapy for the ITP that complicates Hodgkin's disease or chronic lymphocytic leukemia does not differ from that for classic immune thrombocytopenia, and often overlaps with treatment of the lymphoproliferative disorder [302–305]. High-dose corticosteroids such as pulse dexamethasone 40 mg/day × 4 days, and intravenous immunoglobulins (IVIg) are generally given first [306]. For patients with presumed, but as yet undiagnosed lymphoma, steroids should be avoided if possible, until an adequate biopsy is obtained for diagnosis. If an adequate platelet count cannot be maintained and bleeding is present splenectomy can be considered. Rituximab therapy alone may be effective enough such that splenectomy can be avoided in certain patients, especially those whose comorbidities make splenectomy risky [306–308]. In the past if removal of the spleen failed to increase the platelet count, immunosuppressive therapy with vincristine, azathioprine, or pulse cyclophosphamide was tried [309, 310]. However, more recent clinical trials show a high rate of success with the thrombopoietin agonists romiplostim and eltrombopag and use of these agents should be considered as the next line of therapy [311, 312].

A search for recurrent Hodgkin's disease should be considered in patients who develop ITP after successful remission is obtained with chemotherapy. ITP does occur in the absence of lymphoma relapse, but caution must be used to ensure no active relapsed lymphoma is present before initiating steroids or chemotherapy which may alter the sensitivity of pathologic evaluation. ITP has even occurred in patients with Hodgkin's disease who have had splenectomy or who were receiving intensive immunosuppressive therapy [291, 298, 313–315].

Acquired von Willebrand Disease and Other Coagulation Inhibitors

Acquired von Willebrand disease (VWD) can complicate lymphomas, myeloproliferative syndromes, myeloma, and monoclonal gammopathies [252, 261, 263, 265, 316, 317]. The most common presentations include diffuse oozing from surgical sites, epistaxis, or gastrointestinal bleeding [318]. Patients with acquired VWD can present as type 1 (decreased protein) or type 2 (abnormal multimers) disease which can be)differentiated via crossed-immunoelectrophoresis [265, 319]. Levels of factor VIII, ristocetin cofactor activity, and von Willebrand antigen are all decreased [265]. Platelet levels of VWF are normal, suggesting depletion of circulating VWF from the plasma.

There are several mechanisms that are through to lead to acquired VWD. The first is the presence of circulating autoantibody against the VWF which can either produce increased VWF clearance [320], or interfere with platelet or collagen binding [265, 321, 322]. The second mechanism is increase absorption of the protein onto abnormal lymphoid cells or platelets in the setting of thrombocytosis [323–326]. For example, a case report demonstrated the aberrant expression of glycoprotein Ib by a marginal zone lymphoma results in acquired VWD [327]. Lastly, increased proteolysis of the von Willebrand proteins has been reported, especially in myeloproliferative disorders [167–169].

Patients with acquired VWD have variable responses to therapy. Therapeutic measures have included infusions of cryoprecipitate or concentrates containing vWF, DDAVP, plasma exchange, intravenous immunoglobulin, or splenectomy (when VWF was shown to bind to the abnormal lymphocytes) [167, 265, 324, 328, 329]. Desmopressin is effective at controlling bleeding in many patients with acquired VWD type 1 and 2, but often has subpar effect at control of bleeding in patients with associated myeloproliferative (21% success rate), or lymphoproliferative (44% success rate) disorders [330]. VWF levels should be checked with therapy. High-dose intravenous immune globulin (1 g/kg) is also effective in reversing acquired VWD by decreasing antibody levels, especially if associated with IgG monoclonal gammopathies, except for those with IgM paraproteins [331, 332]. For patients with significant bleeding, high doses of Humate-P are indicated with frequent monitoring of factor VIII levels [331]. A large series of patients with acquired VWD has suggested the use of recombinant factor VIIa to be effective when other measures had failed [333, 334]. Whenever possible, treatment of the underlying condition should also be undertaken. Cytoreduction, for instance, has been shown to cause remission of acquired VWD in patient with myeloproliferative disorders [335].

Rarely in patients with lymphoproliferative disease, acquired factor VIII inhibitors have been reported [282, 336, 337]. An inhibitor to prothrombin that accelerated clearance of the protein has also been reported [338]. An antibody directed against thrombin has also been reported in a myeloma patient with plasmapheresis being effective in reducing bleeding [339].

Finally, circulating coagulation inhibitors with heparin-like properties have been described in patients with multiple myeloma and other neoplasms [340–343]. These patients present with very severe bleeding along with elevated aPTT's, and thrombin times, but a normal reptilase time. The disease is caused by circulating proteoglycan similar to heparin. This proteoglycan has antithrombin enhancing activity, and can be blocked by protamine sulfate, platelet factor 4, or toluidine blue in vitro [340, 342, 343]. These heparin-like anticoagulants regularly cause severe and unrelenting bleeding which is often fatal. Therapy is difficult but has included intensive chemotherapy to reduce the malignant cell burden, plasmapheresis to remove the anticoagulant, and intravenous protamine sulfate [343].

Therapy-Induced Bleeding and Thrombosis

L-Asparaginase

L-Asparaginase is an enzyme from bacteria that catalyzes the hydrolysis of asparagine, an amino acid required by leukemic, but not normal cells. When used as a chemotherapeutic agent, it has a number of side effects, including hypersensitivity reactions, pancreatitis, liver insufficiency with decreased protein synthesis, neuropathy, and somnolence [344].

l-Asparaginase also lowers circulating hemostatic, anticoagulant, and fibrinolytic factors, with substantial decreases in plasma fibrinogen, factor IX, factor XI, antithrombin III, protein C, protein S, and plasminogen [345–354]. These effects are most likely due to diminished protein synthesis by the liver; there is no evidence for clotting factor consumption or the production of abnormal molecules [355, 356]. This reduction in protein synthesis appears to be in proportion to the effectiveness of l-asparaginase eliminating asparagine from the plasma [357]. As soon as therapy is discontinued, the clotting factors return rapidly to normal. Fortunately, l-asparaginase does not interfere with platelet production, and platelet counts return to normal even during continued administration for remission induction in patients with ALL [358, 359].

The concentrations of the anticoagulant proteins antithrombin III, protein C, and protein S can fall to 30% of normal in some patients receiving l-asparaginase, levels low enough to predispose to thrombosis [348, 360]. Levels of antithrombin III biologic activity have generally paralleled reductions in antithrombin III antigen, although exceptions may occur [360]. Alterations in the multimeric composition of VWF and variable defects in platelet function have also been reported [354, 361].

At first, the coagulopathy induced by l-asparaginase was attributed to DIC. Low levels of fibrinogen, increased FDP, a positive protamine sulfate test for fibrin monomer, and low levels of factor V and factor VIII have all been reported [351]. However, more current studies have shown normal survival of labeled fibrinogen and no evidence of increased thrombin generation [356, 362]. Some of the early reports of DIC may have represented patients who were predisposed to intravascular clotting because of their underlying disease, which then became overt due to l-asparaginase-induced decreases in circulating antithrombin III or other anticoagulant proteins. Although marked reductions in fibrinogen, factor XI, and factor IX due to l-asparaginase have been observed frequently, excessive bleeding is rare [345, 355]. If bleeding does occur, cryoprecipitate or fresh frozen plasma rapidly corrects the hemostatic defects, however fresh frozen plasma should be avoided if possible as this contains asparagine and may inhibit the antileukemic effects of the therapy.

The overall rate of thrombosis in children is 5% but may be as high as 36% if asymptomatic thrombosis are included and can range from 5 to 18% in adult patients with the suggestion the rate may be lower with PEG-asparaginase. The rate of potentially devastating CNS thrombosis is approximately 1–2% of patients with childhood ALL and up to 4% of adults [344, 352, 356, 363–367]. Small cerebral blood vessels can be occluded by thrombus, producing bland or

hemorrhagic infarction. Dural sinus vein thromboses are also common. Thrombosis usually occurs 2–3 weeks after the start of a course of therapy. Most patients recover, although several deaths have been reported and others are left with debilitating neurologic defects. Peripheral deep venous thrombosis seems to be less common [364]. Then presence of a central catheter increases the risk of thrombosis [368].

The pathogenesis of the thrombotic complications of l-asparaginase therapy remains obscure, although decreased levels of antithrombin III, protein C, protein S, and plasminogen could predispose to thrombosis because of inadequate inhibition of circulating activated clotting factors or deficient fibrinolytic activity. The low levels of circulating fibrinogen do not seem to be protective. A patient has been reported for instance who developed a major CNS thrombosis even though the plasma fibrinogen had fallen to 20 mg/dL [364]. The presence of an inherited hypercoagulable state such as factor V Leiden or the prothrombin gene mutation raises the risk of thrombosis with l-asparaginase therapy [368–370].

Optimal therapy of the thromboembolic complications of the l-asparaginase depends on whether intracerebral bleeding or thrombosis is identified on computerized tomography (CT) or magnetic resonance imaging (MRI) scans. If primary intracranial hemorrhage is present, heparin should not be used and coagulation defects corrected. If it is venous thrombosis then systemic anticoagulation with heparin is indicated [371]. Prior to heparin, measuring of fibrinogen should be done—if low (<150 mg/dL) then it should be replaced before anticoagulation. Some authors advocate replacement with antithrombin III and cryoprecipitate (for ATIII level < 60 and fibrinogen <150 mg/dL, respectively) [39]. Fresh frozen plasma should be avoided if possible, as previously stated.

There remains no consensus on prevention of thrombosis given varying results of clinical trials. Most would recommend check aPTT, INR, antithrombin, and fibrinogen as the start of asparaginase therapy and then perhaps every other day for a total of 7 days after each dose. The cutoff for antithrombin replacement remains undefined with levels of 60 or 70% recommended by different centers [272, 372]. In pediatric studies LMWH prophylaxis may be useful for patients with high risk for thrombosis, high WBC counts, or central venous catheters [373]. However, with the lack of clinic trial data no firm recommendations can be made.

Dasatinib and Imatinib

Recent reports of bleeding have been noted in patients with CML undergoing therapy with both first and second generation tyrosine kinase inhibitors [374]. In one retrospective study, multivariate analysis identified thrombocytopenia and advanced phase CML as risk factors for bleeding in patients during dasatinib therapy. Another study from the same group demonstrated that both dasatinib and imatinib induced rapid and marked prolongation of closure time to collagen/epinephrine in normal whole blood on the PFA-100 system, thus theoretically affecting coagulation via abnormalities in platelet function [375].

Ibrutinib

Within the last few years the targeted Bruton's tyrosine kinase (BTK) inhibitor ibrutinib has been trialed in several hematologic malignancies with good effect, however, high rates of bleeding events have been reported with a up to a 44% incidence of low grade, petechial or ecchymotic bleeding [376–379]. The drug appears to inhibit BTK activity in platelets as well as lymphoid cells, which functions in the signaling pathway of the platelet collagen receptor glycoprotein VI (GPVI) [380]. This has been confirmed by the observation that individuals taking the drug have deceased platelet aggregation to collagen, but not to ADP [380, 381]. The drug has also been shown to affect the adhesion of platelets with VWF [382]. Initial trials allowed patients to use concurrent vitamin K antagonists; however these patients were later removed from trials due to an increased rate of bleeding [383]. Concomitant use of vitamin K antagonists should be avoided.

Antibiotic-Induced Coagulopathies

Antibiotics have been recognized as a cause of bleeding in patients treated for infectious complications of hematologic neoplasia. Two categories of hemostatic defects have been described. First, vitamin K-dependent clotting factor synthesis can be impaired, leading to prolonged prothrombin or partial thromboplastin times [384, 385]. Second, platelet function is inhibited by certain β-lactam antibiotics such as high-dose penicillin, carbenicillin, and ticarcillin [385–390].

The mechanisms underlying the reduction of the vitamin K-dependent clotting factors are not clear, although the antibiotics can destroy the bowel bacteria that produce vitamin K [385, 391]. Alternatively, decreased levels of hepatic clotting factor synthesis or inhibition of the posttranslational gamma-carboxylation reaction required for the biologic activity of the vitamin K-dependent clotting factors could occur. The N-methylthiotetrazole side chain found in some of the cephalosporins can inhibit the action of vitamin K [385, 391–393]. Bleeding seems to be more frequent in severely debilitated patients with poor nutrition or liver disease, or those receiving prolonged intravenous feedings. The hemostatic defect can appear within 1 week of starting antibiotic therapy. Fortunately, the disorder may be quickly reversed or

prevented by therapeutic doses of oral or parenteral vitamin K or, if severe, and the patient is bleeding, fresh frozen plasma [385, 393, 394]. Prophylactic vitamin K has been suggested for leukemic patients who are likely to require long-term antibiotics; however, this intervention has been studied prospectively in children and was not found to be protective against development of a coagulopathy [395–398].

The antibiotic-induced defect in platelet function has been described with some, but not all β-lactam antibiotics and the incidence appears to be less with newer β-lactams. Susceptible patients can have markedly prolonged bleeding times, and experience marked bleeding after surgery or other invasive procedures [385, 388, 389, 399]. The incidence of antibiotic-induced platelet dysfunction is not known, although it is higher in debilitated, uremic, or malnourished patients. When healthy subjects are treated for up to 2 weeks, bleeding times are normal or only slightly prolonged [387, 388, 393, 400, 401].

Finally, certain antibiotics can induce immune thrombocytopenia [402]. While numerous drugs can produce thrombocytopenia, Common antibiotics such as vancomycin, piperacillin-tazobactam, and ciprofloxacin have all been implicated in thrombocytopenia and refractoriness to platelet transfusion [403–406]. The mechanism mimics HLA alloimmunization [404, 407]. In two instances antibodies were discovered that were vancomycin dependent and bound to glycoprotein IIb and/or IIIa [407]. Other investigators have isolated IgG and IgM vancomycin-dependent, platelet-reactive antibodies in vancomycin exposed patients that develop thrombocytopenia, which are not present in vancomycin exposed patients with normal platelet counts [408]. Also, antifungals such as amphotericin B can produce both thrombocytopenia and decreased recovery of transfused platelets, as well as rarely fluconazole [409, 410].

Chemotherapeutic Agents and Thrombosis

Chemotherapy is an independent risk factor for thrombosis [411]. Adjuvant chemotherapy for breast cancer for instance has been associated with an increased risk of both arterial and venous thromboembolism (5–7% of patients) [412–414]. The thrombogenic stimulus is not fully understood, but likely is resultant from a combination of damage to the vascular endothelium, increased levels of procoagulant molecules, reduction in endogenous anticoagulants including protein C and/or protein S, cytokine release from tumor cell death, induced platelet activation, and increased expression of macrophage tissue factor [411, 415–417]. Although thrombosis prophylaxis is not currently recommended for outpatients receiving chemotherapy [418], very low levels of warfarin (INR 1.5) or prophylactic LMWH can prevent the thrombotic events [419].

The multiple myeloma disease modifying agents thalidomide and lenalidomide are both associated with substantial rates of thrombosis that can be as high as 36–75% [246, 247]. The incidence is higher with the use of dexamethasone and with chemotherapy, especially doxorubicin [420]. These agents may have a direct toxic effect on the vascular endothelium promoting a prothrombotic state. Aspirin appears useful for thrombosis prevention in low risk patients while those who have had previous thrombosis, receiving dexamethasone or chemotherapy, immobilization, inherited thrombophilia, or have central lines may benefit from warfarin or LMWH prophylaxis [421]. LMWH prophylaxis has been compared to aspirin prophylaxis and warfarin prophylaxis in a prospective clinical trial [422]. The authors concluded that LMWH lead to the lowest risk of VTE, although this was not statistically different. Current guidelines recommend tailoring prophylaxis strategies to the patient's thrombotic risk factors [421].

Therapy-Related Thrombotic Microangiopathy

Thrombotic microangiopathy (TM) syndromes can complicate a variety of therapies for hematologic malignancies and their treatments [423, 424] (Table 59.5). TM can be associated with medications such as the calcineurin inhibitors cyclosporine, tacrolimus, as well as gemcitabine, and clopidogrel. Calcineurin inhibitor associated TM can occur within days after the agent is started manifesting as a falling platelet count, falling hematocrit, and rising serum LDH level [423, 425]. Some cases have been fatal but often the TM resolves with decreasing the dose of the calcineurin inhibitor or changing to another agent. Calcineurin inhibitors likely have directly toxic effects leading to endothelial dysfunction and increased platelet aggregation, possibly through the inhibition of prostacyclin [426].

In the past TM was most commonly seen with the antineoplastic agent mitomycin C, with a frequency of 10% when a dose of more than 60 mg was used [427]. Now, the most common

Table 59.5 Diagnostic criteria for stem cell transplantation related TTP/HUS

Bone marrow transplant clinical trial network criteria [481]
1. RBC fragmentation and ≥2 schistocytes per high powered field
2. Concurrent increase in LDH from institution baseline
3. Concurrent renal and/or neurological dysfunction with no other explanation
4. Negative Coombs test
International Working Group [482]
Increased percentage (>4%) of schistocytes in the blood
1. New, prolonged or progressive thrombocytopenia (< 50,000/uL or >50% decrease from previous counts)
2. Sudden and persistent increase in LDH
3. Decreased hemoglobin or increase transfusions requirements
4. Decreased in serum haptoglobin

antineoplastic drug causing TM is likely gemcitabine [428, 429]. The appearance of the TM syndrome associated with gemcitabine can be delayed, and the condition often is fatal. Severe hypertension often precedes the clinical appearance of the TM [430]. The use of plasma exchange is controversial, particularly as advanced malignancy itself can be associated with a TM-like syndrome that is typically poorly responsive to plasma exchange. There is increasing data that eculizumab may be effective [431]. TM has also been associated with cisplatin and VEGF inhibitors [432, 433].

Stem Cell Transplantation

Hepatic veno-occlusive disease (VOD or sinusoidal obstruction syndromes) is a relatively common complication of stem cell transplantation and is seen in 1–50% of patients, but the frequency seems to vary widely from center to center and the conditioning protocol used [434–436]. The clinical syndrome includes weight gain, hepatic tenderness, and jaundice soon after transplantation which can progress to liver failure and the hepatorenal syndrome. In older data hepatic VOD was common with rates up to 54% with a mortality of 39% but with use of less toxic preparatory regimens rates in the current era average 11% [437, 438].

Early thrombosis of the hepatic venules leading to obstruction and eventual fibrosis is the most commonly accepted mechanism for VOD [434]. Preexisting liver dysfunction, especially hepatitis C, prior therapy with gemtuzumab ozogamicin, the use of vancomycin in the pre-transplant period, and advanced age are some of the important risk factors for development of the disorder [434, 439–442]. Conditioning regimens that include Busulfan also increases the incidence [434, 437]. The risk is higher in patients undergoing allogeneic rather than autologous transplantation, unrelated donor transplants, and HLA mismatched transplants [437, 443].

Multiple coagulation defects have been demonstrated, but low levels of protein C prior to transplant were a strong and reproducible predictor of VOD [444–447]. For example, all patients with a baseline protein C value of less than 66% of normal developed the syndrome [446]. At present, it is unclear whether the decreased level of protein C is simply a surrogate marker for underlying liver disease, or constitutes a specific pathogenetic mechanism. Elevated levels of plasminogen activator inhibitor-1 have been suggested as a noninvasive test for VOD [448, 449]. Factor V Leiden mutation and the prothrombin 20210 mutation have also been reported as potential risk factor for the development of VOD [186]. Prothrombotic cytokines such as TNF and IL-6 have been shown to be elevated in patients with VOD, and markers of activation of hemostasis such as F1.2 and TAT are also increased [450].

Antithrombotic therapy has been employed in an attempt to prevent against VOD in high-risk patients. A randomized trial demonstrated that heparin at a dose of 100 U/kg/day beginning 8 days prior to transplant and continuing for 30 days thereafter decreased the rate of VOD from 13 to 2.5%, and in patients receiving allogeneic transplants from 18 to 0% [451]. Thrombolytic therapy with urokinase or tissue plasminogen activator (t-PA) has been trialed for treatment of patients with established VOD [452]. A small pilot study of 7 patients with severe VOD treated with 10 mg/day × 2 days of t-PA followed by heparin showed a response in 5/7 patients but a larger follow-up study demonstrated a high risk of bleeding, especially in patients who already had developed multi-organ system failure [453]. Current guidelines recommend against the use of t-PA due to the associated risk of hemorrhage [454].

Early reports indicating the use of defibrotide—an oligonucleotide with multiple anti-inflammatory actions—is effective in the treatment of VOD [455, 456]. This was recently confirmed by a large phase III trial of defibrotide compared against historical controls in which 102 patients were given defibrotide 25 mg/kg per day [457]. Complete resolution occurred in 25.5% of patients receiving defibrotide and 12.5% of control patients, with significantly higher day 100 survivals in the group receiving defibrotide. Rates of hemorrhage were not dissimilar between the two groups. Previous trials of defibrotide have suggested that predictors of survival included younger age, autologous SCT, and abnormal portal flow, whereas busulfan-based conditioning and encephalopathy predicted worse outcome. Decreases in mean creatinine and plasminogen activator inhibitor1 (PAI-1) levels during defibrotide therapy predicted better survival [438, 458, 459].

Thrombotic microangiopathies (TM) can complicate both autologous and allogeneic hematopoietic stem cell transplants [460–463]. The reported incidence varies widely in the literature from 0 to 74% which is likely a reflection of poor understanding of the disease and a lack of standard definitions [464–466]. Rates are significantly higher with allogeneic transplant. Risk factors include high-dose chemotherapy, radiation, unrelated donor, HLA mismatch, exposure to calcineurin inhibitors (CNIs), graft-versus-host disease (GVHD), and systemic infections [467, 468]. The etiology of post transplantation TM is felt to be different than that of "classical" TM, more likely being secondary to direct endothelial damage and subsequent release of cytokines, as ADAMTS13 levels are generally unchanged [460]. Complement dysfunction has been suggested as well [469, 470]. Mortality rates are quite high, with reported rates up to 100% [471].

Patients may present with a fulminant multi-organ failure, which occurs early after transplantation (e.g., within 20–60 days) which has been associated with severe cytomegalovirus (CMV) infection and is often fatal [472]. TM can be directly caused by cyclosporine/tacrolimus as outlined previously in this chapter. TM that is associated with the

conditioning regimen used in the transplantation protocol can occur 6 months or more after total body irradiation, and is associated with primary renal involvement.

Given the diagnosis of any TM is a clinical one and transplant patients are prone to have many complications that can mimic TM, it is easy to see why there is great center to center variation in incidence. Two groups have proposed diagnostic criteria that share the common features of evidence of a microangiopathic hemolytic anemia and elevated LDH. However, applying these criteria to an individual patient still require clinical judgment (Table 59.5).

The best management of hematopoietic stem cell transplantation-related TM is uncertain. For cyclosporine/tacrolimus associated TM the initial therapy is stopping the medications. In patients with mild TM and high serum levels of these agents one can lower the dose to see if the symptoms abate. For conditioning TM the course is progressive with no specific therapy available. For systemic CMV associated TM aggressive treatment of the CMV is the cornerstone of therapy. Treatment modalities for fulminant TM with multi-organ failure remain unsatisfactory. First steps include treatment of any process that may be aggregating the TM such as GVHD, infections, etc. Unlike in classic TTP, the role of plasma exchange remains controversial. Most series report very poor response rates and outcomes with high rates of complications. It is common the patient may respond for a few days but then relapse. A practical approach would be to use one plasma volume/day exchange daily in patients with TM until it is clear they are not responding to therapy [473–475]. Small series have evaluated the role of agents such as eculizumab [476], rituximab [477], vincristine [478], defibrotide [479], and pravastatin [480] with varying results. Unfortunately there remains no satisfactory treatment approach.

Summary

Hematological neoplasms can have protean effects on hemostasis. Not only can these be due to the tumor itself but can also be a complication of therapy. Knowledge of what complications to expect with both the tumor type and treatment can help prevent bleeding and thrombotic complications.

60 Psychological Aspects of Hematological Neoplasms

Tomer Levin T. Levin and Judith Cukor

Introduction

In an era of evidence-based medicine, it is important to choose psycho-oncology treatments that are as efficacious as possible. Psychosocial cancer care that is ineffective may be worse than no care at all. The ultimate aim of psychosocial care is to facilitate better medical outcomes.

Approximately, one-third of oncology patients will have significant psychological distress. Oncologists are often first responders for treating psychological problems; hence, there is a great need to equip them with solid psycho-oncologic skills. Clinicians should have demonstrable basic competence in managing disorders such as anxiety, depression, panic, alcohol withdrawal, delirium, and aptitude in handling physician–patient–family communication.

Furthermore, all oncology departments should have psycho-oncology consultation and referral resources for helping their patients, families, and clinical staff. This means investing in psycho-oncology programs and collaborative networks with other psychosocial care providers such as social workers, chaplains, integrative medicine, patient representatives, survivorship groups, and online support networks. A team approach is vital.

This chapter focuses on clinically substantiated interventions that are practically useful to the clinician. It will discuss anxiety, depression, delirium, psychosocial challenges of transplant, cognitive sequelae of treatments (chemo brain), doctor–patient communication, and physician burnout. It will also review a new population-based approach called Integrative and Collaborative Care.

Anxiety

What Is Anxiety?

Anxiety is an unpleasant psychobiological response, activated in response to a perceived threat. It allows an individual to mobilize resources to minimize exposure to a danger, and in so doing, triggers the primal fight, flight, or freeze reaction. The anxiety phenotype has cognitive, emotional, behavioral, and physiological elements (Table 60.1) [1].

Anxiety, like pain and fever, is not necessarily pathological. An optimal dose of anxiety can motivate the individual to take action to minimize a threat. For example, worry is positively associated with increased breast cancer screening via both self-examination and mammography ($r = 0.12$) [2].

Anxiety becomes pathological when it is activated disproportionately to a threat, independently of an actual danger or when it becomes chronic. Such maladaptive anxiety has a

Table 60.1 Components of the anxiety phenotype

Cognitive	Evaluation of the danger versus one's coping resources. Focus is on the perceived threat while extraneous environmental details are blocked out (tunnel vision). For example, a patient may focus on the risk of stem cell transplant to the exclusion of marital or financial issues
Emotional	Feeling nervous, edgy, scared, alarmed, terrified, worried, etc.
Behavioral	This refers to behaviors associated with anxiety: avoidance (e.g., nonadherence), flight (e.g., signing out against medical advice), fight (e.g., angry or litigious), immobility, unable to speak (e.g., a passive or overtly shy patient)
Physiological	Cardiovascular (palpitations, hypertension, faintness/fainting), respiratory (tachypnea, chest pain, lump in throat), neuromuscular (startle reflex, twitching muscles, tremor, unsteady, restless), gastrointestinal (discomfort, anorexia, nausea, diarrhea, vomiting), urinary (urgency, frequency), dermatological (flushed, pale, sweaty, itchy, hot, shivers, blushing)

noxious intensity that impairs a person's functioning and also wears out their family and friends because, unlike effective problem-solving, it serves no end point.

Consider an anxious chronic lymphocytic leukemia patient receiving watchful waiting treatment. Significant effort may be expended on fruitless worry, hypervigilance, self-palpation of lymph nodes, and amplification of nonspecific physical symptoms. All of these do not improve prognosis beyond that of a rational surveillance program. In this chapter, the term anxiety refers to the maladaptive variety rather than normal anxiety.

Whether anxiety is adaptive or pathological is moderated by a person's sense of self-efficacy or confidence in dealing with potential threats as well as the resources available to them. Loss of work or family roles, negative medical experiences such as misdiagnosis, or physical weakness leading to a self-image of a weak or vulnerable person, can all erode confidence and increase anxiety.

Prevalence of Anxiety

The prevalence of cancer anxiety is estimated to be in the 10–30% range, but this range should be assessed within the context of the ubiquity of anxiety in the general population (2–6%) and primary care (8–12%) [3, 4].

Risk Factors for Anxiety

Specific demographic factors such as younger age, female sex, separated, divorced, widowed, and lower socioeconomic status are associated with greater anxiety levels. Conversely, older, married, more experienced patients with social support and financial and educational resources can better manage anxiety [5, 6]. Nearing death or having a worse prognosis is probably not associated with increased anxiety [7, 8]. Genetic factors are also increasingly recognized as contributing to the risk for anxiety disorders; however, genes are not always the answer. For example, a spider phobia may have greater valence to a child as compared to an adult but, with appropriate nurturing, an anxious child may grow into a confident young adult. In other words, experience and maturation can override a biological propensity towards anxiety.

Finally, childhood sexual abuse is associated with an increased risk for generalized anxiety disorder and panic disorder (also major depression, substance abuse, and bulimia nervosa). This risk is doubled when the victim is subjected to sexual intercourse [9], highlighting the importance of considering sexual abuse when interviewing anxious cancer patients. Furthermore, because trust in parental figures has been betrayed at an early age, sexually abused oncology patients may have difficulty trusting their physicians and be more difficult to reassure.

Screening and Measuring Anxiety

Asking, "Are you worried?" or using the Distress Thermometer, where patients are asked to rate their distress from 0 to 10 [10], are simple ways of assessing anxiety. The Generalized Anxiety Disorder-7 scale (GAD-7), used widely in medical cohorts, matches DSM-IV criteria for generalized anxiety disorder (Table 60.2) [11]. It can be used to screen for anxiety where a

Table 60.2 Generalized anxiety disorder-7

Over the *last 2 weeks*, how often have you been bothered by the following problems?				
	Not at all	Several days	More than half of the days	Nearly every day
1. Feeling nervous, anxious, or on edge	0	1	2	3
2. Not being able to stop or control worrying	0	1	2	3
3. Worrying too much about different things	0	1	2	3
4. Trouble relaxing	0	1	2	3
5. Being so restless that it is hard to sit still	0	1	2	3
6. Becoming easily annoyed or irritable	0	1	2	3
7. Feeling afraid as if something awful might happen	0	1	2	3
	Total Score________ =	Add columns_________ +	______________ +	_______________

If you checked off *any* problems, how *difficult* have these problems made it for you to do your work, take care of things at home, or get along with other people?			
Not difficult at all	Somewhat difficult	Very difficult	Extremely difficult
❍	❍	❍	❍

Interpretation of scoring: 0–4 minimal anxiety (below threshold of significance), 5–9 low anxiety, 10–14 moderate anxiety, 15–21 severe anxiety. Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt K. Kroenke and colleagues, with an educational grant from Pfizer Inc. No permission required to reproduce, translate, display, or distribute

cutoff of ≥5 represents significant anxiety. Alternatively, it can be used to measure anxiety severity, e.g., before and after starting a benzodiazepine.

Specific anxiety syndromes are discussed next.

Generalized Anxiety Disorder

When diagnosing generalized anxiety disorder (GAD) in psycho-oncology settings, the usual 6-month duration of symptoms is impractical because it would lead to underdiagnosis. A sensible clinical modification is a 2-week symptom duration [11]. Nevertheless, most GAD patients will have suffered from generalized anxiety, on and off, for many years previously; average duration of symptoms before diagnosis is 5–10 years. These patients tend to be greater users of primary and specialist medical care, have greater social impairment, demonstrate less work productivity and more absenteeism [3], and frequently display intercurrent depression.

How is GAD colored by the oncology setting? These patients may worry excessively about prognosis, uncertainty of recurrence, treatments, role changes, loss of income and status, transportation, and dependency. "Markeritis" describes overly worrying about elevated cancer markers. The "tyranny of positive thinking" is where patients are told that they "must" think positively, implying that negative thinking will worsen the prognosis. It is, however, impossible to be perpetually optimistic, even in the best of times, but especially when seriously ill. Thoughts about mortality are normal and understandable. Telling a cancer patient "not to think negative" is similar to saying, "don't think of a purple elephant"—quite impossible, and this increases anxiety.

Adjustment Disorder with Anxiety

The cardinal features of this category are anxiety symptoms within 3 months of a stressor that should resolve within 6 months of termination of the stressful trigger. The presumption is that, without the stressor, the patient would not have anxiety or worry symptoms.

The advantages of this classification are that it is not pejorative and semantically empathic with an expectation of recovery. Disadvantages are that it is hard to predict who will recover versus who will progress to chronic generalized anxiety. Even when cured, cancer remains a long-term stressor with multilevel effects on patient, family, employment, and finances, suggesting that it is overly simplistic to view the stressor as an on–off button. This categorization also invites the argument that anxiety is "normal" in a cancer setting, which may in turn lead to underrecognition and undertreatment, e.g., not initiating pharmacotherapy or psychotherapy.

Panic Disorder with or Without Agoraphobia

Panic attacks are discrete episodes of intense apprehension, fear, terror, or a sense of impending doom that peak within 10 min. They are associated with physical symptoms such as chest pain, shortness of breath, choking or smothering sensations, and a fear of going crazy or losing control. Agoraphobia, fear of being trapped in a crowded place where escape might be difficult or embarrassing, often is a consequence of panic attacks. When panic attacks become recurrent, with persistent worry about additional attacks or concern about its implications (going crazy, heart attack) or significant "avoidance" because of the attacks, panic disorder can be diagnosed. An isolated panic attack may not have great clinical significance in some patients but in others it can be a cardinal event setting off a cascade or fear and avoidance.

Panic in cancer patients may occur de novo or reflect an exacerbation of a preexisting panic. It is often underdiagnosed; one cancer center reported a fifth of referrals to its psycho-oncology service with panic symptoms [12]. Cognitively, panic is conceptualized as the misinterpretation of bodily symptoms, for example, a stem cell transplant patient who misinterprets pain and discomfort catastrophically. Occasionally, panic disorder presents as a patient who wants to leave hospital "against medical advice" or who suddenly refuses chemotherapy.

Social Anxiety Disorder

This is characterized by persistent fear that social scrutiny will be humiliating or embarrassing, resulting in severe anxiety or reactions such as avoidance, withdrawal, or paralysis. As this disorder is largely a chronic condition that starts in teenage years, these patients are often underachievers in life. The cancer journeys of such painfully shy and inhibited patients are uncomfortable. They have difficulty negotiating the medical bureaucracy and speaking up because their biggest fear is being the center of attention. Scars, radiation burns, disfiguring surgery, intrathecal catheters, or anything that makes the patient stand out in a crowd can exacerbate social anxiety. For these shy patients, obtaining a second opinion is commonly an anxiety wrought experience, which is often avoided, to the patient's ultimate detriment.

Specific Phobia

Seen in 3.5% of the general population, blood–injection–injury phobia may result in fainting during procedures and avoidance of injections, blood tests, or dental care. As self-injection becomes increasingly common, blood–injection–injury phobia should be considered in patients who refuse or

have difficulty self-injecting. Claustrophobia is very common in the setting of imaging (e.g., closed MRI scans) and radiation treatments.

Anticipatory Anxiety and Nausea

Anticipatory anxiety and nausea are classically conditioned responses (Pavlovian conditioning) to nausea induced by oncology treatments. For example, when patients, feeling nauseas, because they have just received chemotherapy, are offered a bite to eat, food can inadvertently be paired with the noxious stimulus of nausea. Anxiety and nausea are then generalized beyond the cancer treatment so that all food cues result in anxiety and nausea, resulting in food avoidance. Preexisting anxiety, younger age, vulnerability to motion sickness, prior emetic chemotherapy, and abnormal taste sensations, all predispose to anticipatory nausea and anxiety [13].

Anxiety Due to a General Medical Condition

No oncologist wants to misattribute anxiety as psychological when it actually is due to an underlying medical illness [14]. Medical causes of anxiety are listed in Table 60.3. Treatment is primarily that of the underlying medical illness, although this may not necessarily eliminate the anxiety.

Shortness of breath is a common pathway that increases anxiety. It is rare to encounter a patient with shortness of breath from a pulmonary condition, arrhythmia, sepsis, or blood loss who does not feel anxious.

Table 60.3 Medical conditions and medications associated with anxiety

Metabolic	Hyperkalemia, porphyria, hypo- and hypercalcemia, hyperthermia, hypoglycemia, hyponatremia, vitamin deficiencies, hypovolemia, sepsis
Neurological conditions	Pain, raised intracranial pressure, central nervous system neoplasms, postconcussion syndrome, seizure disorder, vertigo
Endocrine	Adrenal abnormalities, hyper/hypothyroidism, parathyroid abnormalities, pituitary abnormalities, pheochromocytoma, carcinoid syndrome
Cardiovascular	Arrhythmia, congestive heart failure, coronary artery disease, anemia, valvular disease, cardiomyopathy
Pulmonary	Hypoxia, pulmonary embolism, asthma, chronic obstructive pulmonary disease, pneumothorax, pulmonary edema
Medications/toxic conditions	Corticosteroids, bronchodilators, antipsychotics, thyroid preparations, theophylline, sympathomimetic agents, levodopa, serotonergic agents, psychostimulants, antibiotics (cephalosporins, acyclovir, isoniazid), interferon, caffeine, cocaine, marijuana, withdrawal states (alcohol, opioid analgesics, benzodiazepines, caffeine)

Pain is a common cause of anxiety in cancer patients. In one study of hospitalized cancer patients, the prevalence of pain was 96% for patients with anxiety as opposed to 80% for patients without anxiety [15]. Patients in severe pain appear diaphoretic, restless, and nervous. Anxiety assessment can only be completed after adequate pain relief. Anxiety often resolves after the pain is treated, reflecting the often heard truism that acute pain causes anxiety and chronic pain results in depression.

Substance-Induced Anxiety Disorder

Substance-induced anxiety is the direct effect of a drug, medication, or toxin. Bronchodilators raise the pulse rate, compounding the anxiety caused by air hunger. Anti-inflammatory cytokines such as interferons can cause anxiety and panic, perhaps via serotonergic and dopaminergic pathways, although they may be better tolerated than previously thought [16, 17]. Corticosteroids commonly cause anxiety, emotional lability, insomnia, agitation, and restlessness. Thyroxine, psychostimulants, sympathomimetic agents, serotonergic agents, anticholinergics, immunosuppressants, antihistamines, and certain antibiotics may all produce symptoms of anxiety. Akathisia (motor restlessness), when an extrapyramidal side effect of the antiemetics prochlorperazine and metoclopramide, is often misdiagnosed as anxiety. Substance withdrawal (alcohol, benzodiazepines, barbiturates, opioids, nicotine), frequently unrecognized, may present with sudden, intense anxiety and agitation.

Depression

What Is Depression?

A depressed person feels down, sad, hopeless, and loses interest in life, hobbies, and things that previously were a source of pleasure (anhedonia). Their facial expressions (affect) are sad and their overall demeanor and posture reflect their morose mood. In severe depression, nothing can brighten the affect, not even a little humor or encouragement. Psychiatrists describe this as nonreactive affect. Irritability, decreased concentration (e.g., "I can't read anything beyond the newspaper headlines"), middle insomnia (falling asleep but waking up after a few hours), loss of appetite or excessive eating, psychomotor slowing, and guilt (e.g., "If only I had …") are other symptoms.

Prevalence and Impact of Depression

The prevalence of depression in oncology ranges from 10 to 25%. It is frequently comorbid with anxiety. One study found that two-thirds of depressed oncology patients also

met anxiety criteria [5]. The treatment implications of this are that depression and anxiety should be targeted simultaneously, e.g., by starting an antidepressant together with a benzodiazepine or behavioral therapy.

Depression is not more severe in early compared to advanced disease (e.g., watch and wait vs. late stage CLL), nor in milder versus more demanding treatments (e.g., autologous stem cell transplant compared to allogeneic). Depression does not become more severe as death approaches [7], a fact that can be used to reassure patients and families who are concerned that depression is ubiquitous with the dying phase of an oncological illness.

Depression will worsen the quality of life and is associated with longer admissions and lesser adherence but, according to current research, does not trigger cancer or increase vulnerability to relapse [18].

Risk Factors for Depression

Of the malleable risk factors, substance abuse is common and of most urgent concern. In addition, less social support has been associated with depression and an overall increase in mortality of cancer patients [19]. It is hard to battle cancer alone. Poverty also limits access to treatments and resources and when health literacy is low, it is more difficult to manage care, e.g., understand medical instructions is harder. These speak to the importance of identifying and helping resource-deprived oncology subgroups.

Differential Diagnosis of Major Depression

Mood disorder due to a general medical condition is where the depression is judged to be a direct physiological effect of the medical condition, e.g., stroke and hypothyroidism. Hypoactive delirium is an important consideration in patients who are lethargic or labeled as “failure to thrive” or who seem depressed but are also disoriented (see “Discussion” later in this chapter).

A *substance-induced mood disorder* is where a drug of abuse or medication is causing depressive symptoms, e.g., alcohol or tobacco withdrawal. A number of medications have been associated with depression, but the strongest correlations are with steroids, interferon alpha, and taxanes. Smoking cessation predisposes an individual to a higher rate of major depression in the year subsequent to quitting [20].

Bipolar disorder is common and should be considered where there is a family history of bipolar or other affective disorders, or when depression does not respond to a standard 4-week antidepressant course.

Measuring and Screening for Depression

One measure for depression screening is the Patient Health Questionnaire-9 (PHQ-9) that has been widely validated in medical populations (Table 60.4) [21]. Items one (anhedonia) and two (depressed mood) must be positive in order to

Table 60.4 The PHQ-9

PHQ-9. Over the *last 2 weeks*, how often have you been bothered by any the following problems?

	Not at all	Several days	More than half of the days	Nearly every day
1. Little interest or pleasure in doing things	0	1	2	3
2. Feeling down, depressed, or hopeless	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much	0	1	2	3
4. Feeling tired or having little energy	0	1	2	3
5. Poor appetite or overeating	0	1	2	3
6. Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed. Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
9. Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3

Total score___________ = Add columns_________ + ______________ + ______________

If you checked off *any* problems, how *difficult* have these problems made it for you to do your work, take care of things at home, or get along with other people?

Not difficult at all	Somewhat difficult	Very difficult	Extremely difficult
❍	❍	❍	❍

Interpretation of scoring: 0–4 none (below threshold of significance), 5–9 mild depression, 10–14 moderate depression, 15–19 moderately severe depression, 20–27 severe depression

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt K. Kroenke and colleagues, with an educational grant from Pfizer Inc. No permission required to reproduce, translate, display, or distribute

meet the depression threshold. In fact, Veterans Affairs hospitals in the USA use these first two items (known as the PHQ-2) to screen all of their patients. A score of ≥5 on the PHQ-9 represents significant depression. Thus the PHQ-9 can be used as a screening measure in oncology clinics and to assess depression severity, e.g., before and 3 weeks after starting an antidepressant. Translations into other languages such as Spanish, Chinese, and Russian are widely available online and are another useful resource for oncologists. If a response to item nine (thoughts of being better off dead) is positive, further questions about suicidality are necessary. Even use of a single question, “Are you depressed?” had a specificity and sensitivity of 1.00 for identifying depression in a palliative care cohort [22].

Anxiety, Depression, and Suicide

Cancer patients have twice the risk of suicide compared to the general population, and risk factors include depression, hopelessness, helplessness, loss of control, perceived burden to others, pain, cognitive function and delirium, poor social support, personality disorders, and existential distress [23].

While the association between depression and suicide is well known, more recently, there has been an increasing awareness that anxiety is another risk factor for suicide [24]. It seems likely that interactions between other vulnerabilities such as younger age, less social support, and specific anxiety subtypes (e.g., panic) might confer increased risk of suicidality [6]. Depression is associated with a greater desire for physician assisted suicide and, conversely, treating depression decreases the number of such requests.

Medical Workup for Depression

A thorough medical history and physical examination should consider vital signs, cardiovascular, neurological, gastrointestinal, and respiratory systems. Diagnostic tests may include laboratory examination (such as electrolytes, thyroid function tests, liver function tests, albumin, blood urea nitrogen, creatinine), electrocardiogram, brain imaging studies to exclude structural CNS lesions, electroencephalogram when seizure activity is suspected, and cerebrospinal fluid analysis (if CNS infection, subarachnoid hemorrhage, or leptomeningeal disease is suspected).

Psychopharmacological Treatments of Anxiety and Depression

Because psychological symptoms occur in approximately one-third of cancer patients, oncologists should have demonstrable competency treating their patients with antidepressants and antianxiety agents. Starting an antidepressant together with a benzodiazepine makes clinical sense where there is comorbid anxiety or prominent sleep disturbance, as the patient will experience some relief straight away. Adherence with antidepressants is also improved when they are prescribed together with benzodiazepines.

Although serotonin norepinephrine reuptake inhibitors (SNRIs) and selective serotonin reuptake inhibitors (SSRIs) and other such medications are called antidepressants, when taken regularly, they also have significant antianxiety effects; hence, the term antidepressant does not entirely match the function of the drug class. They might be better described as antidepressant–antianxiety agents.

Antidepressants

SNRIs, such as venlafaxine and duloxetine, and SSRIs, such as citalopram and sertraline, are considered first-line agents for treating depression in patients with comorbid medical conditions. One advantage of using an SNRI is that they have been found to be helpful in reducing neuropathic pain associated with diabetic neuropathy; however, SSRIs have no impact on pain pathways.

Antidepressant Titration Protocol

A good rule of thumb is to prescribe half of the lowest starting dose for 3–7 days to ensure that the medication is well tolerated. To illustrate, venlafaxine SR 37.5 mg is given for 1 week, after which it is increased to 75 mg daily. The dose of an antidepressant is reevaluated every 3–4 weeks by a clinical examination and measuring the PHQ-9 and GAD-7 for a 50% decrease in score. If there is no improvement, the dose is usually doubled, e.g., venlafaxine SR is increased from 75 to 150 mg/day after 1 month. If there is still no improvement after 2 months, the dose could be increased to 225 mg/day for a further month. If the depression still has not improved significantly by month three, the next step would be to (1) add an antidepressant from a different class (e.g., mirtazapine or bupropion), (2) switch antidepressants, or (3) augment with psychotherapy.

After symptoms remit (e.g., PHQ-9 score of <5) patients should continue the antidepressants for another 6–8 months to consolidate the remission. Discontinuing the antidepressant earlier increases the statistical chance of relapse. If depression is recurrent, the patient should consider continuing treatment for 2–5 years. It is not recommended that an antidepressant be stopped during the winter months due to the tendency of symptoms to worsen when they overlap with seasonal affective disorder. Spring or summer months are better times to wean antidepressants.

Side Effects of Antidepressants

SNRIs and SSRIs should be taken with food to minimize the most common initial side effect, transient nausea. Patients should be warned about this and told not to stop the medication if they experience nausea or other gastrointestinal symptoms because tolerance usually develops after a day or two.

A serotonergic withdrawal reaction occurs in one out of five patients when these medications are stopped suddenly. This presents as intense discomfort, and flu-like symptoms and electric-like shocks. Generally, it is prudent to tell patients that when antidepressants are stopped, the dose should be weaned gradually over 1–2 weeks. In the event of serotonin discontinuation syndrome, the antidepressant should be restarted and weaned even more slowly over the course of 4–6 weeks.

Sexual side effects can be bothersome and manifest as decreased libido in both sexes or delayed ejaculation in males. This is not, however, universal; many patients experience an improvement in their libido as the depression lightens.

Hyponatremia secondary to syndrome of inappropriate antidiuretic hormone has been recognized with SNRIs, SSRIs, and mirtazapine with a mean time to onset of 13 days (range 3–120) [25]. Those older than 65 are at particular risk.

There is an increased risk of gastrointestinal and uterine bleeding with SSRIs and SNRIs. The mechanism is believed to be via depletion of platelet serotonin which impedes coagulation in vulnerable patients, e.g., those taking nonsteroidal anti-inflammatories.

Some antidepressants have specific side effects: Mirtazapine is a sedating antidepressant and some patients complain of feeling groggy in the morning. Patients with a prominent sleep disturbance may, however, appreciate a combination antidepressant-sleeping tablet. Mirtazapine may also cause weight gain and, anecdotally, this can be helpful to some oncology patients.

Bupropion, unique among antidepressants, works via a dopaminergic mechanism. It is particularly useful as an aid to nicotine cessation where it increases the chance of successful quitting. It may, however, be too activating for some patients who complain of tremors or feeling wired. It may also reduce the seizure threshold, requiring caution in patients with a seizure diathesis.

Venlafaxine may cause a dose-related increase in hypertension although doses up to 225 mg are usually safe.

Cytochrome P450 drug–drug interactions can also occur. For example fluconazole, commonly used in the transplant setting, inhibits CYP2C19, the enzyme that metabolizes the antidepressant citalopram [26]. The result may be serotonin toxicity, a syndrome of neuromuscular hyperactivity (tremor, clonus, myoclonus, hyperreflexia, and the advanced stage pyramidal rigidity), autonomic hyperactivity (diaphoresis, fever, tachycardia, tachypnea, and mydriasis), and altered mental status (agitation and confusion in advanced stages). Serotonin toxicity is reversible upon cessation of the triggering medication. An identical serotonin syndrome occurs in overdoses of SSRIs and SNRIs. Mirtazapine has not been associated with serotonin toxicity.

Paroxetine and fluoxetine were, until recently, prescribed for postmenopausal hot flashes. However, they inhibit CYP2D6 which reduces the metabolism of tamoxifen to its active metabolite, endotamoxifen. The result is an increase in breast cancer relapse [27]. For this reason venlafaxine is preferred for the treatment of hot flashes in patients receiving tamoxifen.

Tricyclic antidepressants may result in orthostatic hypotension, anticholinergic side effects, and quinidine-like effects. They are dangerous in overdose. Monoamine oxidase inhibitors require a tyramine-free diet. Hence, these drugs are now considered third- or fourth-line agents.

Benzodiazepines

Although there are a few controlled trials of benzodiazepines for anxious cancer patients they are widely used from diagnosis to survivorship and from acute hospitalization to terminally ill care. They can be administered in a variety of ways, which is an important consideration in medical settings where oral intake may be compromised (e.g., lorazepam: orally, intramuscularly, intravenously; clonazepam: orally, orally disintegrating tablet). Longer acting benzodiazepines, such as clonazepam or extended release alprazolam, may provide more persistent relief of anxiety symptoms, but patients often report satisfaction from short-acting alprazolam because of its quick onset and offset. They find it helpful to reduce worry prior to brief procedures such as MRI scans, radiation, bone marrow aspirations, or when they are in the physician's waiting room, nervously awaiting the results of an important test.

In addition to treating anxiety, benzodiazepines are also useful for insomnia, nausea, vomiting, and panic attacks. Both lorazepam and alprazolam have been shown to reduce postchemotherapy as well as anticipatory nausea and vomiting [28, 29]. It is also hypothesized that given before chemotherapy or a procedure, benzodiazepines may reduce conditioned aversion responses due to their amnesic properties [28, 30].

The Society of Critical Care Medicine guidelines for the management of anxiety in critically ill adult patients recommend the use of lorazepam for prolonged (i.e., more than 24 h) treatment of anxiety in critically ill patients [31]. Lorazepam is probably the most widely used benzodiazepine in acute cancer settings.

How do benzodiazepines compare to behavioral interventions for anxiety? Their efficacy is similar. For instance, one randomized trial of alprazolam versus progressive muscle relaxation found that both treatments resulted in a significant reduction in anxiety symptoms, but the effect of alprazolam was faster [32]. For the oncologist, this means that there are efficacious behavioral options for patients who wish to avoid antianxiety drugs.

Side Effects of Benzodiazepines

Sedation, drowsiness, and ataxia, the commonest side effects of benzodiazepines, increase the risk of falling in elderly patients.

Another big drawback of benzodiazepines is that they increase the risk of delirium, especially in the elderly and in those with multiple comorbidities. It is prudent to stop benzodiazepines when a patient becomes delirious. Memory difficulty, sexual dysfunction, and incontinence are encountered less frequently.

Impaired hepatic function or drugs that compete for the liver enzymes that metabolize benzodiazepines (e.g., erythromycin, estrogen, and isoniazid) may necessitate lower doses of benzodiazepines to minimize side effects. Lorazepam, oxazepam, and temazepam are preferred if hepatic function is impaired because they are metabolized by conjugation with glucuronic acid and have no active metabolites [30, 33].

Benzodiazepines have a dose-related effect on the respiratory center, but when their use is carefully monitored, they may reduce anxiety and improve the respiratory function among patients with anxiety due to dyspnea.

Antihistaminergic agents are occasionally used in anxious patients with severely compromised pulmonary function for whom benzodiazepines are contraindicated. Antihistamines, however, do not have anxiolytic properties. Their sedative effects most likely result in a sense of anxiety relief. The anticholinergic effects of these medications must be monitored carefully as they increase delirium risk.

Psychostimulants

Methylphenidate and dextroamphetamine are often used as energizing agents in oncology patients who are depressed, fatigued, or both. Evidence for their efficacy comes from open labeled trials, where 4/5 studies found them to be effective but, unfortunately, there are currently no placebo controlled studies [34]. Nevertheless, for patients who are depressed, fatigued, suffer from narcotic-induced sedation, or have difficulties concentrating, a stimulant can be helpful. Low doses are used initially, e.g., methylphenidate 5 mg at breakfast and 5 mg at lunchtime. This can be titrated up to 10–20 mg twice daily until some improvement in fatigue or function occurs. Stimulants should be used cautiously in patients with cardiac problems as tachycardia is a potential side effect. They are thought to have a low abuse potential in oncology settings.

Modafinil is a newer wakefulness promoting agent that lacks abuse potential and, although there are no studies of its efficacy in depressed cancer patients, it is anecdotally reported to be helpful. The starting dose is 50–100 mg. Lack of insurance reimbursement for this off-label use renders it an expensive option for many patients.

Psychotherapy

The following section focuses primarily on evidence-based psychotherapies. If possible, oncologists should refer their patients to therapists who employ such techniques. Cancer centers should recruit therapists with competency in these psychotherapies over “eclectic” practitioners. Nevertheless, treatment should be tailored to the patient’s and family’s needs rather than assuming that one solution will fit all. Comorbidity such as intercurrent alcohol, drug, or nicotine dependence should be addressed first and foremost.

Psychoeducation

This provides information (verbal, written, visual, or a combination) to help people learn ways of mastering a novel situation. To illustrate, an orientation to the stem cell transplant ward can demystify what lies ahead and help patients and families plan for the transplant. Acquisition of new knowledge is essential to navigate an often foreign medical system; unfamiliarity increases anxiety and uncertainty. A related concept is that of patient navigators who provide barrier focused assistance to ensure completion of a discrete episode of cancer-related care.

Typical of many, one psychoeducation RCT involved an orientation tour of the clinic, written resources for coping (e.g., support groups), and a question and answer meeting with a counselor; anxiety was significantly less at follow-up [35]. A meta-analysis of 116 psychoeducational studies [36] reported a moderate effect size but another failed to show an effect [37].

Cognitive Therapy

This is considered by many to be the most effective psychotherapy for anxiety and depression. Cognitive therapy is based on the principle that it is not a situation that results in

Table 60.5 Maladaptive cancer cognitions that are associated with anxiety

Cancer-related automatic thought	Consequence
I will die in my sleep	Insomnia, nocturnal anxiety, hypervigilance
Chemotherapies are toxic, poisonous chemicals	By over-generalization of all anticancer treatments into the drain cleaner category, well-tolerated regimens and effective symptom management are negated. Patients may flee to "natural" medicine cures.
I *must* think positively!	This is called the "tyranny of positive thinking." Everyone tells the patients to "think positive" but, invariably, a realistic or pessimistic thought crosses the cancer patient's mind. They then feel guilty, feeding into despair and depression.
Cancer *means* death	The term cancer is over-generalized. In fact cancer is a heterogeneous, nonspecific term. The majority of cancer patients are cured. This belief often leads to paralysis and demoralization.

an emotion but rather the preceding automatic thought [38]. To illustrate, one person undergoing a CT scan may think, "I know that the pain is cancer," and feel sad. The next person through the scanner may think, "I am glad that I will finally have an explanation for the pain," and feel relief.

Typical maladaptive cancer-related automatic thoughts associated with depression and anxiety are listed in Table 60.5.

One meta-analysis found a small but significant effect size of cognitive therapy; another in cancer survivors found a larger effect size [37]. Data in nonmedical populations support the efficacy of cognitive therapy, with large to moderate effect sizes reported [39].

Behavioral Activation

Consider two equally depressed patients with identical hematological malignancies. One remains in bed, alone in the dark. The other is forcing himself to walk around the nurses' station. Who will feel more depressed? It is reasonable to assume that the withdrawn, isolated person will feel more depressed and the activated patient less so. This is the basis of Behavioral Activation (BA): that activity and engagement improve mood while withdrawal and avoidance maintain depression. BA strategies include scheduling, self-monitoring, rating the degree of pleasure and achievement during daily activities, and exploring alternative behaviors with techniques such as role-playing. In one (nononcological) RCT, BA was as efficacious as antidepressants in severe major depression [40].

Problem-Solving Therapy

This therapy is based on the paralysis consequent to dealing with multiple health, employment, financial, and family problems simultaneously. Through this therapy, patients learn to define the problem, brainstorm possible options, evaluate potential solutions, implement solutions, monitor the degree of their success, and make adjustments to the solutions. A family member can also be incorporated as a coach. Examples of target ideations in problem-solving therapy are a patient who may erroneously believe that "All of my problems are due to the cancer." [The cancer is probably not to blame for every problem that s/he has], or an individual who expresses the belief that *"No-one* can help." [Many patients are helped.] In one RCT of oncology patients, problem-solving effectively reduced patients' distress [41].

Behavioral Therapies

Behavioral therapies are among the most widely used psychosocial treatments offered to cancer patients. They are efficacious for anxiety, the "here and now" distress associated with cancer treatment side effects and anticipatory nausea but constitute an array of interventions.

In *distraction*, attention is diverted away from the distressing stimulus, e.g., wiggling toes during venipuncture, guided imagery, storytelling, or video games. *Systematic desensitization* involves gradual reexposure to a feared stimulus where relaxation is combined with gradual visualization of cues associated with the trigger. The end point is habituation to the feared stimulus so that the aversive reaction is contained, e.g., an aversive reaction to eating after chemotherapy induced vomiting. *Hypnosis* is where, via relaxation techniques, the patient learns to focus attention on thoughts and feelings unrelated to the source of distress, at which point the clinician introduces suggestions for calm and well-being, reducing anxiety. *Relaxation training* uses techniques such as progressive muscle relaxation (systematic tensing and releasing of muscle groups), meditation, or deep breathing. Slowing down breathing is a key ingredient in relaxation training because hyperventilation increases panic. Relaxation training should be used with caution in patients with a history of sexual or physical abuse, for whom relaxation might be perceived as being dangerous. Relaxation training can also be self-administered. One study effectively used print and audiovisual media to instruct patients in paced abdominal breathing, progressive muscle relaxation with guided imagery, and coping self-statements, with only 10 min of instruction from the clinician [42].

Support Groups

Cancer support groups have a high degree of user satisfaction but heterogeneity in methodologies makes it hard to compare their effects on anxiety and depression [43]. Online support groups such the Cancer Support Community (https://www.cancersupportcommunity.org/) are now well established and bridge physical barriers and bricks and mortar costs. "Supportive expressive group therapy" has been shown to help depression or helplessness/hopelessness [44, 45]. Support groups constitute an important resource for oncologists.

Psychotherapy vs. Psychopharmacology vs. Combined Treatment

In meta-analyses (conducted on nononcology patients), pharmacotherapy for anxiety and depression works faster than psychotherapy, but longer term outcomes are more robust for psychotherapy [46, 47], i.e., talking through your problems has lasting benefits. Although combined cognitive and pharmacotherapy does not have a clear advantage in meta-analyses, these data are not without controversy [46, 47]. In practice, combined treatment seems to be the most beneficial [30, 48, 49]. Interestingly, compared to medication alone, combined therapy patients report fewer side effects of medications [50]. Psycho-oncology, due to the urgency of its context, also favors treatments that work faster; rapid symptom relief may facilitate more timely, definitive cancer treatment. For patients who are too sick to enter a talk therapy or who are not psychologically minded, timely psychopharmacological treatment is a valuable tool in their recovery.

Delirium

Delirium, or confusion, is a complex neuropsychiatric condition that manifests in one-third to one-half of inpatients; terminally ill patients are affected at even higher rates. Acute delirium is a medical emergency because it reflects brain malfunctioning due to an underlying systemic condition that demands immediate treatment. The term derives from the Latin "De," which means away from and "lira" which is a furrow in a field and, thus, literally means going off the plowed track.

Pathophysiology

Generalized cerebral dysfunction is reflected in the electroencephalogram which shows diffuse slowing of the dominant rhythm and functional imaging that shows generalized cortical hypoperfusion, both of which normalize with resolution of the delirium. Multiple neurotransmitters are implicated, but hypoactivity of the cholinergic system is seen as a common pathway. This is the basis of using neuroleptics to treat delirium symptoms—as dopamine antagonists, they increase cholinergic activity. Gamma aminobutyric acid (GABA) excess (hepatic encephalopathy, propofol, benzodiazepines) or deficiency (alcohol withdrawal) are other delirium pathways. More recently, noradrenergic hyperactivity has been viewed as an important common pathway [51].

Risk Factors

Delirium is more likely in individuals with the following risk factors: age > 75, preexisting cognitive impairment, sleep deprivation, hypoxia, metabolic abnormalities, alcohol or drug abuse, visual impairment (increases risk 3.5 times but not auditory impairment), severity of underlying illnesses, restraints, catheters, leg compression devices, casts, ventilation, and polypharmacy (especially those medications with high anticholinergic potential).

Clinical Features

Delirium is characterized by an abrupt onset of altered consciousness (alertness) with difficulty in focusing, sustaining, or shifting attention. Typically symptoms fluctuate throughout the day and night. Mood is impaired and it is not uncommon for these patients to be referred to psychiatry for evaluation of depression because they seem depressed or withdrawn. Cognitive problems such as disorientation, memory loss, incoherent or rambling speech, dysnomia, dysgraphia, and perseveration are seen. Perceptional problems such as hallucinations and delusions are common and are disturbing to patients and their families alike. Psychomotor activity may be increased in agitated delirium but lethargic, hypoactive delirium is more frequent. Neurological signs such as asterixis, tremor, frontal release, myoclonus, and altered muscle tone are common [14].

Course

Delirium lasts on average 10–12 days (range 1–8 weeks), but 15% of cases last more than 30 days. Although delirium was originally seen as completely reversible, it is now recognized that, in 20%, there are signs of dementia or cognitive decline 1 year later. In cases of recurrent delirium, cognitive decline is even more pronounced and mortality is greater. Delirium results in a prolonged length of hospital stay, greater medical expenses, and secondary complications such

as falls, nosocomial infections, and pressure sores. Terminal delirium is important to recognize as a harbinger of approaching death.

Mortality

The 6-month mortality in ICU patients is 34% in delirious patients vs. 15% in nondelirious, 8% in delirious hospitalized patients vs. 1% in nondelirious hospitalized patients, and 11% in elderly delirious patients vs. 3% in nondelirious patients [51].

Management

Delirium, like anemia, is not a diagnosis but rather a clinical syndrome, therefore its treatment addresses the underlying cause (Table 60.6). Often the triggers of delirium are multifactorial with medications being well-known iatrogenic culprits. Narcotics are common causes of delirium in oncology settings and, of the narcotics, meperidine has the greatest propensity for delirium. Antihistamines, benzodiazepines, and steroids are also commonly implicated.

It is often not appreciated that a variety of common medications have an anticholinergic load including furosemide, digoxin, theophylline, prednisone, and nifedipine. Anticholinergic activity correlates directly with delirium [52]. Elderly patients who take multiple drugs with anticholinergic burden have measurably decreased physical strength and worse functional ability [53]. As the cholinergic load of drugs is not usually available on standard pharmacy databases, common sense wisdom suggests stopping all unnecessary medications in delirious patients, including antidepressants.

Table 60.6 Clinical risk factors for delirium

Infection: UTI, pneumonia, sepsis, meningitis, infected line, or device
Cardiac: acute infarction, hypotension/hypoperfusion, arrhythmia, congestive heart failure
CNS: stroke, normal pressure hydrocephalus, bleed, trauma
Renal: failure
Hepatic: failure
Respiratory: Hypoxia, pulmonary embolus, respiratory failure
Nutritional: malnutrition, thiamine/Wernicke's encephalopathy, dehydration
Endocrine: hyper/hypothyroidism, hyper/hypoglycemia, hyper/hypokalemia, hyper/hyponatremia, cortisol deficiency, or excess states
Sleep: deprivation, over sedation
Environmental: Hyper/hypothermia, trauma/surgery, fractures
Substance withdrawal, intoxication, heavy metal poisoning
Pain: poorly controlled

Nonpharmacological treatments include normalizing night/day, sleep/wake cycles (an ICU patient gets less than 2 h sleep/night), avoiding restraints, ensuring the calming presence of family, 1:1 nursing, and precautions against falls.

Intravenous haloperidol is considered the gold standard for targeting agitation, hallucinations, and for reducing the overall length of the delirium episode [54]. Oral haloperidol should be avoided because of its propensity to cause extrapyramidal symptoms. A dose of 0.5–2 mg IV can be administered every 2–6 h, or less frequently if necessary. Alternatively, it can be given as a continuous infusion. The maximum daily dose of 20 mg/day is usually considered adequate, although, it is safe to increase the dose as long as the QTc is not prolonged. A QTc > 480–500 ms or a 25% increase from baseline is of concern. QTc prolongation causing Torsades de Pointes and sudden death is the most dangerous side effect of this class in medical settings but the incidence of neuroleptic malignant syndrome, manifested by stiffness, fever, and a raised CPK, is less common.

Intravenous chlorpromazine 12–50 mg every 4 h and oral or orally disintegrating olanzapine 2.5–5 mg every 12–24 h are other common alternatives. Clinicians prescribing atypical antipsychotics such as olanzapine should be familiar with FDA black box warnings for increased risk of mortality and cerebrovascular disease in the elderly [55]. Olanzapine has recently been shown to be helpful for delirium prophylaxis when 10 mg is given immediately prior to surgery and immediately after [56].

Dexmedetomidine has been shown to significantly reduce the rate of postoperative delirium after cardiac surgery and represents an exciting future direction, representing a therapy targeted to the norepinephrine common pathway [57].

Benzodiazepines should generally be avoided as they can worsen delirium, the only exception being alcohol withdrawal, where benzodiazepines are used as a treatment and antipsychotics are not usually given. Flumazenil, a benzodiazepine antagonist, has been shown to be helpful for hepatic encephalopathy, where GABAminergic excess is postulated.

In terminal delirium, the goal is comfort and benzodiazepines or other sedating agents such as barbiturates, which are usually avoided in delirium, can be given for terminal agitation.

Hematopoietic Stem Cell Transplant

Hematopoietic stem cell transplant (HSCT) offers a chance for cure but at the risk of morbidity and mortality. After the transplant, patients and their families must deal with three types of problems: physical, psychological, and community reintegration [58].

Physical problems after a HSCT include fatigue, physical disability (e.g., Graft Versus Host Disease (GVHD),

complications of steroids, hair loss), complications (e.g., shingles, sepsis), eating problems, nausea, vomiting, immune restrictions (e.g., limitations in gardening, being in crowds), difficulties with sex, and infertility. Even if patients survive the acute phase, they still must be wary of the need to manage long-term sequelae such as chronic GVHD, osteoporosis, cataracts, hypothyroidism, respiratory problems, and secondary cancers.

Psychological problems include anxiety and depression colored by a pervasive caution and fear of relapse or infection. Due to immune restrictions, isolation often contributes to loneliness and boredom. Patients may have survivor's guilt that fellow transplant patients did not make it or true bereavement at having lost "hospital" friends. They may be angry at the world, asking, why me?

After the dislocating HSCT, a further challenge is reintegration back into family life, working, social and sporting environments. Relationships are stressed especially where caregivers are vulnerable to burnout. Intimacy may be altered by the prolonged illness, neuropathy, or dry mucous membranes. Not infrequently, couples have marital conflict or separate. Resuming family roles with the expectation that life will continue where it left off before the transplant is common but unrealistic. Stigma is real and patients may encounter work discrimination or feel tainted. Infertility complicates attempts to date and form relationships and the question of what to disclose, and when, is always worrying. Stress resonates through the whole family network; often the whole family suffers financially as the cost of medical expenses balloons.

Therefore, it is not an exaggeration to say that full recovery from a myeloablative HSCT is a 3–5 year process. At 3 and 5 years, about 20% of these patients still have major physical limitations. In addition, 42% and 13% still report significant distress at the 3 and 5 year marks [59].

Are physical outcomes predicted by whether the transplant is autologous or allogeneic or whether the patient develops chronic GVHD? One would think so but this is not necessarily the case. Depression, radiation pretransplant, and higher medical risk but not the transplant type or chronic GVHD, predict physical outcomes [59].

Chronic GVHD is, however, associated with greater depression but depression is not predicted by the transplant type or high vs. low medical risk. Nevertheless, depression does resolve faster in autologous transplant patients. Overall, 22% of HSCT patients will develop major depression at one point or another during the transplant, supporting the need for skills to manage and treat depression. By 5 years, 84% of survivors without recurrence, who worked prior to the HSCT, have returned to full-time employment [59].

Finding a donor can be stressful. If a sibling is a donor but the patient ultimately dies, that sibling may feel responsible or attribute the death to his/her own shortcomings. Where there is sibling rivalry or conflict, willingness to donate may not be a given. The matching process may also reveal that a parent or sibling is not biologically related to the patient and this may be unwelcome knowledge at a sensitive time.

Psychiatrists and psychologists perform an important role in screening patients for suitability prior to transplant and all HSCT programs should consider the benefits of this type of screening program. Such screening programs are already the norm in solid organ transplantation programs. In pretransplant evaluations, transplant psychiatrists (or psychologists) must make it clear that they represent the transplant team and that the report generated will be sent to the transplant oncologist and become part of the medical record. It is equally important to state that the assessment is not a pass/fail exam but rather aims to identify psychological or family problems as early as possible so as to resolve difficulties effectively. Thus, the stance is one of teamwork, problem-solving, and anticipation.

Patients should be screened for current depression, anxiety, and substance use (alcohol, cannabis, nicotine, stimulants, narcotics, etc.). A detailed history should probe for past depression, anxiety, substance use, and other psychiatric issues, as the past is predictive of the future. Personality traits should be considered but in reality, only low functioning borderline or other personality disorders, for whom adherence has been demonstrably poor in the past, represent contraindications to transplant. This is because poor or inconsistent adherence represents a clear danger to patients who require immunosuppressive treatments posttransplant. Schizophrenia and bipolar disorder are not contraindications to transplant and many such patients have been successfully transplanted. Family cohesion, conflict, and supports are also an important part of the pretransplant psychiatric assessment.

A number of behavioral strategies can be useful to patients entering the transplant process. Anticipation leads to better planning and preparation. A tour of the transplant floor is helpful to demystify the aura of the transplant and to promote future-oriented planning. For example, the patients should consider how they will occupy their time productively during the long admission. Hobbies can be adapted to the hospital setting. Video games such as "Wii Fit" can be brought to hospital. Early involvement of physical therapists is beneficial. Modified exercise and stretching promotes an early expectation of rehabilitation and wellness. The hospital can provide exercise bicycles that remain in the room permanently. Exercise bands can be used to maintain muscle tone. Integrative medicine and music therapy can be very helpful in promoting wellness, and hope, counteracting potential patient passivity.

Planning for the best, worst, and most likely outcomes facilitates an open dialogue for discussing the possibility of death and advance care directives. Health care agents should be involved in this discussion.

Patients often experience the transplant infusion as an anticlimax. This point can be used to educate patients that, technically speaking, the transplant will not be dramatically different from the various infusions and treatments that they have received to date.

Discharge home can paradoxically trigger depression—this is known as the "vacuum effect." Patients transiently feel lost and abandoned after weeks of intensive inpatient treatment. When their doctor instructs them to return to the hospital in a week's time, they have difficulty adjusting to life outside the cocoon. Usually, educating the patient and the family about the "vacuum effect" is all that is required but antidepressants may be helpful if major depression develops.

Physician burnout is an important issue as transplant physicians are extremely hard working and conscientious. Treatments are prolonged and fatiguing. Mortality is high. Furthermore, physicians often feel pressured to accept patients with a low likelihood of survival, but few alternative oncology treatment options. One transplant physician dubbed these transplants, which are likely doomed to failure, as "Hail Mary transplants." Burnout is discussed in further detail later in this chapter.

Future developments will likely see an increase in outpatient transplant volumes, widened indications, older patients, and newer technologies, e.g., chord transplants, all of which have challenges for psycho-oncology.

Neurocognitive Effects of Cancer Treatments

Once referred to colorfully as "chemo brain," it is now appreciated that a variety of anticancer treatments can cause neurocognitive damage. Typically these patients complain of difficulty with executive functioning, such as multitasking, and diagnosis is made via formal neurocognitive testing. Possible mechanisms include direct neurotoxicity, an immunologic inflammatory response, or microvascular injury. Neurocognitive changes can last from 2 months to 3–10 years or more. Particular vulnerability is seen in carriers of the Alzheimer's susceptibility gene, Apolipoprotein (APOE) [60].

Communication Skill Training

Patients generally recall only about 25% of the data that oncologists consider important and, furthermore, poor information provision increases rates of depression, which is understandable because not knowing what is going on can be demoralizing.

Communication skills training can help physicians to more effectively break bad news, discuss prognosis, manage angry patients (or families), discuss unanticipated adverse events, end-of-life goals of care, Allow Natural Death (Do-Not-Resuscitate) directives, and the withdrawal of life-extending care. Knowing how to effectively conduct a family meeting is an essential skill that is not taught in most training programs. Programs such as Oncotalk or Memorial Sloan-Kettering Cancer Center's Comskil program use role-playing with simulated standardized patients, which has been found to be an effective training method. All oncology programs should consider the value of adding communication training to their educational program.

Burnout and Compassion Fatigue

Burnout is a well-defined and measurable psychological triad of emotional exhaustion, depersonalization (cynicism towards patients), and a sense of reduced personal accomplishment (inefficiency) that is common in oncology settings [61, 62]. Ramirez described a 28% prevalence of burnout among cancer physicians, a rate that is similar in nononcology physicians [63].

Burnout at work can be moderated by an oncologist's personal happiness, family cohesion, personal psychiatric problems (such as depression), physical fitness, and creativity. Work difficulties in combination with problems outside of work can increase the risk of overwhelming the individual and precipitate burnout. Younger (age < 55), single and female physicians are more likely to develop burnout. The Physician Work Life Study found that women may be 1.6 times more likely to report burnout than males. Additionally, for every 5 h worked over the typical 40 h per week, the odds of burnout increased 12–15% for female physicians, but not for males [64]. In other words, working reasonable hours is important if a woman is expected to juggle both an oncology career and a family. In these studies, career support from a spouse provided a buffer for female physicians against burnout.

Unfortunately, there is evidence that the mental health of physicians has worsened over time. In 2002, compared to 1994, physician psychiatric morbidity had increased from 27 to 32% and burnout from 32 to 41%, with worse results in physicians working in oncology compared to radiology or gastroenterology [65]. Worsening burnout rates may also reflect an overburdened health system.

As recognition of this vulnerability of physician burnout, the Joint Commission on Accreditation of Healthcare Organizations in the USA has mandated a distinct process that deals with physician well-being, separate from the disciplinary processes.

Burnout can be addressed either prophylactically or remedially; a tailored approach is probably most effective. Meta-analytical data provides preliminary support for individual-focused and organization-focused burnout interventions [65].

Collaborative Care

Collaborative Care is a new population-based approach which targets the patient, clinician, and system of care. Its aim is to measurably improve psychological outcomes and, in so doing to, improve medical outcomes and utilization of services. The latter is important in Accountable Care Organizations where fee-for-service is replaced by capitated arrangements providing an incentive to keep patients out of hospital, reduce emergency department utilization and length of stay.

Care managers (usually nurses or social workers) are supervised by a psychiatrist and, in so doing, act as physician extenders embedded into primary care or oncology settings. Thus, mental health is integrated into medical care. It also addresses the problem of access to psychiatric care which has long frustrated oncologists.

Collaborative care has shown that by treating depression and teaching patients to better manage chronic illness, cardiovascular and diabetes outcomes are improved [66].

A large multisite trial of collaborative care for depression in cancer patients used nurses to deliver up to 10 sessions of treatment comprised of psychoeducation, problem-solving, behavioral activation, and symptom monitoring, followed by 8 months of symptom monitoring with additional sessions as needed [67]. Depression was significantly improved in the collaborative care group as compared to treatment-as-usual (62% vs. 17%) and there were also greater improvements in anxiety, pain, fatigue, functional ability, quality of life, and perceived quality of care.

Conclusion

Because psychosocial problems are so prevalent in patients with hematological malignancies, oncologists should show demonstrable competency in treating depression, anxiety, delirium, and other such issues. Psychosocial oncology services, preferably integrated with palliative care, should be developed as it is almost impossible for one clinician to meet complex medical and psychosocial challenges alone. A multidisciplinary team approach is required and Collaborative Care is a new way to organize delivery of care effectively. Communication skills training has received increasing attention as a way for oncologists to improve their ability to manage complex scenarios or cancer decision-making more effectively. Finally, burnt-out oncologists represent a burden to their own personal health and happiness, to their families, and to their patients and colleagues. First and foremost, look after yourself!
