Polymers and Polymeric Composites: A Reference Series

Series Editor
Sanjay Palsule
Indian Institute of Technology, Roorkee
Saharanpur, India

This series provides a comprehensive collection of reference handbooks on all aspects around polymers and polymeric composites. Polymeric materials of all sorts have been emerging as key materials for many applications and for meeting the challenges of the twenty-first century. From commodity applications to engineering and high-tech applications, even including aerospace subsystems, these materials have an important role to play. The study of polymeric and polymeric composite materials is one of the most important and vibrant focus areas in chemical and material scientific research. "Polymers and Polymeric Composites: A Reference Series" compiles the most comprehensive reference handbooks on these materials under one roof. Readers will find all they need to know in well-organized and thoroughly structured reference works covering various topics, such as the structures and properties of polymers and polymeric materials and composites (e.g. structures of amorphous and crystalline polymers, viscoelastic properties, mechanical and thermal properties, and many more); methods and methodology (including polymer characterization, polymerization reaction engineering, polymer processing, and many more); and different compound classes (from polymer additives, polymer blends, and fiber-reinforced composites to liquid crystalline polymers, nano-polymers, and nano-polymeric composites and even bio-polymeric materials). While each volume is dedicated to a selected topic, concisely structured and thoroughly edited by experts, with contributions written by leading scientists, the complete collection provides the most comprehensive and most complete overview over the entire field of polymers and polymeric composites. Volumes in this series serve as reference compilation for every scientist working with or on polymers and polymeric materials and composites, whether at universities or in industry, from graduate student level to practitioners and lead scientists alike.

Preface

Hydrogels are a particular class of macromolecular gels obtained by the chemical stabilization of hydrophilic polymers in a three-dimensional network, in which the dispersed phase is water. They are able to absorb and retain large volumes of water from any aqueous solution or biological fluid and release it in response to specific environmental stimuli. The applications of hydrogel technologies are being widely used as absorbent cores in hygiene products (such as baby diapers, personal healthcare products, etc.), for drug delivery, in tissue engineering, in pharmaceutical and biomedical products, as water retainers, and as carriers of agrochemicals (such as fertilizers, insecticides, etc.) in agriculture and biotechnology. The flexibility and high water content properties of hydrogels are similar to those of natural tissue, making them extremely suitable for biomaterial applications. The rapidly growing business has motivated multinational companies to develop new hydrogel technologies, with a focus on consumer expectations.

However, most of the superabsorbent hydrogels that are currently on the market are acrylate-based products. Hence, they are not biodegradable and biocompatible, and, most importantly, some concerns exist about their toxicity. This limits their application to products related to human use or consumption. As a result, the renewed attention of institutions and public to the environment has led manufacturers to consider the development of nontoxic, biodegradable, and biocompatible superabsorbent hydrogels.

Cellulose is the most abundant, relatively simple, easily accessible, and cheap biomolecule in nature. In addition, the fabrication of cellulose-based superabsorbent hydrogels is cost effective and environment friendly. Cellulose is a promising natural polymer material because of its hydrophilicity, renewability, biodegradability, biocompatibility, and nontoxicity. Thus, cellulose-based hydrogels, as well as other natural polymer-based hydrogels (or bio-based hydrogels), can have the abovementioned favorable properties.

This book presents the first comprehensive reference concerned exclusively with this topic. The book provides easy access to the subject, both for those who are just starting to work in the field and for experienced academic and industrial professionals. It presents a broad survey, with insight, of synthesis, hydrogel modification, mechanism of formation, characterization, behavior, structure and functions relationships, and applications of cellulose-based superabsorbent hydrogels as well as other

bio-based hydrogels. The potential applications of cellulose-based hydrogels are in the fields of drug delivery, pharmaceuticals and biomedicine/biomaterials, tissue engineering, wound dressing, food packaging, water purification, agriculture, horticulture, etc. The book thus covers all these fields. The references in each chapter of the book provide a basis for deeper investigation of the recent advances in the field.

This book deals with cellulose-based hydrogel functioning materials and other bio-based materials. Each chapter explains the current status of research and technology in the study of synthesis routes or design concepts, methods and fabrication strategies, characterization and applications of cellulose-based hydrogels, as well as future prospects for research in the subject area. The book is intended mainly for polymer chemists and experts in materials science. Other potential readers are industrial scientists and engineers, agricultural engineers, pharmaceutical and biomedical scientists, and biotechnologists engaged in research and development on absorbency, absorbent products, and superabsorbent hydrogels. This book can also be helpful to graduate and undergraduate students.

Cellulose-Based Superabsorbent Hydrogels is a comprehensive major reference book. It is divided into two volumes that are organized into five parts:

Part I. Fundamentals of Cellulose, Superabsorbents, and Hydrogels
Part II. Synthesis of Cellulose-Based Hydrogels
Part III. Characterization Tools and Techniques of Hydrogels
Part IV. Applications of Biocompatible Hydrogels
Part V. Other Bio-Based Hydrogels and Their Applications

There are altogether 60 chapters in these five parts.

Part I, Fundamentals of Cellulose, Superabsorbents, and Hydrogels, concentrates on the fundamental aspects and the theoretical basis of different types of common and smart hydrogels. This part covers synthesis, structure formation mechanism, functions, and performance of both synthetic- and cellulose-based superabsorbents. It also covers stimuli-responsive, enzyme-responsive, and multifunctional hydrogels. This part discusses some of the important specific features of hydrogels that should be considered and understood in synthesis for target applications, such as technological feasibility of cellulose-based hydrogels with respect to environmental sustainability, physicochemical properties in structure–property relationships, mechanistic roles of cellulose and cellulose derivatives in cellulose-based absorbents, absorption and gelation mechanisms for superabsorbency, and the advantages of biorenewable hydrogels over synthetic hydrogels. The up-to-date research advances, future research scope, and diverse applications of cellulose-based hydrogels in pharmaceuticals, biomedicine, and agriculture are overviewed in this part.

Part II, Synthesis of Cellulose-Based Hydrogels, summarizes major design concepts, synthesis routes, preparation and modification methods, and fabrication of different types of cellulose-based hydrogels. Cellulose is very susceptible to various organic and inorganic chemicals, due to which many cellulose derivatives, as well as hydrogels, with either hydrophilic or hydrophobic characteristics, are

possible. The production methods of superabsorbent hydrogels and aerogels, composite and nanocomposite hydrogels, surface-functionalized hydrogels, and conductive and smart hydrogels from cellulosic materials by various polymerization reaction methods and irradiation techniques are described in this part. To develop 3D-cross-linked cellulose-based hydrogels, polymerization reaction engineering as well as its kinetics and mechanisms are also highlighted.

Part III, Characterization Tools and Techniques of Hydrogels, covers the characterization and analysis of cellulose-based hydrogels using different physicochemical and instrumental techniques. Physicochemical, morphological, structural, thermal, and the relevant instrumental analyses are discussed in this part to elucidate the three-dimensional network structure of cellulose-based hydrogels. Their structural, functional, surface, and interfacial absorption and swelling mechanisms are also described. Experimental methods to measure the elastic modulus of hydrogels, depending on their measurement scale, whether macroscale, mesoscale, or microscale, are also reviewed. The designed hydrogels can be characterized by physicochemical and sol-gel analyses and instrumental analyses, such as Fourier-transform infrared spectroscopy (FTIR), nuclear magnetic resonance (NMR) spectroscopy, X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), atomic force microscopy (AFM), polarized optical microscopy (POM), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), and thermomechanical analysis (TMA), to investigate and elucidate the desired product structure, functions, and application performance.

Part IV, Applications of Biocompatible Hydrogels, covers the diverse range and uses of biodegradable and biocompatible cellulose-based hydrogels. This part discusses different important applications which are essential and sustainable for human beings, other living things, and the environment. Each chapter describes specific types of applications in detail. The superabsorbency, permeability, flexibility, and high water content properties of hydrogels give this class of materials an amazing array of uses. These uses range from antimicrobial, antifungal, nontoxic, hygiene, biodegradable wound dressing, personal care, and food packaging products to products used in the fields of drug delivery, pharmaceuticals and biomedicine, tissue engineering, and regenerative medicine. These materials are also widely used for a range of smart applications, such as stimuli-response materials, oil contaminant removal, smart corrosion inhibitors, delivery of agrochemicals (pesticides, fertilizers, etc.), water treatment, and water retention in desert and arid areas. All these applications are vividly described in detail with tables, figures, and illustrations in this part.

Part V, Other Bio-Based Hydrogels and Their Applications, summarizes synthesis, design concepts, mechanism of formation, fabrication, characterization, performance, and applications of important bio-based hydrogels. The biodegradable bio-based hydrogels are derived from polysaccharides, carbohydrates, chitosan, protein, gelatin, collagen, and silk. Two chapters in this part differ slightly from the others: ▶ Chapter 46 summarizes the applications of synthetic hydrogels as absorbing materials for the removal of pollutants, dyes, heavy metals, and

radioactive elements as well as for controlled and sustained release of agrochemicals and explains their impacts on health and the environment. ▶ Chapter 52 highlights the importance of PLA-based hydrogels in biomedical applications, with a significant focus on scaffolds for the treatment of damaged tissues.

All the authors who were invited to write chapters in this book have many years of experience in hydrogel research, and their knowledge is succinctly condensed in this volume. Each chapter is an authoritative treatise on its specific topic and can be read independently. Vivid schematics and illustrations in each chapter, as well as throughout the book, enhance the accessibility of the theory and technologies described therein. All chapters of this book were reviewed by at least one reviewer, revised by the authors according to reviewers' comments, and then edited by the editor.

The editor would like to express his gratitude to all prominent academics and professionals for their excellent contributions to this book and to the reviewers for their efforts and valuable comments. He gratefully acknowledges Springer International Publishing AG, Switzerland, for allowing him the opportunity to participate in this publication and also expresses his sincere thanks to Lydia Mueller and Dr. Sylvia Blago, Support Staff for Major Reference Works of Springer International Publishing AG, for their support and helpful suggestions along the way.

The editor wishes to express his sincere thanks and gratitude to his teachers, especially Professors C. M. Mustafa (his elder brother), F. I. Farouqui, and Md. A. Sayeed of the Department of Applied Chemistry and Chemical Engineering, University of Rajshahi, Bangladesh, who helped him with their valuable suggestions, from the beginning and over the years. The editor would also like to express his indebtedness to Professor Akira Kai of Tokyo Metropolitan University, Japan; Professor Duncan A. S. Phillips and Dr. Hunter Renfrew of the University of Manchester Institute of Science and Technology (UMIST), UK; Professors Yasumitsu Uraki and Makoto Ubukata of Hokkaido University, Japan; and Professors Rokiah Hashim and Othman Sulaiman of Universiti Sains Malaysia for their generous help and guidance. He also thanks Professor Md. Ahsan Habib and his research team, especially graduate students Md. Obaidul Haque, Firoz Ahmed, Md. Nazmul Huda, and Mrs. Moslima Khatun, who helped him with the editorial work. And finally, the editor wishes to take this opportunity to express his deep appreciation to his family, especially to his wife Khadijatul Qubra (Mita) and his daughters Ishrat Maria and Ishrat Rafia, for their encouragement, understanding, support, and patience during the course of the project.

The editor hopes that the book will serve as a useful reference to students, researchers, academics, and industrialists in the field of bio-based hydrogel research.

Any constructive suggestions and comments are therefore welcome for future revisions and corrections.

Volume 1

About the Editor

Dr. Md. Ibrahim H. Mondal is a Professor in the Department of Applied Chemistry and Chemical Engineering at the University of Rajshahi, Bangladesh. He obtained his M.Sc. in Applied Chemistry and Chemical Technology from the University of Rajshahi, Bangladesh, in 1986 and his Ph.D. from Tokyo Metropolitan University, Japan, in 1997. Dr. Mondal was a Commonwealth Visiting Scholar at the University of Manchester Institute of Science and Technology (UMIST) in the UK during 2003–2004, Visiting Professor at the Hokkaido University in Japan during 2006–2007, and a Visiting Scientist at the Universiti Sains Malaysia, Malaysia, during 2009–2010. His research area includes natural polymers, cellulose and cellulose derivatives, textiles, and textile wet processing. He is an author, co author, or editor of more than 140 research articles, book chapters, and seven books.

Abstract

Hydrogels are insoluble three-dimensional cross-linked polymeric network that swells in presence of water and other fluids. They can hold plenty of water compared to its own mass. The absence of dissolution attraction toward water is due to hydrophilic nature of the polymeric chain. Hydrophilicity arises because of holding hydrophilic functional groups in the chain. Highest portion of the world production of hydrogels is petrochemical based which is neither renewable nor biocompatible. In spite of some drawbacks like nondegradability, synthetic hydrogels are superior to natural one in water absorbency, diversification in chemicals, and longer service life. Taking into consideration sustainability factor, scientists are interested in preparation of hydrogels from renewable cellulosic sources. As cellulose possesses intrinsic nature of degradability, biocompatibility, and nontoxicity, also available in nature, and some cellulose derivatives show smart behavior, cellulose-based hydrogels can be an alternative to synthetic petrochemical-derived hydrogels. Numerous research articles concerning the synthesis and utilization of hydrogels in different fields have been published, and still restless labor is giving for the betterment of the product quality. It is a crying need to make available and adequate information on synthesis and characterization of cellulosic hydrogels for individual researchers. For this the specific aim of this paper is to accumulate some crucial information which will cover synthesis, detailed classification, characterization, and technological feasibility of application about hydrogels of renewable source. As of consequence, the research on hydrogel concerning current environmental issues will reach to its target of making the greener solution of sustainability. In addition, recent trend of hydrogel research is also discussed in this review.

Cellulose · Cellulosic hydrogel · Cellulose derivatives · Hydrophilic · Renewable · Biocompatible · Sustainability

1 Introduction

Hydrogels are gel-like materials with hydrophilic functional groups in polymeric chain and capable of holding large volume of hydrofluids compared to its own mass. It can also be defined as hydrogels are water-absorbing natural or synthetic polymeric substance which swells in water and retain a significant amount of water within the structure without dissolving in water [1–3]. Hydrogels attract water due to polar functional groups on the skeleton of macromolecule and inhibit dissolving due to cross-linking. Both types of cross-linking, chemical or physical, can exist in the macromolecular chain. After absorption, generally hydrogels swell until the thermodynamic force of swelling is totally counterbalanced by the elastic, retroactive force exerted by the cross-links. The volume of water taken up by macromolecule depends on the structure of the polymer network itself and on the environmental conditions, such as the temperature, pH, and ionic strength of the water solution in contact with the polymer [4, 5]. The most important variable that affects the diffusive, mechanical, optical, acoustic, and surface properties of the hydrogel for given environmental conditions is the volume or mass swelling ratio of the hydrogel.

Hydrogels are of mainly two categories based on their natural or synthetic origin: biopolymer-based and synthetic. Hydrogels prepared at the early stage are non-biodegradable and originated from nonrenewable petroleum based. Among various biopolymers, cellulose is largely available in nature and shows hydrophilic nature and good mechanical properties because of enormous hydroxyl groups. The mechanical strength and its insolubility in water and in the major part of solvents depend mainly on the complex system of hydrogen bonds between hydroxyl groups. Due to plentiful hydrophilic functional groups, it gives possibility to cellulose as promising material for hydrogel preparation. Generally natural polymers, especially polysaccharide-based hydrogels, find application in many fields (agriculture, tissue engineering, drug delivery, biosensors, etc.) and make scientists interested about the matter due to some unique qualities like eco-friendly, renewable, and low cost. Among various polysaccharides, few have been investigated on hydrogel formulations, such as chitosan [6, 7], starch [8, 9], cellulose [9], alginate [10], carrageenan [11], and gellan gum [12].

Manufacture of hydrogels from cellulose generally is accomplished in two steps [4, 6, 7, 11], (i) dissolving of cellulose fibers or powder and (ii) cross-linking (chemical and/or physical) of the chains, in order to obtain a three-dimensional network of hydrophilic polymer chains, which is able to absorb and retain a significant amount of water. It is also reported that cellulose-based hydrogels were prepared and used as a novel porous bioabsorbent by graft copolymerization for absorption of heavy metal ions from aqueous solutions. Therefore, the diversified application of cellulose-based hydrogels is flourishing gradually. After the invention of first hydrogels by Otto Wichterle in the 1950s [13], from then scientists are trying to improve the qualities and to make novel superabsorbent which will fulfill the required expectations. The modern application of cellulose and its derivatives

includes environment-friendly and economic nonaqueous gel polymer electrolytes for lithium and sodium ion batteries [14–16], aqueous electric double-layer capacitors, dye-sensitized solar cells [17], and starting materials for proton-exchange membranes (PEMs) in PEM fuel cells (FCs) [18].

It is obvious that cellulose and cellulose derivatives will not replace petroleum-based superabsorbent materials completely, but incorporation or use of the materials will bring some good qualities in hydrogels like biodegradability, biocompatibility, nontoxicity, cost-effectiveness, etc. As we know cellulose is the main constituent of plant and at the end use it decomposes. Moreover, the cellulose-based hydrogels are reusable, and processes involve less wastage of chemicals and not releasing greenhouse gases to environment, so the process can be mentioned as greener technology.

The aim of the review paper is discussion from cellulose-based published literature of hydrogels and focuses the types, use, and world consumption scenario, synthesis, controlling factors of reaction, etc. of cellulose-based hydrogels which will be an informative and fruitful tool to solve the sustainability problem. After discussing characterization techniques, some well-established and innovative applications of synthetic and cellulose and its derivatives hydrogels both are also discussed, with some suggestions for future developments.

2 History and Market Size of Hydrogels

In 1938, the first water absorbent was synthesized by thermal polymerization of acrylic acid and divinyl benzene in aqueous medium [5]. Later in 1950, Otto Wichterle [13] synthesized first generation hydrogels which were based on poly (hydroxyethylmethacrylate) (PHEMA) and used in contact lenses. Though the swelling capacity of hydrogels from same type of monomers was only 40–50%, it was a revolution in ophthalmology [19].

The first commercial synthetic-type superabsorbent polymer (SAP) hydrogel was starch-graft-polyacrylonitrile (SPAN), and its hydrolyzed product (HSPAN) was developed in the 1970s at the Northern Regional Research Laboratory of the US Department of Agriculture [20]. The product did not get commercial success due to expenses and inherent structural disadvantage (lack of sufficient gel strength) of this product. Japan started their first commercial production of hydrogel in 1978 for use in feminine napkins and later in 1980 Germany and France started using in baby diaper. Japan started manufacturing diaper in 1983 with 4–5 g SAP, hydrogel in every single piece of diaper. Within very short time, other countries in Asia, USA, and Europe also started manufacturing diaper with hydrogels. Practically SAP, hydrogels brought a drastic change in the concept of diaper item to replace fluff cellulosic materials. Finally, the diaper became thinner by the use of hydrogels. Actually within one decade, huge development occurred in personal health-care product.

From an online data analysis, it has been found that the worldwide hydrogel production and consumption are increasing. In this case, China is the biggest market

in the Asia-Pacific region, and the USA is the largest end user and producer of SAP in the North American region. Both countries are the largest consumers in their respective regions and are expected to compete with each other to dominate the market by 2020, with advanced SAP materials for end users. Current market size of superabsorbent polymer was estimated at 2.07 million tons in 2014 and is likely to exceed 3.1 million tons by 2023 growing with an expected compound annual growth rate (CAGR) of over 5.5%. It has also estimated that the worth of global market value of SAP will reach USD 7.96 billion by 2020.

Renewable raw materials such as starch, cellulose, natural gums, and chitin have been used in the manufacture of biobased SAP. Biobased superabsorbent polymers provide environmentally sustainable alternatives to fossil-based materials. They also offer effective moisture retention and absorbency for applications such as baby diapering, packaging, feminine hygiene, and adult incontinence products. It is also reported that the Archer Daniels Midland Company (ADM) has launched newest generation of biobased product such as BIOSAP (the company patented the technology of preparing using modified starch with similar technique of acrylic-based SAP preparation) – Lysorp 218 and Lysorp 220.

Few companies are catering to large part of the demand of global superabsorbent polymer market share. The key companies involved in this market which bear largest share include the BASF, Nippon Shokubai, Evonik, Sumitomo, and LG Chemical. Some other prominent companies also have significant share of market which include the Formosa Plastics, KAO Corporation, SDP Global Corporation, Yixing Danson Technology, and Songwon Industrial Corporation Limited.

3 Classification of Hydrogels

Hydrogels can be classified from various perspectives and depend on many factors. Properties of hydrogels are governed by the sources from where they are prepared. One of the specific aims of this classification is to make an understanding about the nature of hydrogels of biocompatibility, on the basis of sources from where they are originated:

(i) **Classification based on source:** Hydrogels are of mainly two groups according to their origin, i.e., natural and synthetic. Depending on the natural sources, this category includes collagen, fibrin, hyaluronic acid, Matrigel, and derivatives of natural materials such as chitosan, alginate, and silk fibers. On the other hand, hydrogels prepared from synthetic sources are mainly petrochemical based. As biocompatible hydrogel (i.e., biobased) carries extra emphasis according to the title, the author finds responsible to give brief discussion on biobased hydrogel in Sect. 3.1.

(ii) **Hydrogels based on polymeric composition:** The methods of preparation of hydrogels alter the types of product. The use of number of monomers gives hydrogels with different properties. Types of hydrogels based on polymeric composition are [21] described below:

Hydrogels from homopolymer: Polymeric network is formed from single monomer, and it is the fundamental structure on which the whole chain grows. The growing chain can also be cross-linked to alter properties by various polymerization techniques.

Hydrogels of copolymers: Hydrogels are formed by two or more different monomer species, among them at least one hydrophilic component arranged in a random, block, or alternating arrangement along the chain of the polymer network.

Hydrogels of interpenetrating polymeric network (IPN): This important class of hydrogels is prepared from two independent cross-linked synthetic and/or natural polymer components, arranged in a network form. In semi-IPN hydrogel, one component is of cross-linked polymer, and the other is a non-cross-linked polymer.

(iii) **Classification based on crystallinity:** Hydrogels are polymeric materials and gain various crystal structures during manufacture on the basis of technique applied. They are of mainly crystalline, amorphous, and combination of the previous two semicrystalline.

(iv) **Classification based on type of cross-linking:** Cross-linking is a common practice in hydrogel preparation. Two types of cross-linking are observed in hydrogels, chemical or physical. As a result, two types of networks are formed. In chemical cross-linking, the junctions formed are permanent, while in physical cross-linking, networks formed are fragile in nature. Transient junctions arise either from polymer chain entanglements or physical interactions such as ionic interactions, hydrogen bonds, or hydrophobic interactions.

(v) **Classification based on sizes:** Hydrogels can be given many expected shapes according to requirements and polymerization technique applied. The common shapes are film, microsphere, rounded, matrix, etc.

(vi) **Classification based on ionic particle:** Some hydrogels contain charged particles inside the polymeric chain and show conductive property. They can be divided into four classes depending on electrical charge available on the chain:
   (a) Nonionic
   (b) Anionic or cationic
   (c) Amphoteric electrolyte (ampholytic) containing both acidic and basic groups
   (d) Zwitterionic, containing both anionic and cationic groups in each structural repeating unit

(vii) **Classification based on mechanism during the drug release:** Hydrogels that are formulated for using in drug delivery system and their mechanism should be in controlled manner. It is of four types:
   (a) Release systems controlled by diffusion.
   (b) Release systems controlled by swelling.
   (c) Release systems controlled by chemical.
   (d) Release systems controlled by stimuli.

3.1 Biobased Hydrogels

Biobased hydrogels are mainly synthesized from natural sources which include mainly polysaccharides (e.g., cellulose, starch, chitosan, and natural gums such as xanthan, guar, and alginates) and protein (e.g., gelatin). Polysaccharide-based hydrogels are prepared either by graft copolymerization of monomers in presence of cross-linkers or direct cross-linking. Both processes give hybrid hydrogels. The first commercial polysaccharide-based hybrid hydrogel was starch-g-PAN, obtained by direct cross-linking [22]. The product showed path for conversion of other polysaccharides into hydrogels.

Hydrogels can also be formed from chitosan and its derivatives. Physical entanglement happens during curing at the temperature between 5 °C and 60 °C and within minutes to weeks time duration [23]. Derivatives of chitosan give better hydrogel product as it is soluble in water or acid. The hydrogel formation takes place either physical or by chemical cross-linking, and obtained hydrogel is thermoset and pH sensitive [24]. Sometimes chemical cross-linking is preferable due to stable structure and better swelling properties [25, 26]. By adding some synthetic part with natural polymer, composite or hybrid hydrogels with specific properties is obtained [27].

Not a good number but few works have been reported on hydrogels prepared from protein sources. In this regard, proteins from fish, soybean, and collagen are the three members which are practiced most frequently. It requires to modify the protein to convert it into hydrogel network [28]. Modified fish protein-based hydrogels showed the swelling capacity of 540 g/g in deionized water and assumed to be dependent on pH and ionic strength of swelling media and suggested for water absorption under load such as diapers [29].

Gelatin, collagen-based protein, and hydrolyzed collagen have been used for hydrogel preparation by graft polymerization of AA/AM, and the formed hydrogel is gelatin-g-poly (NaAA-co-AM). The hydrogel was high sensitive to pH [30].

Hydrogel preparation has been practiced with various natural sources due to sustainable factors, such as availability, low cost, easily processable, and biocompatibility. Cellulose is the best option for the researchers due to inheritance of the mentioned properties.

4 Factors Influencing Cellulose to Be Perfect Alternative for Sustainability

In principle, a product is said to be safe for sustainability when renewable, biobased materials are incorporated or made from such materials. Another perspective of sustainability is that the product goal is achieved with reduction in material consumption. It is well known that cellulose is renewable and biodegradable, and its derivatives are also highly biodegradable. Previously discussed requirements can be fulfilled by abundant renewable resource cellulose and its derivatives (Fig. 1a).

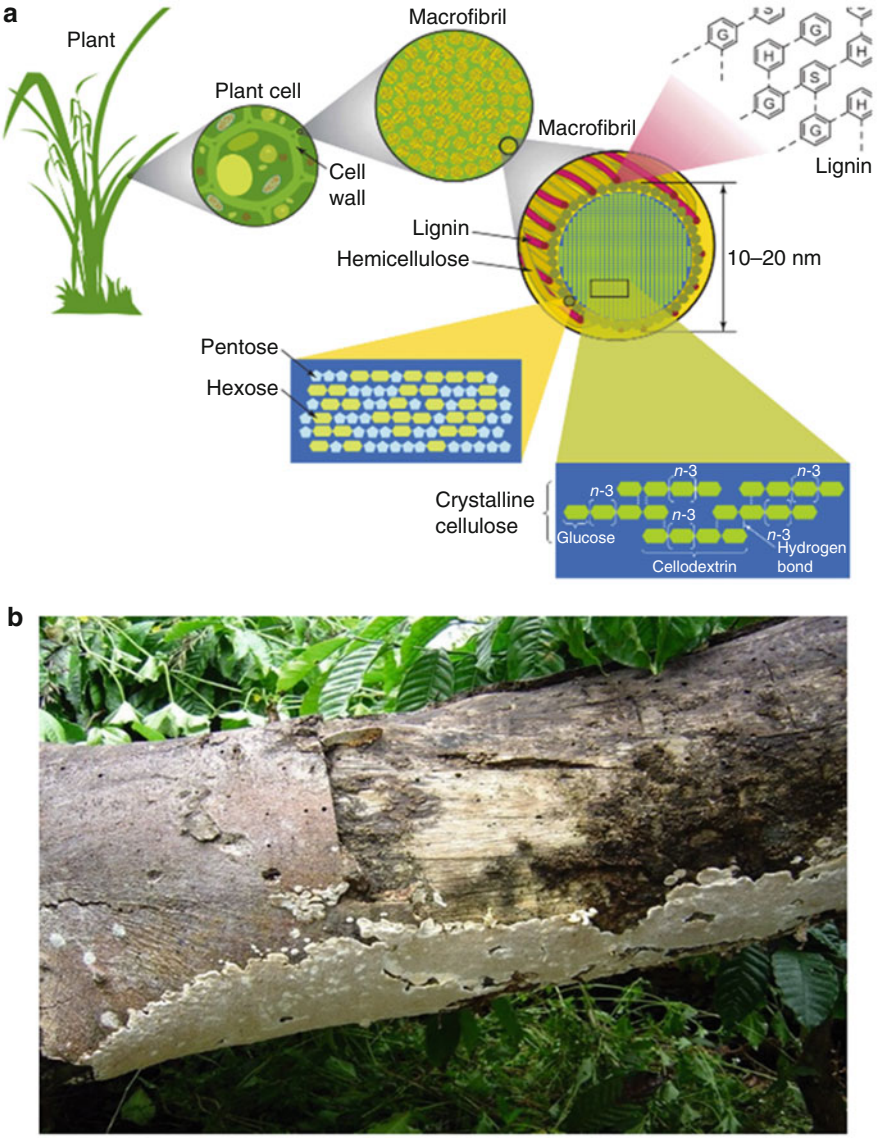

Fig. 1 (**a**) Indicates renewability of cellulose as it is the common ingredient of plant and (**b**) degradation of wood log by microorganism [36, 37]

Many researchers have been intentionally designed and tested to reach a suitable degree of biodegradability [25, 31]. Cost of materials is a key factor for consumer products, but conserving environment is more important. Hydrogels from non-renewable sources might be cheap, but lack of biodegradability gives scientists

motivation for development of cellulose-based and combination of cellulose and acrylic, hybrid hydrogels [32].

4.1 Unique Structure of Cellulose and Biodegradability

Cellulose is a polymer of glucose and also the main constituent of plants and natural plant fibers. It is found most abundantly in nature. Besides plants, some bacteria can also synthesize as extracellular product inside their body. Both the cellulose found in plant and bacteria are chemically identical but *different* in physical properties and molecular structure. The glucose units which are common for bacterial cellulose (BC) and plant cellulose (PC) are held together by 1,4-β-glycosidic linkages and responsible for higher crystallinity (usually in the range 40–60% for PC and above 60% for BC). Because of this, they are insoluble or partially soluble in water and other common solvents. BC can be synthesized and obtained fibers are nanosized, and about two orders of magnitude are smaller than PC fibers. For this BC cellulose shows a peculiar, ultrafine fiber network with high water-holding capacity and superior tensile strength compared to PC. Compared to PC, BC is found in pure form, and usually PC is associated with other biogenic compounds, such as lignin and pectin. As a result, to make in use, PC requires purification and modification. Modification via chemical change of cellulose is common which usually involves esterification or etherification of the hydroxyl groups. The chemical modification generally forms cellulose derivatives, named cellulosics. Cellulosics are easy to process and have numerous consumable applications. Cellulose and its derivatives are eco-friendly as they degrade by some bacteria and fungi present in air, water, and soil (Fig. 1b) [33]. The degradation process of cellulosic materials has been investigated by many researchers. Degradation process leads to decrease in molecular weight, lower mechanical strength, and lower degree of crystallinity and improved water solubility [34]. The abundance and degradation nature of cellulosic materials have trigger down the use of them in biomedical application [35]. As humans are unable to synthesize cellulose, they can't digest cellulose. The degradation of cellulose can be expressed as.

$$\text{Cellulose} \xrightarrow[\text{Hydrolysis}]{\text{Cellulase}} \text{Cellobiose} \xrightarrow[\text{hydrolysis}]{\text{Cellobiase}} \text{Glucose}$$

$$\text{Glucose} \xrightarrow{\text{Oxidation}} \text{Organic Acids} \xrightarrow{\text{Oxidation}} CO_2 + H_2O$$

4.2 Potentiality of Cellulose and Its Derivatives for Hydrogel Synthesis

The outer surface of cellulose is crystalline regions which can interact with water but unable to imbibe any water [38]. The amorphous region of cellulose and

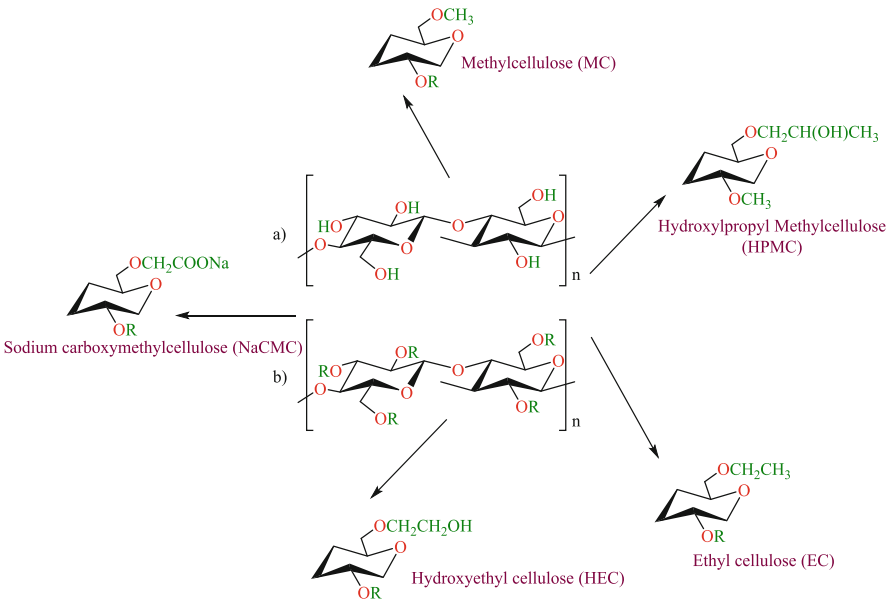

Fig. 2 (**a**) Repeating unit of cellulose, also termed "cellobiose." (**b**) Repeating unit of cellulose derivatives. The substituent group "R" is indicated for methylcellulose (MC), hydroxypropyl methylcellulose (HPMC), ethyl cellulose (EC), hydroxyethyl cellulose (HEC), and sodium carboxymethylcellulose (NaCMC)

hemicellulose can absorb water and swell [39]. Derivatization of cellulose makes it more biodegradable. The reaction of the hydroxyl groups of cellulose with organic species, such as methyl and ethyl units, gives most water-soluble cellulose derivatives via etherification. Cellulose derivatives with given solubility and viscosity in water solutions can be obtained by controlling the degree of substitution (as the average number of etherified hydroxyl groups in a glucose unit). The most widely used cellulose derivatives are cellulose ethers, such as methylcellulose (MC), hydroxypropyl methylcellulose (HPMC), ethyl cellulose (EC), hydroxyethyl cellulose (HEC), and sodium carboxymethyl cellulose (NaCMC). Figure 2 represents the chemical structure of cellulose and its derivatives. Many researchers have synthesized hydrogels from the abovementioned cellulose derivatives [25, 31]. NaCMC, among the other cellulose derivatives, is polyelectrolyte in nature, shows sensitivity to pH and ionic strength variations, and thus is a "smart" cellulose derivative. Due to a Donnan-type effect [40], the polyelectrolyte nature of NaCMC assists NaCMC-based hydrogels a double effect on the swelling capability.

Synthesis of cellulose-based hydrogels involves either physical or chemical stabilization of aqueous solutions of cellulosics. During synthesis, addition of natural or synthetic monomers or polymers gives composite hydrogels with

specific properties [41, 42]. The polymer network can be formed in both physical and chemical means. In physical network formation, hydrophobic association of polymer chains takes place at low temperature. At higher temperature, macromolecules gradually lose their water of hydration, entangled with one another, and hydrogel network is formed. Physically cross-linked hydrogels have some drawbacks like degrade in uncontrollable manner, and reversibly [43] for this, they cannot be applied in many fields (e.g., biomedical application). The ill points of physically cross-linked hydrogels of cellulose derivatives (MC and HPMC) can be replenished by inducing the formation of chemical, irreversible cross-links among the cellulose chains. The degree of cross-linking which affects many properties (diffusive, mechanical, and degradation) can be controlled in required extent during synthesis. In some cases, chemical modifications of the cellulose backbone might be performed before cross-linking, in order to obtain stable hydrogels with given properties [44]. Some cross-linking agents are toxic in nature. Taking into consideration environmental and health safety concerns, radiation cross-linking of polymers, based on gamma radiation or electron beams, has been receiving increasing attention in the last couple of years. The irradiation technique is governed by irradiation dose as well as by the cellulose concentration in solution [45–47]. As radiation treatment does not involve additional chemical reagents, is easily controllable, gives some benefits to biomedical applications, and allows the simultaneous sterilization of the product, the researchers are more interested to apply in hydrogel preparation.

4.3 Biocompatibility of Cellulose-Based Hydrogels Over Synthetic Hydrogels

Hydrogels manufactured from nonrenewable petrochemical sources are available in the market, and consumers are familiar with the products. With unconscious mind of the consumers after the end use, the thrown debris with hydrogels are making the environment more intolerable. The reason behind this is nondegradable nature of currently available hydrogels. If the petrochemical-based hydrogels are degraded by any means, the degraded products are gaseous and toxic to both human being and animals including environment. As cellulosics are more environment friendly, the hydrogels originated from them should also be biodegradable in nature [33]. In addition to biocompatible factor, the world petroleum source is limited compared to renewable cellulose and its derivative sources. It has been largely investigated by many researchers that cellulose and its derivative-based hydrogels degrade by cellulose enzyme, which is unable toward noncellulosic hydrogels [34]. This suggests cellulosic hydrogels can be used in biomedical application. Cellulose and its derivatives have many widespread perspectives and contribute positive attitude toward enhanced absorption performance of hydrogels. It has also been reported that introduction of cellulose not only increases the biodegradability but also absorption (up to 2500 g/g) [48] and other performances.

5 Methods of Preparation of Cellulose-Based Hydrogels

In a very simple sense, hydrogels are hydrophilic polymeric network cross-linked in some fashion to produce elastic structures. As a result, any suitable technique can be used to create a cross-linked polymer to produce a hydrogel. Among various techniques, copolymerization/cross-linking free-radical polymerizations are commonly used to produce hydrogels by reacting hydrophilic monomers with multifunctional cross-linkers. By using any of the polymerization techniques (bulk, solution and suspension polymerization), the formation of the gels is possible. The integral components of whole process of hydrogel formation are monomers, initiators, and cross-linking agents. In addition, diluents like water or other aqueous solutions can be used to control the heat of polymerization. In the final stage, the end product requires washing to remove impurities left from the preparation process like non-reacted monomer, initiators, cross-linkers, and unwanted products produced via side reactions showed in Fig. 3b as a general scheme for preparation. In this respect, water-soluble monomers from both natural and synthetic origins are polymerized and then cross-linked to form hydrogels in a number of ways:

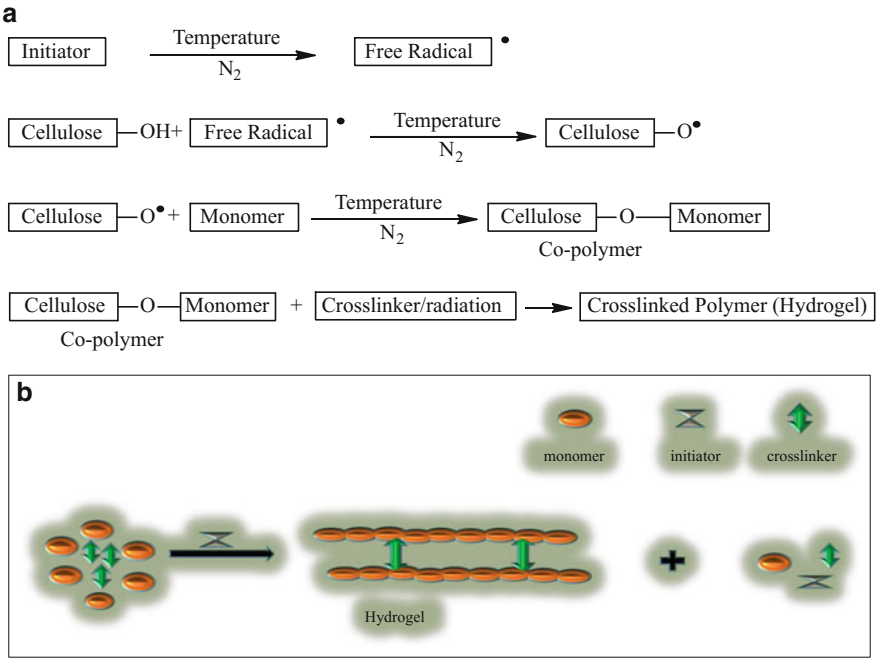

Fig. 3 (**a**) General scheme for hydrogel preparation and (**b**) schematic diagram for hydrogel preparation

1. Attachment of polymer chains via chemical reaction
2. Generation of main chain free radicals using ionizing radiation which can recombine as cross-link junctions
3. Physical interactions such as entanglements, electrostatics, and crystallite formation within chains

Considering environmental protection and to establish the thought that partially or complete replacement of synthetics by greener alternatives, cellulose gaining the prime importance to synthesis hydrogels [49]. The most important polysaccharides (chitin, cellulose, starch, and natural gums) are the cheapest and most abundant, and renewable organic materials are available. Among them cellulose is most abundant in nature. Generally two types of chemical reactions are performed for the synthesis of cellulose-based hydrogels: (a) in the presence of a cross-linker graft copolymerization of suitable vinyl monomer(s) on polysaccharide (cellulose) and (b) polysaccharides which are directly cross-linked.

To obtain hydrogel through graft copolymerization, generally a polysaccharide (cellulose) interacts with initiator by either of the two separate ways. In first case, the neighboring OHs on the saccharide units and the initiator (commonly $Ce^{4+)}$ interact to form redox pair-based complexes. Subsequently these complexes are dissociated to produce carbon radicals on the polysaccharide substrate via homogeneous cleavage of the saccharide C–C bonds. Created free radicals initiate the graft polymerization of the vinyl monomers and cross-linker on the substrate. On the other hand, in the second case, an initiator such as persulfate may abstract hydrogen radicals from the ~OHs of the polysaccharide to produce the initiating radicals (oxygen radicals) on the polysaccharide backbone (Fig. 3a). As these are thermal initiators, this reaction is more temperature sensitive compared to other methods.

In case of direct cross-linking of polysaccharides (cellulose), various cross-linking agents were employed like polyvinyl compounds (e.g., divinyl sulfone, DVS) or polyfunctional compounds (e.g., glycerol, epichlorohydrin, and glyoxal) [22, 50]. Most recently $POCl_3$ and citric acid have been used to synthesize natural cellulosic hydrogels [51, 52]. The overall polymerization technique was shown schematically in Fig. 3b.

6 Characterization of Hydrogels Through Analytical Technique

Physical and chemical characterizations of hydrogels both are essential for academic and industrial applications. The following tests are conducted to characterize the hydrogels. Some experiments related to physical characterization are as follows.

6.1 Free-Absorbency Capacity

Absorption capacity is a common but fundamental property of hydrogel. When the term swelling and absorbency are used without specifying its conditions, it implies

uptake of distilled water, while the sample is freely swollen, i.e., without applying load on the test sample. Several simple methods for the free absorbency test are available. These methods are dependent mainly on the amount of the available sample, the amount of water absorbed by the sample, and the method's precision and accuracy. Among various methods mostly followed are *tea bag method*, *centrifuge method*, and *sieve method*. Tea bag method is simple and fast, but sieve method requires a large amount of sample (1–2 g). On the other hand, the measured values in centrifuge method are often more accurate, reliable, and lower than those obtained from the tea bag method values due to removal of interparticle liquid. For convenience, only *tea bag method* is discussed below.

6.1.1 Tea Bag Method

For limited amounts of samples, this method is the most convenient, fast, and suitable ($M_0 = 0.1$–0.3 g, sample weight) [53–55]. The hydrogel sample is placed into a tea bag (acrylic/polyester gauze with fine meshes), and the bag is dipped in an excess amount of water or saline solution for 1 h to reach the equilibrium swelling. Then excess solution is removed by hanging the bag until no liquid is dropped off. The tea bag is weighed (M_1), and the swelling capacity is calculated by Eq. (1). The method's precision has been determined to be around ±3.5%.

$$\mathrm{Se} = (M_1 - M_0)/M_0, \tag{1}$$

where Se is the equilibrium swelling capacity

Centrifuge method is more accurate than the tea bag method and is occasionally reported in patents and data sheets [20]. Sieve method requires a large amount of sample (1–2 g) and is also called filtering and rubbing method [56].

6.2 Absorbency Under Load

The absorbency under load (AUL) is also another representation of absorption data which is more reliable and authentic. Because of this, usually it is given in the patent literature and technical data sheet by industrial hydrogel (SAP) manufacturers [57]. The AUL is generally measured under some specified conditions but without specifying its swelling media. The process measures an uptake of 0.9% NaCl solution, while the test sample is pressurized by some loads (often specified to be pressures 0.3, 0.6, and 0.9 psi). For testing, a typical AUL tester (Fig. 4) is a simple but finely made device including a macro-porous sintered glass filter plate (porosity # 0, d = 80 mm, h = 7 mm) placed in a petri dish (d = 118 mm, h = 12 mm). During experiment, the weighed dried hydrogel sample (0.90 ± 0.01 g) is uniformly placed on the surface of polyester gauze located on the sintered glass. To apply load, a cylindrical solid load (Teflon, d = 60 mm, variable height) is put on the dry hydrogel particles, while it can be freely slipped in a glass cylinder (d = 60 mm, h = 50 mm). For the calculation of AUL, desired load (applied pressure 0.3, 0.6, or 0.9 psi) is placed on the hydrogel sample (Fig. 4), and saline solution (0.9% NaCl) is added up

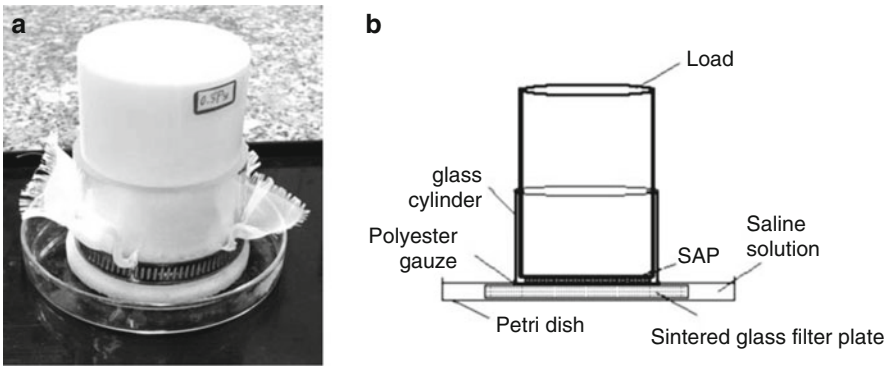

Fig. 4 (**a**) A typical AUL tester picture and (**b**) various parts [59]

to the height of the sintered glass filter. To prevent surface evaporation and probable change in the saline concentration, the whole set is covered. The swollen particles are weighed again, and AUL is calculated after 60 min, using Eq. (2):

$$\mathrm{AUL}_{(g/g)} = \frac{M_2 - M_1}{M_1} \tag{2}$$

where M_1 and M_2 denote the weight of dry and swollen SAP, respectively. The AUL indicates the swollen gel strength of SAP materials [58].

6.3 Wicking Capacity and Rate

The wicking capacity (WC) of SAP (hydrogels) materials is a measurement of capillary action. To quantify this, a simple test has been suggested by pioneering researchers Fanta and Doane [60] with conventional physical appearance, i.e., sugar-like particle. The test is accomplished as hydrogel sample ($M_1 = 0.050 \pm 0.0005$ g) is added to a folded (fluted) filter paper cone prepared from an accurately tared circle of 9 cm Whatman 54 paper. To settle the sample into the tip, the cone was lightly tapped, and the tip of the cone is then held for 60 s in a 9 cm Petri dish containing 25 mL of water. Within a minute, water wicks up the entire length of the paper, and excess water is allowed to drain from the paper by contacting the tip for 60 s with a circle of dry filter paper on a square of absorbent towel. For calculation, weight of wet paper plus swollen polymer is determined (A), and the absorbency of the sample in g/g is then determined after correcting for the weight of dry paper and the amount of water absorbed under identical conditions by the paper alone in the absence of sample (Eq. 3). Repetition for 3–5 times each test is preferred and the results are averaged.

$$\mathrm{WC} = (\mathrm{A} - \mathrm{B} - \mathrm{M}_1)/\mathrm{M}_1 \tag{3}$$

where B is weight of wet paper without polymer.

Assuming a steady absorption for the duration of 60 s, an estimation of wicking rate (g/g.s) of the hydrogel may be obtained by dividing the WC value by 60.

6.4 Swelling Rate

Swelling rate is also an important parameter for determining quality of manufactured hydrogel. It can be calculated in a number of ways. Among them two common methods are *vortex method* and *swelling-time profile*. Vortex method is the most simple and rapid method for calculating swelling rate of hydrogel sample and is often employed in R&D and technical laboratories [61]. For a conceptual understanding, *swelling-time profile* is described below.

6.4.1 Swelling-Time Profile

Actually this is a graphical representation of swelling versus time and is obtained via separating swelling measurements of sample absorbed desired fluid at consecutive time intervals. For swelling measurement, any of the methods (tea bag, centrifuge, or sieve methods) can be used for the measurements depending on the amount of the available sample and the desired precision. This profile is helpful to the study of swelling kinetics of hydrogels. In a measurement, several 2 L Erlenmeyer flasks containing distilled water or desired solution are labeled, and SAP sample (e.g., 1.0 g, 50–60 mesh) is poured into each flask and is dispersed with mild stirring. The absorbency of the sample is measured by the abovementioned method at consecutive time intervals (e.g., 15, 30, 45, 60, 90, 120, 180, 300, 600, 1800 s). A typical profile is shown in Fig. 5.

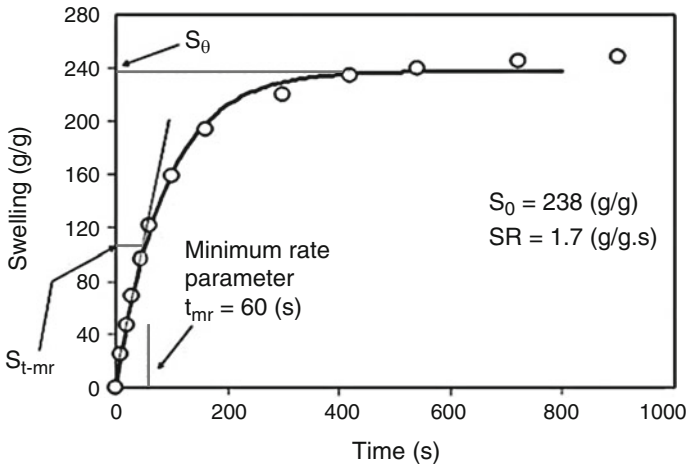

Fig. 5 Representative curve for swelling kinetics of a hybrid SAP sample in distilled water [61]

6.5 Swollen Gel Strength

From a practical viewpoint in specified area of application, the mechanical strength or modulus of swollen SAPs (hydrogels) is important. Rotational rheometry can be an important tool to quantify the swollen gel strength of hydrogels with conventional shape, i.e., sugar-like particles [62]. The method works by using parallel plate geometry (plate diameter of 25 mm, gap of 3 mm) at 25 °C. The strain suggested for the experiment is to be in the linear viscoelastic (LVE) range, where the G' and G'' are independent of the strain amplitude. Frequency test sweeps are done after a strain sweep test, and the test conditions are selected to ensure that the test is really carried out in the LVE range. In the determination of LVE, approximately 100–150 mg of dried SAP with average particle sizes of 180 μm is dispersed in 200 mL of distilled water for 30 min to reach maximum swelling. The swollen gel particles are made free of excess water and then placed on the parallel plate of rheometer, and the rheological properties are evaluated.

6.6 Soluble Fraction

Soluble fraction (sol) for a hydrogel is an important criterion. It is a sum of all water-soluble species including non-cross-linked oligomers, β-hydroxypropionic acid (HPA), and non-reacted starting materials such as residual monomers. The amount is simply measured by extraction of hydrogel sample in distilled water (because of this, the sol is frequently referred to "extractable"). For calculation, a certain amount of the hydrogel sample (e.g., 0.10 g) is poured into excess amount of water and dispersed with mild magnetic stirring to reach equilibrium swelling (0.5–3 h depending on the sample particle size), filtering the sample after swelling and dried in oven. The weight loss of the sample is the soluble fraction. The gel content which is also important for a synthesized hydrogel can also be obtained by simple Eq. (4). The equation indicates that gel content may be taken as an actual yield of the cross-linking polymerization.

$$\text{Sol}\ (\%) + \text{Gel}\ (\%) = 100 \tag{4}$$

6.7 Residual Monomer

Residual monomer content is of very significant in case of hydrogel materials, particularly SAPs used in hygiene product where the residual acrylic acid should be in safe level. To quantify residual monomer, high-performance liquid chromatography (HPLC) is often taken as a preferred method. Orthophosphoric acid solution is usually used as an extractant for this method. The total residual monomer is removed in form of either acid or salt from the hydrogel network and is measured in the next step. At lower pH, the acrylic salt is converted to acrylic acid both the extracting and the eluting media, i.e., mobile phase (pH < 3) [63]. Isocratic mode at

a 1.8 mL/min flow rate and ambient temperature on an analytical column (e.g., 250 × 4.6 mm, 5 μm) are used for separation. An aqueous 0.01% orthophosphoric acid is used as the mobile phase [64]. UV-Vis absorbance can also be used to serve the purpose, in that case over the 190–400 nm range is registered and the wavelength used is 200 nm.

6.8 Ionic Sensitivity

It is a measure of sensitivity of hydrogel materials toward the kind of aqueous fluid absorbed. To quantify a dimensionless swelling, factor, *f*, is defined as follows (Eq. 5) [65]:

$$f = 1 - (\text{absorption in a given fluid}/\text{absorption in distilled water}) \quad (5)$$

For better performance, hydrogels with lower *f* are usually preferred, as higher *f* value indicates the higher absorbency loss of the sample swollen in salt solutions. Negative values of *f* are rare but happen, which reveal that the absorbency is not decreased, but it is increased in salt solutions. It is reported that the hydrogels with betaine structures exhibit such surprising behavior [53].

In addition to physical characterization, the synthesized product requires structural confirmation so that their application becomes flawless. Few relevant instrumental analyses give reliable data for the product. The commonly used instrumental techniques are briefly discussed.

6.9 FTIR Analysis

The observation of functional groups present in samples within the frequency range from 400 to 4000 cm^{-1} is generally used. Finely ground samples are mixed with KBr and pressed to form a KBr pellet. The FTIR spectra of sample (generally a characteristic peak of fuctional groups at specified wavelength) is observed by the method of transmission. This method supplies sufficient data by forming relevant peak to ensure about the functional groups that formed during reaction.

6.10 TGA and DSC

Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) are two reliable tools for the thermal analysis of the product. During decomposition, exothermic or endothermic nature of the hydrogel sample can be examined. TGA determines selected characteristics of materials that exhibit either by mass loss or gain due to decomposition, oxidation, or loss of volatiles (such as moisture). On the other hand, DSC measures the difference in the amount of heat required to increase the temperature of a sample and reference as a function of temperature.

6.11 SEM, TEM, and AFM

Surface morphology of the prepared hydrogels can be observed by SEM analysis. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) are also two helpful tools for the study of surface morphology with high resolution. In case of SEM, the micrographs were taken at a definite magnification using (kV) accelerating voltage to observe the surface construction.

On the other hand, TEM is capable of imaging at a significantly higher resolution than light microscopes and can capture fine detail – even as small as a single column of atoms. TEM is also used to observe modulations in chemical identity, crystal orientation, electronic structure, and sample-induced electron phase shift as well as the regular absorption-based imaging. AFM serves three information about the product; force measurement determines physical properties like stiffness, image formation of the three-dimensional shape (topography) of a sample surface at a high resolution, and manipulation of forces used to change the properties of the sample in a controlled way.

6.12 XRD Analysis

X-ray diffraction (XRD) method is used to study the structure, composition, and physical properties of materials. It is a rapid analytical technique for phase identification of a crystalline material and can provide information on unit cell dimensions. XRD gives the idea of crystalline and amorphous region of the sample. One can predict about the nature of the product, how it has been transformed from one phase to another.

All diffraction methods rely on generation of X-rays in an X-ray tube. These X-rays are directed at the sample, and the diffracted rays are collected for analysis of specimen. An important factor of all diffraction is the angle between the incident and diffracted rays.

6.13 Biodegradability Test

Decomposition data carries immense importance for cellulose-based product. As it is mentioned earlier, biocompatible products are those when thrown to the environment decomposed by microorganism and leave nothing harmful for human being or animals. The two mostly exercised degradation tests are soil burial test and direct microbial studies. In the case of soil burial test, the test specimen is buried in soil, and after definite time interval, the sample is washed and weighted. The result is expressed as percent weight loss for specific time duration. At the same time, direct microbial studies also determine weight loss of the product, but the decomposition is carried out in presence of direct contact of cultured microorganism.

7 Application of Cellulose-Based Hydrogels and Their Biocompatibility

It is a proven truth that synthetic hydrogels have some better qualities, but when biodegradability or eco-friendliness of a hydrogel is required or recommended, cellulosics are prime choice hydrogel precursor materials, due to their low cost,

the large availability and biocompatibility of cellulose, and the stimuli-responsive properties. Current research has unveiled the fact that cellulose-based hydrogels cannot be complete replacement of synthetic hydrogels but would be the most potential competitor. Some of the recent and conventional uses of cellulose-based hydrogels have been discussed below.

7.1 Hydrogels for Personal Hygiene Products

The recent trend is to use acrylate-based superabsorbent hydrogels in personal hygiene product to absorb body fluids. These products keep individuals dry and ensure healthy skin and personal comfort. It is observed that the majority of parents in developed countries, along with thousands of hospitals and day care centers around the world, use disposable diapers containing a superabsorbent polymer (SAP) for the infant. The use of SAP material in training pants and adult incontinence products is increasing day by day worldwide. In recent years, a number of papers have been published in the favor of the use of superabsorbent materials in personal care products and their safety and effectiveness [66, 67]. The leakage of diapers is very significant to raise the risk of fecal contamination and spread of illness in day care play areas [68]. The SAP helps control the spread of germs keeping the skin dry and preventing diaper rash. Now it is a true fact through several medical studies that disposable diapers play an important role in reducing the risk of spread of gastrointestinal illnesses and are significantly more effective than double cloth diapers and plastic overpants [69]. Although Harper [70] and Harmon [71] separately patented their superabsorbents in 1966, superabsorbent was used for the first time in diaper industry by the Unicharm in 1982 in Japan, following its use in sanitary napkins. The superabsorbent materials introduced a new generation of high-performance diapers. It made the diapers not only thinner but also improved retention performance compared to cloth diaper which helped reduce leakage and diaper rash [72]. In this regard, premium diapers reduced leakage values and the average weight by below 2% and about 50%, respectively. Considering environmental and economic issue, the reduction of packaging cost was advantageous. For better understanding the current ecological impact of disposable diapers and other similar articles, it is substantial to provide a brief estimate of diaper consumption. In a published article, it has been shown that a child till the age of 30 months uses approximately six disposable diapers a day. If a diaper has an average volume of 500 cc, so one child produces on average 3000 cc of garbage a day, i.e., 1.092 cubic meters per year. As it is considered that there are about 50,000 diaper users per million population, every day it would be necessary to remove 1500 cubic meters of diapers from a city of one million inhabitants. Taking into account the benefit of recycling, different attempts have been made to recycle disposable diapers, napkins, hospital bed sheets, sanitary towels, and other similar products [73]. The structure of all these cellulose-containing products is almost the same: an envelope of non-woven tissue, a plastic cover material, and an absorbent fluff of wood pulp cellulose, mixed in most cases with SAP. The main objective of diaper recycling is to recover

separately the cellulose, which is biodegradable and recyclable, the plastic cover material, and the SAP, both of which are not biodegradable but might be recycled for other uses. The difficulties during recycling process have prompted the parallel development of biodegradable diapers, i.e., possessing a biodegradable SAP. An alternative solution has been found to replace SAP by cellulose-based hydrogels, which are totally biodegradable. Sodium carboxymethylcellulose (NaCMC)- and hydroxyethyl cellulose (HEC)-based novel hydrogels cross-linked with divinyl sulfone (DVS) possess swelling capabilities comparable with those displayed by SAP and high water retention capacities under centrifugal loads. Cellulose-based hydrogels show some advantages over current SAP that encompasses their biodegradability and environment-friendly nature. In this respect, recent innovations and total success of the cellulose-based hydrogels described above depend on the implementation of an eco-friendly production process [74] and the use of nontoxic cross-linking agents [75, 76]. Radiation technique for cross-linking instead of using chemicals might be a valuable alternative in the development of novel environmentally friendly superabsorbents.

7.2 Water Conservation in Agriculture

Due to continuous deficiency in surface water, the interest of using superabsorbent hydrogels in agriculture is increasing. Another important objective is to reduce water consumption and optimize water resources in agriculture and cultivation. Research articles have been published in the promotion of using a novel material to replace human habit and culture toward water so that it can be benefited to save and not make an excess to waste. It is well known to all that during the swelling process of a hydrogel, the material turns from solid to a gel-like material, which is able to store large volume of water even under significant compression. Consequently the swollen hydrogel can slowly release up-taken water through a diffusion-driven mechanism, if a gradient of humidity exists between the inside and the outside of the material. In addition up-taken water and other ingredients can be released in a controlled and sustained manner by means of diffusion. In arid and desert regions of the world, where scarcity of water resources is a burning issue, the xerogel (i.e., dry hydrogel), in the form of powder or granules, is spread in the area close to plant roots. The hydrogel can also be loaded with nutrients and/or plant pharmaceuticals. At the time of cultivation, water or nutrients mixed water is sprayed; the water is absorbed by the hydrogel, which then releases to the soil as needed, thus keeping the soil humid over long periods of time. The use of hydrogels in cultivation allows a high saving of water, which is not lost soon after the watering due to evaporation and drainage. Such distribution of the water resources available for cultivation can be used for other applications. Another observation of using hydrogels is that the swelling with water itself on the soil increases volume of dry hydrogels, and this increased volume of hydrogels changes the dimension, resulting increasing soil porosity and providing a better oxygenation to the plant roots. The aeration mechanism also suggests that large-granule hydrogels are likely to yield better results than fine-granule ones, if

properly mixed with the soil. A number of commercially available products are able to absorb, retain, and release water to the soil. It has also been proven that all these products are effective in water conservation due to their extremely high water retention capacity for cultivation. It is also reported that overdosage of such products is potentially dangerous and should be avoided. Yet enough research studies have not been carried out to determine appropriate amounts of hydrogels and application rates for different environmental conditions and different plant species [77]. It is worth mentioning that being acrylate-based, most commercial products are not biodegradable. Cellulose-based hydrogels can be the perfect alternatives to the recent trend of acrylate-based superabsorbent hydrogels. It is reported that Sannino and coworkers recently developed a novel class of totally biodegradable and biocompatible microporous cellulose-based superabsorbent hydrogels [9, 78–80], and such products are able to absorb up to 1 l of water per gram of dry material, without releasing it under compression. It is possible that hydrogel can be prepared both in form of powder and of a bulky material with a definite shape and a strong memory of its shape after swelling. The hydrogel can be entrapped with small molecules, such as nutrients, to be released under a controlled kinetic. Among the various applications of this material, a study has been performed on its specific use as water conservation in agriculture. Sorption capacity of hydrogel has been tested at different ionic strength of the swelling medium, with the expected target to simulate as much as possible the hydrogel-soil interaction. A pilot-scale production plant has been developed to prove the feasibility and the efficacy of the proposed technology and to produce the amount of hydrogel necessary for some studies being carried out in experimental greenhouses in the south of Italy, where the scarcity of water is a common problem. Early experimental results show great achievement. The soil with small quantities of the hydrogels is able to remain humid for periods more than four times longer compared to the soil watered without the presence of the hydrogel. When mixing the soil with a fine-granule gel, air flow is limited, and a layer of substrate/gel mixture might form, which further limits the flows of air and water within the soil. With a large-granular gel, a better air flow through the soil is yielded, resulting in higher oxygenation to plant roots. As the added cellulose-based hydrogels are biodegradable in nature and will decompose in soil at the end of its action, it will not make any adverse effect to soil or environment.

7.3 Body Water Retainers

Cellulose and cellulose derivatives are biocompatible, and hydrogels originated from them also show this property. In addition, they display versatile properties which suggest their use in biomedical applications. As hydrogels swell in water, cellulose-based hydrogels can be used as devices for the removal of excess water from the body, in the treatment of some pathological conditions, such as renal failure and diuretic-resistant edemas. In time of treatment, the hydrogel in powder form is taken up orally and absorbs water in its passage through the intestine, where the pH is about 6–7, without previously swelling in the acid environment of the stomach. The

hydrogel is then expelled through the fecal way, thus performing its function without interfering with body functions. Cellulose hydrogels, based on NaCMC and HEC, have been investigated for such applications [81] due to pH sensitivity. This type of application is in research level, sufficient data are not available, but petroleum-based hydrogels might show toxic effect compared to cellulosic hydrogels.

7.4 Stomach Bulking Agents

From the findings of the World Health Organization, at least one in three of the world's adult population is overweight and almost one in ten is obese. Moreover, there are over 20 million children under age 5 who are overweight. Obesity and overweight are responsible for several chronic diseases, such as type 2 diabetes, cardiovascular disease, sleep apnea, hypertension, stroke, and certain forms of cancer. It is also found that overweight or obese often has a dramatic impact on the psychological well-being, reducing the overall quality of life [82–84]. The treatment of overweight and obesity generally includes supervised diet or dietary supplements and is combined with adequate physical exercise. In the most cases, dietary supplements are claimed to act either by binding fats and so reducing fat absorption by human body or by directly reducing the appetite, which is done by absorbing liquids and swell inside the stomach, thus giving a sense of fullness [85, 86]. The first pathway is reported for chitosan-based products and the next for different natural fibers and herbal products. The natural fibers and herbal products use natural fillers or bulking agents that are very interesting for its great potential of reducing the amount of food intake by reducing the available space in the stomach. Though there is no clear evidence of the effectiveness of currently available bulking agents in promoting weight loss, neither in the short term nor in the long term, whereas their adverse effects, one should be taken into account the harmful effect of the products. Some hydrogels have required properties so that they can serve the purpose of using a stomach bulking agent. It is reported that novel cellulose-based hydrogels, obtained by cross-linking aqueous mixtures of NaCMC and HEC, have been shown to be appealing for the production of dietary bulking agents [87]. The polyanionic nature of the NaCMC hydrogels provides higher swelling capabilities at neutral pHs rather than at acid ones; the swelling ratio obtained at acid pHs might still be significant for use of the hydrogel as stomach filler where the environment is acidic. Indeed cellulose-based hydrogels obtained from nontoxic cross-linking agents are particularly attractive for this kind of application [52].

7.5 Devices for Controlled Drug Delivery

Among various cellulose derivatives, cellulose ethers (e.g., hydroxypropyl methylcellulose (HPMC)) have long been used in the pharmaceutical industry as excipients in many drug formulations [88]. These materials work as active ingredient carrier; they swell in presence of body fluids and release the drug molecule later. In the

progress of swelling at certain period, the drug dissolves in water and diffuses out from the polymer network. The rate of drug release from hydrogel depends on the water content of the swollen hydrogel, as well as on its network parameters, i.e., degree of cross-linking and mesh size [89, 90]. In recent time not only the swelling tablets but also more sophisticated hydrogel-based devices have also been developed for controlled drug delivery. In some cases, they are not only taking less time but also can function at a specified site. The loading of the drug in a hydrogel is performed either after cross-linking or simultaneously during network formation. Smart hydrogels modify the mesh size of the hydrogel network by responding in physiologically relevant variables, such as pH, temperature, and ionic strength, and are particularly useful to control the time- and space-release profile of the drug. Cellulose-based polyelectrolyte hydrogels (e.g., hydrogels containing NaCMC) are particularly suitable for the application of oral drug delivery which is usually based on the strong pH variations encountered when transitioning from the stomach to the intestine. Anionic hydrogels based on carboxymethyl cellulose have been investigated recently for colon-targeted drug delivery [91]. The most recent practice of controlled release through a hydrogel matrix dealt with the delivery of proteins, growth factors, and genes to specific sites, the need for which has been prompted by tissue engineering strategies. The direct delivery of drugs or proteins to different body sites requires the hydrogel biodegradation, in order to avoid foreign body reactions and further surgical removal. Injectable hydrogel formulations are particularly appealing and currently under investigation. In this case, the cross-linking reaction has to be performed under mild conditions in order not to denature the loaded molecule. Injectable formulations of hydrogels based on HPMC have been developed to deliver both biomolecules and exogenous cells in vivo [92]. The microenvironment resulting from degradation of the polymer should be mild. Change is the mesh size of the network, which determines the free space available for diffusion and thus regulates the diffusion of molecules (e.g., drugs) through the network itself. From the above discussion, it is mentionable that petroleum-based hydrogels may include toxic effect inside the body and may remain as part of the body which requires surgery. So cellulose-based hydrogels are suitable than petroleum-based nondegradable and non-biocompatible hydrogels.

7.6 Scaffolds for Regenerative Medicine

Regenerative medicine is a branch of translational research in tissue engineering and molecular biology which deals with the induced regeneration of cells, tissues, and organs in vivo, by means of a scaffolding material or template that guides and supports the cells during the synthesis of new tissues. Cellulose-based hydrogels have large water content capacity, are biocompatible, and possess rubbery mechanical properties close to those of soft tissues and usually allow the incorporation of cells and bioactive molecules during the gelling [93]. During regeneration, adhesion problem of cells to highly hydrophilic surfaces can be easily modified with extracellular matrix (ECM) domains of hydrogels, which promote cell adhesion as well as

specific cell functions [94]. This property gave opportunity to scientist to consider hydrogels for the design of biomimetic scaffolds for tissue regeneration. In the last decade, the excellent biocompatibility and good mechanical properties of cellulose and its derivatives have received increasing attention, as biomaterials for the design of tissue engineering scaffolds. It has been published that cellulose and its derivatives can be applied as scaffold material for the treatment of severe skin burns and in the regeneration of cardiac, vascular, neural, cartilage, and bone tissues [95–98]. A few independent investigations show that cellulose-based hydrogels are potentially useful for inducing the regeneration of bone, cartilage, and neural tissues. From the various research, it has been pointed out that as the final product of cellulose degradation is glucose, which is a nutrient for cells, there are the advantages in using cellulose rather than other synthetic or natural polymers for tissue engineering applications. Independent investigations have reported that novel biomimetic hydrogels, based on cross-linking cellulose derivatives with hyaluronic acid (HA), show potential as scaffolds for regenerative medicine, with a tunable degradation rate. The degradation rate is dependent on the amount of degradable sites as well as the degree of cross-linking of the network, which affects enzyme diffusivity through the mesh size. The degradation nature of the cross-linking agent used is particularly important, especially in cases where reactive groups of the cross-linker are incorporated into the hydrogel network and might then be released upon degradation. Recently hydrogels based on HEC, NaCMC, and HA have been cross-linked with a water-soluble carbodiimide, which is both nontoxic and a "zero-length" cross-linker. It is also reported that the carbodiimide washed out from the polymer network after the synthesis; thus cellulose-based hydrogels cross-linked with carbodiimide show potential for a tunable biodegradation rate, even without containing HA [99]. Although biodegradation behavior of hydrogels cross-linked with carbodiimide has not investigated yet. Another important factor that affects the development of regenerative templates is the scaffold porosity, which enhances the attachment, infiltration, and survival of cells within the scaffold. Several types of novel manufacturing techniques are being investigated to develop porous hydrogels and might be of great value in enhancing the regenerative potential of cellulose-based hydrogels [100–103].

7.7 Wound Dressings

To release people from pain, expressing wound dressing is a must during wound healing progression, and application of hydrogels in this field is a recent practice. Protecting the wound from infection is important particularly in cases of chronic wounds (e.g., ulcers), appropriate wound dressing is essential. In such cases, a moist environment encourages rapid healing, and hydrogels are suitable for the development of wound dressings, either as sheets or in amorphous form. Cross-linked amorphous hydrogels with low viscosity may be packaged in tubes or in foil packets to serve the purpose. The gels are reinforced with a gauze or a polymeric mesh to allow an easy removal and prevent gel liquefaction. Accurate moisture balance in the wound bed is necessary, and hydrogels should be designed to maintain moisture by

Table 1 Some commercially available hydrogel for wound dressings containing carboxymethyl cellulose (CMC) or sodium CMC (NaCMC) are given with producer company. These are mostly available in two forms, either as sheets or as amorphous gels. Products with silver ions show antimicrobial activity

Hydrogel wound dressing (producer)	Composition
IntraSite™ gel (Smith and Nephew)	Water Propylene glycol NaCMC
GranuGEL™ (ConvaTec)	Water NaCMC Propylene glycol Pectin
Purilon gel™ (ColoPlast)	Water CMC Calcium alginate
Aquacel Ag™ (ConvaTec)	NaCMC Silver ions (1.2%)
Silvercel™ (Johnson & Johnson)	Calcium alginate CMC Silver ions (8%)

hydrating the wound surface or absorbing the wound exudates. Hydrogels provide nonadherent dressings which result easy removal without any damage to the wound bed, and transparency of it is a further advantage in this application to monitor easily. A number of hydrogel dressings have been patented so far and are available in the market, based on synthetic or natural polymers or a combination of them. The recent patented hydrogels are in situ forming gels (e.g., based on sprayable formulations and consisting nanoparticles with antimicrobial agents and those of radiation cross-linked. In this regard, bacterial cellulose (BC) has been widely investigated for wound healing due to its purity and high water retention capacity, and they are available in the market. Some commercially available hydrogel dressing contains NaCMC, in combination with propylene glycol, which works as a humectant and a preservative (Table 1). It should be mentioned that the products developed are usually indicated for the treatment of specific wounds and often require the use of secondary dressings. Thus, currently a number of investigations have shown that the development of cellulose-based novel hydrogels cross-linked with hyaluronic acid for wound dressings with improved performance [75]. Wound dressing requires nontoxic, anti-allergic, transparent, and indicative for specified wounds which can be met by cellulose-based hydrogels, as in some cases cellulosic hydrogels give better options to the consumers than hydrogels from nonrenewable sources.

7.8 Plastic Surgery

As hydrogels resemble very close to body tissue, attempts were made to introduce hydrogels like new materials for plastic reconstruction (Fig. 6). In this case,

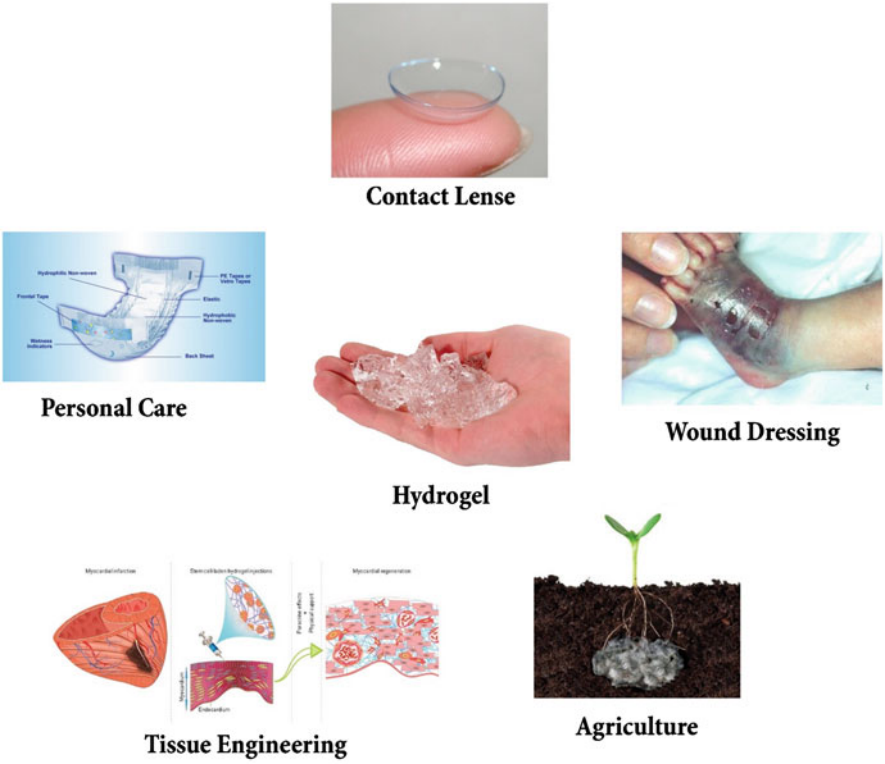

Fig. 6 Hydrogels in different forms of use

hyaluronic acid (HA) considered the panacea to resolve the problem as one notable company Macrolane^{TM} was using HA in tissue-filling applications to enhance breast size and shape and offer a more biocompatible alternative to standard and aggressive silicone prosthesis [104].

Hydrogel is such a field of research where multidisciplines have been involved and taking the fruit for the application of their own field.

8 Prospects of Cellulose-Based Hydrogels

Cellulose and cellulose derivatives are pioneer biocompatible materials for hydrogel synthesis. Compared to cellulose, other natural sources have scarcity all over the world, and in some cases, there is huge difference in costing. Again as much derivatives of cellulose have been practiced, but others from rest of the sources still remain unworked. Though synthetic hydrogels have better performance in some instances, non-biodegradation is the motivational factor for cellulose-based hydrogel research. Again synthesis of hybrid hydrogels through combination of some synthetic part with cellulose minimizes the property compromising

factor. Research have reached in such a position that cellulose-based hydrogels have gained almost same capability of absorbency and in some published article inform better performance than a synthetic one [48].

9 Conclusion

Hydrogel is an interesting and attractive research topic to the scientists for the last one decade. In this review, authors tried to give an idea of synthesis, application, characterization, and the development of cellulose-based hydrogels from simple polymeric network to smart materials. Another core objective was to establish cellulose and its derivatives as the eligible alternative for the protection of environment. To meet definite demand in applied field, many researchers have gained success in preparation of their hydrogel network. Biodegradability and biocompatibility are of the prime importance where there is no room for compromise. Petrochemical-based acrylic hydrogels are dominating due to some competitive reasons, but considering environmental sustainability hydrogels from biomaterials is drawing more attention to the researchers as well as consumers. Though cellulose-based hydrogels possess typically higher cost and less performance than the synthetic one and most of the volume of world production is consuming in hygienic uses, i.e., disposable diapers (as baby or adult diapers, feminine napkins, etc.), currently cellulose-based hydrogels are applying in numerous fields like contact lenses, hygiene products, wound dressing, biomedical, tissue engineering and drug delivery. Other than hygienic products, other commercial hydrogels are still limited. Much improvements have been made in the properties of hydrogels, but further improvements need to be made to improve the applicability of hydrogels. Though there are many patents on hydrogels, only a few reached in the market. In spite of the development of hydrogels, there are some drawbacks which should be overcome. Especially in hydrogels in drug delivery and tissue engineering, more progress is expected. Considering high cost and other hindrances, the necessity of preparation of renewable source-based hydrogels seems more obvious. The motivation for making greener world will show light to the researchers in the further development of hydrogels in the near future.

Abstract

Cellulose is an abundant and renewable natural resource with biodegradability and nontoxicity. Furthermore, cellulose and cellulose derivatives also have unique properties such as hydrophilicity, mechanical strength, biocompatibility, and tunable functionality due to the strong versatile hydrogen bonding. Cellulose-based hydrogels are prepared by physical or chemical cross-linking of cellulose derivatives with various functional molecules, which covalently bind different functional molecules and form a highly porous hydrogel, with three-dimensional network structure consisting of nanofibrillar-regenerated cellulose. Such cellulose-based hydrogels have great advantages due to high water-holding capacity, abundance, biodegradable biocompatibility and nontoxicity, which can be applied as superabsorbent in wastewater treatment (such as oil, heavy metals, dye, organic pollutants), as superabsorbent biomaterials, in pharmaceutical and biomedical field, in personal care and hygiene products, and tissue engineering and wound dressing. Moreover, they have also been used in catalysis, sensors, luminescence, and energy storage. This chapter will introduce the smart applications of cellulose-based hydrogels including native cellulose, cellulose derivatives, and cellulose-composite hydrogels. Among those, we will focus our discussion herein on the adsorption application of cellulose-based hydrogels. Most excellent research works are highlighted in this chapter, and cellulose-based hydrogels will be expected to be applied in agriculture, food, environment, industry, medical care, and personal health field. At last, we also give a prospect on cellulose-based hydrogels in the future.

Keywords

Cellulose-based · Hydrogel · Super-hydrophilic · Cross-linking · Superabsorbent

1 Introduction

Hydrogels are defined as cross-linking three-dimensional (3D) polymer networks filling great deal of water (or biological fluids) and mainly formed from biopolymers and/or polyelectrolytes [1]. According to the materials source, hydrogels can be classed into natural polymers and synthetic polymers. The polymer networks are formed as a result of the cross-linkers swelling in the aqueous solvent and retractive force exerted by the cross-linkers, until the elastic is totally able to neutralize the thermodynamic force of swelling [2]. This “solid-like solution” of polymer and water contained chemical or physical cross-linkers among the macromolecular

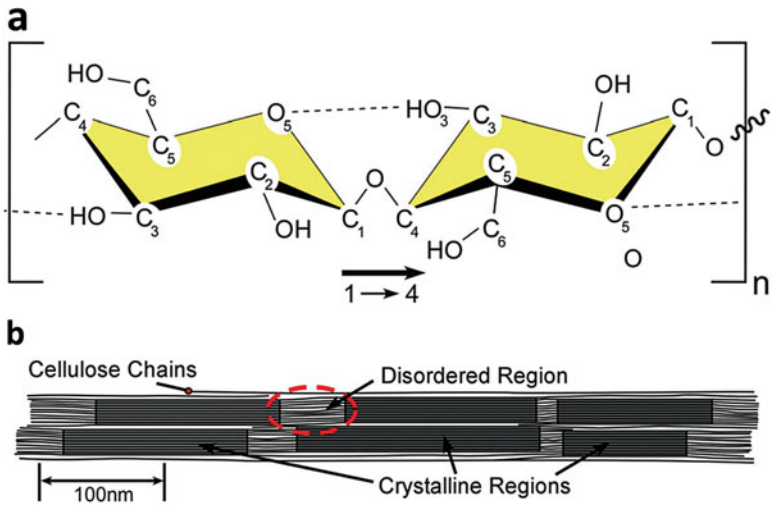

Fig. 1 (**a**) Repeating unit of cellulose, (**b**) the crystalline and amorphous regions of cellulose chains [11]

chains [3, 4]. Hydrogels could be synthetized by either physical method (including twine of chain, hydrogen bonds, van der Waals forces, and/or ionic interactions) or chemical method (covalent bonding). The 3D network is able to virtually prepare from any flexible polymers or semi-polymers and survive in several physical forms including papers, membranes, beads, microgels, microspheres, and nanoparticles, and even some hydrogels become cryogels or aerogels by directly drying or freeze-drying or supercritical drying, respectively [5–7].

A variety of hydrogels from natural polymers have been developed and showed potential application in biomaterials field because of their safety and nontoxicity [8, 9]. Cellulose is the most abundant reproducible resource on earth, meets the development of eco-friendly material, and will become the main material resource in the future [10]. Moreover, cellulose consisting of polymer of glucose (Fig. 1) was discovered as the main constituent of plants such as cotton and linen [11]. Some bacteria (*Acetobacter xylinum*) are also able to synthesize cellulose. Besides, microbial or bacterial cellulose (BC) has similar chemical properties with plant cellulose (PC) but impresses different macromolecular structure and physical properties [12]. The glucose units are bonded together by 1,4-β-glucosidic linkages among both BC and PC, leading to their insolubility in water and other common solvents, and the difference is crystallinity of cellulose (common in the range 40–60% of PC and greater than 60% of BC) [11]. In addition, numerous novel functional materials derived from cellulose are being developed over a diverse of applications, due to the increasing demand for hydrophilic, environmentally friendly, biodegradable, and biocompatible products [13, 14]. Cellulose hydrogels combine hierarchical micropore structures with the chemical nature of cellulose [15]. When blending with other functional materials, the resulted composites can combine desirable bulk properties

for the described one. So it is essential to study cellulose-based hydrogels in both fundamental research and industrial application [16].

Sol–gel technique is one of the most common synthetic processes used for the preparation of both polymer networks. In fact, native cellulose has poor solubility in water and other common solvent characteristic due to the inter- and intramolecular hydrogen bonds, so specific solvent systems are required to dissolve them [17]. The widely accepted view is that hydrogen bond connector (N-O, Cl-, OAc-, and so on) of the solvent breaks up the hydrogen bonds of macromolecule in the biopolymer chains under the mechanical or thermal treatment [18]. In this chapter, we review the physical hydrogels formed from native cellulose, cellulose derivatives, bacterial cellulose, and chemical hydrogels by chemical cross-linkers (including esterifying agents and etherifying agents). Cellulose that mixed with another polymer (natural polymer and synthetic polymer) or inorganics (metal nanoparticles, metallic compound, carbon materials) for novel gel materials with advantages of both components can be obtained. In addition, we elaborate some possible applications of cellulose-based hydrogels, which include water purification (such as dyes, heavy metal ions), water absorbents (personal care and hygiene, agriculture), biomedical applications (drug delivery, wound dressings, tissue engineering), and other applications (energy storage systems, catalysis, fluorescent light, templates).

2 Cellulose and Cellulose-Based Hydrogels

Cellulose is an abundant natural macromolecule and constructed by a polymer of glucose, commonly produced from plants and natural fibers or bacteria. Hydrogels are three-dimensional networks expanding with great amounts of solvent and cross-linked by physical interactions (such as hydrogen bonds, hydrophobic interactions, electronic interactions, van der Waals forces) or chemical actions (covalent bonds). For physical interactions, cellulose hydrogels are mainly synthesized from four sources: native cellulose (dissolved in appropriate solvents, such as polar solvents, ionic liquids, and alkali/urea), cellulose derivatives (dissolved in water or acid), bacterial cellulose (BC, also dissolved in specific solvents like native cellulose, or biosynthesized directly into gels). For chemical actions, they have been mainly prepared through the chemical cross-linkers, small bifunctional or multifunctional molecules. The cross-linkers can be classed into two types, agents with esterification including carboxylic acids and carboxylic anhydrides and agents with etherification including organochlorine, epoxide, and vinyl compounds. In fact, there are massive hydrogels mixed with another polymer or inorganics to obtain multifunctional hydrogels for versatile applications.

2.1 Hydrogels from Native Cellulose and Cellulose Derivatives

Cellulose hydrogels can be directly fabricated from cellulose solutions due to many hydroxyl groups forming hydrogen bonding and linking networks. However, the

existence of highly swollen hydrogen-bonded structure also makes cellulose lacking specific solvents to dissolve [19]. To date, a few of solvents have been developed to dissolve native cellulose, such as polar solvents like lithium chloride/dimethylacetamide (LiCl/DMAc), *N*-methylmorpholine-*N*-oxide (NMMO), ionic liquids (ILs), and alkali/urea. The exploration of LiCl/DMAc as solvent started the development of native cellulose hydrogel production. Glasser et al. fabricated cellulosic hydrogel as bead forms through dropwise cellulose into LiCl/DMAc solution to azeotropic methanol or isopropanol as non-solvent system [20]. The LiCl/DMAc solution can be used to dissolve cellulose polymers with a weight range (from degree of polymerization, DP 100–4000). In addition, a battery of the polar solvent systems such as LiCl/DMAc for cellulose powder (0.5–8 wt%), paraformaldehyde (PF)/dimethyl sulfoxide (DMSO) for cellulose pulp (4 wt%), and triethylammonium chloride (TEAC)/DMSO for the wood pulp (0.5–1 wt%) have been applied [21–23]. NMMO solution provides a simple viscose technology for preparing cellulose products. Zhang et al. manufactured cellulose gels by dissolving cotton pulp (7-11 wt%) with NMMO under stirring and heating at 85 °C and found that the cellulose concentration is a determining factor [24]. However, there are few transparent hydrogels synthetized from the native cellulose solution with a NMMO system. Some hydrophilic ionic liquids can also dissolve cellulose. Li et al. used 1-allyl-3-methylimidazolium chloride as solution and water as coagulant to prepare cellulose hydrogels [25], while Kadokawa et al. reported 1-butyl-3-methylimidazolium chloride dissolving cellulose for gels [26]. The cellulose products are obtained from ionic liquids by following addition of water, alcohols, or ketones, presenting the same DP as the initial cellulose. Recently, alkali and alkali/(thio)urea system have been alternatives for cellulose solution. Zhang et al. prepared 7 wt% NaOH/12 wt% urea aqueous and precooled below −10 °C; the cellulose could dissolved rapidly and be adjusted by changing the cellulose content and the post-treatment (Fig. 2a–d) [27]. They also reported a NaOH/thiourea aqueous system by employing a pre-gelation processing [28].

Cellulose presents as random nanofibers, semirigid chains, and/or tangled chains in these solutions, with the degree of crimp lying on the cellulose concentration [29, 30]. The cellulose is completely isotropic when its solution is in low concentration, and a solution to a liquid crystalline gel takes place with the increase of the solution concentration, and then gelation forms solid hydrogels which have a twine structure [31]. Physical interactions are common reversible progress, with a thermo-reversible and "green" sol–gel transformation. The transparency property of hydrogels is defined as their ability to transmit light. The transparency of hydrogel is diverse and varies with the processing temperature or coagulation bath during the gelation. This parameter is caused by the degree of phase separation (or spinodal decomposition, where liquids or solids form one thermodynamic phase to two coexisting phases) [21, 32]. In majority of situation, higher strength means higher transparency and similarly lies on the degree of phase separation. Moreover, employing a pre-gelation process before the coagulation bath can improve the mechanical strength of native cellulose hydrogels. The most common cellulose derivatives are hydrophobic modified cellulose. The derivatives became water

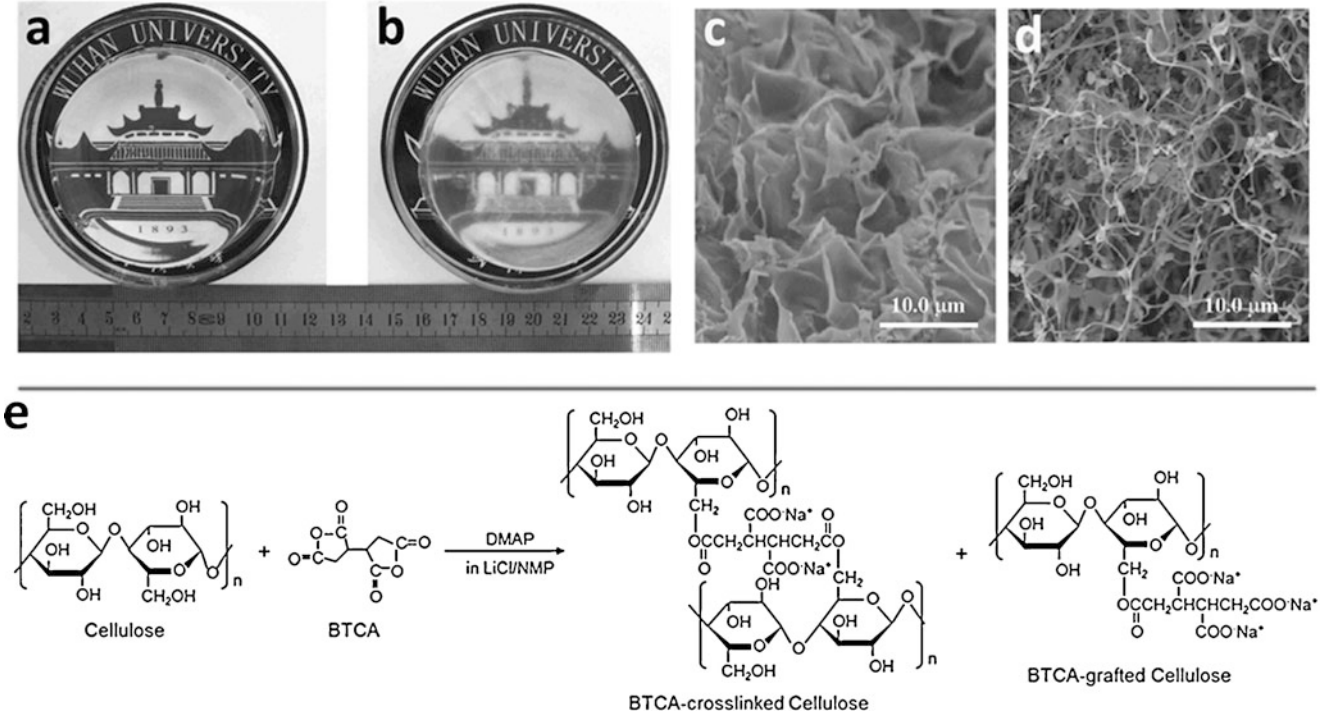

Fig. 2 Photographs and SEM images of the cellulose hydrogels prepared by heating and freezing methods in NaOH/urea: (**a**) and (**c**) heated hydrogels, (**b**) and (**d**) frozen hydrogels [27], (**e**) reaction of chemical cross-linking (1,2,3,4-butanetetracarboxylic dianhydride) and cellulose for gels [45]

soluble as a result of the introduction of pendant groups and can form hydrogels more easily [33]. By hydrophobic or electrostatic associations, these derivatives could be prepared to thermoset and pH-sensitive hydrogels [34]. For an example of these gels, elastic and thermo-reversible hydrogels were obtained above a critical temperature through heating the modifying cellulose aqueous solution. The mechanism of this gelation is solvent reorganization during heating process of the solution, where the solvated 3D framework structure (formed through hydrogen bonds) is destroyed that leads to the exposure of hydrophobic regions of modified cellulose, therefore forming the hydrophobic aggregates [35].

2.2 Bacterial Cellulose (BC) Hydrogels

Bacterial cellulose prepared from microbial strains is generally called *Acetobacter xylinum* with an ultrafine network structure [14]. BC has quite different properties from plant cellulose, including high tensile strength and modulus, high moldability, high hydrophilicity, and high biocompatibility [36]. During gel layer formation, first a gel pellicle emerges on the surface, and its thickness enhances steadily with time increasing [37]. On the basis of such superior properties, BC hydrogels have been applied in a broad range of the biomaterials fields. These BC hydrogels helped the aerobic cells of bacterial cellulose to keep their position near the oxygen-rich surface and protect themselves from sterilizing under extreme conditions including dehydration, ultraviolet lights, and heavy metal ions [38].

Gelin et al. have investigated the effect of the water present in as-synthesized BC gels by dielectric spectroscopy [39]. The results indicated that only about 10% of water molecules in BC gels behaved like free bulk water, and the majority in the gels are more or less tightly bound to the cellulose. Putra et al. used proper fibril orientation to fabricate a tubular BC gel [40]. Here, BC gels can be easily formed into desired shapes and sizes due to their inappropriate orientation at the air/liquid interface. They found desired length, inner diameter, and thickness with uniaxially oriented fibrils could be produced from culturing BC in oxygen-permeable silicone tubes (BC–TS gel) (<8 mm).

2.3 Hydrogels with Chemical Cross-Linkers

However, gels from pure cellulose solution with physical interactions express weak after heating or storage for a long time. To ensure the stable structure of cellulose hydrogels, it is significant to develop a covalently bound 3D network during gelation. Small bifunctional or multifunctional molecules are the widely used chemical cross-linkers. Such linkers can be divided into two categories in accordance with the mechanism: one is esterification of cross-linkers including carboxylic acids and carboxylic anhydrides, resulting in formation of -COOR bonds; another is etherification of cross-linkers including organochlorine, epoxide, and vinyl compounds, resulting in formation of R-O-R bonds.

Sannino et al. prepared superabsorbent hydrogels by using divinylsulfone (DVS) as cross-linker to connect carboxymethyl cellulose [41]. Hirsch et al. explored mechanical properties and swelling capacities at different cross-linking temperatures; the as-synthetized gels swelled at lower temperatures while contracted at higher temperatures [42]. Marsano et al. synthesized thermally sensitive hydrogels by cross-linking hydroxypropyl cellulose (HPC) with poly(ethylene glycol) diglycidyl ether [43]. Yan et al. reported a hydrogel cross-linked by HPC with epichlorohydrin (ECH) exhibited an excellent ability in adsorption of anionic dye [44]. However, both DVS and ECH are toxic reagents, so they must be effectively removed after the hydrogels are produced. In general, not only the degree of spinodal phase separation affected transparency of chemical hydrogels compared to physical hydrogels, but the extent of cross-linking also has an effect. Kono et al. fabricated superabsorbent cellulose hydrogels by esterification cross-linkers with 1,2,3,4-butanetetracarboxylic dianhydride (BTCA) under mild conditions (Fig. 2e) [45]. Chemical cross-linker contributes to a highly hydrophilic 3D network with a homogeneous structure. The initial pore size of the hydrogels is dependent on the preparation process, for example, when the process temperature is above the lower critical solution temperature, the hydrogels are microporous. The mechanical strength of chemical hydrogels is dependent on biopolymer concentration and cross-linkers' density; the stress increased with the concentration and density.

Irradiation is an advanced method for achieving chemical hydrogels, including irradiation of solid polymer, monomer, or polymer aqueous solution [46]. Such radical cross-linkers lead to a higher purity of the hydrogel product due to their nontoxicity. Radiation cross-linker of carboxymethyl cellulose (CMC) with a diverse degree of substitution (DS) was investigated by Fei et al.; they found that a high DS and a high concentration in an aqueous solution were effective to form cross-linkers of CMC [47]. Liu et al. prepared hydrogels by using radiation-cross-linked CMC-Na as a substitute by gamma irradiation below gelation dose; such gels can be used at room temperature and produced at low dose [48]. Wach et al. fabricated HPC hydrogel by electron beam irradiation, which gave higher gelation up to 90% than gamma irradiation [49]. Electron beam (EB) technique has revealed that the process is dependent on concentration. Both electron beam and gamma-ray processes, used to degradation and cross-linking, take place at high-energy irradiation of cellulose derivatives with either.

2.4 Cellulose-Polymer Composite Hydrogels

In fact, most of the pure cellulose hydrogels could not be applied in some specific usage as a result of the lack of appropriate structure or property. Novel hybrid hydrogel materials can be obtained with the advantages of both components through blending with other polymers or inorganics, which enormously improve the performance of the as-prepared composite hydrogels in various fields. It is an extremely attractive choice by mixing different polymers, providing an extremely inexpensive route and advantage to obtain new hydrogels. Zhou et al. synthetized biodegradable

cellulose/chitin gels in 6 wt% NaOH/5 wt% thiourea aqueous solution, which showed a high adsorption ability to heavy metals [50]. The hydrophilic framework and micropores of cellulose improve the adsorption ability of chitin. Li et al. reported a chitosan–cellulose hydrogel cross-linked with ethylene glycol diglycidyl ether, which improved the chemical stability of gels at low pH [51]. Tang et al. fabricated chitosan/methylcellulose hydrogels with the addition of salts including NaCl, Na_3PO_4, $NaHCO_3$, and glycerophosphate (GP); which processing temperature followed the order NaCl > GP > Na_3PO_4 > $NaHCO_3$, gels rate followed the order GP > $NaHCO_3$ > Na_3PO_4, and strength of gels followed the order GP > $NaHCO_3$ > Na_3PO_4 (at 37 °C) [52]. Baumann et al. prepared a series of physical hybrid hydrogel composed of hyaluronan and methyl cellulose, which displayed the advantages in design criteria of injectability and safe swelling [53]. Rao et al. developed a NaAlg/hydroxy ethyl cellulose hydrogel by precipitating the viscous blend solution in alcohol and cross-linking with calcium chloride, and the ability of controlling the release of diclofenac drugs has been investigated [54]. Chang et al. prepared cellulose/sodium alginate macroporous hydrogels by cross-linking with epichlorohydrin and characterize the structure, morphology, gelation conditions, strength, and equilibrium swelling ratio [55].

Polyvinyl alcohol (PVA) is a good alternative cross-link network for the preparation of hydrogels through diverse technologies such as chemical bonding, electron beam, and physical linking. Abitbol et al. reported PVA/cellulose hydrogels by cyclic freezing and thawing (Fig. 3a–f); the confined compression and the elastic moduli of hybrid gels have been enhanced relative to pure hydrogels [56]. Zhang et al. further investigated the structure and properties of cellulose/PVA gels with the effect of cross-linking; all as-prepared gels exhibited homogeneous porous structures and a certain miscibility [57]. Taleb et al. fabricated PVA/carboxymethyl cellulose gels using electron beam irradiation as a cross-linking agent, and they studied the thermal behavior and swelling properties of composite hydrogels [58]. Polyvinylamine (PVAm) is commercially available, containing a series of copolymers such as poly(*N*-vinylformamide) (PNVF), which could be applied as cationic polymers to prepare carboxymethyl cellulose, PVAm/carboxymethyl cellulose, and PVAm-co-PNVF/carboxymethyl cellulose hybrid with macroscopic, homogeneous, and transparent properties. Feng et al., respectively, prepared carboxymethyl cellulose/pure PVAm and carboxymethyl cellulose/PNVF gels and measured the tensile strength and tensile modulus with the effect of polymer ratio, molecular weight, and water content [59].

Two or more polymers blending into one network are defined as interpenetrating polymer networks (IPNs). IPNs in the context of cellulose-based hydrogels could be classed into two types, sequential IPN and semi-IPN, which the cellulose is conducted as the first network and polymerizing in the presence of the cellulose network is used as second network; such mixture networks can be called as sequential IPN. For the semi-IPN, hydrogel formed from cellulose or its derivative is linear or branched with a cross-linking network. Gelatin gels are easily broken into fragments under a modest compression; Nakayama et al. synthesized double-network hydrogels with high-mechanical-strength combined polymers BC with gelatin [60].

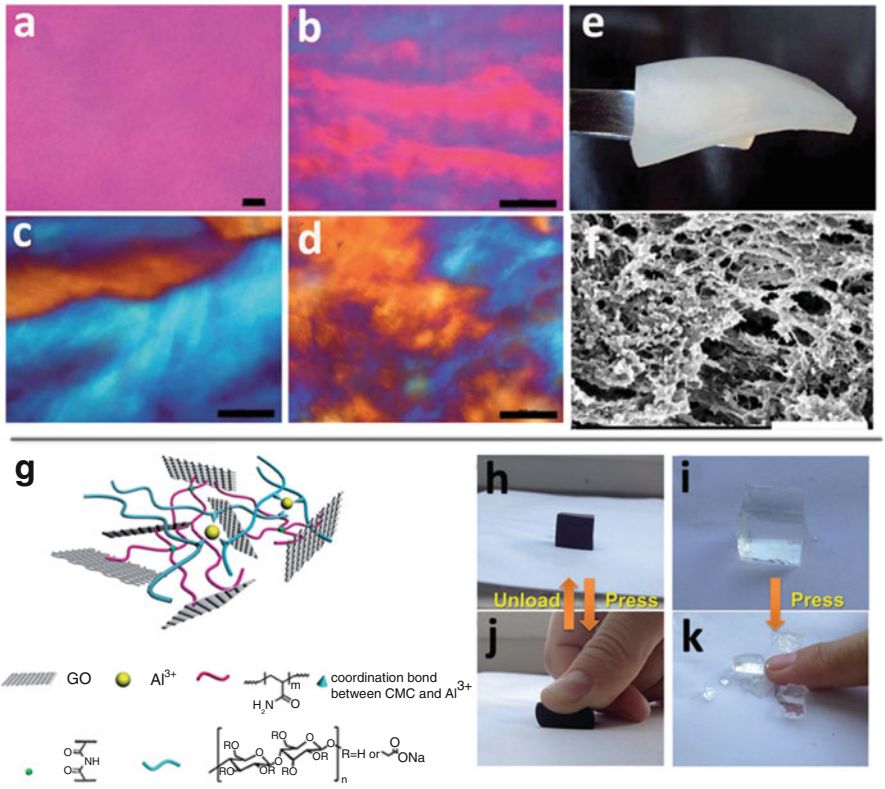

Fig. 3 (**a**–**d**) Polarized optical micrographs of different cellulose loading hydrogels, (**e**) and (**f**) photographs and SEM images of PVA/cellulose hybrid hydrogels [56], (**g**) schematic diagram of GO/PAM/CMC ternary nanocomposite hydrogels, (**h**–**k**) photographs of GO/PAM/CMC and PAM/CMC hydrogels under pressure [71]

Buyanov et al. prepared hybrid gels through synthesis of PAAm networks into the BC matrices; the hydrogels displayed excellent mechanical properties (such as compression strength up to 10 MPa) [61]. Caykara et al. reported a linear HPC and cross-linked P(NTBA-*co*-AAm) hydrogels by the semi-IPN technique; such semi-IPN hydrogels underwent a volume phase transition between 18 °C and 22 °C as a function of the amounts of MBAAm and HPC [62].

2.5 Cellulose-Inorganic Hybrid Hydrogels

In recent years, introduction of inorganic into cellulose hydrogel is a creative way to prepare materials with highly effective functionality and has attracted increasing attention in diverse fields. Simply mixing the target inorganics with the cellulose solution and then shaping into a gel is a rapid and effective approach. Chang et al.

fabricated cellulose and quantum dot (CdSe/ZnS) hydrogels in a NaOH/urea aqueous system via a mild chemical process [63]. The cellulose/quantum dot hydrogels showed strong photoluminescence (PL) emission and nearly pure color depending on the size of the QDs. By introducing inorganic target from inorganic precursor into the cellulose solution (or suspension) along with (or followed by) gelation is also an advanced technique to fabricate cellulose-inorganic hybrid hydrogels. Sequeira et al. synthesized cellulose/silica hybrid using eucalyptus-bleached kraft pulp as the cellulose source and tetraethyl orthosilicate (TEOS) as the silica precursor and the heteropoly acids (HPAs) as catalysts by a sol–gel method [64]. Bagheri et al. developed cellulose-ZnO gels through the dissolution of cellulose with microwave assisted in ionic liquid 1-butyl-3-methylimidazolium chloride and then added premixture of $Zn(CH_3COO)_2{\cdot}2H_2O$ and NaOH [65]. The as-prepared gels have a catalyst behavior due to zinc oxide nanoparticles in the cellulose matrix.

In situ transition of the precursor in the cellulose gel takes advantage of guaranteeing the structural integrity of gel networks and has attracted a great attention. Wu et al. synthesized Ag nanoparticles decorated by an eco-friendly hydrothermal process on porous cellulose with a sol–gel transition processing; the hybrid exhibited good catalytic activity [66]. Luo et al. prepared regenerated cellulose microspheres followed by in situ synthesis of Fe_3O_4 nanoparticles into the gels and created the magnetic-induced transference [67]. Ashori et al. immersed BC hydrogels into an aqueous solution of tetraethoxysilane (TEOS), followed by pressing the disposed BC matrices (at 120 °C and 2 MPa) for obtaining water-free translucent blended gels [68]. While Katepetch et al. synthesized and simultaneously incorporated ZnO into 3D BC networks by ultrasonic-assisted in situ synthesis [69]. Hutchens et al. applied calcium-deficient hydroxyapatite (CdHAP) deposited in a natural BC hydrogel, exhibiting potential application in an orthopedic biomaterial [70]. The fermentation of BC as a template for the ordered support of target inorganics is a biosynthesized technology according with ecological economy. Graphene oxide (GO) has inspired great interests for nano-reinforcement of polymer because of its high special surface area. Zhang et al. prepared GO/polyacrylamide (PAM)/carboxymethyl cellulose sodium hydrogel with superior mechanical strength and good swelling behavior (Fig. 3g–k) [71].

3 Applications of Cellulose and Cellulose-Based Hydrogels

Cellulose and cellulose-based materials are fascinating hydrogel precursor, as a result of their low cost, large availability and regeneration, and environment-friendly abilities. In most cases, such glamorous biodegradability of hydrogel is required or recommended to various applications. This section reviews some possible applications of cellulose-based hydrogels; these applications are attributed to macroporous structure, hydrophilicity, and biocompatibility of cellulose-based hydrogels such as water purification, water reservoirs for agriculture or personal care and hygiene, drug delivery, wound dressings, tissue engineering, and other applications.

3.1 Water Purification

Water pollutions have not only brought about severe environmental problems but also threaten people's health and the sustainable development of economy. The wastewater is commonly complex with diverse pollutions, such as oil, organic pollutants, heavy metal ions, and dye contamination [72]. A large number of liquid- and/or solid-phase extraction techniques have been implemented for the purification of pollutants from water including chemical precipitation, burning, mechanical collection, membrane filtration, ion exchange, and electrochemical catalysis [73–75]. Hydrogels, which exhibit high adsorption ability due to porous structure, abundant functional groups, and relatively low density after drying, have achieved particular attention for pollution removal from water, especially cellulose-based hydrogels with biodegradability, biocompatibility, and nontoxicity. Besides, decoration of another component into the hydrogel matrix entrusts the resulting hybrid networks with abilities to remove different aquatic pollutants.

Heavy metal ions are highly toxic even at low concentrations and can accumulate in vivo leading to body disorders and diseases. Therefore, it is extremely urgent to reduce or clear up the heavy metals from industrial sewage diffusing into the environment. For an adsorbent, the adsorption efficiency often depends on its specific surface area and surface functional groups [76, 77]. Blending two or more polymers has become a charming technique for the investment of novel biomaterials, which exhibits advantages of combinations that could not be available by the single polymer. Zhou et al. prepared carboxylated cellulose/chitosan hydrogel which exhibits an adsorption capacity of 171.0 mg g^{-1}, and the carboxylate groups on the carboxylated cellulose surface played key role in Pb(II) adsorption [78]. Liu et al. prepared Fe_3O_4 coated cellulose–chitosan hydrogels as reusable adsorbent for heavy metal ions; it greatly enhanced the stability of nanoparticles through preventing their aggregation and oxidation and made recycling more convenient (Fig. 4a–b). Moreover, it also showed high absorbency with the abundant amino and hydroxyl functional groups from polymers [79]. Isobe et al. introduced nitroxyl radical-catalyzed oxidation with hypochlorite/bromide (TEMPO oxidation) oxidation onto the surface of the cellulose hydrogel; the TEMPO oxidation carboxyl groups onto the surface of the cellulose hydrogel and the hybrid displayed high adsorption capacity for diverse toxic metal ions such as Zn^{2+}, Fe^{3+}, Cd^{2+}, and Cs^{+} [80].

Dyes are widely used for different purposes such as in textile, tannery, printing, cosmetic, and petroleum. These dye molecules or their metabolites are hard to biodegrade under natural conditions and thus may be potentially hazardous to living organisms [81]. Activated carbon is used in common adsorption technique due to its effectivity and inexpensive. Cellulose-based hydrogels are the effective potential adsorbent for the removal of toxic dyes due to their advantages of low-cost, nontoxic, synergistic effect between the nanosize and polymer matrix and excellent mechanical, higher surface area and hydrodynamic radius. Pei et al. fabricated quaternized cellulose gels, and it exhibited dye adsorption capacity of 0.95 mol kg^{-1} for Congo red and 1.10 mol kg^{-1} for acid green 25 because of their high specific surface area and surface cationic charge density. Besides, the cellulose could also

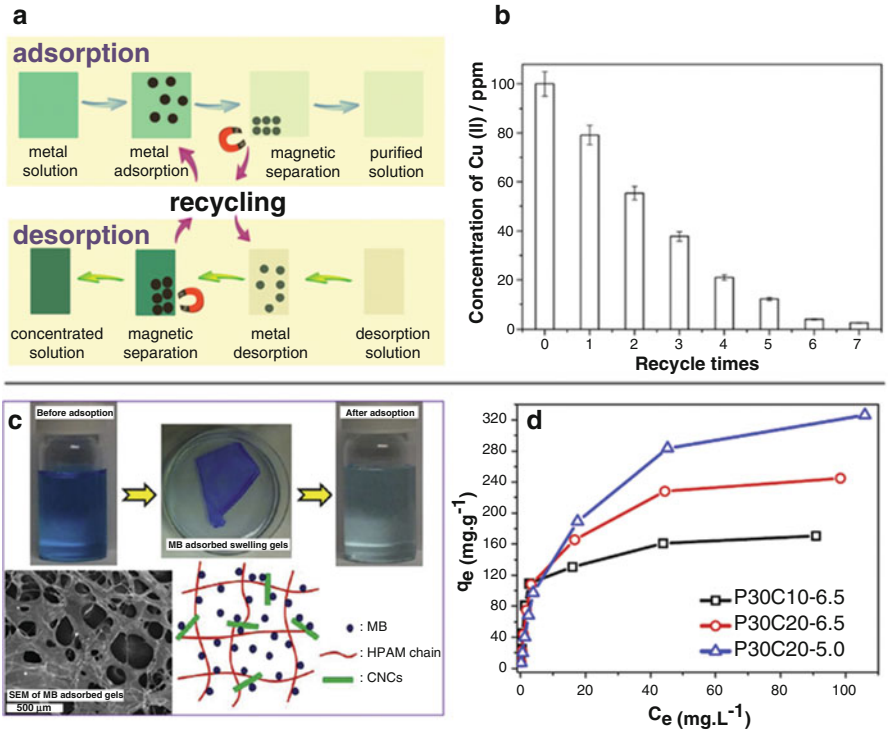

Fig. 4 (**a**) Overall process of adsorption and desorption of heavy metal ions, (**b**) recycling times as a result of the concentration of Cu^{2+} [79], (**c**) scheme of the MB adsorption behavior of nanocomposite hydrogels, (**d**) adsorption isotherms of MB on diverse hydrogels. P30C10-6.5 represents a gel comprised of 90 wt% of HPAM with 30% of anionicity and 10 wt% of CNCs [83]

high-efficiently remove cationic and anionic dyes [82]. Zhou et al. obtained hydrolyzed polyacrylamide (HPAM)/cellulose nanocrystal (CNC) hydrogels by a simple thermal treatment, which exhibited maximum methylene blue adsorption about 326.08 mg g^{-1} (Fig. 4c–d) [83]. Liu et al. prepared cellulose-based hydrogels by grafted acrylic acid and acrylamide; such hydrogels could remove anionic dye acid blue 93 (AB93) and cationic dye methylene blue (MB) from single and binary dye solutions [84]. The maximum adsorption capacities of hydrogels were 1372 mg g^{-1} for AB93 and MB.

3.2 Superabsorbent Cellulose-Based Hydrogels

3.2.1 Superabsorbent for Personal Care and Hygiene

Biocompatibility superabsorbent hydrogels can absorb fluids and keep moisture and humidity away from the skin in order to improve health and comfort of consumer [85, 86]. However, conventional superabsorbents like acrylate-based

hydrogels are currently extensive and sophisticated. There is an estimation that thousands of hospitals and group care centers in the majority of countries employ disposable diapers containing a superabsorbent polymer. Moreover, demand trends of such products in training pants and adult incontinence have been raising worldwide. Research have reported a great deal of documents that elaborate the advantages of using superabsorbent materials in personal care and hygiene including safety and effectiveness [87, 88]. The superabsorbent not only prevents the diaper rash caused by dry skin but also controls the spread of germs, which is significant in decreasing the risk of derelict contamination and reducing the potential for the spread of illness in care centers. Adalat et al. studied the incidence and prevalence of diaper dermatitis that varies in detail; they found disposable diapers that were crucial to decrease risks of spreading gastrointestinal illnesses [88].

In 1982, superabsorbent was first used in the diaper fields and was only introduced by Unicharm in Japan and followed by application in sanitary napkins. After that, different attempts have been carried in diverse personal care and hygiene including disposable diapers, napkins, hospital bed sheets, and sanitary towels [89]. In majority of cases applied in superabsorbent, the cellulose exhibited the similar structure: they contain non-woven tissue as a wrappage, plastic material as a cover, and fluff of wood pulp cellulose as an absorbent. Recycle diaper must be separately collected to recover the biodegradable fraction of cellulose and the other portion including acrylate-based hydrogels which are not biodegradable but also could be recycled for other uses [90]. Recently, the cellulose-based hydrogels have been developed as a substitute to deal with the problem of recycling of superabsorbent; thus the recycle diaper is totally biodegradable. Sannino et al. prepared novel hydrogels based on cellulose derivatives including sodium carboxymethyl cellulose and hydroxyethyl cellulose chemically cross-linked with divinylsulfone, which exhibited superior swelling capabilities than those displayed by superabsorbent and high water retention capacities after centrifugal loads [91]. Cellulose-based hydrogels used as superabsorbent take the main advantage of their biodegradability and environmentally friendly nature. Demitri et al. synthetized new cellulose-derived eco-friendly hydrogels, and such superabsorbent hydrogels showed excellent biodegradable properties [92]. Moreover, swelling properties have been adjusted performing on the degree of cross-linkers of the polymer networks, and the hydrogel biocompatibility has been investigated according to its capability either to guide nitric oxide and lactate dehydrogenase release by macrophages or affect viability of macrophages. The biocompatibility is consistent with the hypothesis and displays a high level of biocompatible ability which indicate this gel may be an alternative to diuretic therapies in special pathologic conditions. Esposito et al. prepared an orally administered cellulose-polyethyleneglycol gel; the gel demonstrated their high water-sorption properties (Fig. 5a), and biocompatibility studies showed that the hydrogel would not influence negatively cell viability (Fig. 5b), which indicated the obtained hydrogel could serve as a potential treatment for intractable edemas [93].

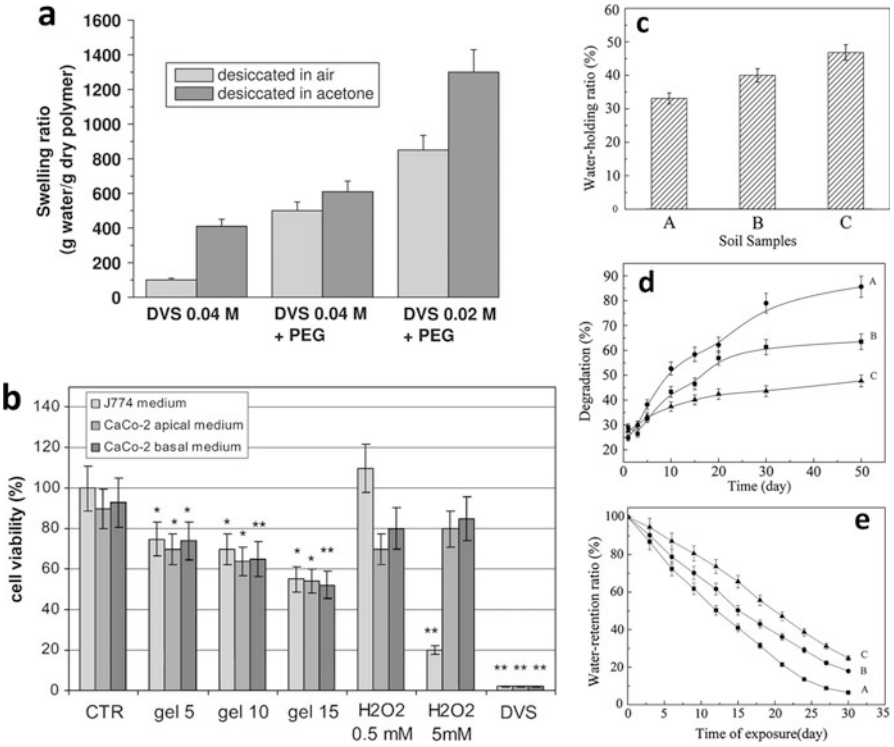

Fig. 5 (**a**) Hydrogel equilibrium swelling ratio in distilled water, (**b**) cell viability measured by contacting with the gel or with CaCo-2-conditioned medium of cellulose-PEG hydrogels [93], (**c**) and (**e**) largest water-holding ratio and water retention behaviors of different soil samples (A, pure soil; B, 1 g coated CRF; C, 2 g coated CRF), (**d**) degradation of P(AA-AMPS-NHMAAm)/WS superabsorbents [99]

3.2.2 Water Reservoirs in Agriculture

Agriculture and horticulture require decreased water consumption and manage water resources. Superabsorbent hydrogels have achieved increasing interest and deserved the attention of both academic and industrial research in agriculture [94]. The hydrogels play an important role in the enhancement of newly human habit toward water, which to be considered as a benefit to save and not as a surplus to waste. It is known that the hydrogels have a translation from the glassy to the rubberlike state during swelling process; meanwhile they could store large amounts of water even under compression [95]. In addition, the swollen hydrogel is able to slowly release water when in the interior and the outside of the material exists a gradient of humidity. Water molecules, loaded in the polymer skeletons along with the synthesis of hydrogels, can be released through a controlled and sustained management with diffusion method. Xerogel (dry hydrogel), which exists in the form of powder or granules, is introduced for the purpose of planting by envisaging to be blended with

the clay in arid and desert regions, where there are absolute scarcity of water sources and lacking of flora. As the hydrogel absorbed the water or nutrients followed by cultivation, they release water and nutrients to the soil when required following diffusion-driven mechanism, thus guaranteeing the sufficient moisture for plants over a long period. Another advantage of using hydrogels is connected with the effect of the swelling, hydrogel granules has fine dimensions before swelling as well as the substrate granules, and they promote the dimension after adsorbing water to enhance the porosity and support a better oxygenation to the plant roots.

A few of commercial product absorbents, retaining and releasing water, have been applied in this field and exhibit their good efficiency in saving water [96]. However, their water retention capacities are extremely high and hard in management, presenting the risk for cultivations. For cellulose-based hydrogels, the cellulose is a renewable natural resource with biodegradability and nontoxicity and fits perfectly as superabsorbent in the agriculture to replace the acrylate-based hydrogels. Sannino et al. reported a series of absolutely biodegradable and biocompatible 3D cellulose-based hydrogels with numbers of micropores served as superabsorbent [97]. Such hydrogels were able to absorb up to 1 L water per gram of dry material, without releasing it even under compression. The hydrogels could be prepared both as the type of a powder and a bulky material with a well-defined shape and a superior shape memory after swelling. While mixed with small molecules such as nutrients, the hydrogels could be released under a controlled kinetic in agriculture. The soil with the addition of hydrogels remained humid for four times longer than those of pure soil. Marcì et al. prepared cellulose hydrogels as non-petrochemical reserves and renewable superabsorbent [98]. Paradoxically, a small difunctional molecule divinylsulfone (DVS), used as a cross-linker for the hydrogel, was highly toxic. The toxic agent was efficiently removed along with the unreacted polymers and irradiated by the environmentally sustainable heterogeneous TiO_2 with photo-catalyzed process. The treated hydrogels as newly superabsorbent showed tendency of water retention in the agriculture. However, it is necessary for carrying out experimental greenhouse on the spot where the paucity of water has been a common problem. Xie et al. prepared coated controlled-release fertilizer (CRF) based on wheat straw; the CRF granules indicted high water-holding abilities and good degradation properties in soil solution (Fig. 5c–d), which could be promising for applications in agriculture and horticulture [99].

3.3 Biomedicine Application of Cellulose-Based Hydrogels

3.3.1 Drug Delivery

Cellulose allows a drug release derived from swelling as physiological fluids and is involved in contacting with the tablet itself while being used in solid tablets [100]. It starts to swell on the tablet surface and is transformed into a physical hydrogel with chain entanglements and followed by the drug that gradually dissolves in water and diffuses out from the hydrogel network. Thus drug release was a complex process with combination of swelling, diffusion, and erosion [101].

Incorporating another component into the hydrogels with diverse dosages would obtain different structures and morphologies in the 3D network, therefore governing their diffusion properties. Chang et al. prepared hydrogels from carboxymethylcellulose (CMC) sodium and cellulose cross-linking with epichlorohydrin in the NaOH/urea aqueous [101]. As-synthetized hydrogels displayed smart swelling and constriction in NaCl or $CaCl_2$ aqueous solution; besides, managing CMC portion could control the release of bovine serum albumin (BSA, Fig. 6a–f). Lignin, as another biopolymer developed by Ciolacu et al., also resulted in a more homogenous and less

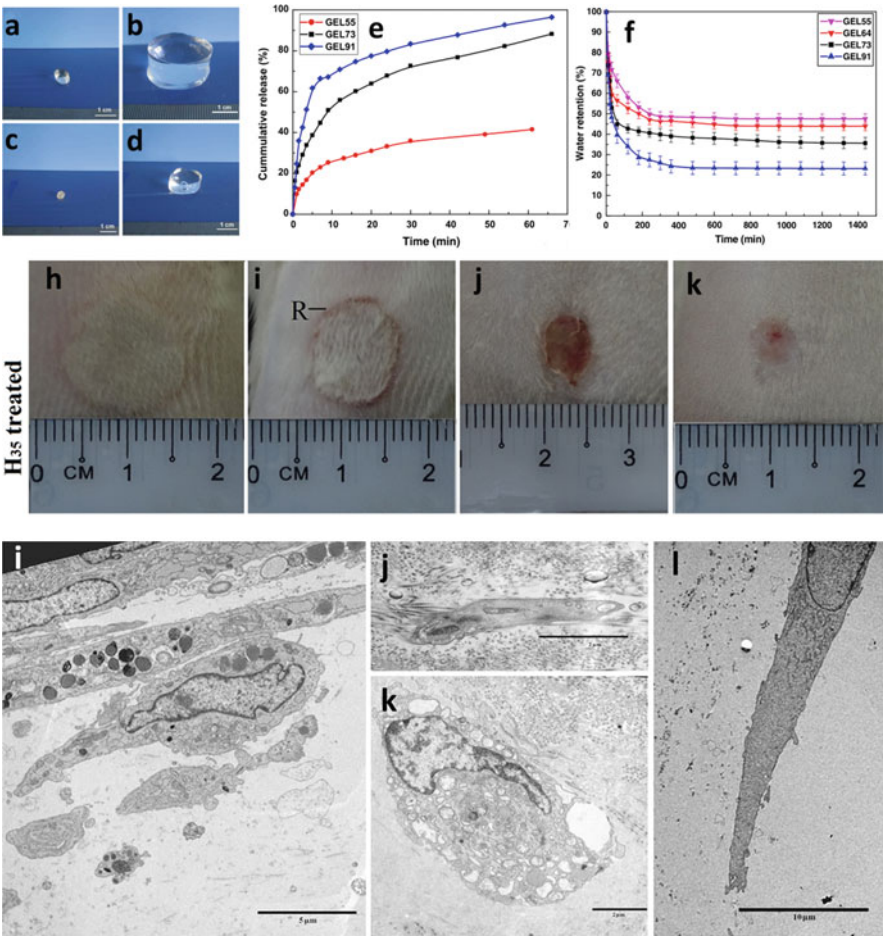

Fig. 6 Photographs of original hydrogel and swollen hydrogel (**a**–**b**) in water and (**c**–**d**) in NaCl solution; (**e**) deswelling kinetics of cellulose/CMC hydrogels in 0.1 M NaCl solution at 37 °C; (**f**) percent cumulative release of BSA in vitro [101]; (**h**–**k**) photographs of wounds treated with hydrogels by electron beam irradiation at doses of 35 kGy ($H_{3.5}$) after days 1, 3, 7, and 14 [115]; morphology of human chondrocytes grown in (**i**) native BC; (**j**) articular cartilage surface; and (**k**) articular cartilage bulk, ingrowth of human chondrocytes in native BC [124]

dense structure and an increase in the release rate as a result of an addition of lignin content [102]. These revealed that the higher density and smaller pores contribute to a reinforcing structure and a slow release rate. Wang et al. reported cellulose/poly (*N*-isopropylacrylamide) hydrogels by controlling the content of MBAAm to adjust the swelling ratio of hydrogels [103]. Dimethyl methylene blue was used as a model drug to examine the loading and releasing performances of the hydrogels. Besides, hydrogels that can reversibly change in response to environmental condition can also manage drug release. The most commonly researched type of environmentally sensitive systems is temperature-sensitive hydrogels in drug delivery field. Sanna et al. developed thermo-responsive poly(*N*-vinylcaprolactam)/nanocrystalline cellulose hydrogels; the gels displayed a decreased swelling ratio along with increased temperature and therefore could be used as "on–off" release devices [104].

All efforts are deserving if drug release could be adjusted in a manner that precisely fits the physiological requirements at specific sites (site-specific targeting). Controlling pH triggering is an attractive and the most common route of targeted release. The pH gradient in the human intestines and stomach impresses different values (stomach 1–3, saliva 5–6, colon 6.4–7.0, and intestine 6.6–7.5) [105]. Amin et al. fabricated pH-responsive BC/acrylic acid hydrogels for drug delivery; the hydrogel systems showed minor swelling at acidic pH and large swelling around neutral pH, which can be applied in intestine or colon-specific delivery [105]. Pandey et al. grafted polymerization of acrylamide on BC as superabsorbent smart-swelling hydrogels; the hydrogels exhibited higher porosity, drug loading, and releasing efficiency for oral drug delivery contrasted to the hydrogels synthesized using dispersed BC [106]. Thermoset hydrogel systems are able to be injected into the body directly as a liquid and in situ transform in the form of a gel, while their critical solution temperature is below the body temperature and has the potential to act as targeted drug carriers without requiring invasive surgeries. In addition, such hydrogels could comparatively prolong the release time reaching a few weeks because of the efficient encapsulation of drugs. Luo et al. reported Fe_3O_4/cellulose gels by in situ synthesized route; the prepared microspheres perform a key role in both the formation of the magnetic transference and the improvement of the behavior delivery and release targeting protein [107].

3.3.2 Wound Dressings

During wound healing, inflammation, debridement, proliferation of granulation tissue, and reepithelialization are the normal processes that occur [108]. A desirable gel for wound dressing should guarantee the suitable moisture and constant temperature of the wound, allow exchange of gases between the wound and outside, adsorb excess exudates, prevent the bacteria from infracting and contamination from the wound, accelerate healing, and relieve pain [109, 110]. It should also be nontoxic, non-adherent, and easily removed without trauma. Diverse species of hydrogel based on synthetic or natural polymers or a combination for dressings have been investigated so far and are commercially purchased.

However, cellulose itself has no antimicrobial activity; some antimicrobial agents can be incorporated into the cellulose hydrogels to protect the wound

against bacteria [111]. Maneerung et al. impregnated silver nanoparticles into BC gels; the freeze-dried silver nanoparticle and BC hybrid exhibited the superior antimicrobial activity against *Escherichia coli* (Gram-negative) and *Staphylococcus aureus* (Gram-positive) [111]. Similarly, Li et al. synthesized cellulose–silver gels with microwave-assisted synthesis, possessing a high thermal stability and antimicrobial property [112]. ZnO/BC gels were synthesized by ultrasonic-assisted route and the composited hydrogel as well as showed excellent antibacterial activity against *Escherichia coil* and *Staphylococcus aureus* with high efficiency [69]. Moreover, the mechanisms of the antibacterial abilities of ZnO and Ag nanoparticles were distinguished: for the ZnO, it is considered that decorated ZnO nanoparticles can react with water molecules, resulting in the production of reactive oxy-radicals or hydroxyl radicals which could induce oxidative injury inside bacterial cells. For the Ag NPs, it was able to directly penetrate inside the bacteria or paste to the surface of the bacteria destroying permeability and respiration functions. Eukaryotes can undertake higher concentrations of ZnO or Ag NPs than bacterial cells to achieve appropriate toxic effects, leading to biocompatibility of the materials for human cells. Chiaoprakobkij et al. developed the novel BC/alginate sponges without the antibacterial property; such gel can be applied as a temporary wound dressing material due to its many advantages including appropriate cell attachment, skin tissue compatibility, excellent water uptake ability, high mechanical strength, and good tear resistance properties [113]. Chitosan is antimicrobial, permeable, nonirritating, and without allergic reactions, especially the desired ones for wound dressings [114]. Hybridization with cellulose can improve the healing effect due to the high bioactivity of cellulose whose main components are collagen and a few protein amylases. The behavior of wound dressings consistent with the tissue scaffolds is connected with the drying technology and water retention. Dressings with nanopores or porogen-induced pores obtained from air-drying are twice stronger than the porous ones obtained by freeze-drying. Mohamad et al. synthesized BC/acrylic acid hydrogel by electron beam irradiation; the as-prepared hydrogel exhibited suitable physical and mechanical characteristics and was able to accelerated burn wound healing (Fig. 6h–k) [115].

3.3.3 Tissue Engineering

Recent tissue engineering has been a fascinating application since hydrogels catch the attention of researchers, where they are used as skeletons to imitate the roles of extracellular matrices and to engineer new tissues; these skeletons support space and nutrients for new formation of tissue and potentially control the structure and function of the engineered tissue in situ or in vitro [1, 8]. Now, hydrogel skeletons are at near clinical uses to engineer many tissues in the body including the cartilage, bone, muscle, skin, fat, artery, liver, ligament, tendon, bladder, and neurons [116, 117].

Cellulose-based hydrogel skeletons should appropriately satisfy a great deal of design criteria of multifunction and promotion of new tissue formation, including processability, biodegradability in tissue engineering system, and cell adhesion

ability [118]. Saska et al. prepared BC gels by cross-linking of type I collagen; the BC-collagen hydrogels were cultured on high protein content and ALP activity at day 17 in cells, suggesting this gels enabled the growth of the osteoblastic phenotype in vitro [119]. It was shown that the optimal pore sizes of skeletons in tissue engineering were to be 5 μm for neovascularization, 20–125 μm for regeneration of the skin, and 100–350 μm for regeneration of the bone [120–122]. It was suggested that the microarchitecture played a role in tissue regeneration; the bone can be regenerated in freeze-dried skeletons with medium pore sizes as low as 16 μm via hematoma osteoinduction instead of osteoconduction in big pores [123]. Pore sizes of hydrogels were impacted by various factors such as drying methods, biopolymer concentration, and cross-linking degree, and they can also be improved by adding a "porogen." Svensson et al. prepared native BC hydrogels, which supported chondrocyte proliferation at levels of approximately 50% of the native tissue substrate, collagen type II, and it showed significantly higher levels of chondrocyte growth contrasted to tissue culture plastic and alginate (Fig. 6i–l) [124].

3.4 Other Applications

Cellulose-based hydrogels are applied widely in many other diverse applications. One of the most potential applications is energy storage systems such as capacitor or battery. Yamazaki prepared acidic cellulose–chitin hybrid gel electrolyte for a double layer with a high ionic conductivity at room temperature, and the capacitor using the acidic cellulose–chitin showed the higher special capacitance and a better cycle performance than with the H_2SO_4 [125]. These indicated that the acidic cellulose–chitin gel electrolyte has the practical applicability with excellent stability and working performance in capacitors. Lee et al. investigated the swelling behavior of carboxymethyl cellulose that influences a natural graphite suspension from the aspects of stability and chemical properties for Li-ion battery; experiment results displayed that Li/organic electrolyte/nature graphite with the swelling cellulose has exhibited an initial discharge capacity above 340 mAh g^{-1} and an improved charge–discharge efficiency [126]. Combining with inorganic catalysts, cellulose-based heterogeneous catalysis has attracted some interests of researchers recently. Kemell et al. prepared the TiO_2/cellulose composite and verified its photocatalytic activity of photocatalytic reduction of Ag(I) from to Ag nanoparticles on the TiO_2 surface [127]. The TiO_2/cellulose composites were more mechanically stable than the free-standing TiO_2 replicas and potentially suitable as lightweight, high-surface-area photocatalysts.

Nanometal and metal oxides, carbon materials, conducting polymers, and ionic liquids can be mixed (through doping, blending, or coating) into the cellulose frameworks. Such composites form a biocompatible surface for microelectronic devices, implantable biosensors, and neuronal prostheses. Van den Berg et al. prepared cellulose nanofibers and conducted π-conjugated polymer nanocomposites, which exhibited the electronic property of the conducted polymers as well as the outstanding mechanical property of the cellulose networks

[128]. Besides, cellulose could serve as template to synthesize diverse nanocrystals that present nanoscale size- and shape-dependent properties. Olsson et al. constructed flexible magnetic aerogels by cellulose nanofibrils as a facile template approach; due to the BC, they have a crystal structure with high-molar-mass, hydrogen-bonded chains in an extended chain conformation [129]. Lin et al. developed a general strategy to craft a series of plain nanorods, core–shell nanorods, and nanotubes with accurately controlled dimensions and compositions with well-defined structures and narrow molecular weight through amphiphilic cellulose-g-(PAA-b-PS) as nanoreactors [130].

Cellulose hydrogels having strong fluorescence have been successfully fabricated by Chang et al. Photoluminescence (PL) spectra indicated that the cellulose matrix in the composites performs a significant role in the protection of the CdSe/ZnS structure [63]. The cellulose–QD hydrogels exhibited strong PL emission and nearly pure color from green to red, depending on the size of the QDs. Moreover, the hybrid hydrogels possessed a good transparence and compressive strength. Phase change materials, widely applied in energy fields as potential heat energy storage and release media with effective thermal management, have attracted more and more attention. Yang et al. combined defect-free graphene with microcrystalline cellulose for phase change composites; the lightweight cellulose/graphene gel exhibited a high thermal conductivity of 1.35 W m^{-1} K^{-1} [131].

4 Conclusions

We have discussed on solvents which have been used for the dissolution of native cellulose or cellulose derivatives, and there are only a few solvents including polar solvents (such as *N*-methylmorpholine oxide, dimethylacetamide), ionic liquids (such as 1-butyl-3-methylimidazolium chloride or 1-allyl-3-methylimidazolium chloride), and alkali/urea to date. Blending two or more polymers (such as chitosan or/and polyvinyl alcohol) endows cellulose hydrogels with high adsorption ability for anionic and cationic dyes, and magnetic inorganic nanoparticles like Fe_3O_4 grafting polymer networks make hydrogels to be easily recycled after adsorption. The abundant functional groups and specific surface area of cellulose-based hydrogels guaranteed their removal efficiency for heavy metal ions. Hydrogels can also store large amounts of water even under compression; meanwhile they swell after adsorbing water from xerogel (with a fine dimensions), so they can serve as water superabsorbents for personal care and hygiene, agriculture, and biomedical applications (changing the structure and morphology of the network, subsequently controlling their diffusion properties, pH-triggered, targeted drug delivery, guaranteeing the suitable moisture and constant temperature of the wound, allowing exchange of gases between the wound and outside, absorbing excess exudates, preventing the bacteria from infracting and contamination of wound dressings, and are used in tissue engineering). Moreover, cellulose hydrogels are able to be energy storage systems, grafted with inorganic catalyst (TiO_2, Ag nanoparticles) for catalysis, grafted with quantum dot (CdSe/ZnS) for fluorescent light, and so on.

5 Perspective

For future studies, more attentions should be focused on green chemistry such as using safe solvents, nontoxic cross-linkers, and green synthesis and low-energy processing. It is necessary to prepare modified hydrogels with unique characteristics such as highly elastic, super-stretchable, and self-healing properties and to develop novel biopolymer isolation methods to produce cellulose with high molecular weights and such unique hydrogels. For water purification, cellulose-based hydrogel should improve their efficacy, selectivity, and recycling for the sake of economical development. For biomedical fields, parameter-based (such as pH) trigger release should accurately arrive at targeted sites, and injected hydrogels without the requirement of surgery form safely inside the body applied for drug release or tissue engineering. Moreover, degradation of hydrogel in vivo could be considered with a controlled manner in both applications. New applications of cellulose-based hydrogels (such as solid-state hydrogels for energy systems, flexible electronic device) could be further investigated. Undoubtedly cellulose-based production will be available to substitute for petroleum-based materials in near future.

Structure-Property Relationships in Cellulose-Based Hydrogels

3

Diana Elena Ciolacu

Contents

Abstract

Hydrogels are widely used for different biomedical applications, due to their ability to absorb, retain, and release water solutions in a reversible manner and in response to specific environmental stimuli. The review is focused on the preparation methods, main characteristics, as well as biomedical applications of hydrogels prepared from the most abundant biopolymers on earth, cellulose. The chapter emphasizes the latest developments in the design and manufacture of cellulose-based hydrogels. The preparation of hydrogels without covalent cross-links (physical hydrogels) and with covalent cross-links (chemical hydrogels) is discussed. The behavior of gels upon coagulation and the swelling

capacity in water were analyzed. A systematic investigation into the structure and physical-chemical properties of cellulose-based hydrogels was performed in order to describe the relationships between the network structure and gel properties. The degree of cross-linking of the hydrogels, the morphology of the three-dimensional (3D) matrices, the bulk geometry, and the description by different complementary techniques which offered insight into structure-property relationships of hydrogels are reviewed. The sorption properties of cellulose-based hydrogels and the effect of the design parameters of hydrogels on their biomedical applications are also discussed.

Cellulose · Hydrogel · Gelation · Cross-linking · Swelling · Drying · Morphology

1 Introduction

Hydrogels are defined as a hydrophilic polymers structure, capable to absorb and retain a relatively large amount of water or aqueous fluids (up to 10 g/g for ordinary absorbent hydrogels or more for superabsorbent hydrogels). The water-absorbing capacity and mechanical property of hydrogels usually rely on their three-dimensional (3D) network structure which can be driven by both chemical and physical interactions [1–3].

The classification of hydrogels depends on their physical properties, nature of swelling, method of preparation, origin, ionic charges, sources, rate of biodegradation, and the nature of cross-linking [4]. A detailed classification of hydrogels is presented in Fig. 1.

On the basis of the preparation method, the hydrogels can be divided into (i) *physical hydrogels*, which are achieved via physical processes, such as hydrophobic association, chain aggregation, crystallization, polymer chain complexion, and hydrogen bonding, and (ii) *chemical hydrogels*, formed by chemical covalent cross-linking. Physical hydrogels are reversible due to the conformational changes, while chemical hydrogels are permanent and irreversible because of configurationally changes [4]. Concerning the source, hydrogels can be divided into those obtained from natural polymers, synthetic polymers, and the hybrid hydrogels. Over the past two decades, natural polymers have been slowly replaced by synthetic ones or were hybridized to provide a higher service life, gel strength, and water absorption capacity [5].

The physicochemical properties of hydrogels are based on a number of factors, including the chemical nature of the monomer, the method of polymer synthesis, their molecular weight due to the reaction environment, and macromolecular structure. On the other hand, the physical structure of the polymer relies on the strength of the covalent bonds, the rigidity, and intermolecular force strength within the polymer chain [6].

The volume or mass-swelling ratio of the hydrogel is the most important variable to be evaluated for given environmental conditions, as it affects the diffusive,

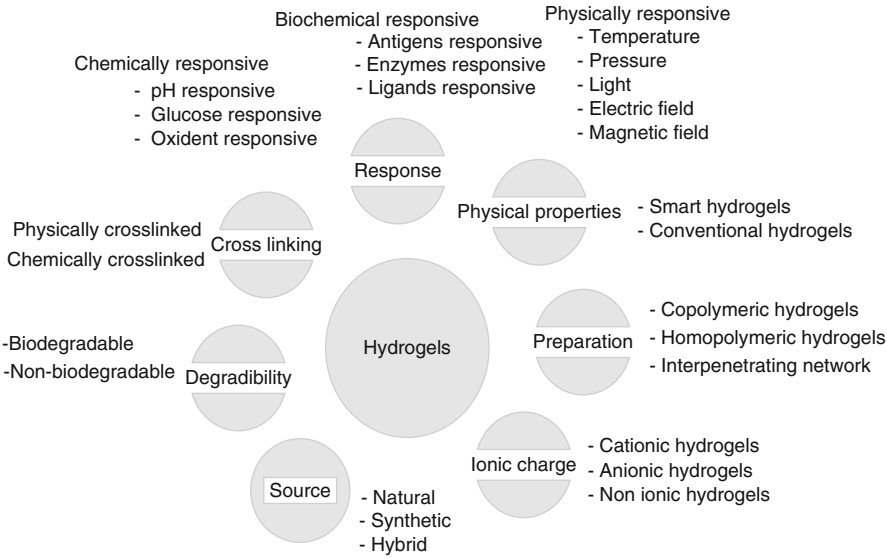

Fig. 1 Classification of hydrogels based on the different properties. (Reprinted with permission from [4]. Copyright © 2015, Elsevier.)

mechanical, optical, acoustic, and surface properties of the hydrogel itself. The amount of water retained by the mesh of the hydrogel network depends on the structure of the polymer network itself and on the environmental conditions, such as the temperature, pH, and ionic strength of the water solution in contact with the polymer [7].

The interactions responsible for the water sorption include capillary, osmotic, and hydration forces, which are counterbalanced by the forces exerted by the cross-linked polymer chains in resisting expansion. The equilibrium swollen state depends on the magnitudes of these opposing effects and determines to a large extent some important properties of the hydrogel, including internal transport and diffusion characteristics and mechanical strength. Many of these properties are governed not only by the degree of swelling, but also directly by the chemical nature of the polymer network and the network morphology [8].

The physical or chemical processes are adjustable based on the desired characteristics, such as structure, matrix density mechanical strength, biocompatibility, and biodegradability, which are subjective to the specific field and function to which they will be applied [9].

Since environmentally friendly products and processes are of great importance nowadays, much industrial research has focused attention on the synthesis of novel cellulose-based hydrogels. In fact, cellulose is a natural polymer that can be employed as renewable-based polymeric material with biodegradable properties [7].

The hydrogels from natural polymers, especially those from cellulose, are promising for their application in biomaterial field, because of their unique advantages,

such as abundance, non-toxicity, biocompatibility, biodegradability, and biological functions [10–12].

Innovative cellulose-based hydrogels have been developed either as water absorbents for specific applications, including personal hygiene products, underwater devices, body water retainers [7, 13], or biomedical devices, as ocular bandages [14], artificial cartilage [15, 16], controlled drug delivery [17–19], scaffolds for regenerative medicine [20, 21], stomach bulking agents [22], and wound dressings [12, 23, 24].

This chapter explores the synthesis and design of cellulose-based hydrogels, including pure cellulose and cellulose composite. The recent developments with emphasis on the fabrication, properties, and possible applications are highlighted. In particular, the attention is focused on the structure-property relationships of hydrogels and their biomedical and pharmaceutical applications.

2 Cellulose and Its Applications

Cellulose is the most common organic polymer and is considered an almost inexhaustible source of raw material for the increasing demand of environmentally friendly and biocompatible products [25]. This biopolymer exhibits some excellent properties, such as mechanical robustness, biodegradability, hydrophilicity and biocompatibility, properties responsible for the extensive use of cellulose in a wide spectrum of applications that include pharmacy, agriculture, medical science, industries, and many other related branches [26].

In contrast with its vast potential of applications, it is known that there are certain difficulties in producing cellulose-based products such as films, fibers, membranes, hydrogels, and beads, due to its partially crystalline structure and strong hydrogen bonds. The long-chain cellulose polymers consist of D-glucose subunits which are linked together by β-1,4 glycosidic bonds. These linear polymers are linked together by different inter- and intramolecular bonds, which allow them to be packed side by side in planar sheet and bundled into microfibrils (Fig. 2). Hence, the cellulose is insoluble in water as the hydroxyl groups in sugar chains are bonded to each other, making a hydrophobic scenario [27].

Unlike other types of water-soluble polysaccharides, cellulose requires separate solvent systems for its dissolution, which have remained limited because of the lack of a suitable solvent. In the early days, the use of concentrated sodium hydroxide (NaOH) solution as cellulose solvent interested researchers due to numerous applications of cellulose treatments with NaOH solution in fiber modification, dissolution, and regeneration [28]. Moreover, there were other solvent systems, from which the most widely used until the 1950s was cuprammonium hydroxide (Cuam) solution, while the aqueous solutions of cupriethylenediamine (Cuem) complex and some tetraalkylammonium hydroxides were used as solvents for analytical purposes in those days. In the decade of the 1960s, the discovery of numerous metal-complex solvents brought in more variations of cellulose solvents from which the most important were ferric sodium tartrate (FeTNa) and cadoxen solvent systems.

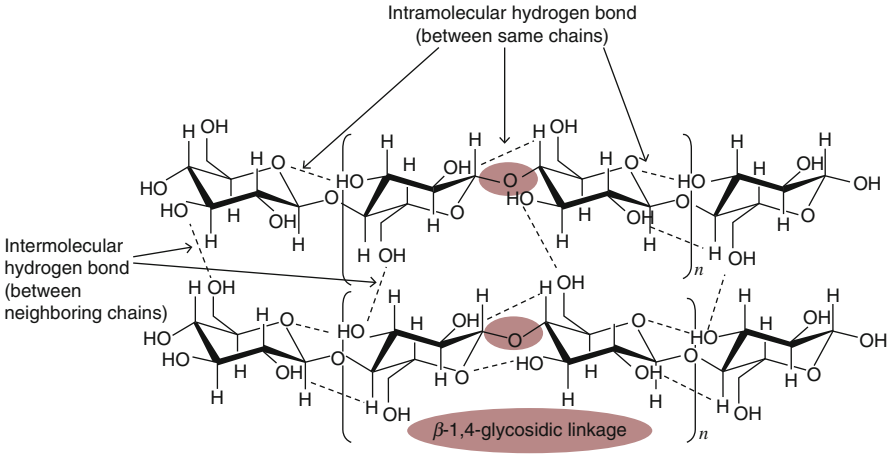

Fig. 2 Chemical structures of cellulose chains. (Reprinted with permission from [27]. Copyright © 2014, Hindawi.)

In recent years, considerable attention has been directed to several cellulose-solvent systems for dissolving cellulose, such as N,N-dimethylacetamide/lithium chloride (DMAc/LiCl) systems [29, 30], *N*-methylmorpholine-*N*-oxide (NMMO) [31, 32], tetrabutylammonium fluoride/dimethylsulfoxide (TBAF/DMSO) [33], paraformaldehyde/dimethylsulfoxide (PF/DMSO), triethylammonium chloride/dimethylsulfoxide (TEAC/DMSO) [34], ionic liquids [35–37], and alkali aqueous solutions [38–41].

In spite of its poor solubility characteristics, cellulose has versatile uses in many industries such as veterinary foods, wood and paper, fibers and clothes, cosmetic, and pharmaceutical industries [42, 43].

Generally, cellulosics are strong, low cost, reproducible, recyclable, and biocompatible [44]. Thanks to all of these properties, they are often used in various biomedical applications such as blood purification membranes in artificial kidneys [45], membranes in plasmapheresis [46], body water retainers [13], ocular bandages [14], artificial cartilage [15], scaffolds for regenerative medicine [47], and stomach bulking agents [48].

3 Synthesis of Cellulose II-Based Hydrogels

Cellulose hydrogels are a special class of cellulose materials which can be based on:

- **Cellulose I**, case of bacterial cellulose (BC) or cellulose nano-/microfibrils (CNF) or cellulose nanocrystals (CNC) [49, 50]
- **Cellulose II**, prepared via cellulose dissolution-coagulation route [51, 52]

Both types show high water retention, from several hundred to several thousand percent.

Cellulose-based hydrogels can be obtained via either physical or chemical stabilization of aqueous solutions of cellulosics. Additional natural and/or synthetic polymers might be combined with cellulose to obtain composite hydrogels with specific properties [7]. The synthesis of cellulose-based hydrogels generally consists of two steps [53]: (i) dissolution of cellulose fibers or powder, and (ii) chemical and/or physical cross-linking, in order to obtain a three-dimensional network of hydrophilic polymer chains, which is able to absorb and retain a significant amount of water. By tuning the cross-linker and cellulose concentrations, it is possible to optimize the hydrogel mechanical properties and swelling capabilities.

3.1 Dissolution of Native Cellulose

Due to its highly extended hydrogen-bonded structure, cellulose is very difficult to dissolve in common solvents, and thus only few solvents have been used for it solubilization.

A series of solvent systems such as LiCl/DMAc for cellulose powder, paraformaldehyde (PF)/dimethyl sulfoxide (DMSO), and triethylammonium chloride (TEAC)/DMSO for cellulose pulp have been used to fabricate cellulose hydrogels [52]. The obtained physical properties of hydrogels, such as transparency, strength, and water content, mainly depend on the composition of the coagulation/regeneration bath, while in the case of a nonaqueous solution, the maximum transparency of the hydrogels was obtained. A novel method, deionization of the cellulose/LiCl/DMAc solution with ion exchange resins, has been reported for preparation of gel beads that appear colorless and transparent without a fibrous texture compared with the "water-coagulated gel," probably because the molecular association (crystallite formation) precedes the phase separation during ion exchange [54].

By using N-methylmorpholine-N-oxide (NMMO), with low toxicity, high thermal stability, and the possibility of being recovered and reused, an opalescent cellulose-based hydrogel was obtained by adding excess water into the cellulose/NMMO/water solution [55].

Another solvent system for cellulose dissolution and gelation is ionic liquids (ILs). The preparation of the clear and homogeneous cellulose solution was done under mild conditions by using N-ethyl-N′-methylimidazolium methylphosphonate ($[C_2mim][(MeO)(H)PO_2]$) [56]. The mechanical strength of cellulose hydrogels strongly depends on the concentration and degree of polymerization (DP) of cellulose. Moreover, the mechanical property of cellulose gel remained unaltered after treatment with boiled water, indicating the excellent thermal stability of cellulose hydrogels. Various ILs used for cellulose dissolution have been applied in the preparation of cellulose-based hydrogels, such as 1-ethyl-3-methylimidazolium acetate ($[C_2mim][OAc]$) [57, 58], 1-butyl-3-methylimidazolium chloride ($[C_4mim]Cl$), and 1-allyl-3-methylimidazolium chloride ([Amim]Cl) [54].

A recent alternative for cellulose solubilization and hydrogel preparation is the alkali aqueous system, which uses freezing at low temperature followed by the thawing of the mixture, instead of stirring at room temperature or high temperatures. The obtained physically cross-linked hydrogels have a dense texture with heterogeneous morphology, which presents pores between 4 and 8 μm [59]. The bulk density for the physical cross-linked hydrogel is twice higher than for chemical cross-linked hydrogel. An interesting fact is that the physical cross-linked hydrogels are opaque, while chemical cross-linked hydrogels become more and more transparent, by increasing the cross-linker concentration (epichlorohydrin).

The cellulose dissolution at low temperature arises as a fast dynamic self-assembly process among solvent small molecules (NaOH, urea, and water) and the cellulose macromolecules [38]. Cellulose in solution behaves as random coils, semiflexible chains, or entangled chains, and the degree of entanglement depends on the polymer concentration. The gel structure becomes more and more organized and stable as cellulose concentration increases due to the higher degree of entanglements and the more hydrogen-bonding interactions that exist. Cellulose hydrogels can be formed via destructing the stability of cellulose solution by increasing the temperature to 50 °C or reducing it to −20 °C [52]. When a low temperature was used, active NaOH hydrates were bound to cellulose to bring it into the solvent, whereas urea hydrates served as the hydrogen-bonding donor and receptor to prevent the approach toward each other of the cellulose molecules, leading to a good dispersion of cellulose in the solution. At elevated temperature the NaOH and urea hydrates bounded on the cellulose chains were perturbed, so the junction between cellulose molecules occurred as a result of the self-association force of cellulose, resulting in the formation of a network structure [60].

3.2 Physical and Chemical Gelation

A key step in the formation of any hydrogel is "gelation," which can be interpreted as the interconnecting of the macromolecular chains in some manner, such that essentially the whole structure becomes linked together [61, 62].

Cellulose in solution behaves as random coils, semiflexible (or semirigid) chains, or entangled chains, and the degree of entanglement depends on the polymer. While polymer solutions of low concentrations are completely isotropic, with increasing polymer concentration, the transition from solution to a liquid crystalline gel takes place followed by gelation into a solid gel that has an anisotropic structure [54]. The gel structure becomes more and more organized and stable as biopolymer concentration increases due to the higher degree of entanglements and the more hydrogen-bonding interactions that exist [58].

The gelation mechanism involves hydrophobic associations among the macromolecules possessing the methoxy group. At low temperatures, polymer chains in solution are hydrated and simply entangled with one another. As temperature increases, macromolecules gradually lose their water of hydration, until polymer-polymer hydrophobic associations take place, thus forming the hydrogel network [51].

The stability of the hydrogel can be enhanced by coagulation in different anti-solvents, as water [57], ethanol [63], methanol [64], H_2SO_4/Na_2SO_4 [65], or by curing (i.e., keeping the solution at various temperatures between 5 °C and 60 °C) [66].

Covalent cross-linking has emerged as the preferred means of converting suitable hydrophilic polymers into absorbent hydrogels, and the cross-linking optimization implies a balance between achieving high absorbency, suitable mechanical strength, and minimizing the amount of material that dissolves into the bulk of the liquid when a highly absorbent hydrogel is in use [61, 67, 68]. Stable and stiff networks with irreversible cross-linking bonds between the cellulosic chains can be obtained by chemical cross-linking reaction in the presence of chemical agents (epichlorohydrin, aldehydes and aldehyde-based reagents, urea derivatives, carbodiimides, and multi-functional carboxylic acids) or physical treatments (i.e., high-energy radiation) [51].

Intense research has focused on the preparation of cellulose-based hydrogels via cellulose dissolution/coagulation route, with continuous improvements of efficiency in solvents such as NaOH aqueous solutions and similar systems (i.e., NaOH/urea, NaOH/urea/thiourea, LiOH/urea) [69–72], which are non-derivatizing, inexpensive, and nontoxic cellulose solvents. In the presence of 7–9 wt% NaOH-water solvent, cellulose solutions undergo a physical gelation with the increase of time and temperature [73].

Gelation occurs due to cellulose chains self-association because of the preferential cellulose-cellulose and not cellulose-solvent interactions; this physical gelation is accompanied by a micro-phase separation [59]. By adding epichlorohydrin (ECH) as cross-linker in cellulose-NaOH-water solution, cellulose chains become chemically cross-linked. Two mechanisms are therefore present and can possibly compete: physical gelation due to chains self-association and chemical cross-linking (Fig. 3a).

It was suggested that chemical bonds act as "spacers" preventing, at least partly, the self-association of cellulose chains, as shown on a sketch in Fig. 3a. A schematic presentation of the structure of physical and chemical cellulose gels is shown in Fig. 3b. Chemical gelation (i) perturbs cellulose chains self-association and packing which leads to the decrease of crystallinity, (ii) leads to a more homogeneous morphology which results in transparent swollen coagulated cellulose hydrogels, and (iii) increases swelling in water and adsorption of water vapors due to a more porous structure. As a consequence, the difference in the structure and swelling of physical vs. chemically cross-linked cellulose influences their release properties: in chemically cross-linked cellulose, a larger amount of drug can be loaded, and the release kinetics is faster compared to physically cross-linked matrix. By varying cellulose concentration and the amount of cross-linker, it is possible to prepare versatile cellulose hydrogels and dry porous networks with controlled morphology and porosity.

Compared to chemically cross-linked hydrogels which require covalent bonding for the formation of 3D networks, physically cellulose-based hydrogels are formed mostly by hydrogen bonding via a self-assembly process.

In the presence of strong organic solvents such as N,N-dimethylacetamide (DMAc)/LiCl, the gradual dissolution of cellulose starts by the formation of hydrogen bonding between the hydroxyl protons of the anhydroglucose unit within cellulose with the Cl^- in LiCl. The Cl^- is then attracted to the $(LiDMAc)^+$

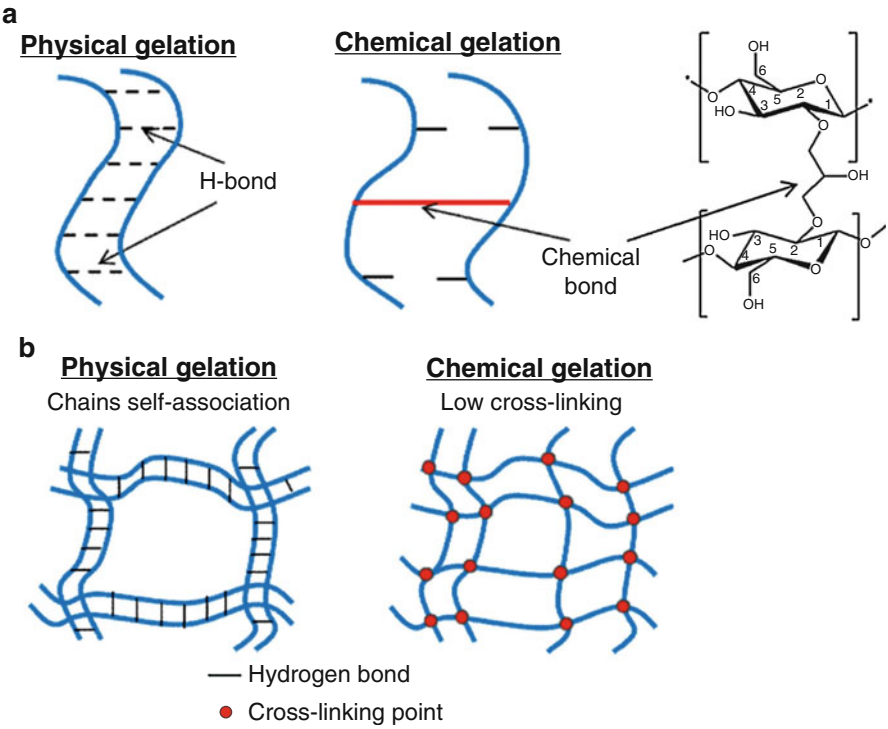

Fig. 3 (**a**) A sketch of network formation in cellulose solutions: physical gelation via self-association of chains and chemical cross-linking, (**b**) a schematic presentation of the structures of physical and chemical cellulose gels. macrocation with the formation of repulsive forces between different segments of the host cellulose. The repulsive forces will then open more micropores, allowing more solvent to penetrate into the cellulose matrix. Due to the anhydrous nature of the above solution, the presence of moisture leads to the regeneration of hydrogen bonding between the dissolved cellulose segments, that is, gelation [62]. Throughout this process, the cellulose main chains assemble into a 3D network structure by reforming hydrogen bonds between various OH^- groups on the anhydroglucose units. Due to the fast reaction kinetics and high hydrophilicity of the anhydroglucose units, large amounts of moisture are trapped in the gel. Since the water molecules are present mostly between the anhydroglucose chains, the drying of hydrogels will lead to the formation of new hydrogen bonds and cause the collapse of micropores.

Ionic liquids enable the dissolution of cellulose by disrupting and breaking hydrogen-bonding networks. By using N-ethyl-N′-methylimidazolium methylphosphonate ($[C_2mim][(MeO)(H)PO_2]$), a 10 wt% homogeneous cellulose solution, under mild conditions, has been prepared [56, 74].

Recently, cellulose-based hydrogels was prepared through the physical aggregation of polymer chains determined by hydrogen bonds, crystallization, helix

formation, and complexation (Fig. 4). Cellulose was completely dissolved in $[C_2mim][(MeO)(H)PO_2]$ through the breaking of the hydrogen bonds among cellulose backbones, and the dissociated cellulose chains were partially aggregated during the solvent exchange process by treating them with methanol vapor. The structure was set uniformly by a spinodal decomposition-type phase separation during the treatment with methanol vapor, and the partial aggregation of cellulose chains acted as a network junction point in three-dimensional networks [37].

Cellulose hydrogels containing 95–99% water have been fabricated using the solvent exchange of homogeneous cellulose solutions without the use of chemical cross-linking (Fig. 4c). Water was incorporated within the three-dimensional network of the hydrophilic cellulose chains containing hydrogen-bonded network junction points.

4 Synthesis of Cellulose I-Based Hydrogels

4.1 Nanocellulose Hydrogels

Nanocelluloses are a class of natural materials derived from cellulose, the most abundant renewable polymer on earth, which include cellulose nanofibrils (CNFs) and cellulose nanocrystals (CNCs). Cellulose nano- and microfibrils are

substructural elements of cellulosic fibers that can be mechanically disintegrated (high-pressure homogenization and refining, microfluidization, grinding, cryocrushing, and high-intensity ultrasonication combined with chemical or enzymatic treatments) from the cell wall matrix, while cellulose nanocrystals are isolated from microcrystalline cellulose using acid hydrolysis and/or sonication process.

The most crystalline form of cellulose is cellulose nanocrystals (CNCs), which are shorter than the nanofibrils. In addition, CNCs present many advantages, such as nanoscale dimension, high specific strength and modulus, high surface area, unique optical properties, and therefore wide possibilities of application [75]. Cellulose sources are variable and their degree of crystallinity strongly influences the dimensions of the liberated crystals [49, 76].

The physical and chemical properties of nanocelluloses have enabled their use in a wide variety of hydrophilic and hydrophobic composite matrices and hybrid materials, including hydrogels and aerogels. Furthermore, their high surface area-to-volume ratio enables enhanced interactions with, and binding to, polymers, other nanoparticles, and small molecules [77].

Hydrogels prepared only from CNCs at a concentration above 10 wt% will enter an aggregated gel-like phase [78, 79]. Other methods to prepare CNC hydrogels are by destabilizing the CNC suspensions with salt or acid, or by cross-linking of CNCs with multivalent ions or chemical bonds [80, 81]. In practice, the CNC concentration at which a gel is formed may be manipulated via changing the solution conditions, surface modifications, and/or adding adsorbing or non-adsorbing water-soluble polymers [82, 83]. It was observed that by increasing the ionic strength of CNC suspensions via salt addition, the electrostatic repulsion was suppressed, which led to dominant attractive forces (e.g., van der Waals and hydrogen bonding) and, consequently, to gelation. Thus, the increasing of the charge number and the radii of the ions both led to increases in gel stiffness [79, 81].

Due to their increased flexibility and tendency for entanglement, cellulose nanofibrils are more liable to hydrogel formation than CNCs.

The NFC suspensions (Fig. 5) bear the appearance of highly viscous shear-thinning transparent gels and have high aspect ratios and specific surface areas combined with remarkable strength and flexibility, low thermal expansion, high optical transparency, and specific barrier properties [84].

Typical CNF hydrogels contain 0.05–6 wt% CNFs, but CNF gels have been reported at concentrations of 0.125 wt%, following an enzymatic treatment and homogenization of bleached sulfite pulp [85]. These hydrogels are of two orders of magnitude concentration lower than that required for CNC gelation.

Hydrogels with oriented fibrils can be prepared by flow focusing CNF suspensions, followed by inducing gelation through pH reduction or salt addition, and these can be used as templates for anisotropic nanocomposites (Fig. 6) [79, 86, 87].

The flow-induced CNF-oriented alignment displayed exceptional mechanical properties that were enhanced as the degree of orientation was increased; however, filament stability drastically decreased in the presence of water, representing a key limitation of this technique [88]. Similar to most CNC hydrogels, CNF hydrogels lack macroscopic structure or hierarchy, which is a

serious disadvantage when developing biomimetic materials or hydrogels for many biomedical applications [79].

4.2 Bacterial Cellulose Hydrogels

Bacterial cellulose (BC), also known as microbial cellulose, is produced by different bacteria genera, such as *Gluconacetobacter*, *Sarcina*, and *Agrobacterium*, but *Gluconacetobacter xylinus* is probably the most commonly referred strain in this context [84]. A consideration of the nanocrystallinity of cellulose leads directly to BC, because this is synthesized in highly crystalline forms and in very high yields by *Gluconacetobacter xylinus* (*G. xylinus*), which is the most widely studied source of BC [89, 90]. BC can be produced as a highly swollen hydrogel and, depending on the static or agitated nature of the culture media, as a membrane (Fig. 5d, d′) or in the

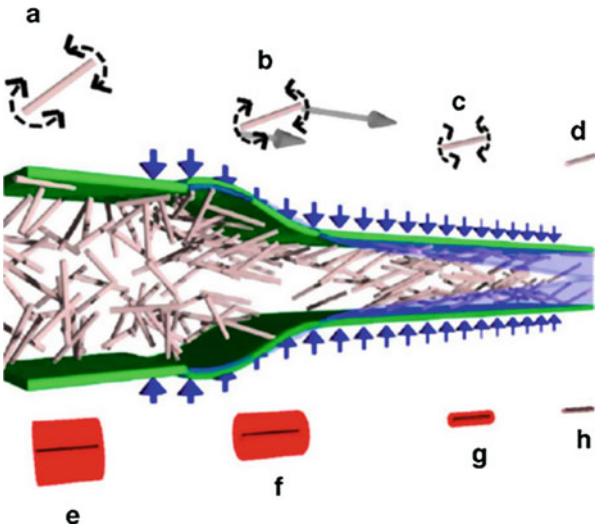

Fig. 6 Illustration of the flow focusing CNF hydrogel assembly process. The diffusion of Na+ ions into the flow channel is depicted by blue arrows, the concentration of which increases as the channel narrows, shown by the shaded blue area. (**a**) Initially, CNFs undergo Brownian diffusion, which decreases as (**b**) individual particles undergo hydrodynamically induced alignment. (**c**) Particles are constrained uniaxially and (**d**) "frozen" in place as the increased Na+ ions cause gelation of the system. (**e**–**h**) The electrostatic repulsion and the Debye length of CNF fibrils (shown in red) decrease along the channel as surface carboxyl groups become uncharged/shielded. form of small beads. More precisely, BC is a 3D network consisting of nano- and microfibrils with the dimensions of 3–4 nm thickness and 70–80 nm length (Fig. 5d′); that is, the fibrils are approximately 1000 times thinner than typical plant cellulose fibrils. These dimensions explain the unique properties of BC. Additionally, BC is free of lignin, hemicelluloses, and other natural components usually associated with cellulose isolated from the cell wall of plants [84]. BC has been shown to have superior properties compared to plant-derived cellulose, such as high surface area, degree of polymerization, wet tensile strength, purity, crystallinity, and nanostructured fibers [91]. BC is known to be biocompatible, perhaps because of its flexibility and porosity, resembling properties of collagen in the human body [92].

A detailed analysis of the water interaction properties in as-biosynthesized BC gels indicates that only about 10% of the 99 wt% water present in BC gels behaved like free bulk water, and the majority of the water molecules in the gels are more or less tightly bound to the cellulose [93]. In a recent study, BC nanocellulose was shown to effectively control the uptake and release of albumin and demonstrated the retention of protein integrity, which can sometimes be compromised during the manufacturing process [94].

On the basis of the high purity and unusual physicochemical properties, BC-based hydrogels offer a wide range of applications in biomaterials fields such as tissue engineering scaffold [95], meniscus implant [96], and dental implants [97].

5 Multipolymer Hydrogels Based on Cellulose

The multipolymer hydrogels have been prepared from cellulose and other polymers by interpenetrating polymer networks (IPNs) technology, in order to combine the different properties of cellulose and other polymers. Generally, the preparation processes include the dispersion or dissolution of two or more polymers (usually using the same solvent) and the cross-linking step.

Cellulose can be blended with *natural biodegradable polymers*, such as chitin [98], chitosan [99], starch [100], xanthan [101], lignin [102], and alginates [103].

The blending of cellulose and chitin in the same solvent system is an effective way to produce phase-separated composite hydrogels. Chitin/cellulose beads have been prepared by coagulating a mixture of 4 wt% cellulose solution and 2 wt% chitin solution in 6 wt% NaOH/5 wt% thiourea aqueous system [52]. The adsorption ability of obtained beads is higher than that of pure chitin flakes, owing to the relatively large surface area and their high hydrophilicity. The hydrophilic skeleton and microporous-network structure of cellulose improve the adsorption ability of chitin [104].

Cellulose/chitosan hydrogel beads have been prepared by blending cellulose powder with chitosan solution, in the presence of ethylene glycol diglycidyl ether, as cross-linker. These hydrogel beads are denser, have improved chemical stability in the solutions with pH values down to 1, and have high adsorption capacity for Cu adsorption [99]. Cellulose/chitosan hydrogels have been also prepared when the polymers were mixed in NMMO and then processed under a pressure of 70 kg/cm^2 exerted by a compression molding machine, at 100 °C for 8 min. The films have smooth surface when containing 3 wt% chitosan, while for a higher concentration, of 5 wt% chitosan, they become rough due to phase separation [105]. These blended films have shown nondiffusible antibacterial properties.

Cellulose/xanthan hydrogels have been obtained from different allomorphic forms of cellulose (cellulose I, II, and III) and xanthan, by using epichlorohydrin as cross-linker [101]. The increase in xanthan concentration determined an increase in swelling degree of hydrogels, while using cellulose II led to the highest value of the swelling degree (2146%), which demonstrates the superabsorbent character of these hydrogels. The optical image of the hydrogel reveals a smooth surface and a homogeneous aspect, explained by a good incorporation of cellulose within the xanthan matrix.

Cellulose/lignin hydrogels were prepared in the presence of epichlorohydrin [102]. The color of the hydrogels changes from light to dark brown, as the incorporated lignin amount increases. It appears that the structure is uniform and densely packed (Fig. 7) [106].

Fig. 7 Photo images of CL hydrogels with different compositions: (**a**) CL3, (**b**) CL5. (Reprinted with permission from [106]. Copyright © 2013, Cellulose Chemistry and Technology)

The swelling capacity of these hydrogels increased by increasing lignin content (from 2300 to 3000 wt%). This behavior is explained by the chemical uniqueness of lignin, which contains a high number of polar groups (aromatic and aliphatic hydroxyls, carbonyls, ethers). By involving lignin in cross-linking reactions, some hydroxyl groups are blocked by forming C-O-C linkages, but many other remain free, conferring hydrophilicity to the resulted 3D matrix; thus, pores with different structures and polarities could be formed. An increase in lignin content in cellulose/lignin hydrogels produces a more relaxed network with higher swelling capacity.

Cellulose/sodium alginate hydrogels have also been reported. The introduction of sodium alginate into cellulose hydrogels significantly increases the pore size and swelling ratio of hydrogel samples, while cellulose contributes to enhancing the mechanical properties of the hydrogels. These hydrogels have macroporous structure, excellent mechanical strength, and high equilibrium swelling ratio in water [103].

Bacterial cellulose/gelatin double-network (DN) hydrogels have been synthesized. It was observed that gelatin gel was brittle and easily broken into fragments under a modest compression, while the fracture strength and elastic modulus of a BC/gelatin DN gel were several orders of magnitude higher than those of gelatin gel and almost equivalent to those of articular cartilage. A similar enhancement on the mechanical strength was reported for the combination of bacterial cellulose with other polysaccharides such as sodium alginate, gellan gum, and carrageenan [107].

Bacterial cellulose and gelatin were successfully used to develop a hydrogel composite material [19]. The bacterial cellulose network was filled with gelatin, the glutaraldehyde was employed as a cross-linker, and a malleable and easily shaped at ambient temperature without any external stimuli hydrogel was obtained (Fig. 8).

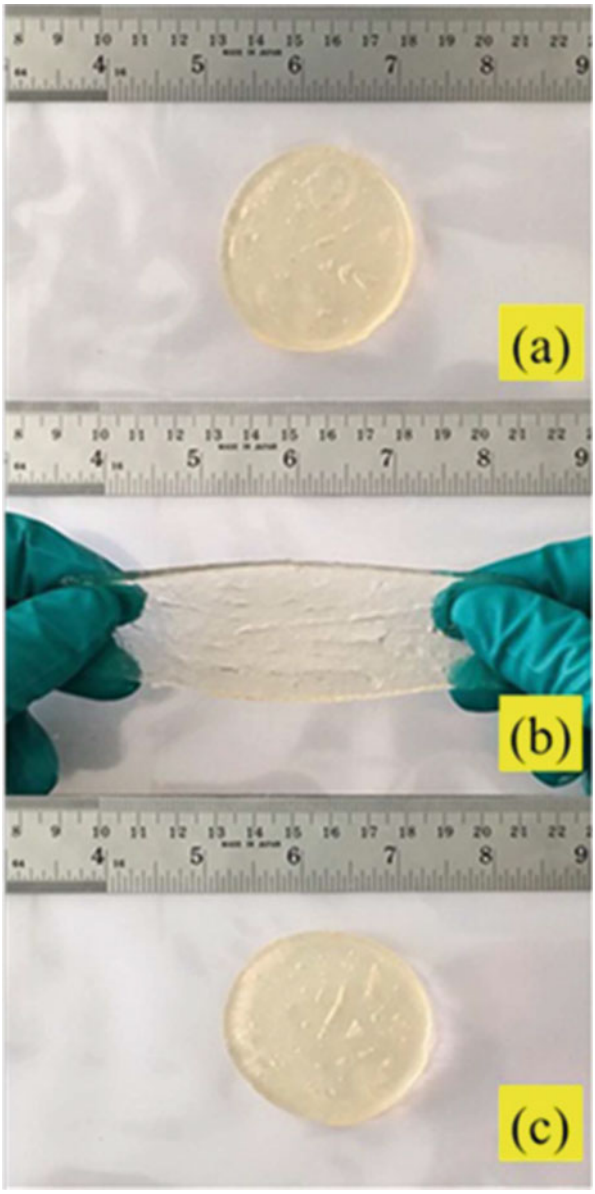

Fig. 8 Photograph of bacterial cellulose-based hydrogel composite (**a**) original form, (**b**) stretchable form, (**c**) reformable form. (Reprinted with permission from [19]. Copyright © 2017, Elsevier.)

The hydrogel composites presented excellent benefits in terms of their thermal stability, chemical resistance, and mechanical properties. Moreover, the swelling ratio of the hydrogel network in water was estimated to be 400–600%.

As many CNC-containing hydrogels target biological or biomedical applications, there has been an increasing amount of research on natural polymer-based hydrogels, primarily based on alginate [108–110], gelatin [111–113], and agarose [114, 115].

Cellulose can also be blended with *synthetic polymers*, such as poly(vinyl alcohol) [116, 117], poly(ethylene glycol) [118], and poly(N-isopropylacrylamide) [119], in order to obtain novel materials for special applications.

Cellulose/PVA hydrogels obtained by physical cross-linking method are of importance for biomedical applications, due to the avoiding of residual amounts of toxic chemical cross-linker and of a higher mechanical strength, higher than that obtained by chemical cross-linking method [116]. The effect of cross-linking methods on structure and properties of cellulose/PVA hydrogels revealed that the chemical cross-linked hydrogels, prepared in the presence of ECH, have a high swelling ratio but low mechanical strength as a result of the weak hydrogen bonding between cellulose and PVA. However, physical hydrogels prepared via solution blending of cellulose and PVA and repeating freezing/thawing cycles exhibit a dense structure between cellulose and PVA, leading to high mechanical strength.

Novel cellulose/PVA hydrogels obtained via physical cross-linking method showed an improved swelling capacity and an increased strength of the hydrogels, due to the presence of cellulose within the 3D network [117]. Moreover, the study regarding the release of vanillin from cellulose/PVA matrices demonstrated an increased percent of bioactive agent released with the increasing of cellulose in the hydrogels and also the shortening of the half time and maximum time of release.

In addition, BC/PVA hydrogels with mechanical properties similar to that of soft tissues have been successfully prepared [120]. Specifically, compositions of the hydrogels that have mechanical properties similar to that of the porcine aorta and the aortic heart valve have been identified. For hydrogel preparation, BC fibers produced by the *Acetobacter xylinum* with an average diameter of 50 nm have been used in combination with PVA and physically cross-linked through freezing/thawing cycles to form biocompatible nanocomposites with good mechanical properties.

CNC/PVA hydrogel showed moderate increases in mechanical properties toward the relatively weak PVA-only hydrogel [121–123]. CNF nanocomposite hydrogels have been used as absorbents due to their relatively high swelling capacity. The macroscopic core-shell hydrogels based on PVA and alginate showed higher storage and shear moduli accompanied by slightly increased dye absorption capacity when CNFs were chemically cross-linked into the core [124].

New hydrogels were prepared from cellulose and poly(N-isopropylacrylamide) (PNIPAAm) with high mechanical strength and adjustable thermosensitivity [119]. The first network was obtained by the chemical cross-linking of cellulose in NaOH/urea aqueous solution, in the presence of epichlorohydrin (ECH), while the second network was prepared by in situ polymerization/cross-linking of N-isopropylacrylamide in cellulose network. The obtained hydrogels exhibit high mechanical strength and adjustable thermosensitivity, which strongly depend on the weight ratio between of both polymer networks.

Thermoresponsive poly(N-isopropylacrylamide) (PNIPAM) polymer networks have also been investigated with CNC fillers, showing characteristic temperature-dependent swelling properties along with tunable mechanics [79, 125]. Yang et al. further demonstrated how CNC surface charge and aspect ratio affected reinforcing

ability in polyacrylamide hydrogels, showing that a higher surface charge density led to better dispersibility, while a higher aspect ratio contributed to increased mechanical properties [126].

Synthetic hydrogels like PEG-based hydrogels have advantages over natural hydrogels, such as the ability for photopolymerization, adjustable mechanical properties, and easy control of scaffold architecture and chemical compositions, but PEG hydrogels alone cannot provide an ideal environment to support cell adhesion and tissue formation due to their bio-inert nature [52, 127].

High-strength cellulose/poly(ethylene glycol) gels have been prepared by swelling cellulose gel membranes in a low-molecular-weight polyethylene glycol (PEG). The cellulose gel membranes have been fabricated by a pre-gelation method through employing cellulose solutions in aqueous NaOH/thiourea at low temperature [66]. These materials exhibit high mechanical performance, and their tensile strength increased sharply from 3.5 to 7.9 MPa with an increase in the molecular weight of PEG from 200 to 800 g/mol [52, 118].

Recently, the ionic interactions between amine-terminated PEG and carboxylated CNFs allow these nanocomposite hydrogels to exhibit a reversible sol-gel transition upon either strain or temperature ramping [79, 128].

6 Factors Affecting the Swelling Capacity of Cellulose-Based Hydrogels

There is little research on the swelling of physical gels due to their weak structure or low swelling, so the majority of the literature is related to the swelling of chemical hydrogels [54].

In order to investigate the *effect of the cross-linking degree on the swelling properties of cellulose hydrogel*, two types of swelling experiments were performed: (i) gels just after synthesis were placed in water, and their volume and weight at equilibrium, i.e., after cellulose complete coagulation, were measured, and (ii) cellulose cryogels swelling in water was recorded (Fig. 9) [59].

The influence of ECH concentration on the swelling degree of cellulose hydrogels (never dried, at equilibrium) showed a dramatic increase up to the maximal value of $Q = 3500\%$ for $R = 1$ and then a decrease at higher R values, reaching $Q \approx 1500\%$. The increase in swelling with the increase of cross-linker concentration is "against" the trends known for classical polymer gels for which the increase in cross-linking leads to the decrease of swelling. The higher the cellulose concentration, the lower the swelling degree of hydrogels, as expected (Fig. 9a). Another interesting point is that with the increase of ECH concentration, samples become more and more transparent: for example, samples prepared with $R = 0$ or $R = 0.25$ are opaque, whereas with $R \geq 2$ they are completely transparent. The transition from opaque to transparent coagulated swollen cellulose stands between $R = 1$ and 2. It may be deduced that the increase of cross-linking thus leads to a more homogeneous structure of coagulated cellulose [59].

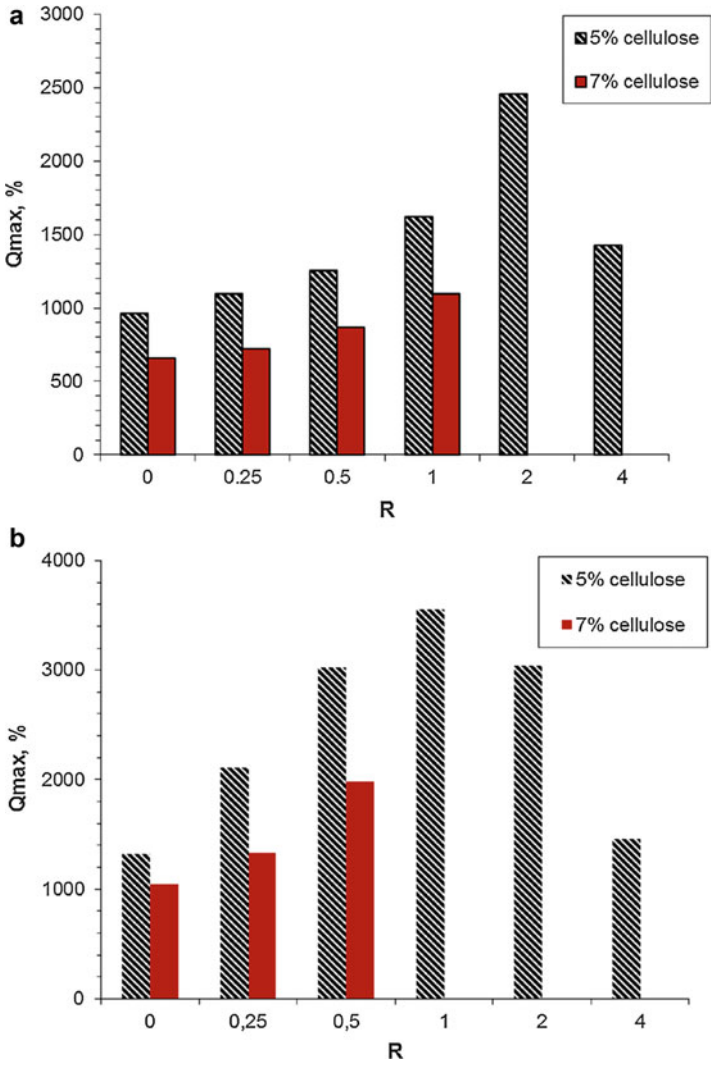

Fig. 9 Swelling degree of (**a**) cellulose hydrogels (never dried, at equilibrium) and (**b**) of cellulose cryogels in water at 37 °C, prepared from 5 to 7 wt% cellulose solutions, as a function of R. (Reprinted with permission from [54]. Copyright © 2017, Elsevier.)

Similar to hydrogels, the degree of swelling of cryogels in water first increases and then decreases with the increase of ECH concentration, for both studied cellulose concentrations (Fig. 10b). However, the absolute values of cryogel swelling are lower: for example, for samples prepared from 5 wt% solution, the minimal swelling of cryogel is around 900% and the maximal is around 2500%, while for hydrogels it is 1300% and 3500%, respectively. Lower swelling of dried compared to never-dried cellulose is due to the well-known hornification phenomenon. What is important is

Fig. 10 Examples of an aquagel and samples after drying with different techniques (aerogel, cryogels, and xerogel) obtained from 7 wt% cellulose solution. (Reprinted with permission from [63]. Copyright © 2016, Springer International Publishing AG.)

that even freeze-dried samples show the "anomalous" swelling, i.e., increase in swelling degree with the increase of ECH concentration, up to a certain value.

It is known that the drying procedure affects the water absorbency capacity of hydrogels. Supercritical or freeze-dried hydrogels retain the microporosity of the gel systems and thus significantly increase the swelling properties compared to air-dried, oven-dried, or vacuum-dried hydrogels, whose capillary retention decreases due to the recrystallization of the biopolymers in the gel systems [54].

However, the morphology of the porous material obtained after lyophilization or supercritical CO_2 drying is very different. While freeze-drying leads to the formation of large pores and channels from several microns to tens of microns, due to the growth of ice crystals, supercritical drying better preserves fine network structure leading to the formation of mesopores and small macropores which is reflected by specific surface area of several hundreds of m^2/g [63, 129–131].

For a systematic study of the *influence of drying method on the morphology and properties of porous cellulose materials*, the "aquagels" obtained after the coagulation in ethanol of cellulose solution in ionic liquid/DMSO mixture, three different drying methods were employed: supercritical CO_2 (aerogels), freeze-drying (cryogels), and vacuum drying (xerogels) (Fig. 10) [63]. Aerogels and both kinds of cryogels are white and opaque, whereas xerogels are yellowish, translucent, and much more shrunk.

Vacuum drying induces strong pore collapse resulting in samples with very low porosity, not-measurable specific surface area, and densities close to that of microcrystalline cellulose. Supercritical CO_2 drying yields nanostructured aerogels with bulk densities between 0.12 and 0.215 g/cm^3 and specific surface area up to 300 m^2/g. Freeze-drying gives highly macroporous cryogels with much lower specific surface areas (at the order of tens of m^2/g), but which can be as light as 0.05 g/cm^3. The difference in the density of aerogels vs. cryogels is due to sample volume contraction during drying step which is more pronounced for aerogels of low cellulose concentrations [63].

The morphology of aerogels is hierarchically structured with pore size varying from few tens of nanometers between the fibrils to few microns between the "hairy" beads. Cryogel morphology is a sheet-like cellulose network with large interconnected pores of several microns. Moreover, it is also possible to vary the pore size within one cryogel sample by applying a unidirectional freezing before

freeze-drying. This allows decreasing pore size in the direction of temperature gradient, from lower to higher temperatures [63].

The pore sizes are affected by the biopolymer concentration, the cross-linking degree, and the drying processes. The pore sizes are generally determined by SEM after lyophilizing (i.e., freeze-drying) the hydrogels, and the resulting cryogels mostly have pore sizes within the average range of 3–8 μm, which decrease with increasing biopolymer concentration and cross-linking degree [54].

In order to establish the *influence of polymer concentration on the average pore size of the hydrogels*, one example that focused on cellulose/lignin (CL) hydrogels was used (Fig. 11) [102]. For CL hydrogel preparation, cellulose was dissolved in NaOH solution at low temperature, it was mixed with different amounts of lignin (CL1, 3:1; CL2, 2:1; CL3, 1:1; CL4, 1:2; CL5, 1:3; as gravimetric ratios), and it was cross-linked in the presence of epichlorohydrin. The SEM micrographs of hydrogels obtained from cellulose (C) and from cellulose/lignin are presented in Fig. 11.

The cross section of the cellulose hydrogels indicates a macroporous structure with an increasing average pore size by increasing lignin content, a fact which suggests that a higher quantity of water can be uptaken. This assumption is in good correlation with the data obtained for swelling degree (Qmax, from 1145% for C hydrogel to 3061% for CL5 hydrogel). An explanation for this behavior is the fact that the incorporation of a higher amount of lignin in the network, owing to a bulky and branched structure, contributes to an increase of ether linkages and implicitly to an increase of the swelling degree of the hydrogels.

Figure 12 clearly evidenced that the hydrogels with a high amount of lignin exhibit a broader pore size distribution than the ones with small quantity of lignin [106].

Thus, it can be concluded that the polymeric ratio significantly influences the average pore size of hydrogels, as well as pore size distribution. By increasing the amount of lignin in the cellulose matrix, the pore size distribution becomes wider, and the share of large pores increases. Such a suggestion confirmed the data obtained from the swelling measurements, showing that the increase of lignin in the CL hydrogels permits a higher water uptake.

Recently, the influence of cellulose concentration on average pore diameter of aero- and cryogels [63] has been studied. For both types of cryogels, the pore size decreases with increasing concentration. For example, the pore size in cellulose cryogel (freeze-dryer) decreases from almost 6 μm to around 1.5 μm when the concentration goes from 3 to 11 wt%; the same trend is observed for prefrozen samples. Overall, using unidirectional pre-freezing and/or varying cellulose concentration allows tuning pore sizes in cellulose cryogels. A similar result, i.e., the decrease of pore size with the increase of cryogel density, was reported for microfibrillated cellulose [132]. Finally, xerogels are, due to strong pores contraction during slow vacuum drying, very dense, and their porosity is close to zero. No macro- or mesopores are visible on SEM images of xerogels [63]. As expected, vacuum drying cannot be used as a drying technique for the preparation of porous non-modified cellulose materials.

The swelling capacity of the hydrogels and their structural parameters, such as the degree of cross-linking, the average pore size, etc., are important parameters for their biomedical and pharmaceutical applications, i.e., the rate of drug release [133]. Depending on the network nature, chain dissolution may take place along with swelling due to the physical nature of the hydrogel network; thus, drug release results from the complex combination of swelling, diffusion, and erosion mechanisms [51]. When using hydrogels to modulate the drug release, the loading of the drug is performed either after cross-linking or simultaneously, during network formation [134]. Moreover, the bioactive molecule can be covalently or physically linked to the polymer network, to further tune the release rate.

Due to their large water content, hydrogels are highly biocompatible, possess rubbery mechanical properties close to those of soft tissues, and usually allow the incorporation of cells and bioactive molecules during the gelling [51, 135]. Moreover, although cells do not readily attach themselves to highly hydrophilic surfaces, the bulk or surface chemistry of hydrogels can be easily modified with extracellular matrix (ECM) domains, which promote cell adhesion as well as specific cell functions. Hydrogels are thus likely to be ideal platforms for the design of biomimetic scaffolds for tissue regeneration.

7 Applications of Cellulose-Based Hydrogels

Cellulose-based hydrogels are successfully applied to the fields as pharmacy, tissue engineering, and regenerative medicine, due to their unique properties such as hydrophilicity, biodegradability, soft and flexible nature, and biocompatibility. Therefore, cellulose and its derivatives have been used for drug delivery systems,

as well as for burn wound regeneration and cardiac, vascular, neural, cartilage, and bone tissue regeneration:

(a). ***Cellulose I-Based Hydrogels*:** Hydrogels based on bacterial cellulose mimic basic living processes and are of growing importance as bioactive scaffolds, such as skin tissue materials [136], meniscus implant [96], scaffold for chondrocyte proliferation [137], and dental [97]. In medical field, the main applications are wound dressings [138]. Nanoparticles from cellulose I are generated from bacterial cellulose and cellulose from plants. These cellulose nanoparticles were used in drug delivery systems [76, 139], or as scaffolds in artificial ligaments or tendon substitutes, with an excellent cytocompatibility [140]. The formulations from cellulose nanoparticles and silver nanoparticles can be used as microbial medicaments, antibacterial agents in wound dressing, bandages, implants, skins replacements for burnings, face masks, artificial blood vessels, cuffs for nerve surgery, drug delivery, cell carriers and support matrices for enzyme immobilization, cosmetic tissues, etc. [141].

(b). ***Cellulose II-Based Hydrogels*:** The main areas in which cellulose II-based hydrogels are used as biomaterials are in contact lenses [142], wound coverings [143], drug delivery systems [59, 92, 102], and organ and tissue replacements, such as skin, tendon, cartilage, heart valve stents, and bone [54, 139].

8 Conclusions

This chapter emphasizes the recent advances in the design and synthesis of cellulose-based hydrogels. Different methods of cellulose dissolution in common organic solvents, or in novel solvents, such as LiCl/DMAc, NMMO, ILs, and NaOH/urea (or thiourea) aqueous solution, have been reported. A systematic investigation on the physical-chemical properties of the 3D cellulosic networks was done. In addition, the important factors that have an influence on the swelling capacity of cellulose-based hydrogels have been discussed. The large availability of cellulose in nature and its attractive advantages, such as biocompatibility, biodegradability, low cost, and non-toxicity, alongside the possibility to design various formulations of composite hydrogels, meet the demands for many areas of medical applications. A growing interest in the development of bio-nanocomposite structures based on cellulosic materials is expected. In the near future, cellulose-based hydrogels might be ideal platforms for the design of scaffold biomaterials in the field of tissue engineering and regenerative medicine.

Cellulose Solubility, Gelation, and Absorbency Compared with Designed Synthetic Polymers

4

Robert A. Shanks and Isaac R. M. Pardo

Contents

Abstract

Swelling and solubility of polymers, and in particular cellulose, are controlled by interactions, molecular symmetry, chain flexibility, and order/disorder. Theory is used to explain and predict which liquid systems, polymer structures, and chemical modifications form gels and polymer solutions. Extension of these principles leads to super-absorbent polymers. Cellulose is not water soluble, though some water systems can dissolve cellulose, particularly alkaline or strongly hydrogen-bonding solutions. Less hydrophilic derivatives such as methyl cellulose dissolve in water; while with increasing substitution with methyl groups, cellulose becomes soluble in organic solvents such as dichloromethane. Sometimes temperature can enhance solubility or gelation; alternatively adjusting chemistry through functional group modification to reach an optimum between

intermolecular versus solvation interactions will create exceptional changes in absorbency. The solvation power can be increased by adding strongly ionic, hydrogen bonding or acid–base solutes such as lithium chloride, urea, or sodium hydroxide. Synthetic polymers have been designed and commercialized with specific solubility, solution rheology, gelation, and absorbency for many applications. Synthetic water-absorptive polymers begin with the choice of monomer(s), molar mass, and chain architecture. Cellulose is separated with exact structure that can be derivatized, grafted, or modified to change its native resistance to super-absorbency, gelation, or dissolving in water. Molecular modeling and simulation are used to evaluate parameters that will describe super-absorbent character. This review explores and evaluates the chemistry and structural symmetry of celluloses and synthetic polymers, leading to solubility, and gelation leading to super-absorbency. Cellulose is emphasized and compared with synthetic polymers where chemistries are designed and created at all levels of structure.

Cellulose · Solubility · Absorbent · Gel · Super-hydrophilic · Super-absorbent · Solubility parameter · Interaction parameter · Critical solution temperature

1 Introduction

Super-absorbent polymers must have strong affinity for a solvent or swelling liquid, typically water. The affinity for the liquid must exceed the polymer–polymer affinity. The polymer likely to contain functional groups that interact with the liquid, and they will interact similarly with the polymer either intermolecularly or intramolecularly. A tetramer segment of cellulose is shown in Fig. 1 as a stereo-structure and as a molecular model with charge density surface superimposed and a molecular model with hydrogen bonding highlighted. The latter model illustrates that the surface of cellulose is abundant in hydrogen bond donors and receptors for interaction with other cellulose molecules in crystals and with absorbed water. Intermolecular polymer interactions create parallel sheet-like structures such as found in native (type I) and textile cellulose (type II) [1]. Intramolecular polymer interactions form helical structures, such as exhibited by starch and some proteins. Introduction of chemical irregularities into a structure can limit polymer–polymer interactions and favor interactions with a swelling or dissolving liquid. A divide between dissolving and swelling can be made by crosslinking the polymer, whereby solvent can be absorbed until chains and crosslinks become saturated and at thermodynamic equilibrium. An equilibrium swollen polymer or gel is formed when the solvation force is equal to the force for formation of polymer random coils.

Super-absorbent polymers are exceedingly hydrophilic polymers, which form molecular networks that allow exceptional swelling but prevent dissolving. They may be able to absorb 1000 times their mass of water. Natural substances such as carbohydrates, proteins, and their derivatives feature in this class of material because

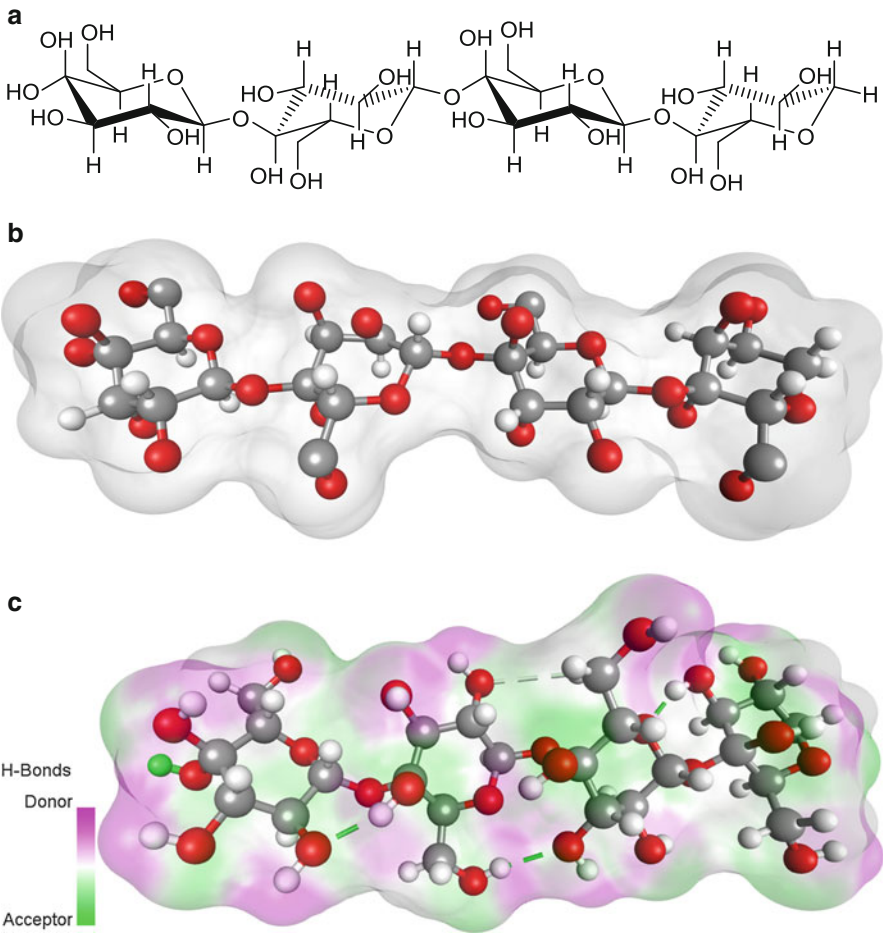

Fig. 1 Molecular structure of cellulose chain segments: (**a**) structure drawing, (**b**) molecular model with total charge density surface, (**c**) molecular model with hydrogen bonding highlighted

most natural species have high water content; water is a necessity for life. There are many synthetic super-hydrophilic polymers that may be based on bio-systems (biomimetic) or principles derived from biomaterials. Solvation principles based on ionic, dipolar, or hydrogen-bonded interactions have been established as an integral part of molecular science. When macromolecules are involved, conformation, packing of chain segments, chain branching, crosslinks, and hydrodynamic volume are additional concepts for solvation. Thermodynamics and kinetics are important for absorption capacity, while absorption rate, desorption rate or hysteresis, gel strength, wicking mechanisms, pH, and ionic sensitivity are additional characteristics. Synthesis and evaluation factors, classified as internal and external factors, of natural and synthetic super-absorbent polymers have been reviewed by Zohuriaan-Mehr and Kabiri [2].

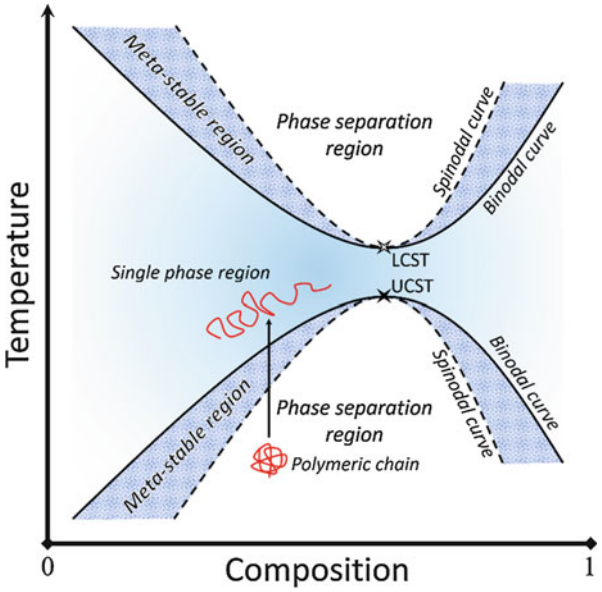

Fig. 2 Schematics of LCST and UCST phase diagram for polymer solutions and blends, showing changes in polymer conformation in one- and two-phase regions

The forces between polymer–polymer, polymer–liquid, and liquid–liquid will all be diminished by increase of thermal energy, or more specifically temperature. Those interactions that decrease most with temperature will determine the nature of the gel or solution. If polymer–polymer interactions decrease most, solvation will increase with temperature, and a lower critical solution temperature (LCST) phase diagram will result (Fig. 2). Solvation and gel formation will increase with temperature. If polymer–liquid interactions decrease most, solvation will be decreased, and polymer solvation and gel formation will reverse upon heating, resulting in an upper critical solution temperature (UCST) phase diagram (Fig. 2). The phase diagram usually shows two boundaries between the separated (two-phase) and solution (one-phase) regions, a coexistence curve (bimodal) for equilibrium phase separation and a stability curve (spinodal) for spontaneous phase separation. The LCST and UCST are the critical points for maximum or minimum temperatures at critical concentrations. Some phase diagrams can combine LCST and UCST behavior when there is an intermediate temperature range within which solubility is favorable.

Other than by thermal changes, polymer–polymer interactions are reduced by decreasing interactive functional groups and/or chain symmetry/regularity. Cellulose is insoluble in water, but monomethyl cellulose is soluble in water and used as a thickening agent, structures shown in Table 1. Replacing some hydroxyl groups with non-hydrogen-bonding methoxy groups reduces inter-cellulose interactions more than it reduced interactions with water, thus allowing water solubility. A synthetic polymer example is poly(vinyl alcohol) (PVAlc). PVAlc is prepared from poly(vinyl acetate) (PVAc), since its virtual monomer, vinyl alcohol, is not stable. PVAc is then hydrolyzed to convert acetate groups to hydroxyl groups. When completely

Table 1 Structures for water-absorptive and water-soluble polymers

Celluloses (monomers)	Poly(vinyl alcohol)	Poly((meth)acrylic)s
 Cellulose	 Poly(vinyl alcohol)	 Poly(methacrylic acid)
 Methyl cellulose	 Poly(vinyl alcohol-co-acetate)	 Poly(hydroxyethyl methacrylate)
 Trimethyl cellulose	 Poly(vinyl acetate)	 Poly(isopropylacrylamide)

hydrolyzed, the pure PVAlc is insoluble because it crystallizes due to symmetry and strong intermolecular hydrogen bonding. When partially hydrolyzed and about 87% hydrolysis seems to be an optimum, with 13% acetate groups remaining, water solubility is optimized. Returning to methyl cellulose, when completed methylated to give trimethyl cellulose, it is water insoluble, but it can be dissolved in polar organic solvents such as dichloromethane. Poly(hydroxyethyl methacrylate) (HEMA) and poly(*N*-isopropylacrylamide) (NIPAM) are much studied polymers with complex interactions with water forming interesting gels, solutions, and phase diagrams.

Another way to increase solubility of polymers is to increase the solvent power. Adding a strong hydrogen-bonding agent to water increased it solvent power. Water–urea mixtures can dissolve cellulose. Acid–base reaction can for salts that are more water soluble so that cellulose is soluble in sodium hydroxide solution. Salt that forms ions in solution increases the solvent power of water, such as lithium chloride solutions that are stronger solvents for highly polar polymers. Sodium chloride and calcium chloride are confirmed to modify water absorption to tapioca starch and contribute anti-plasticization by competing for water with the starch [3].

The consideration of solvation discussed above is about interactions or enthalpy as quantified with solubility parameters, or cohesive energy density, which in a particular polymer–liquid system are equated to the interaction parameter. Entropy is the other thermodynamic parameter that determines solubility or swelling. A swollen or solution polymer becomes less ordered than in the solid and thus gains entropy. The liquid or solvent is even more controlled by entropy because many small liquid molecules that are randomized in the liquid phase lose randomness when they are absorbed into a polymer gel or solvating a polymer in solution. The entropy and interaction parameter concepts are typified by the Flory–Huggins equation (Eq. 1) and the thermodynamic equation defining free energy from enthalpy and entropy (Eq. 2):

$$\frac{\Delta G}{RT} = \frac{\theta_p}{n_p} ln\theta_p + \frac{\theta_s}{n_s} ln\theta_s + \chi\theta_p\theta_s \tag{1}$$

$$\Delta Gm = \Delta Hm - T\Delta Sm \tag{2}$$

where ΔG is the free energy change that must be negative for a spontaneous process such as solubility, χ is the interaction parameter that is a measure on secondary bonding and favors solubility when negative, θ is the volume fraction and n the number of moles of polymer (p) and solvent (s), T is temperature, and R is the gas constant. The entropy (ΔS) is determined by mole fraction and molar volume, the two logarithmic terms in the Flory–Huggins equation. The enthalpy (ΔH) term is a function of interaction parameter and mole fractions of polymer and solvent, the last term in the Flory–Huggins equation. The Flory–Huggins equation is an expanded version of Eq. 2.

This review aims to expand upon these introductory concepts by exploring polymer interactions, solutions, and gels, with emphasis of cellulose and the structures and interactions that lead beyond to super-absorbency. Objectives are to evaluate structure interaction character of synthetic polymers that have been researched or commercialized as super-absorbent materials or solution viscosity modifiers, illustrated in Fig. 3. Molecular modeling and simulation will be applied to evaluate structural, kinetic, and thermodynamic parameters that will typify polymer properties leading to super-absorbent characteristics.

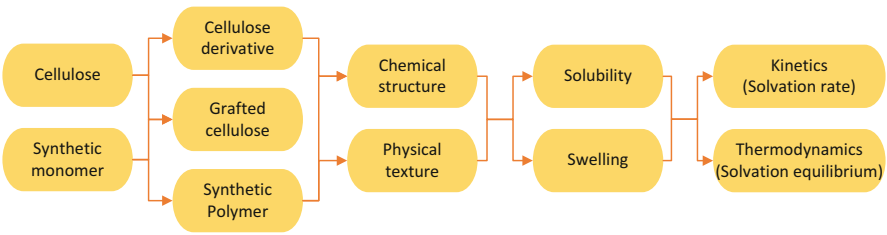

Fig. 3 Review outline, concept, and structure

2 Absorbency, Solubility, and Gelation

Polar polymers absorb and approach equilibrium with atmospheric moisture, that is, humidity. Cellulose and starch typically contain 8–10% water at average humidity of about 50%·RH. Polyamide 6,6 averages 1–2% moisture, and in fiber or thin films, it equilibrates rapidly. The water in polar polymers is a plasticizer. Cellulose fibers become brittle when dried so part of their properties when used as reinforcement in another matrix polymer depends upon their water content, so drying the fibers prior to processing deteriorates composite properties. Starch films are brittle even with equilibrium water content, so they require additional plasticizers such as glycerol, alkyl polyols, poly(vinyl alcohol), and related water-soluble polymers. Water absorption can be increased by destructuring native cellulose and starch with treatments that separate molecules from other components of the natural materials and crystal melting. Melting of these biopolymers means disrupting crystal structure to give an amorphous material, rather than melting in the sense of creating a flowable liquid.

Water absorption causes swelling of polymers in the first instance. Swelling proceeds until polymer–polymer interactions resist further separation of the polymer segments. An extreme of polymer–polymer interactions is chemical bonds or crosslinking where swelling is restricted by the crosslink density. Thermodynamically there are polymer–solvent (water) forces causing absorption, swelling, and potentially dissolving, counteracted by polymer–polymer forces and solvent–solvent forces, combined with loss of entropy or degrees of freedom by the solvating solvent molecules. Poly(2-hydroxyethyl methacrylate) swells to about 36%·w/w of water to form a equilibrium gel that does not proceed further toward dissolving.

Diffusion of liquids and gases through or into polymers displays the same phenomena, though diffusion is typically considered as transport through polymers. Diffusion is the product of solubility and permeability. The diffusing liquid or gas must be soluble in the polymer; this means that the liquid or gas dissolves in the solid to give a solid solution. Additionally, permeability is the transport of liquid or gas across the polymer due to a concentration gradient. Transport through a polymer must be through amorphous regions because any crystalline structures are regular and close-packed, without spaces for foreign molecules. Amorphous regions contain free volume that increases with temperature and expands rapidly at the glass transition temperature (*Tg*). Permeating molecules must pass through a tortuous path that forms by linking of free volumes. Above *Tg* rapid segmental motions create rapidly changing free volume array allowing diffusing molecules to move as free volumes open along their path. Below *Tg* segmental motions are restricted by lack of activation energy, and free volumes become static, preventing diffusing molecules from finding new free volumes for movement. The concentration gradient restricts reverse motion, so the molecules are forced onward. Permeability combined with solubility gives diffusion.

When the polymer–solvent interactions dominate, swelling continues until polymer molecules break from the swollen gel and disperse into a true solution. The separated dissolved polymer molecules adopt a random coil conformation. In a poor solvent, the random coils will be relatively compact because polymer–solvent

Fig. 4 Random coil comparison of poly(acrylic acid) and sodium polyacrylate

interactions are just sufficient to dissolve the polymer. In a good solvent, the random coils in solution are increasingly expanded. If the polymer chains contain charged groups such as carboxylate anions, repulsions between the charges expand and elongate the random coils. Figure 4 illustrates expansion of random coils by interactions or repulsions according to three different surface criteria calculations based on Connolly surface, smooth solvent surface, and smoothed accessible solvent surface. Sodium poly(acrylate) is shown to expand more than poly(acrylic acid). Poly(acrylic acid) can form intramolecular hydrogen bonds that contract the random coils, while sodium poly(acrylate) has carboxylate anions along the chain that repel and expand the random coils.

Stronger polymer–solvent interactions and more expanded random coils increase solution viscosity. The nature of the polymer is important since apart from the relative interactions, the size of random coils is dependent on molar mass. Branching contributes in that a branched polymer, compared with the same molar mass of linear polymer, will have more compact molecules and hence lower viscosity. An extreme of branching is hyperbranched or dendritic polymers, where the radius of the random coils does not increase as rapidly as the molar mass. With these latter polymers, solution viscosity can decrease with molar mass increase at high molar mass has a reverse effect because molar volume grows more slowly.

Rheology is shear rate-dependent viscosity. If the polymer random coils are separated in solution, they move independently, and viscosity increases linearly (Newtonian) with shear rate. If there are interactions between the random coils, then increasing shear rate is likely to disrupt the interactions, and the viscosity will decrease (shear thinning) with increasing shear rate. If the random coils become elongated at higher shear rates, then the elongated coils exhibit increased interactions thus increasing viscosity (shear thickening) with increasing shear rate. Time delay in returning to equilibrium slow shear rate or static viscosity may be experienced after shear thinning or shear thickening; these delays are thixotropy and rheopectic behaviors, respectively.

Gelation is a discontinuity in the rheology where the substance ceases to flow. There are several definitions depending on the context. With oscillatory rheological measurements performed with a sinusoidal shear frequency in the linear viscoelastic region, gelation is where the elastic response (G′) and the viscous response (G″) are equal. The curves of G′ and G″ cross at gelation because the elastic- or solid-like response becomes greater than the viscous- or liquid-like response. The crossover of the curves may occur with increasing frequency, a time-base response, or with decreasing temperature. Gelation in this context is a result of viscosity reaching a value where the substance is in practice a solid, due to intermolecular interactions. When a substance is undergoing a crosslinking reaction, then gelation is defined by the crosslinks as when crosslinked species extend across the system. Figure 5 illustrates the crossing of G′ and G″ curves that indicates a gel point. The curves

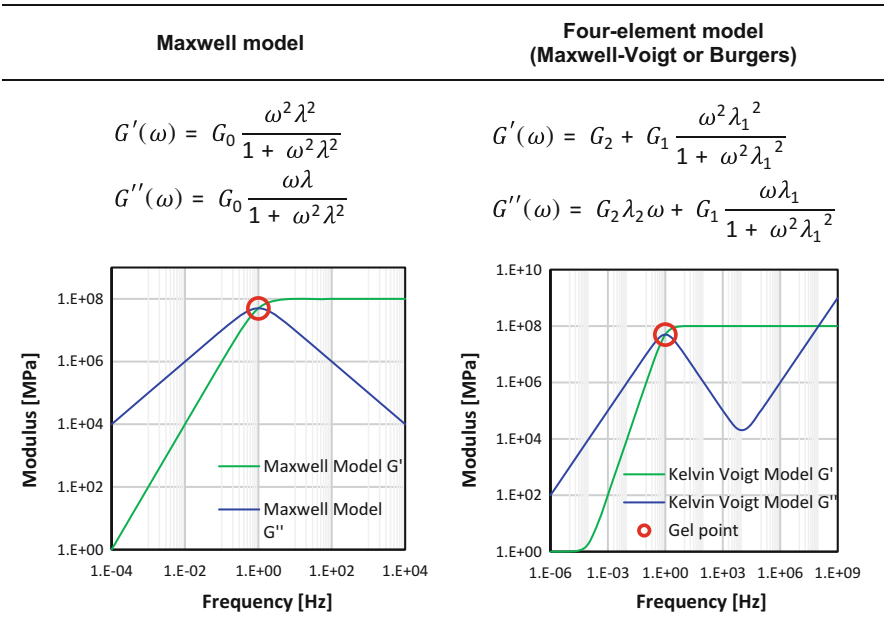

Fig. 5 Complex rheology shear rate curve showing G′, G″ and gel point

were calculated using the Maxwell model and four-element Maxwell–Voigt or Burghers model. A distinction between liquid and solid according to these theories is the relaxation time of the molecules relative to the rate of perturbation.

3 Solubility of Cellulose

Cellulose is not water soluble. As the structural material of plants, it has a configuration enhancing cellulose–cellulose interactions by hydrogen bonding to give two main crystalline forms: native or type I and textile or type II, though other forms are known. Starch has the same chemical structure but opposite configuration about the repeat unit links making it soluble as required for ready metabolism as an energy source. Starch has the linear structure, amylose, like cellulose but with inverted chirality links and a branched structure, amylopectin.

The importance of processing cellulose [4] has resulted in techniques for dissolving it so that regenerated fibers and films can be made. The first technique was complexation with alkaline tetra-ammonia-copper(II), and the cellulose is regenerated by precipitation in acid, such as dilute sulphuric acid. Another route is derivatization using alkaline carbon disulfide to form a soluble sodium xanthate derivative, and the cellulose is again regenerated by precipitation with dilute acid. Cellulose derivatives, crosslinking strategies, and their biodegradability have been reviewed [5], and their response to external physiological stimuli and biodegradability were considered with their use as scaffolding biomaterials, as tissue structures, and in regenerative medicine.

Direct dissolving of cellulose, though not in water, is available using ionic solvents, such as *N*-methyl morpholine *N*-oxide (NMMO). Precipitation of cellulose from NMMO is by extruding the solution into water; after separation of the cellulose, NMMO is recovered for reuse by evaporation of the water due to the high boiling temperature of NMMO. NMMO is used commercially to produce cellulose fibers called Lyocell and Tencel. Other ionic solvents, such as 1-butyl-3-methylimidazolium acetate, have been used to dissolve cellulose. NMMO and ionic solvents have been termed green solvents because they can be purified, dried by evaporating any water, and reused for a new cellulose solution process. Cellulose is regenerated from solution by precipitation into water [6].

Figure 6 shows interactions and phase diagrams for cellulose–water and cellulose–NMMO. The molecular structures reveal hydrogen bond donors and acceptors for the interactions, illustrating the intensity of hydrogen bonds between the species in each case. Calculation indicates a maximum in the free energy of mixing cellulose–water at various temperatures and the energy with molar composition. Cellulose–NMMO exhibits an unexpected minimum in the free energy of mixing with this calculation, which may be indicated by the lower intensity of donor–acceptor sites on the molecular model.

As described above, the configuration of cellulose enhances cellulose–cellulose hydrogen bonding and limits cellulose–water interactions enough to prevent dissolving. The hydroxyl groups on cellulose, particularly the 2-hydroxy, are more

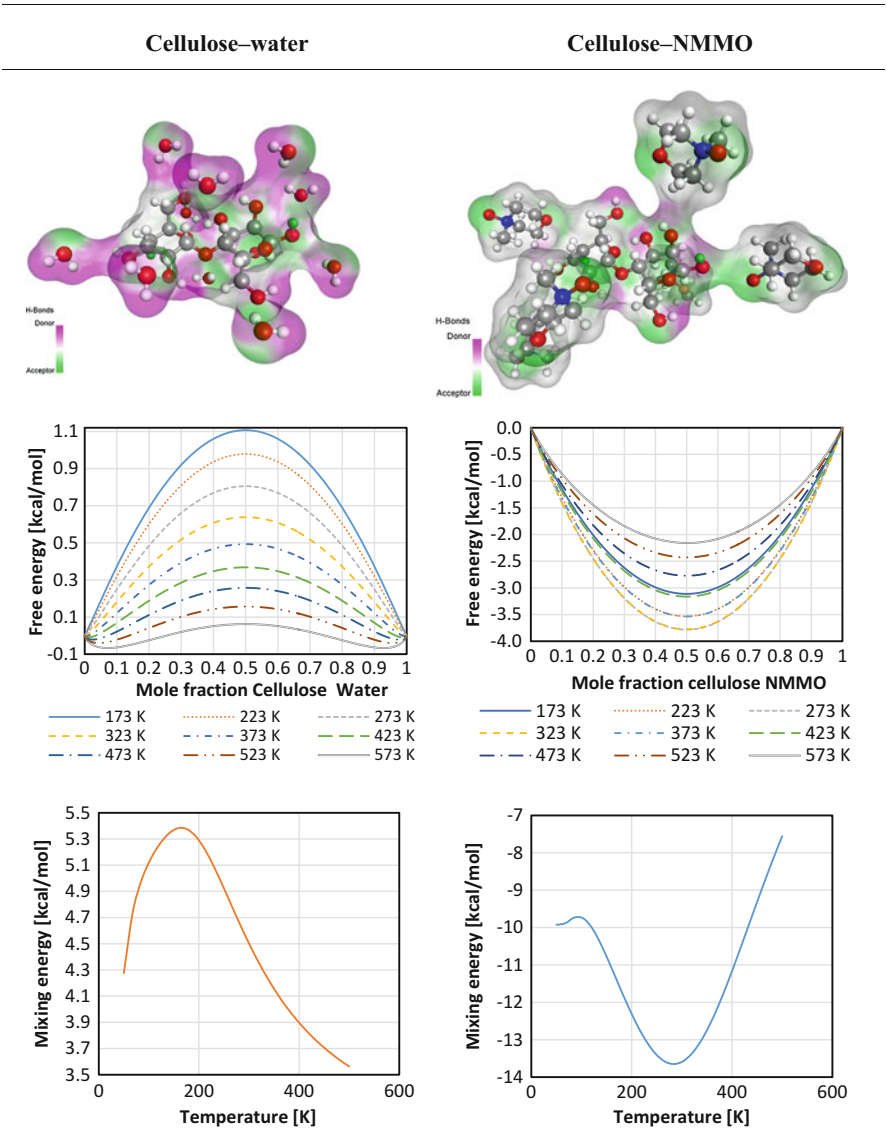

Fig. 6 Cellulose molecular models showing hydrogen-bonding donor and receptors with water (left) and NMMO (right), cellulose solubility predictions in water with UCST, and NMMO with LCST phase diagrams at temperature increments of 50 K from 173 to 573 K; lower curves show the respective mixing energies

acidic than the hydroxyl of a typical alcohol. In sodium hydroxide solution, some sodium salts of cellulose are formed. The sodium salts can accelerate nucleophilic reactions of cellulose, such as formation of methyl, hydroxylalkyl, or carboxymethyl derivatives (see later details of these reactions). The salts facilitate dissolving of

cellulose. Since a lower critical solution temperature (LCST) is involved when dissolving cellulose in sodium hydroxide solution, a suspension of cellulose in sodium hydroxide solution must be cooled. The process involves freeze–thaw cycling, and with each cycle, a small increment of cellulose dissolves. Dissolving cellulose is enhanced with added urea, a strongly hydrogen-bonding agent. Sulphite pulp process-separated cellulose has been dissolved in sodium hydroxide and urea at a low temperature [7]. Hydrogels were prepared from cellulose using water with sodium hydroxide–urea and crosslinking with epichlorohydrin, dissolving the cellulose via heating and freezing cycles [8]. Hydrogels from heating showed macroporous inner structure, while fibrous structures were formed in hydrogels prepared from freezing. Transparency and equilibrium swelling decreased, while re-swelling increased, with cellulose content. Cellulose can be dissolved in aqueous sodium hydroxide–urea, sodium hydroxide–thiourea, and lithium hydroxide–urea at low temperatures and the solutions used to prepare cellulose-based functional materials, such as fibers, films, membranes, microspheres, hydrogels, and cellulose derivatives [9].

4 Super-Hydrophilic Synthetic Polymers

Water-soluble synthetic polymers can serve as a guide for solubility of cellulose and its derivatives. Poly(vinyl alcohol) (PVA) has many –OH group pendant from the chain backbone. The –OH groups can hydrogen bond with water facilitating solubility; however they can hydrogen bond with other PVA segments or molecules detracting from solubility. Pure PVA is semicrystalline due to its symmetric molecules and PVA–PVA hydrogen bonds. If there are some acetate groups remaining from PVA synthesis, then the acetate groups occurring randomly restrict crystallinity and decrease hydrogen bonding, making this type of PVA that has increased water solubility. This occurs with about 10–15% acetate groups. With more acetate groups, solubility decreases and pure poly(vinyl acetate) is completely insoluble in water. The PVA case is analogous to cellulose where –OH groups need to be derivatized to facilitate water solubility.

Poly(acrylic acid) (PAA) is water soluble because of its many –COOH groups that hydrogen bond with water. However, in alkaline (e.g., NaOH) solution, the carboxylate groups become ionized $–COO^{-}\ Na^{+}$, and the anions are more strongly interacted with water. The –COO- groups along the polymer chain repel resulting in uncoiling and hence elongation of the PAA chain, allowing more access for water molecule solvation and much increased viscosity. This is analogous to cellulose methylene carboxylate that is strongly water absorbing and readily water soluble and with high viscosity. Poly(methacrylic acid) (PMAA) is similar to PAA, except that the pendant methyl groups add some hydrophobicity and reduce chain flexibility. PMAA–water interactions are reduced upon heating more than PMAA–PMAA interactions, so heating does not increase solubility; on the contrary, cooling increases solubility. PMAA in water exhibits a LCST, though, while cooling increases solubility, it decreases the rate of solubility. Analogous to cellulose in

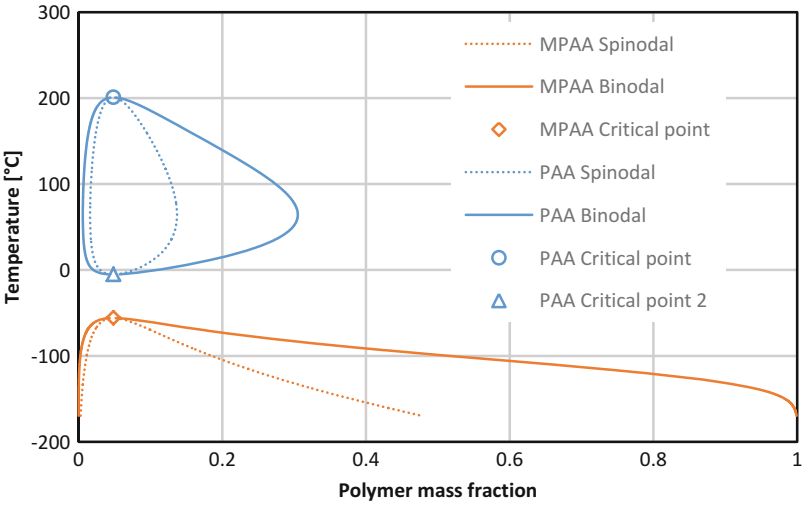

Fig. 7 Composition–temperature phase diagram for poly(acrylic acid) in water

alkaline solutions, PMAA in water is dissolved by freeze–thaw (cool–warm) cycles. A calculated concentration–temperature phase diagram is shown in Fig. 7 including LCST and UCST critical points and binodal and spinodal phase boundaries.

Polyacrylamide (PAM) is a water-soluble polymer or in crosslinked form is used as PAM gels for electrophoresis. PAM gels provide a fixed water phase that allows analyte molecules as large as proteins to migrate under an electrical field. PAM differs from PAA or PMAA in that the polar amide group responsible for solubility can be modified with N-alkyl groups. As the size of the alkyl groups increases, PAM polarity and hence solubility decrease. A critical alkyl group is *N*-isopropyl, *N*-isopropylacrylamide (NIPAM), that exhibits a LCST of 32 °C where the linear polymer becomes insoluble or crosslinked gels shrink considerably. Below LCST hydrogen bonding with water predominates and NIPAM becomes soluble. Concepts relating to NIPAM solubility with its enthalpy of interactions and entropy of movement of water molecules are applicable to cellulose alkyl derivatives.

Polyurethane elastomers are phase-separated materials where the continuous soft phase can be hydrophilic/hydrophobic, depending on structure such as a polyether or polysiloxanediol, and able to expand with water absorption. The urethane segments for a dispersed hard phase function as physical crosslinks and restrains soft phase expansion and hence ultimately solubility [10].

Surfactants display LCST, known as a cloud point. Surfactants are like many water-absorbing or water-dispersible polymers in that they are bipolar with hydrophilic and hydrophobic groups within their molecules. The hydrophobic molecular regions migrate to surfaces, and when all surfaces are saturated, at the critical micelle concentration, they form micelles. When thermal energy disrupts surfactant polar interactions with water, phase separation occurs, and the dispersion becomes cloudy. The cloud point reflects a lower critical solution temperature. Sensitivity of

water–polymer interactions to temperature is an important characteristic of water-absorbing cellulose derivatives, especially as to whether LCST or UCST behavior exists. Enhancement or reversal of water absorbance with temperature can be part of the design of material and products to regulate water content relative to ambient temperatures.

5 Super-Hydrophilic Plants

Super-hydrophilic structures are characterized by their physical surfaces that are in some ways analogous to super-hydrophobic surfaces. Water absorption is facilitated by a low contact angle, typically $<10^{\circ}$. A smooth surface can have increased hydrophilicity if water-absorbing substances are secreted by the plant. Another way is to have high surface porosity giving a larger area over which to absorb water. While convex surface features give high apparent contact angle as in the lotus effect, concave surface features give a low apparent contact angle. Water-absorbing protrusions such as hairs, aerial roots, or sponge-like features are more complex surfaces that increase water absorption rate or create permanent wetness [11]. Super-absorption plant surfaces enhance water and nutrient uptake. Examples are under-water plants and desert plants, the former taking advantage of the environment and the latter surviving in a hostile environment. This description of super-hydrophilic plants concentrates on the surface morphologies that enhance water absorption and retention, as opposed to the chemical structures that attract water.

6 Super-Hydrophilic Cellulose

Cellulose solubility in water is facilitated by reducing hydrogen-bonding groups. This may seem contrary to expectation; however alkylation, particularly methylation, reduces cellulose–cellulose hydrogen bonding, and the alkyl substituent reduces cellulose regularity and ability to pack into crystals. Monomethyl cellulose is water soluble, forming highly viscose solutions. It is used as a thickening agent in many water-based consumer products. Adding further methyl groups reduces hydrogen-bonding capacity further and prevents water solubility. Trimethyl cellulose becomes soluble in polar organic solvents such as dichloromethane. The water solubility of monomethyl cellulose provides a guide for other derivatives to give water solubility.

Reduction of cellulose chain regularity and hence cellulose–cellulose hydrogen bonding can be achieved by using hydrogen-bonding alkyl derivatives. Reaction with propane-1,2-oxide gives hydroxypropyl cellulose with substitution mainly on the more nucleophilic 2-hydroxy position. Hydroxyethyl cellulose can be prepared by reaction with ethylene oxide, though this reaction is less convenient because ethylene oxide is a gas. Structures for hydroxyethyl and hydroxypropyl cellulose are shown in Fig. 8. These cellulose derivatives, together with carboxymethyl cellulose form the basis of cellulose hydrogels, in conjunction with blends with synthetic

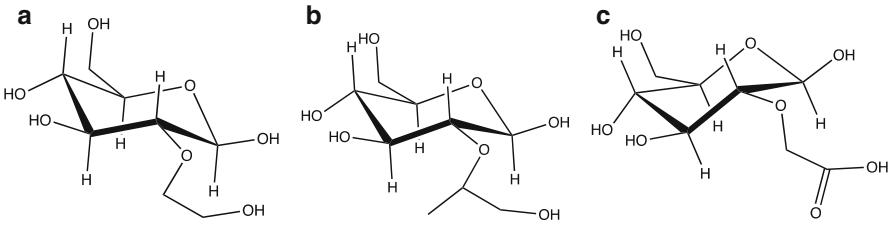

Fig. 8 Water-absorptive and water-soluble cellulose derivatives: (**a**) hydroxyethyl cellulose and (**b**) hydroxypropyl cellulose, (**c**) carboxymethyl cellulose

polymers and polyelectrolyte complexes. Cellulose–inorganic hybrid hydrogels are prepared by dispersing inorganic nanoparticles in a cellulose matrix [12].

Substitution with chloroacetic acid is a nucleophilic reaction that forms the acidic derivative carboxymethyl cellulose (CMC), structure shown in Fig. 8. CMC is soluble in water. In alkaline solution of sodium hydroxide, the sodium salt is formed. Sodium cellulose methylene carboxylate has a negative charge on each substitution. The negative charges reduced cellulose–cellulose interactions by mutual repulsions while increasing interactions with water. Sodium salts are known to be soluble in water, and CMC is no exception; however the repulsions between cellulose chains extend random coils imbibing more water and causing extremely high viscosity to the point of gelation.

Carboxymethyl cellulose has been crosslinked to cellulose using epichlorohydrin in a water solution containing sodium hydroxide and urea [13]. Urea is a hydrogen-bonding additive to assist dissolving cellulose in water, while sodium hydroxide is a base catalyst for the nucleophilic reaction with epichlorohydrin. CMC provided the water affinity and porosity, while cellulose provided structure and strength to the water-swollen gels. Swelling was dependent on CMC content, and swelling diminished with salt concentration in the water.

An extension of cellulose derivatization is formation of graft copolymers between cellulose and another synthetic polymer. With a grafted polymer, the substituent becomes a polymer rather than a single organic group. Grafting is classified as grafting to or grafting from depending on whether the initiating site is on cellulose or the monomer/polymer graft. An example of chain growth grafting from cellulose is the ring-opening reaction with caprolactone. Base catalysis creates an initiating alkoxide from a hydroxyl on cellulose, predominantly the more acidic 2-hydroxy. The alkoxide initiates a nucleophilic ring opening of caprolactone that proceeds with other caprolactone monomers. Radical initiation is induced by redox catalysts such as cerium and peroxide. An oxy-radical is formed that propagates polymerization of styrene, acrylonitrile, and (meth)acrylates including esters or carboxylic acids. The latter carboxylic acids lead to increased water absorbance, while other monomers increase water resistance of cellulose. Cellulose sourced from wheat straw has been grafted with acrylic acid or acrylamide using redox initiation in water with N,N′-methylenebisacrylamide as crosslinker, to obtain materials with up to 134%·w/w water absorbency and 44%·w/w water absorbency in 0.9%·w/w

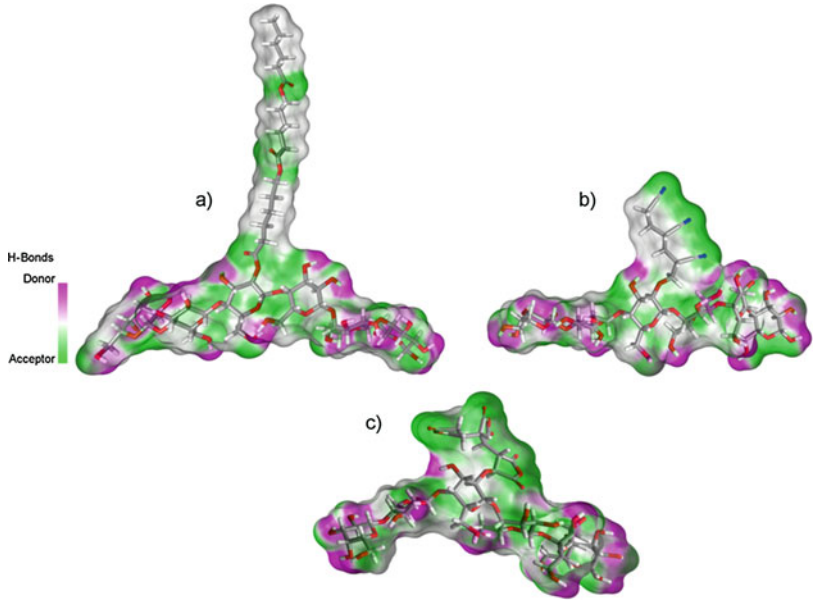

Fig. 9 Grafted cellulose structures with (**a**) caprolactone, (**b**) acrylonitrile, and (**c**) maleic anhydride

sodium chloride solution [14]. Nanocomposite hydrogels have been prepared from carboxymethyl cellulose grafted and crosslinked with methacrylic acid to enhance permeability and drug release. Composition was optimized for swelling and gel strength [15].

Step growth grafting from cellulose can proceed from esterification using maleic anhydride, succinic anhydride, or alkyl succinic anhydrides, linking with diols, glycerol, or formation of some crosslinks within/between cellulose. Cotton cellulose was grafted with succinic anhydride using 4-dimethylaminopyridine as catalyst in solution with lithium chloride and *N*-methyl-2-pyrrolidinone or tetrabutylammonium fluoride and dimethyl sulfoxide. The hydrogels absorbed 400 times by mass of water and functioned adequately in water containing sodium chloride, and they were biodegradable [16].

Figure 9 shows some molecular models of cellulose grafted with caprolactone, acrylonitrile [17], and maleic anhydride. The grafted species may form as compatibilizers for blended polymers or form dispersed phase morphologies within the starch; their resistance to separation is assured by the linking chemical grafts.

Grafting to cellulose can be via the epoxy reaction with cellulose hydroxyls. Typical epoxy resins can be used or copolymer containing epoxide such as poly (ethylene-*co*-glycidyl methacrylate). Another facile grafting to or from reaction is the urethane reaction. An isocyanate-terminated polymer can react with cellulose hydroxyl to form a linking urethane group. Hydroxyl groups undergo many reactions, and those of cellulose being more acidic than typical alcohol hydroxyls are able to participate with advantage in these reactions. A practical problem with

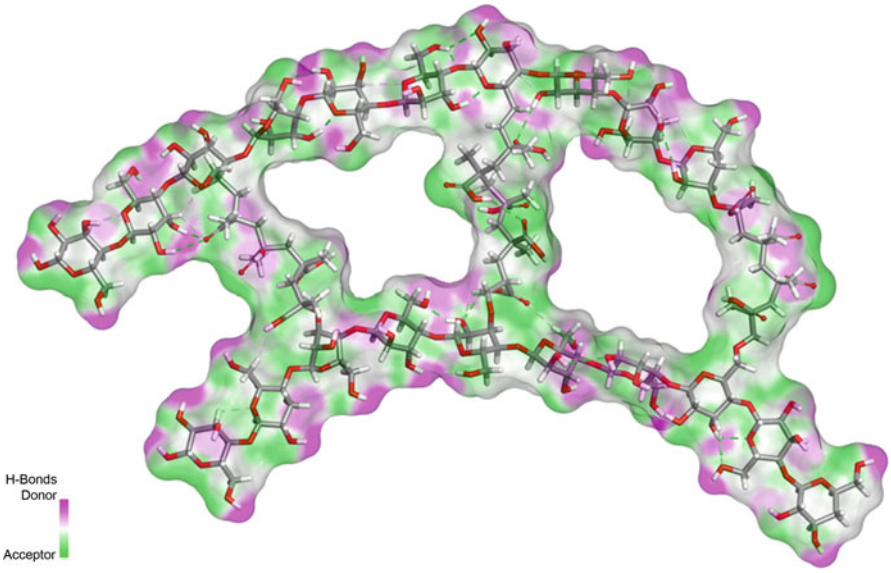

Fig. 10 Grafting and/or crosslinking via epoxy or urethane reactions

performing graft-to reactions is the mutual miscibility or solubility in a mutual solvent since reactions are inefficient when the two reactants are immiscible or incompatible. Some reactions can be performed via reactive extrusion, such as between cellulose dispersed in poly(ethylene-*co*-glycidyl methacrylate) or polypropylene-*graft*-maleic anhydride. Figure 10 shows some schematics of cellulose together with grafted species that may found intermingled or laminar supramolecular structures.

This comparison section is concluded with starch, another hydrophilic natural polymer. Starch differs from cellulose in two structural features. The main distinction is linking of glucose units via alpha-1,4-acetals in starch instead of beta-1,4-acetals in cellulose. This single change in stereochemistry is amplified by the repeating links that may typically be 3000 in cellulose. The alpha links form a helical structure instead of the planar structure that allows close stacking in cellulose. The alpha links create a dihedral bend at each link forming a coil over several links. Thus starch forms an open helical structure that can accommodate absorbed molecules within helices or between helices. Because of this stereochemical difference, starch is more water absorptive and soluble compared with cellulose. Starch with alpha-1,4- links is amylose, a linear molecule similar to cellulose. Another form of starch, amylopectin, contains a small proportion of 1,6-links, where each of these links forms a chain branch. Amylopectin has many branches in each of its very large molecules.

Figure 11 shows amylose and amylopectin chain segments that have partially coiled with energy minimization and molecular dynamics. The bond structure is surrounded by an electron density surface to portray the shape of the molecule. Both

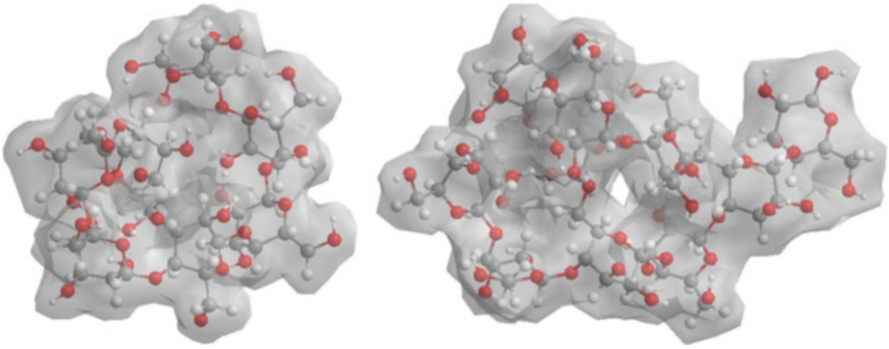

Fig. 11 Starch molecular model showing linear (left), branched (right), and coiling (both)

molecules show an initial inner channel formed by the helical molecules, which for longer chain segments can entrain other molecules such as iodine and stearic acid. Calculation of the electron density surfaces reveals capability as hydrogen bond donors or acceptors in amylose and amylopectin. The electron density surfaces illustrate the ability of starch to absorb and interact with water and other highly polar substances, such as glycerol. Starch interactions with hydrophilic plasticizers such as glycerol and xylitol, in conjunction with water, were shown to limit retrogradation and decrease the glass transition temperature [18]. An anti-plasticizer action was observed for each plasticizer over concentration ranges, which was due to plasticizer–water interactions replacing interactions of both with starch. Xanthan gum and other carbohydrates are strongly water absorptive and may dissolve in water to give highly viscous solutions. Crosslinked gums plasticized with sugars, glycerol, or glycols can be combined with starch to give flexible films with large elongation at break and high water content [19].

Chitosan is closely related to cellulose with the 2-hydroxyl on each glucose monomer unit replaced by an amino group. Chitosan-*g*-poly(acrylic acid)–montmorillonite has been prepared as a super-absorbent nanocomposite, with pH-dependent response [20].

Comparison with synthetic segmented polymers, and trends in behavior described in polymer science theory, is the observation and prediction that branched polymers tend to be less crystalline because branches are an irregularity that inhibits crystallinity and that branched polymers tend to be more soluble than linear polymers of the same chemical structure. Native starches reverse this concept because the branched amylopectin is crystalline while the linear amylose is amorphous. When added to water, it is the linear amylose that is more soluble than the branched amylopectin. Natural polymers or biopolymers and synthetic polymers are sourced or synthesized differently, yet all polymers must conform to the same structure–property relationships that have been established as the basis of polymer science. Fortunately, this chapter is about cellulose, so I can leave it to the reader to consider this contradiction between amylose, amylopectin, and other linear and branched polymers.

7 Comparison Polymers–Super-Absorbent Polymer (SAP) Gel Particles

Poly(hydroxymethyl acrylate) (HEMA) is a water-absorbing polymer used in soft contact lenses. Figure 12 shows polyHEMA segments with associated water molecules and a self-replicating cell containing several polyHEMA chains and absorbed water molecules. It forms a gel upon absorbing about 36%·w/w water; at this water concentration, it reaches equilibrium giving suitable softness, strength, and water content for oxygen transmission for comfort and eye health. From HEMA structure, it could be thought that it should be soluble in water; however water is absorbed, and the HEMA swells until the equilibrium water concentration when polymer–polymer interactions, hydrogen bonds, limit further swelling. Another factor in the equilibrium is the water–HEMA interactions, and the negative contribution of decreased water entropy as bound water has less degrees of freedom than free water. Another possibility is that there is some transesterification in HEMA leading to formation of some ethylene dimethacrylate and methacrylic acid, where the former is a tetrafunctional crosslinking monomer.

Crosslinked poly(acrylic acid) and polyacrylamide have structures where random sequences of the two monomers decrease regularity for polymer–polymer and more water came be absorbed without dissolving the polymer because it is slightly crosslinked. Crosslinking density must be lost to just prevent dissolving while allowing extensive swelling. This copolymer is a typical super-absorptive example that can absorb many times its own mass of water. Increasing pH to form carboxylate salts of the poly(acrylic acid) units further increases water absorption by increased water interactions and expanding the swelling by negative charge repulsions along the macromolecules.

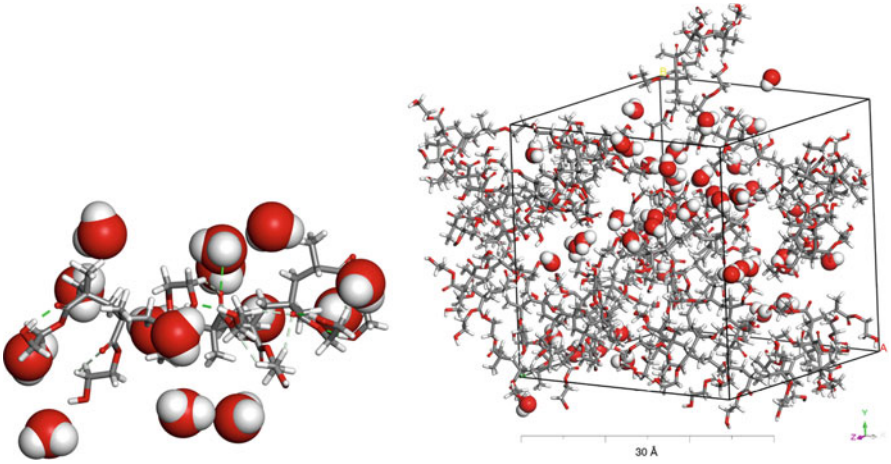

Fig. 12 Molecular model of hydrated poly(hydroxyethyl methacrylate), left, chain segments with absorbed water molecules showing hydrogen bonds; right, a cell containing multiple polyHEMA chains with absorbed water molecules

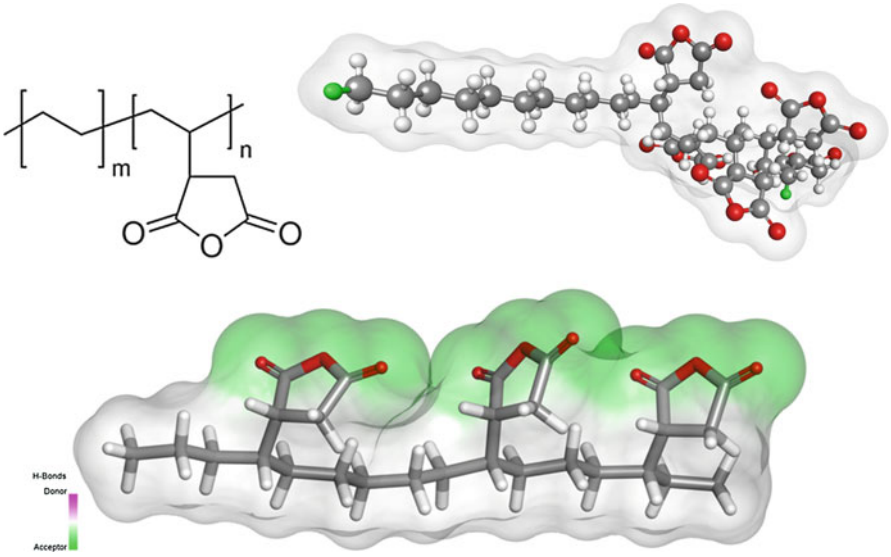

Fig. 13 Molecular structure and models of poly(ethylene-g-maleic anhydride) segment, top, structure and model; lower, model with hydrogen-bonding donors shown

Poly(ethylene-*co*-maleic anhydride) (Fig. 13) is contrasted to the former copolymer in that the ethylene units are hydrophobic while the maleic anhydride units, which are converted into two carboxylic acids when in water, have double carboxylic acid functionality. The reactivity of maleic anhydride, a 1,2-disubstituted alkene, is such that it will not homopolymerize, so each maleic anhydride chain unit will be preceded and followed by an ethylene. While the ethylene units are hydrophobic, they give weak polymer–polymer interactions and reduced regularity within polymer chains allowing random coils to readily swell with absorbed water clustered about the maleate units. When pH is increased and the maleate units, such as dicarboxylates, become salts, water is strongly attracted. This balance of water attraction and polymer–polymer repulsions from the anions and assisted by weak easily disrupted interactions from the ethylene hydrophobic groups is favorable for both sides of the equilibrium equation, resulting in a water super-absorptive polymer.

Sodium acrylic acid-vinyl alcohol copolymer has both monomers with polarity and hydrogen-bonding capacity. Hydrogen bonding within the copolymer chains should cause tight random coils. Water absorption and solubility are likely to occur with this copolymer. Crosslinking should be included to prevent solubility, using a small amount of a diacrylate ester. The pH can be increased to introduce carboxylate anions, again causing ionic repulsions within the polymer and expanding random coils while water will be strongly absorbed forming a super-absorptive gel.

Cationic polymers can be super-absorbents, as well as the more prevalent anionic polymers. Copolymerization of *N*,*N*-diallyl or *N*,*N*-dimethyl ammonium chloride with *N*-vinyl 2-pyrrolidone in the presence of *N*,*N*,*N*′,*N*′-tetraallyl piperazinium

dichloride as crosslinker has been used to prepare cationic water absorbents with the cationic monomers being separated by N-vinyl 2-pyrrolidone units [21]. Typically, 0.5% crosslinking gave the highest swelling ratio of 360 times the mass of water when only the cationic monomer was present. Cationic quaternary ammonium polymers have an advantage of being antibacterial. As for anionic water absorbents, the cationic types are susceptible to ionic strength in absorbing water.

Cationic nano-fibrillated cellulose was prepared by etherification with quaternary ammonium compounds, and they exhibited broad-spectrum antimicrobial activity that was proportional to the extent of etherification. Cationized nano-fibrillated cellulose showed cytotoxicity with human cells, enabling the manufacture of safe, insoluble, and permanently antimicrobial materials by an aqueous synthesis [22].

The examples discussed of polyelectrolyte gels demonstrate the principles for achieving facile swelling with strong attraction and hence absorption of water. The anionic carboxylate gels can be extended to zwitterionic gels provided that regularity is disturbed so that positive and negative species do not associate but are open to hydrogen bonding with water, hence facilitating water absorption.

Combinations of natural polymers with synthetic polymer grafts have been discussed. To conclude this section, a further example of graft-polymerizing acrylamide (AM) onto potato starch is presented. Starch is not sufficiently water attractive or soluble to form a super-absorptive polymer alone. When acrylamide is grafted from starch and some bis-acrylamide monomer is added for crosslinking, then water absorption can be adjusted by composition to give water super-absorption; similarly with grafts of acrylic acid and methacrylic acid. These three monomers are water soluble so grafting can be performed in a water solution of starch and a monomer together with a redox initiator. Functional group reactions with isocyanate have been used to form starch–polyurethane grafted hybrids that decrease solubility of films prepared from the starch [23].

8 Kinetics and Equilibria

Water absorption with swelling occurs until there is a balance of free energy due to interactions between each of the components and entropy of the system. This is a thermodynamic equilibrium that is described by the Flory–Huggins equation (Eq. 1) through temperature, molar volumes, and the interaction parameter. Flory–Huggins is much cited because it presents a high-level, lattice-confined overview of the complex and diverse interactions between polymers and liquids. Atomistic molecular models use the Flory–Huggins concepts with constraint of a lattice and with a temperature-dependent interaction parameter based upon all interactions quantified by a validated force field. The equilibrium state of a hydrated polymer gel does not consider time, that is, the kinetics of absorption and desorption (Fig. 14).

Kinetics is the temperature-dependent rate of absorption of water; in addition to solubility is diffusion rate that is often described by the Fick Law. It is likely that the absorption rate will differ from the desorption rate giving a sorption hysteresis. It might be desirable to have rapid absorption of water so that a swollen gel would form

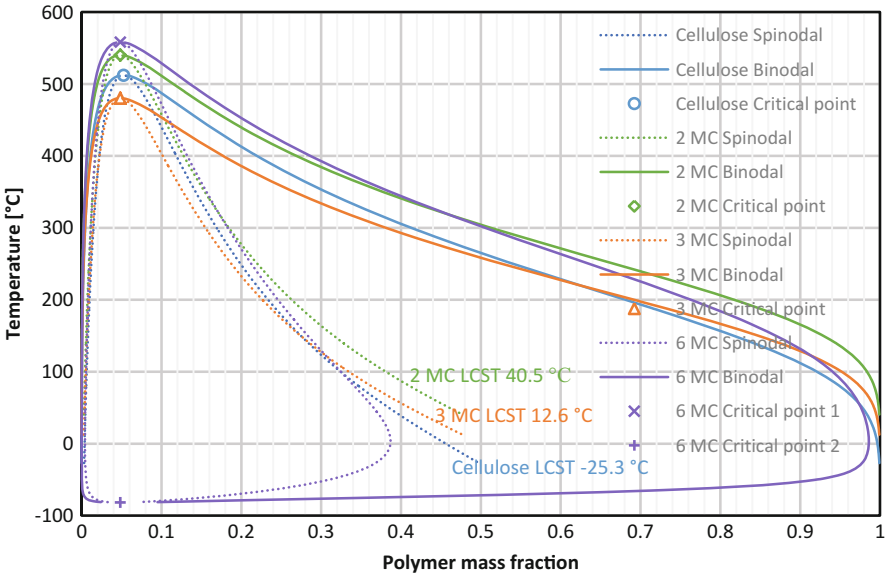

Fig. 14 Molecular model simulated temperature–composition phase diagram for polymer water

rapidly or if a product was designed to contain water spillages that rapid absorption would be preferred. Water-release processes of pre-wetted super-absorbent polymer particles can be slow, so that entrained water would be slowly released, such as over a week, while the water was being released to soil for plants to be grown under constant hydration.

Super-absorptive polymers solvate and bind with water strongly. Water desorption will be resisted both kinetically as observed as hysteresis and thermodynamically since the binding free energy must be overcome by more favorable state for the water. Desorption will be kinetically favored by a low concentration of water, dry conditions, external to the super-absorption polymer gel environment.

9 Applications

Slow release of water to soil for plant growth between watering cycles is important for agriculture and horticulture applications, as mentioned in the previous example. Super-hydrophilic polymers are used in agriculture for water retention on rocky slopes, eco-engineering, soil's water-holding capability, seed germination rate, plant survival, and soil erosion containment [24].

Medical and physiological applications are for wound dressing with included antibacterial agent, especially in the case of burns where an artificial skin is required, controlled release gels, and hot and cold therapy packs. Hydroxyethyl methyl cellulose, hydroxypropyl cellulose, hydroxypropyl methyl cellulose are used in

eye drops, artificial tears, contact lens fluid, cosmetics, adhesives, and excipient/tableting ingredient. Polysaccharide nanoparticle gels for vaccine delivery and treatment of viral or bacterial infections have been described [25]. Tocopheryl acetate has been released from maize starch granules and structural properties; particularly free volume of the macromolecular network was related to release kinetics [26].

Super-absorptive polymers are coated onto or extruded into fibers, yarns, and textiles. These products are used for water blocking, filtration, hygiene, apparel, cable, and related products. Examples include Ultrabloc for dry blocking cables requiring water blocking for fiber optic cables, copper cables, and high-voltage energy cables. Ultrabloc is a spun super-absorbent polymer yarn with a polyester wrap. Another water-blocking and absorbing yarn is Swellcoat. Technical Absorbents manufacture a super-absorbent water-blocking yarn that can be incorporated into cables; it will rapidly absorb liquid from a damaged region and swell to form a gel, blocking any further water ingress. Technical Absorbents can be used for moisture management in garments to transport moisture away from the skin to the garment. Several fabrics for disposable and washable apparel are based on evaporative cooling and wicking. These fabrics create optimum conditions to increase wearer comfort next to the skin and over outer clothing. Star Materials supply fast water-absorbing and high tensile strength yarn, used in communication and optical, power, or marine cables for binding, tightening, and prevention of water penetration.

Swelling controlled by changes in environment, such as acid/base, electrical field, termed smart swelling, can be used for controllable delivery and food packaging. As thickeners and emulsifiers, methyl cellulose will set while hot and liquefy while cold; carboxymethyl cellulose, often as the sodium salt, is used in foods, paint and adhesives as a thickener, in ice-cream to prevent water–ice crystallization, and as an emulsion stabilizer for foods and toothpaste.

Fig. 15 shows the expansion of crosslinked super-absorbent polymers from particles to spheres to enlarged spheres. Expansion occurs until the extended chain segments between crosslinks reach equilibrium with the solvation force of the absorbing water. Pure water typically gives optimal expansion compared with water containing dissolved salts. The water may contain other substances such as nutrients for release to plants or pharmaceuticals for release to assist adjacent tissue healing.

These applications are selected examples since controlling the properties, storage, and delivery of water is a diverse field that includes many materials, with polymers and particularly super-absorptive polymers being substantial contributors.

10 Conclusions

Polymer regularity, polymer–polymer interactions, polymer–liquid interactions, and system entropy have been demonstrated to determine liquid absorbance and solubility. When a polymer is crosslinked, either through chemical bonds or physical interactions, then solubility is prevented, and water absorption is limited by the crosslink density. Super-hydrophilic polymers must be strongly water absorbing

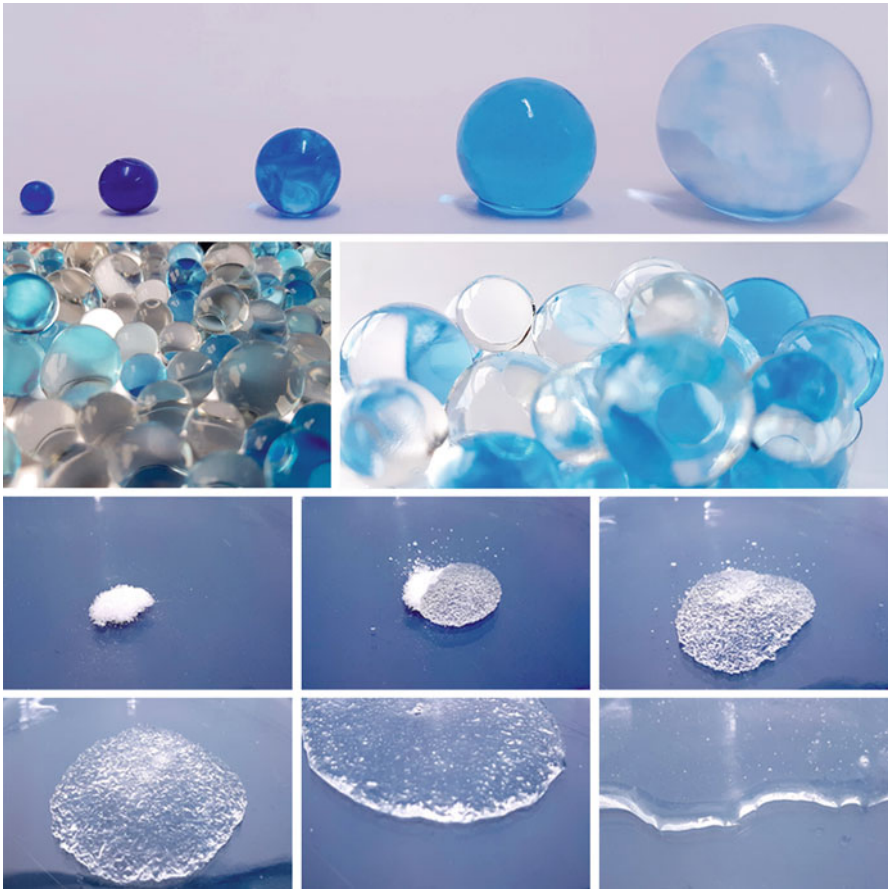

Fig. 15 Images of products using super-absorptive polymers: (top) swelling of polymer beads, (middle) swollen polymer beads, and (lower) swollen polymer particles, white granules, progressively forming a gel as water is added

such that they would dissolve were it not for crosslinks. The interactions thermodynamically contribute to the enthalpy of solvation. Another important thermodynamic factor is the entropy of solvation that is significantly caused by constraints on degrees of freedom of strongly absorbed, hydrogen-bonded water molecules. Enthalpy and entropy combine to give the free energy of solvation that must be negative for spontaneous water absorption. The kinetics of water absorption and any absorption–desorption hysteresis contributes to applications of super-absorbing polymers. Even though a large fraction of water can be absorbed, the time to reach equilibrium must be suitable. Rapid absorption kinetics are favored by surface wetting and porosity, to facilitate diffusion. Cellulose is not sufficiently polar and too regular to be a super-absorbent polymer. Functionalization to form carboxymethyl cellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, and

methyl cellulose increases polarity and decreases packing ability of cellulose. Other grafting monomers such as acrylic acid, methacrylic acid, acrylamide, and maleic anhydride increase polarity, and as polymeric grafts, they prevent ordered cellulose structures. Applications of super-hydrophilic cellulose derivatives include water absorption in sanitary products, water and nutrient release in agriculture, and antiseptic hydration materials for wounds and physiological treatments. Since these hydrated materials contain extremely large proportions of water, they can be considered as a means of storing and delivering quantities of solid water.

Abstract

Cellulose – either in solid form or as a highly hydrophilic chemical derivative of cellulose – can serve multiple and synergistic roles in the preparation of absorbent materials to meet the requirements of diverse absorbent products. Progress in the preparation of nanocellulose products, including nanocrystalline cellulose (CNC), nanofibrillated cellulose (NFC), and bacterial cellulose (BC), is opening up new possibilities for the reinforcement of hydrogels. Conventional cellulosic fibers, including kraft pulp fibers (e.g., fluff pulp), mechanically pulped lignocellulosic fibers, and recycled paper fibers can provide a structure to fine-tune the mechanical and drainage properties of products that can include superabsorbent materials. Carboxymethylcellulose (CMC) is an especially strong candidate for preparation of the swellable phase of a hydrogel. The high content of carboxylic acid groups in CMC gives rise to a strong swelling tendency, especially at neutral to alkaline pH values. The uptake of water can be understood based on concepts of osmotic pressure, in addition to any salinity in the fluid that is being absorbed. The swelling can be adjusted by the choice and amount of a cross-linking agent. Notably, some of the needed cross-linking effect can be optionally provided by nanocellulose or conventional cellulosic fibers. Combinations of solid cellulose entities and water-soluble cellulose-based polyelectrolytes can be used to prepare completely bio-based products that offer an alternative to the presently available disposable absorbents, which are based mainly on petroleum-based superabsorbent hydrogels. Chemical and physical aspects of cellulose and its derivatives also help determine what happens during drying of absorbent products; some swelling ability may be lost irreversibly due to highly organized hydrogen bonding and coalescence of the cellulose-based macromolecular chains. Since cellulose can be involved in both the structural and chemical aspects of highly absorbent products, there will be unique mechanistic roles governing water uptake, water holding, and even the environmental impacts of cellulose-based absorbent products.

1 Introduction

The goal of this chapter is to review the main mechanisms by which cellulose and its derivatives can participate in highly water-absorbent products. A key challenge lies in the fact that cellulose itself – either in its native form or after conventional isolation methods – is merely absorbent, but not highly or "super"-absorbent. To qualify as a superabsorbent, a material must have the capacity to take up at least 10 g or water per g of solids [1], and the system also should be resistant to squeezing [2]. Articles considered in this review chapter most often report absorption capacities in

the range 100–1000 g water per g of superabsorbent polymer. It has been shown that certain chemical derivatives of cellulose, in particular carboxymethylcellulose (CMC), can indeed be used as a main ingredient of superabsorbent hydrogels [3]. Cellulose itself – in the form of fibers, nanofibrillated cellulose (NFC) and cellulose nanocrystals (CNCs) – can potentially be employed as components in highly absorbent hydrogel systems. So, in considering the mechanistic role of "cellulose," the present chapter takes a broad view, considering everything from native lignocellulosic fibers, to nanocellulose products, to water-soluble polymeric derivatives of cellulose for use in highly absorbent products. The fact that cellulose can fulfil so many different and overlapping roles in absorbent-related technologies attests to the unique nature of this remarkable macromolecule. The wider topic of superabsorbency also has been addressed in earlier review articles [1, 2, 4, 5].

Daunting challenges need to be overcome if the goal is to replace the currently used superabsorbent products with cellulose-based materials. Over 90% of the superabsorbent polymer (SAP) presently in use is based on acrylic-based polymers, i.e., lightly cross-linked sodium polyacrylate hydrogels. This is the major absorbent material in disposable diapers and feminine pads. Because manufacturing costs for such SAPs are presently much lower in comparison to any natural-based superabsorbent materials, it is reasonable to expect that the acrylate-type SAPs will remain dominant in the market for the foreseeable future. On the other hand, polyacrylates are derived from petroleum resources, which eventually will become depleted. Though the transition from a fossil resource-based economy to a sustainable economy has been slow, it is important to pursue steps in that direction. One of the most important contributions that researchers can make toward more rapid implementation of cellulosic materials in disposable absorbent products is to find ways to lower the costs of manufacturing such products as CMC.

2 Why Cellulose

2.1 General Aspects

Cellulose is highly available, relatively low in cost, and, at least in its native state, highly eco-friendly. The amount of cellulose grown annually on the planet through photosynthesis has been estimated to be in the neighborhood of 10^{17} g [6]. Though much of the total cellulose that grows each year either decays, is burned for fuel, or is used for wood products, the amounts converted into papermaking fibers, chemical-grade cellulose (dissolving pulp), grown as cotton, etc. are still very large. Table 1 provides some estimates of the amounts of cellulose, in various forms, that are produced in the world each year. Note that the amount of "fluff pulp" shown in the table is highly relevant to the focus of this chapter, since fluff pulp is a major component of typical disposable diapers and other highly absorbent products [7, 8].

Another main component of typical disposable diapers, incontinence pads, tampons, and other such product is superabsorbent polymer (SAP) hydrogels. These currently are mainly based on poly(acrylic acid) or copolymers of acrylic acid and

Table 1 Estimates of annual world production of various classes of cellulose vs. superabsorbent polymer market

Category of cellulose	Annual production (g)	Citation
Total cellulose growth	10^{17}	[6]
Total nontropical forest cellulose growth	3×10^{15}	[6]
Harvested wood (assuming 1 $m^3 = 10^6$ g)	10^{15}	[9]
Delignified fiber (kraft pulp, etc.) production	10^{14}	[10]
Kraft fluff pulp for absorbent products	7×10^{12}	[11]
Dissolving-grade pulp production	2.6×10^{12}	[10]
Current superabsorbent polymer production	2×10^{12}	[12]
Current carboxymethylcellulose production	5.4×10^{11}	[13]

acrylamide, which are nonrenewable, petroleum-based products [8, 14]. A hydrogel will be defined here as a hydrophilic polyelectrolyte having a range of cross-linking that allows it to swell in water but not dissolve. The amount of synthetic SAPs used per year is over 1.5×10^{12} g [5, 12]. By comparing this number with other data shown in Table 1, two things become clear. First, the amount of SAP being produced each year is just a tiny fraction of the amount of cellulose that is being isolated each year in various forms. Second, the amount of SAP is larger than the current worldwide production of carboxymethylcellulose, and it is almost of the same magnitude as the world production of dissolving pulp, which has a variety of current uses. It follows that, if it were decided to replace the present SAP output with cellulose products, the present production capacity for dissolving-grade pulps would not be sufficient.

Perhaps to a greater extent than its abundance, one of the primary reasons that researchers have been motivated to consider cellulose as a source for making highly absorbent products is the environmentally friendly nature of the raw material. Since cellulose is produced naturally by photosynthesis, its usage in place of petroleum-based chemicals has the potential to reduce the net production of carbon dioxide [15]. Based on the assumption that the forests from which wood is obtained are replanted and managed in an efficient and sustainable manner, such practices have the potential to minimize the production of greenhouse gases over the long term.

Although biodegradability has been viewed as an inherent advantage of cellulose-based products, compared to petroleum-derived SAP, a critical examination is needed of each case. On the one hand, native sources of cellulose (e.g., wood, cotton, bacterial cellulose, etc.) all are subject to natural decay [16, 17]. Researchers have shown that various cellulose-based sorbent materials are biodegradable [18–27]. Acrylamide-based or acrylic acid-based materials generally exhibit slow degradation rates [28–31]. However, under well-managed composting conditions, favorable rates of decomposition acrylic acid-based disposable diapers, including detoxification, have been reported [32, 33].

Rates of biodegradation of polymers, including natural polymers, will be affected by chemical modifications. For instance, carboxymethylcellulose is readily degraded

by cellulase enzymes [34]. But other chemical transformations, such as chemical derivatization and cross-linking (see later sections), sometimes have a negative effect on biodegradation [35]. A further difficulty is that SAP-containing products are often buried under conditions where any degradation is either very slow due to lack of oxygen or where decomposition results in the production of methane, which is a highly potent contributor to global warming [16, 17, 28]. There is a continuing need for environmental impact assessments to compare petroleum-based superabsorbent products and similar products based on CMC or other natural-based materials [36, 37]. Future studies will be needed in order to confirm the working hypothesis here that (a) cellulose-based absorbent products are likely to be more biodegradable than currently used SAP materials and (b) the greater biodegradability can have an important ecological advantage either when using state-of-the-art waste disposal practices. Future alternative processes might be based on composting [32, 33, 38, 39] or anaerobic treatments with efficient retrieval of methane [40, 41]. Incineration is often regarded as unattractive due to the high water content of used SAPs [42].

2.2 Chemical Aspects

Two main aspects of cellulose that are likely to be important for the preparation of absorbent products will be considered in this section – the generally hydrophilic nature of cellulosic materials (with attention to the role of –OH groups) and the ionically charged nature of many cellulosic materials, with particular focus on $–COO^-$ groups.

As is well known, pure cellulose is a homopolymer of anhydroglucose units that are joined together by β-glycosidic bonds. Each six-carbon glucose unit contains three –OH groups. Native cellulose from wood commonly has degree of polymerization (DP) values in the range of about 3000–5000 [43]. In woody plant materials, cellulose is present in combination with hemicellulose and lignin, of which the hemicellulose generally causes the mixture to be more hydrophilic [44, 45] and the lignin causes the combined material to be more hydrophobic [46]. Cellulosic plant materials also contain relatively small amounts of extractives, most of which contribute to a hydrophobic tendency [47]. The percentages of these components, in typical wood from temperate climates, fall into ranges of about 40–45% cellulose, 25–35% hemicellulose, 20–30% lignin, and 2–5% extractives [48]. Cotton represents a special case of cellulosic material; as a seed hair material, it consists mainly of cellulose, but in nature it has a hydrophobic coating of wax [49].

Processing of cellulosic materials can change their chemical composition greatly. For example, the kraft pulping of wood and other materials such as sugarcane bagasse and bamboo is intended to remove mainly the lignin portion, along with most of the extractives and a portion of the hemicellulose [48, 50]. By contrast, mechanical pulping of wood typically achieves separation of the fibers from each other while maintaining a yield of over 90% of the original solids. Processing of cotton typically entails removal of the natural wax [49].

2.2.1 Hydrophilic –OH Groups

Due to its polar nature and its ability to participate in hydrogen bonding, the –OH group is well known to contribute to the water-loving nature of many organic compounds [51]. The greater electronegative character of the oxygen atom, compared to that of hydrogen, creates a dipole of approximately 1.7–2.5 D [52]. In aqueous solutions, such dipoles contribute to a transient (pico-second duration) lining up of –OH groups belonging to the water, as well as to other compounds [53], and the energy of such interactions contributes to wetting and solubilization of various materials in water. Due to its partly crystalline structure (see later), the cellulose does not dissolve, though it is generally agreed that the polar interactions are favorable for the swelling of cellulosic materials in water [54].

A second way that –OH groups can contribute to hydrophilic character is via hydrogen bonding. The hydrogen atom is unique in nature in having only one electron per atom. When a hydrogen atom is covalently bonded to oxygen, a more electronegative atom, the pair of electrons participating in bonding (or the density of the wave function) tends to spend a disproportionate amount of time or be enriched near to the oxygen [55]. This leaves the hydrogen nucleus (a proton) relatively exposed and available for secondary interactions with the lone pairs of electrons on the oxygen atoms of other water molecules in the neighborhood. The hydrogen bonds thus formed have energies ranging from about 1.4 to 7 kcal/mole [56]. The lifetime of an individual hydrogen bond in the bulk phase of water is about 0.4×10^{-12} s [57]. The ability of hydrogen bonds to very rapidly form and detach from each other, in a continually shifting structure, helps to account for the strong cohesive forces within water, in combination with an ability to flow as a liquid, if not frozen. Figure 1 provides a pictorial representation of an –OH group-rich cellulosic surface with a "snapshot" of possible orientations of water molecules as they participate in transient preferential orientations with the surface groups and as clusters with each other [53].

Though there are three –OH groups for each anhydroglucose unit that comprises cellulose, only a small portion of such groups are typically available for interaction with the surroundings, including water molecules. That is because a large proportion of such groups will be arranged in highly organized patterns of intramolecular and intermolecular hydrogen bonding within the cellulose phase [58]. Typical native

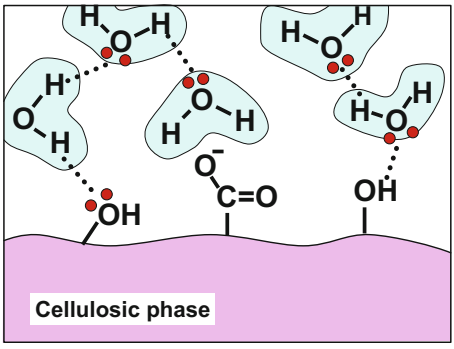

Fig. 1 Schematic diagram illustrating a possible transient orientation of water molecules at a cellulosic surface under the influence of polar interactions and hydrogen bonding

celluloses have crystalline contents in a range of about 40–80% [59], and it is clear that –OH groups located in the interior of such regions have essentially no ability to participate in interactions with water molecules [60].

2.2.2 Charged $–COO^-$ Groups

Native cellulose, in its raw forms, is of neutral charge in aqueous suspension. However, ionic functional groups attached to cellulose chains can play a large role in the ability of cellulosic materials to swell in water. To begin with, hemicellulose macromolecules of various types either already contain carboxylic acid functionalities or they contain acetate groups that can be easily converted to charged form by hydrolysis reactions [61]. Further amounts of $–COO^-$ groups are provided by lignin structures [48] and by various extractives, such as fatty acids and resin acids [47, 48]. Table 2 provides some typical values for the amounts of $–COO^-$ groups within native woods, compared to those in a cellulose derivative and polyacrylate.

The energy associated with the interaction of a $–COO^-$ group (in its Na^+ salt form) with surrounding polar water molecules is approximately 4 kcal/mole [65]. This value may at first suggest that ionic groups will have a large influence on swelling and absorbency properties of cellulosic materials. But that will be true only when the densities of such groups are either naturally high (e.g., due to the presence of hemicellulose) or that there has been chemical derivatization of the cellulosic material. Common cellulosic fiber materials have carboxylic acid contents ranging from just 5 μeq/g in the case of cotton to about 44–66 in the case of bleached hardwood kraft pulps [62]. These are very low values in comparison to SAPs, as shown in Table 2. Thus, for purposes of achieving high absorbency of water, there is a strong motivation to consider chemical derivatization as a means of increasing the charge density and increasing the absorption capacity of native cellulose.

Figure 2 depicts the main reaction for the preparation of carboxymethylcellulose (CMC), usually starting with dissolving pulp (e.g., highly delignified wood pulp) [66]. Commercial grades of CMC are widely available. The degree of substitution (per anhydroglucose unit) can range from about 0.4 to about 2.2 [18, 63, 64]. A DS value of 0.4 is generally high enough to allow solubilization of the polymeric material, as long as the pH is high enough to dissociate the carboxylic acid groups. But it is the relatively high-DS CMC products, with their correspondingly higher swelling tendency and strong solubility in water, which are regarded as promising components of highly absorbent hydrogels [18]. Such hydrogels are often cross-linked by application

Table 2 Typical levels of carboxylic acid groups in common cellulosic materials

Type of cellulosic material	Carboxylic acid content (μeq/g)	Citation
Cotton linters	5	[62]
Bleached softwood kraft fibers	29	[62]
Bleached hardwood kraft fibers	44–66	[62]
Unbleached softwood kraft fibers	83	[62]
Carboxymethylcellulose (DS 0.64–2.2)	3277–8127	[18, 63, 64]
Polyacrylic acid, sodium salt	10,600	Calculated

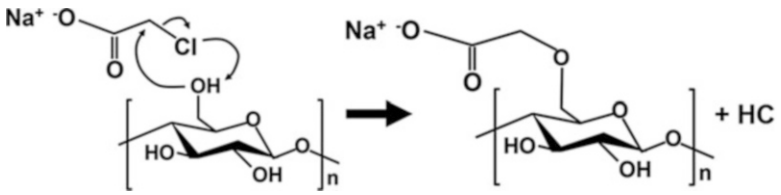

Fig. 2 Alkali-catalyzed reaction of cellulose with chloroacetic acid (sodium form) to produce carboxymethylcellulose (CMC)

of gamma radiation [16, 18, 19, 64, 67]. Though highly absorbent materials also can be obtained with other ethers and esters of cellulose, the results generally have not been as favorable as those achieved with CMC [68].

An alternative way to increase the level of carboxylic acid groups at the cellulose surface is by grafting. For example, Gurdag et al. [69] and Margutti et al. [70] carried out pioneering work in the grafting of acrylic acid chains to cellulose. The resulting structures from such reactions show greatly enhanced water-absorbing capabilities.

Another chemical reaction that has important implications for cellulose-based absorbent products is formation of sulfate ionic groups, which are often referred to as sulfate half-esters [71]. As will be described more in Sect. 2.3.4, treatment with concentrated sulfuric acid is widely used for the preparation of cellulose nanocrystals (CNCs). In addition to liberating the crystals, such treatment yields cellulosic surfaces that are covered with $–OSO_3^-$ ionic groups. Since sulfuric acid is a strong acid, such groups maintain their negative charge throughout the range of pH values considered by most investigators. Zhang et al. [72] showed that sulfate half-ester groups can be especially effective in increasing the water retention value [73] of bleached kraft fibers.

2.3 Structural Aspects

Absorbency typically involves swelling of an absorbent material, i.e., a change of it dimensions as the liquid enters. It follows that structural aspects of cellulosic materials, including their ability to expand or their tendency to restrain expansion, can affect absorption performance.

Some aspects of cellulose material structure are determined by its chemical composition, while others are related to details of plant growth. Yet others are related to the higher-level organization of cellulose, hemicellulose, and lignin into fibers and larger parts of woody plants. Further structural details depend on how the cellulosic material may have been separated into component fibers (i.e., pulping) or subsequently converted to nanofibrillated or nanocrystalline forms. These structures, if present, may affect properties of the absorbed products, so some aspects will be considered here.

2.3.1 Inherent Structural Tendencies of Cellulose

Cellulose is inherently fibrillar. This characteristic becomes clear if one attempts to prepare spherical cellulose structures at a nanoscale [74]. When cellulose is precipitated from solution, usually by introducing a non-solvent or otherwise changing the conditions of the medium, the precipitated matter is generally in the form of fibers or an extruded filament or sheet composed of fibrillar elements at the nanoscale [75]. This behavior can be attributed, at least in part, to details of cellulose's molecular structure – which is linear, free of branches, and having –OH groups in a suitable position to form both intra-chain and interchain hydrogen bonds [58]. The intramolecular bonds tend to hold the molecules in a straight-line position. The tendency for linear alignment is reinforced by the action of hydrogen bonding that can develop between adjacent cellulose molecules, especially if the chains are lined up in parallel. The molecular conformation, including the participation of hydrogen bonds in that conformation, has been confirmed by X-ray crystallography [58] as well as by molecular dynamics simulations [76].

During biosynthesis of cellulose, there is evidence that individual cellulose chains are formed from glucose in six-sided rosette-shaped proteinaceous structures in the cell walls of plants [77] and that the extruded chains somehow come together in a parallel, proto-crystalline form [78]. The result, in typical plant materials, is the formation of crystalline zones having widths of about 3–8 nm [79]. In woody plants, these crystalline zones are enmeshed within a matrix of noncrystalline components, mainly consisting of hemicellulose and lignin [48]. In addition, X-ray crystallography consistently indicates that some of the cellulose is also present in either a noncrystalline (amorphous) form or at least having defects in the pattern of crystallinity [79]. For instance, Nishiyama et al. [80] found evidence that sequences of approximately 4–5 anhydroglucose subunits tend to deviate from crystallinity within native cellulose material and that the adjacent parts of the chains are within crystalline zones. It is widely believed that these noncrystalline zones of cellulose have an enhanced tendency to interact with water [60, 81, 82].

At nano-dimensions, the ability of cellulosic materials to swell and accommodate water is generally attributed to either (a) swelling of noncrystalline zones or (b) opening up of spaces between crystalline zones, i.e., a form of partial nanoscale delamination.

2.3.2 Fibers

A typical softwood kraft fiber of the "fluff pulp" type [7] will readily take up about 12 g or water per g of solid matter [1, 5]. Though this value is high enough to meet Kabiri's [1] criterion of superabsorbency, as given earlier, it is well known that water can be easily squeezed from fluff pulp. To understand why fluff pulp takes up water so readily, it can be useful to consider the layered structure of natural fibers in wood, as illustrated in Fig. 3.

The mechanical ability of kraft fibers to increase their radial dimensions when exposed to aqueous solution can be understood based on the directionality of cellulose macromolecules and microfibrils within the dominant (S2) sublayer of the cell wall [83]. Within that layer, the chains are oriented not far from a parallel

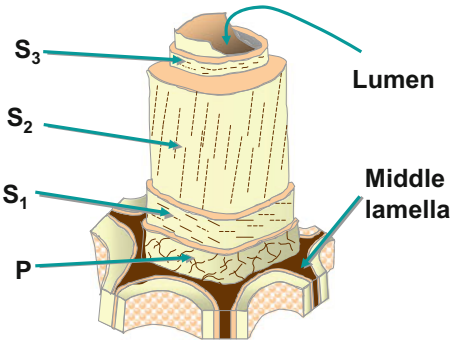

Fig. 3 Schematic diagram of a fiber within wood, showing the relative thicknesses of different layers and indicating the predominant orientation of cellulosic macromolecules and fibrils in those layers

alignment (often deviating by 10–15°) from the fiber axis. Since the stiffness and crystalline content of the fibrils prevents them from stretching much in the lengthwise direction, most expansion resulting from immersion in water occurs perpendicular to the fiber length. Within intact wood such swelling is limited by three factors, namely, (a) the presence of a stiff, relatively hydrophobic lignin-rich zone (the middle lamella) that joins the fibers to each other; (b) the presence of an S1 layer, in which the cellulose macromolecules and microfibrils essentially wrap around the fiber circumferences, thus constraining their outward expansion; and (c) the close integration of the cellulose microfibrils with densely packed matrix materials, mainly lignin and hemicellulose. Eriksson et al. [44] showed that selective removal of lignin from solid wood greatly increased the uptake of water. Chemical pulping, employing such reagents as NaOH and Na_2S, can effectively remove lignin and a part of the hemicellulose, thus rendering the material porous within a range of about 2–100 nm [84]. The mesoporous nature can be regarded as a first step in enabling subsequent internal delamination and swelling of the fibers.

Delamination and swelling of delignified fibers is further enabled if and when the fibers are subjected to mechanical refining, which is an almost universal practice when preparing the fibers for papermaking. Common refining practices entail passage of a 4–8% solid suspension of fibers between a rotor and stator having raised rectangular "bar" areas, which repeatedly compress and shear bunches of the fibers. Even a relatively short application of refining, especially after delignification, is able to break up and remove both the primary (P) layer and the S1 sublayer, such that the remaining material in the S2 layer is no longer impeded from expanding outward from the fiber axis. The shearing action of refining also tends to open up spaces between fibrils within the S2 layer, causing partial delamination. Concurrently, the fibers become increasingly swollen with water.

At this point in the discussion, a reality check may be helpful. Although an ordinary paper towel can take up about 5–10 times its mass of water [85], this is only a minor fraction of what is expected for modern superabsorbent materials, e.g., an absorbency mass ratio of 100–1000. While kraft fibers may constitute a major component of such products as disposable diapers, it is clear that they do not account for the majority of the absorbency. Fluff pulp fibers, which are about 3 mm long and about 30–50 μm thick, provide three main functions within highly absorbent

products: providing a place for the SAP to be contained, serving as channels for the wicking of liquid so that it can reach all the SAP quickly, and providing structure to the highly absorbent garment.

2.3.3 Nanofibrillated Cellulose (NFC)

Very extensive mechanical refining of cellulosic fibers, such as from kraft pulps, cotton, and other plant sources, will eventually yield a highly swollen, gelatinous mass that is mostly water but highly viscous [86, 87]. The solid material within such gelatinous mixtures is highly fibrillated cellulose, in which the individual strands may have diameters in the range of 20–60 nm [88]. Rather than consisting of individual fibrils, most published images of NFC (or microfibrillated cellulose, a term often used when the material has not yet been reduced to nano-dimensions), the material is usually described as a network, or "highly branched," or a "weblike structure" [88]. Although the term "cellulose nanofibrils" (CNF) is widely used in the literature for the products of such preparations, that term does not appear to be well suited to describing the highly branched and networked structures most often described in the studies that were considered when preparing this chapter. Equipment used for production of NFC includes not only conventional refiners, of the type used by papermakers, but also "micro-grinders," in which the pulp is passed multiple times through the gap between a rotor and stator with abrasive mineral surfaces [89]. Alternatively, as shown in Fig. 4a, NFC can be produced by multiple passes through a high-pressure homogenizer, where the suspended material is forced through a narrow gap, within which the solids impinge on a hard surface [90]. In another type of device, the microfluidizer, jets of cellulose suspension are made to impinge upon each other, bringing about mutual fibrillation with less wear of the equipment (Fig. 4b) [91]. In a patented approach, highly fibrillated cellulose also can be prepared by co-grinding in the presence of a suspension of calcium carbonate particles [92].

The production of NFC by mechanical action alone requires a high input of energy [88]. For instance, 70,000 kWh may be required to prepare NFC by homogenization [44]. Such a high consumption of energy is not only environmentally unfavorable, but it also tends to reduce the chance that NFC would be employed as a component in future highly absorbent products. To reduce the required energy, several approaches involving chemical treatments have been demonstrated. Selective oxidation with (2,2,6,6-tetramethylpiperidin-1-yl)oxyl (TEMPO) has been shown to be particularly effective in promoting fibrillation of cellulose with much less energy. Such treatment was found to decrease the required mechanical energy to product NFC by as much as a factor of 100 [93]. The much reduced energy of processing of the oxidized pulp has been attributed to the ionic charges of the $–COO^-$ groups (especially at pH values above about 4), which promote swelling, fibrillation, and internal delamination. The water retention value of NFC, produced by such treatment, can be in the range 1700% [94]. The oxidation reaction is diagrammed in Fig. 5. As shown, the TEMPO-mediated oxidation selectively forms carboxylic acid groups at the C6 position, while having only a minor effect on the anhydroglucose rings of the macromolecule [93]. Similar effects have been

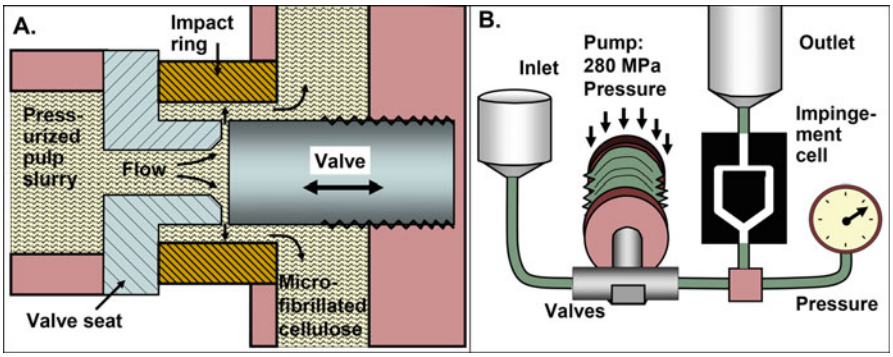

Fig. 4 Two devices for production of nanofibrillated cellulose (**a**) high-pressure homogenizer; (**b**) microfluidizer

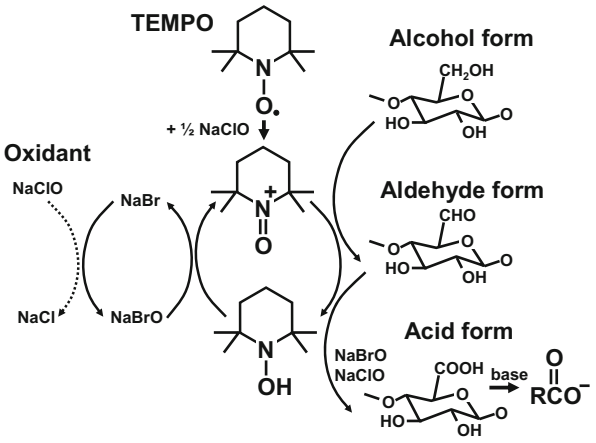

Fig. 5 Reaction scheme for TEMPO-mediated oxidation of a cellulosic material

achieved by treatments with periodate/chlorite oxidation [95, 96] and by carboxymethylation [97].

Another promising approach consists of an optimized treatment with cellulase enzyme [98]. Such treatments must be performed with careful attention to concentrations, temperatures, treatment times, etc., since the enzymes preferentially attack noncrystalline and nanoscale fibrillar parts of the cellulose. Thus, excessive treatment can be expected to break down and solubilize the class of material that one is attempting to form. Pääkkö et al. [98] showed that the optimized use of cellulase, in combination of mechanical energy, can make it possible to produce NFC with less energy consumed.

2.3.4 Cellulose Nanocrystals (CNCs)

Digestion of cellulosic material in strong acid, under optimized conditions, gives rise to cellulose nanocrystals, which also can be considered as a component in certain

highly absorbent materials. The technology of producing CNC has been reviewed [99, 100]. Briefly stated, the strong acid treatment preferentially hydrolyzes the noncrystalline or defect areas in the material, leaving behind crystals having thickness dimensions in the size range of about 4–70 nm [99, 101]. Though the acid eventually would also hydrolyze the crystals, the rate of hydrolysis is sufficiently slower so that it is possible to isolate suspensions of highly uniform crystals. Cheng et al. [102] reported a water retention value of 3.4–3.5 g/g for a water suspension of CNC.

The lengths of CNCs vary widely, depending on both the source material employed and the conditions of preparation [99, 101]. It is possible to shorten the crystals after their preparation by crushing them in the presence of liquid nitrogen [103]. The longest CNC particles, up to several micrometers, have been reported for tunicate cellulose, obtained from the protective spines of marine animals [99, 101]. Lengths of CNCs obtained from wood (after delignification) are typically in the range 100–250 nm [99].

3 Absorbency Mechanisms

The uptake of aqueous solution by cellulose-based products is affected by the chemical groups and structural factors discussed in the previous two sections. As has been described in more detail elsewhere [5, 104–110], one can envision there being competition between certain chemical factors tending to solubilize and swell the material and various structural contributions that prevent complete dissolution and may limit the amount of swelling in a specific case. The chemical factors will be considered here first.

3.1 Hydrophilicity

As was mentioned in Sect. 2.2.1, the formation of a hydrogen bond between a water molecule and an available –OH group on a cellulosic surface releases approximately 5 kcal/mole of energy. This implies that the wetting of dry cellulosic material is favored by the ability to form such bonds with water. One of the greatest uncertainties, when trying to estimate the relative importance of hydrogen bond formation as a contributor to the uptake of water by cellulosic materials, is the fact that only a fraction of the –OH groups on cellulose chains may be available to participate in such interactions. In such materials as wood and cotton, roughly 70% of the cellulose may be in crystalline form, and it has been shown that crystalline regions are essentially impenetrable to water molecules [60]. On the other hand, typical plant-derived cellulose is likely to contain hemicellulose (except in the case of certain dissolving pulps and cotton), and the hemicellulose remains amorphous and much more able to interact with water molecules. A search of the literature did not indicate any work to estimate the density of water-to-cellulose hydrogen bonds formed upon the immersion of common cellulosic materials. Thus, this would appear to be an

excellent area to proposed future research. In particular, it is reasonable to expect that measures to reduce the crystallinity of cellulose, e.g., by chemical derivatization or ball milling [111], would be expected to increase the amount of water-to-cellulose hydrogen bonds in a given mass of material.

The interaction of a water molecule with an ideal cellulosic surface, creating a monolayer coverage, will be energetically favored by hydrogen bonding, but what about subsequent layers of water? Studies of the energetics of water sorption, at a molecular level, indicate that the adsorption of a first and possibly a second layer of water can involve different amounts of energy, compared to the energy of water association with itself in the bulk of solution [112]. However, such differences tend to become unimportant after about five molecular layers of water [113]. This is a key point if one's goal is to achieve superabsorbency. Even if the cellulose-based material has been transformed in a way to make every –OH group available for interaction with water (essentially solubilizing the material), the hydrogen bonds subsequently formed with one, two, or even three layers of water molecules surrounding each cellulosic –OH group (including those from hemicellulose, if present) might not be enough to achieve superabsorbent behavior.

3.2 Dissociation

Another large contribution to the energy of interaction between water molecules and a cellulosic surface can come from ionized groups. As noted in Sect. 2.2.2, the energy of solvation of an individual ionic group in water is about 4 kcal/mole. Whether this is enough to make an important contribution depends not only on how many such groups are present, but also on whether or not the groups are in their charged form. As mentioned earlier, although native cellulose is essentially uncharged, there can be up to about 1000–3000 μeq of carboxylic acid groups per gram the hemicellulose component in typical papermaking pulps [114]. This amount will depend on the type of hemicellulose and whether or not acetyl groups have been hydrolyzed during processing to convert them to –COOH or $–COO^-$ groups [61]. Salam et al. [115] showed that increased absorbency can be achieved by incorporating additional carboxylate groups into hemicellulose.

Carboxylic acid groups can undergo dissociation reactions of the type shown in Eq. 1. In its protonated form, though the carboxylic acid group is capable of participating in hydrogen bond formation [116], it is uncharged. Reaction with one mole of alkali converts the group to its charged, carboxylate form. In the discussion that immediately follows, it will be tentatively assumed that sufficient base is present that the groups are at least mostly in their charged form.

$$RCOOH + NaOH \rightarrow RCOO^- + Na^+ + H_2O \quad (1)$$

In order for there to be a sufficient density of ionic groups to meet the requirements of superabsorbent materials, the carboxylic acid content has to be much higher than what is found in natural cellulosic materials. Most research for the

development of highly absorbent cellulose-based materials have been based on carboxymethylation [3]. Superabsorbent materials with water uptake ratios in the range 20–800 have been achieved with the use of carboxymethylcellulose (CMC) [18, 19, 63, 64, 67, 68]. Even higher levels of water uptake have been achieved with copolymers of CMC and acrylic acid or related monomers [25, 117–129]. In such cases, the level of carboxymethylation is typically in the range of 0.64–2.2 substitutions per anhydroglucose unit. Water absorption capacities in the range 40–1400 g/g have been reported with SAPs based on ordinary CMC.

3.3 Osmotic Pressure

Bound ionic charges within a polymeric material, when it is placed in pure water, create an imbalance of ionic charges vs. location. Because the bound charges cannot move away from the polymer segments, the counterions to the bound groups will be constrained to remain nearby, and there will be a higher concentration of ions in the neighborhood of the polymer segments compared to the bulk of solution. To rectify the imbalance, water molecules will spontaneously diffuse into the charged polymeric material, swelling it, thus increasing the average distance between adjacent charges. Since the range of electrostatic effects can extend to several nanometers, especially in relatively pure water, such effects can involve high ratios of water mass to solid mass, leading to high swelling ratios. Related theories have been applied to hydrogels, including cellulose-based materials [104, 109, 130–134].

The contribution of charged groups to the swelling of a charged polymeric material in water can be expressed in terms of an osmotic pressure, as given by Eq. 2 [109].

$$\pi = RT\left[\Phi\sum_i \overline{C_i} - \phi\sum_i C_i\right] \tag{2}$$

In the equation, Φ is the osmotic coefficient of the external solution, and ϕ is the corresponding quantity for the gel phase. Likewise, $\overline{C_i}$ is the concentration of the ith species in the gel phase, and C_i is the corresponding value in the bulk phase. In principle, the material will continue to expand until there is a balance between the osmotic pressure and a restraining pressure, which may be related to the strength of the material or the manner in which it may be attached together. For example, cross-linking of the macromolecular material may limit its ability to stretch past a certain extent. Alternatively, one might model the solid material in terms of mechanical springs, which represent the resistance to swelling. Scallan and Tigerström [135] showed that such reasoning can be used to estimate the elastic modulus of absorbent cellulosic material in its water-swollen state. Other contributions to net swelling of a hydrogel are contributed by the entropy of mixing and hydrogen-bonding effects [3].

4 Factors Affecting Swelling Extent

The extent of swelling and absorption capacity of cellulose-based materials, including cellulosic fibers and various kinds of hydrogels, depends on many factors, some of which involve the nature of the absorbent materials, and others that depend mainly on what is in the aqueous environment. It will be assumed here, for the sake of discussion, that some form of cross-linking usually will provide the main resistance to swelling. As pointed out by Scallan [104], similar reasoning can be applied to other situations, such as when diffusion of a charged polymeric material is constrained by a semipermeable membrane.

4.1 Cross-Link Density

As outlined in an earlier review [3], several different kinds of cross-linking agent have been employed in published studies of cellulose-based hydrogel materials. Typically, when considering cross-links, one is interested in compounds capable of forming pairs of covalent bonds, thus connecting polymeric segments to each other. In addition, it is important to also consider the role of nanocellulose, which has been shown in some studies to produce effects that have similarities to those of cross-linking agents.

4.1.1 Conventional Links

As illustrated in Fig. 6, with increasing density of cross-linking among the polymeric chains of the material, there is less and less distance that the adjacent chains can move away from each other, on average, before they reach their limit. Studies of cellulose-based hydrogels generally have shown strong correlations between cross-link density and absorption capacity [18, 19, 26, 64, 136, 137]. The highest absorption capacities reported tend to be observed at the lowest cross-link densities considered [19]. One needs to be cautious, however, since the lower limit of practical cross-link density may be governed by how much cross-linking is needed to avoid

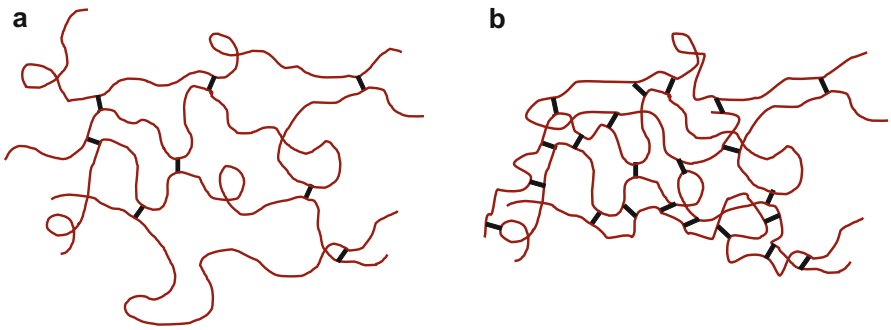

Fig. 6 Schematic illustration of the effects of cross-link density on the swelling ability of hydrophilic polyelectrolyte chains (**a**) low density; (**b**) higher density or cross-linking

mechanical failure or outright dissolution of the gel material [138]. At the limit of low cross-linking density, the molecular mass of the charged polymer needs to be high, thus ensuring that most of the chains are bound by at least one covalent link to the rest of the material. A higher molecular mass has been shown to lead to higher absorption capacity of cross-linked CMC hydrogels [26].

4.1.2 Cellulose-Based Links

Some studies have shown that inclusion of nanocellulose within hydrogel formulations tends to reduce the uptake of water [2, 139–143]. In such cases, the role of the cellulosic material appears to be similar, in some respects, to that of cross-linking agents. Since no covalent bonding is suspected in most such cases, other explanations must be considered. One such possibility is to regard the nanocellulose as a reinforcement within a kind of composite, where superabsorbent polymer may play the role of matrix. There are many examples in which the presence of fibrillar nanocellulose tends to increase the modulus of elasticity of the continuous phase in cellulosic nanocomposite systems [144]. It also has been proposed that the presence of ordinary cellulose fibers within conventional disposable diapers and related products will tend to limit the swelling due to the fibers' resistance to tensile expansion [134]. The high aspect ratios of a cellulose nanofibril, as long as it is intimately associated with the swellable material, are assumed to be important relative to the restraint of swelling.

4.2 Aqueous Conditions

Water can be regarded as a uniquely effective medium for absorbing into and swelling up materials that are inherently hydrophilic and subject to the development of bound ionic charges, i.e., the kinds of highly absorbent materials being considered here. One reason why water is such a welcome guest within hydrogel materials is that it has a high dielectric constant, ε, thus making it an excellent solvent and stabilizer for ionic materials. But changes in the ionic composition of aqueous solutions can have very large effects on uptake by cellulose-based hydrogels and other absorbent materials. Three key factors to be considered in this section are pH, salt concentration, and the presence of multivalent cations.

4.2.1 pH

The proportion of charged carboxylic acid groups on cellulosic materials of various kinds is known to be a strong function of pH. The same principles apply to kraft fibers, CMC, and even to poly(acrylic acid). Kraft fibers, especially if they are rich in carboxylic acid groups, exhibit increased swelling as the pH is raised from acidic to neutral values [145, 146]. A similar trend, but with much higher levels of swelling, has been reported for CMC and for copolymers of CMC and acrylic acid [30, 63, 125, 126, 129, 147, 148].

Effects of pH can be understood based on Eq. 1, which can be rearranged as shown in Eq. 3 to define the acid dissociation constant K_a.

$$K_a = \left(\frac{[A^-][H^+]}{[HA]} \right) \tag{3}$$

The pK_a value can be defined by taking the logarithms of the terms in Eq. 3, where $[A^-]$ is the concentration of the conjugate base, $[H^+]$ is the concentration of the hydronium ion, and [HA] is the concentration of the associated form of the carboxylic acid.

$$pK_a = -\log_{10}(K_a) = \quad -\log_{10} \frac{[A^-][H^+]}{[HA]} \tag{4}$$

In general, there will be an equal number of charged and uncharged carboxyl groups when the pH is equal to the pK_a value, which is approximately 4.4 in the case of CMC [149].

Based on Eq. 4, one might predict that the relative amount of dissociated $–COO^-$ groups ought to increase from 1% to 99% within the pH range of one less than pK_a to one more than pK_a. That would be true if all of the carboxyl groups were equal and noninteracting. But the dissociation of one carboxyl group on a polyelectrolyte chain changes the electrical field in that part of the molecule and tends to discourage the subsequent dissociation of neighboring carboxyl groups [150]. The situation is analogous to the dissociation of citric acid, a compound with three carboxylic acid groups, along with three values of pK_a corresponding to the first, second, and third dissociation. The consequence, in the case of a relatively high-charge-density polycarboxylic acid compound such as CMC or polyacrylic acid, is that the charge-pH curve will tend to be spread out over a wider pH range compared to what would be expected for a simple monomeric compound such as acetic acid. On the other hand, once the pH is as high as 7 or higher, most of the carboxyl groups will be in their charged form.

Investigators sometimes claim that their hydrogels are “smart” due to their ability to respond to pH [151]. For instance, hydrogels that contain carboxylic acid groups tend to remain unswollen in the stomach, which is a highly acidic environment, but they become highly swollen (perhaps releasing a medical agent) in the alkaline environment of the intestine [152–155]. Such behavior is consistent with the dissociation of carboxyl groups when the pH is raised.

4.2.2 Salts

The presence of simple salts such as NaCl tends to limit the range over which electrostatic forces are able to act within aqueous media. The effect can be expressed as Eq. 5, where z_i is the valence of ions opposite to that of the charged body of interest, n_i is the concentration of that ion, e is the electron charge, ε is the dielectric constant of water, k is the Boltzmann constant, and T is the absolute temperature [156].

$$\kappa^{-1} = \left[\Sigma_i \left({z_i}^2 n_i \right) 4\pi e^2 / (\varepsilon kT) \right]^{-0.5} \tag{5}$$

The quantity κ^{-1} is proportional to the distance over which electrostatic forces maintain a given level of influence. It follows from Eq. 5 that osmotic effects, especially those that involve high ratios of water uptake to the mass of absorbent materials, ought to be diminished by the presence of increasing concentrations of salt. Indeed, there is ample evidence of the ability of salts to repress swelling, including such evidence in the case of cellulose-based superabsorbent hydrogels [128, 129, 157]. Many researchers are especially interested in comparing pure water to physiological saline, which is intended to represent typical electrolyte concentrations in human bodily fluids, e.g., the liquid within cells. In that case, various studies have observed an approximately 50% reduction in the amount of water taken up by CMC-based hydrogels with the addition of that amount of salts [3].

4.2.3 Complexation

A much greater repression of swelling can be expected if the aqueous solution contains multivalent cations [25, 125, 131, 151, 159–161]. The term "complexation" is often used when describing such interactions due to the fact that two or more carboxylate functions within the absorbent material may approach one multivalent positive ion simultaneously, thus forming a reversible bridge. Even in the case of divalent ions, such as Ca^{2+}, the effect can be strong enough to be able to prepare strongly bonded "wet wipes," which can be redispersed as fibers only when they become highly diluted with water of much lower Ca^{2+} content when they are flushed [162]. Even stronger deswelling effects have been reported when adding water-soluble aluminum products [151, 158]. Coagulant mixtures based on aluminum are known to contain ions such as Al^{3+} and $[Al_{12}(OH)_{24}AlO_4(H_2O)_{12}]^{7+}$ [163, 164]. The bottom line is that multivalent positive ion concentrations ought to be low when the goal is to achieve high levels of water uptake.

4.3 Temperature

The temperature can have various effects on water uptake capacities, and in some cases the effects can be dramatic. For instance, hydrogels prepared with poly-(*N*-isopropylacrylamide) (iPAM) have been reported to abruptly lose 80–90% of their capacity to absorb water when heated over a range of about 20 °C [165, 166]. Such effects have been attributed to changes in the elastic properties of the hydrogels [167]. In the case of typical CMC-based hydrogels, moderate increases in sorption capacity with temperature have been observed [64].

5 Factors Affecting Rates of Uptake

In many applications of superabsorbent hydrogels, one needs to be concerned not only with the amount of water taken up but also the rate of sorption. The topic of absorption rates by highly absorbent materials has been considered by others [110, 129, 168]. Although ordinary SAP materials can have very high capacity to take up

water, they sometimes can be very effective for blocking the flow of water. For instance, if a disposable diaper gets flushed by mistake, it can easily swell up and obstruct a drain pipe. Once a mass of SAP has become swollen with water, it has been observed that flow from one side to the other, even when encouraged by pressure, can essentially stop [106]. As implied by the word "gel," the material behaves as an elastic material, despite its high content of water. Flow through a compressed, water-swollen mass of SAP can be very slow indeed, sometimes making it difficult for the contained liquid to migrate to parts of the products where dry SAP particles may still be present. So one of the big challenges faced by producers of highly absorbent items has been to allow flow to take place readily within a partly wetted mass of superabsorbent material. One solution to this problem is to create some kind of channels within the material.

5.1 Diffusion

Before considering the possible roles of cellulosic materials with respect to flow within a highly absorbent product, this section will consider factors affecting the diffusion of water through a hydrogel. In particular, engineers need to optimize the size and shapes of SAP phases so that water can diffuse all the way to the core within a practical length of time, depending on the application.

The characteristic time required for diffusion to occur over a distance L can be computed by the Stokes-Einstein version of the equation for diffusion [169].

$$\tau = L^2\, 6\pi\eta a/(k_B\, T) \tag{6}$$

In Eq. 6, τ is the characteristic time for diffusion to take place over a distance L, η is the viscosity of the medium, a is the radius of the diffusing object (modeled as a sphere), k_B is the Boltzmann constant, and T is the absolute temperature. Related calculations have been developed to deal with various geometries of interest, such as diffusion into either spherical or cylindrical SAP bodies [109]. Models are set up on the assumption that water needs to diffuse through a swollen layer in order to reach a core of still-dry SAP. In general, such analyses have emphasized that SAP phases ought to be relatively small and interspersed by zones in which bulk flow can take place. Such predictions are consistent with the work of Tanaka and Fillmore [170], who found that the time constant for swelling of poly(acrylic acid) gels was proportional to the square of the final radius of the SAP.

5.2 Channels

5.2.1 Cellulose-Enabled Channels

A primary role of softwood kraft fibers (fluff pulp) in typical highly absorbent products appears to be to provide wicking of liquids throughout the structure

[106]. The ability of cellulose fibers to facilitate the wicking of water can be appreciated if one looks with a microscope at highly wettable paper that has been printed with aqueous ink-jet ink. Letters printed on such paper will appear ragged, with "feathered" edges. It has been proposed that a related process occurs when fluff pulp fibers are included in a mixture of SAP particles [106]. In other words, the edges of the fibers are expected to provide relatively unobstructed passage of aqueous fluids so that all of the available SAP, as needed, can participate in the absorption. To enhance the effect, fibers can be designed with a lobe structure, which is claimed to provide especially efficient channeling of water. In summary, whereas before about 1960, cellulosic fibers served as the main absorbent material in diaper materials [8], now, in disposable absorbent products, one of their main roles appears to be to provide wicking.

5.2.2 Other Channels through Hydrogels

Progress also continues to be made with respect to the preparation of acrylic-based SAPs, and researchers have shown that the wicking role of fibers can be replaced by forming channels in a completely different way [171]. Instead of relying on fibers, the SAP itself is formulated with gas addition in a way that preserves a network of channels.

6 Strategies to Promote Absorbency

Increasing the accessibility and placement of functional groups onto cellulosic materials are both primary strategies that have been used to increase the water-sorptive capacity of cellulosic materials. Sometimes these two goals are connected. For instance, high levels of chemical derivatization of cellulose can be instrumental in bringing about solubilization of the macromolecular chain, thus exposing the material to water in a more intimate manner.

6.1 TEMPO-Mediated Oxidation

The option of TEMPO-mediated oxidation merits special mention, relative to water-sorptive properties, since it can be used in combination with mechanical processing to achieve not only a reduction in the need for mechanical energy but also a strong contribution to absorbency [172, 173]. For instance, Brodin et al. [173] showed that TEMPO-mediated oxidation of kraft pulp, as a pretreatment before freeze-drying, resulted in highly porous material having a sorption capacity of 21–65 g/g. Especially in cases where the goal is to achieve high levels of absorbency without reliance on complete solubilization of the cellulose, it has been shown that high levels of water uptake can be obtained by TEMPO-mediated oxidation of nanofibrillated cellulose, followed by freeze-drying [98, 174–176].

6.2 Specialized Drying

Once cellulose has been processed to achieve high levels of fibrillation and water retention ability, it often would make sense to be able to store and ship such material in dry form. Unfortunately, such drying ordinarily will tend to irreversibly decrease the water swellability of the material, when it is subsequently placed in water [84, 146, 177]. An irreversible reduction in the ability of the cellulosic material to take up water again, after it has been dried, has been attributed to strong capillary forces, causing the material to be drawn together to molecular distances; at that point a highly regular pattern of hydrogen bonding can take place between the cellulosic surface [178]. To some degree, such effects can be overcome if there is a sufficiently high density of carboxylate groups, in their dissociated form [146]. For example, Butchosa and Zhou [179] showed that treatment of NFC with CMC could help preserve the ability of the nanocellulose to act as a thickener, even after it had been dried. Other promising strategies include the addition of salt before drying [180], though such a strategy can have disadvantages in various potential applications.

Promising results have been achieved in the preparation of highly absorbent aerogels from nanocellulose [181, 182]. Some such compositions have exhibited superabsorbent characteristics [183, 184]. One of the advantages of such materials is that, in principle, one can achieve high absorbency with products that consist mainly of air and cellulose, such that many potential uses can be considered, including food and medical applications.

7 Conclusion

In view of the publications considered in this review chapter, much progress appears to have been made in the development of highly absorbent materials based on carboxymethylcellulose and other forms of cellulose. Ordinary cellulosic fluff pulp fibers, as well as various kinds of nanocellulose, can be used to adjust the properties of such absorbent materials. Factors affecting absorption capacities, as well as rates of wicking, appear to be in line with what is known about the individual components, as well as concepts of absorbency.

8 Future Scope

The subject of cost will be an important area of focus for future research related to cellulose-based highly absorbent products. Because various aspects of cellulose-based superabsorbents have been well demonstrated [3], the fact that such materials have not yet gained an appreciable market share suggests that costs must be unfavorable relative to acrylic-based SAPs. It may be useful in future studies also to consider costs that presently are not fairly distributed in the economy. Such a study could investigate how the relative costs would change if each producer of disposable materials had to arrange for or to directly pay the costs of disposal. Such a study

could estimate the impact on costs if bio-based, sustainable technologies were given favorable economic treatment, for instance, through tax policies. Though many readers of this chapter are likely to be more interested in questions concerning chemistry, it will be important to collaborate with researchers attuned to issues of economics, logistics, and ethical issues related to highly absorbent products.

There appears to be a critical need for fresh thinking and research concerning the best way to dispose of used items containing superabsorbent materials. It has been widely assumed, in published articles, that the cellulose-based products, being inherently biodegradable, are therefore ecologically preferable to petroleum-based SAPs and related absorbent products. But the use of disposable diapers, in particular, places challenges on the already heavily burdened system for solids waste collection and disposal. Studies have shown that even quite highly "biodegradable" materials can take a long time to degrade under typical landfilling conditions [185, 186]. When degradation does eventually occur, usually under anaerobic conditions, one has to worry about the efficiency with which the released methane is collected [187]. The ecological implications of such a system needs to be compared against state-of-the art wastewater treatment systems [188], as well as options such as composting [32, 33, 39]. A well-planned and regulated program of manufacture, collection after use, and composting of highly absorbent products made with 100% compostable components appears to be an attractive option that merits further research attention.

Abstract

Over the past century, hydrogels have emerged as an effective material for an immense variety of applications. This contribution provides a brief overview of recent progress in cellulose-based superabsorbent hydrogels, fabrication approaches, materials, and promising applications. Firstly, hydrogels fabricated directly from various polymerization processes are presented. Secondly, we review on the stimuli-responsive hydrogels such as the role of temperature, electric potential, pH, and ionic strength to control the role of hydrogel in different applications. Also, the synthesis route and its formation mechanism for the production of smart superabsorbent, macro- and nano-hydrogels are addressed. In addition, several applications and future research in cellulose-based superabsorbent hydrogels are also discussed in this chapter.

Keywords

Hydrogel · Polymerization reaction · Superabsorbent · Stimuli-responsive · Biopolymer

1 Introduction

Hydrogels are known as the water-absorbing polymeric materials that are able to form a flexible three-dimensional structure with about 90% of water in the gel base and 10% of polymer chains. The presence of cross-linking interaction between water and hydrophilic characteristic of polymer chains facilitates the water-insoluble product with significant mechanical strength and physical integrity [1, 2]. Since hydrogels can absorb up to 1000 times of dry weight in water, thus this water-absorbing polymers are favorable for a variety of applications, especially for human usage. There is rising demand for hydrogels to be used for personal care and hygiene (baby diapers, sanitary pads, adult incontinence pads, and soft contact lenses), pharmaceuticals (drug carrier system), food (gelatin dessert), agriculture (plant water crystals), and health-care products (scaffolds in tissue engineering, wound care dressings) [3]. In addition to the existing market demand toward the hydrogel, continuous R&D activities have created a new opportunity in the development of intelligent materials for the biomedical areas, such as therapeutics, sensors, microfluidic systems, nanoreactors, and interactive surfaces [4].

Among the various types of biomaterials (e.g., polymers, composites, ceramics, and metals), hydrogels have shown high biocompatibility, tunable biodegradability, improved water retention ability, controlled release (especially for medicine or nutrients), preservation of stored components, easy to modify due to the presence of polar hydrophilic surface, and so on [5]. However, the feasibility of applying hydrogels is still limited due to poor mechanical strength and the fragile nature of hydrogel. In addition, majority of the hydrogels are produced from synthetic polymers (e.g., polyethylene glycol, polyamides, poly(acrylic acid), poly (methacrylamide), poly(*N*-isopropylacrylamide), poly(hydroxyethyl methacrylate)), which is limited particularly in the food industry, due to the likelihood of impurities

in the final product that may cause toxicity and potential environmental hazards [6, 7]. Therefore, novel or natural hydrogels with improved characteristics are still needed and will continue to remain an important direction for research.

Natural hydrogels are mainly derived from natural resources, such as alginate, chitosan, carrageenan, collagen, protein/peptides, matrigel, fibrin, gelatin, hyaluronic acid, and cellulose fibers. These materials render long service life, high capacity of water absorption, biodegradable, high biocompatibility, and high gel strength, which are the green alternative for synthetic polymers [8]. Cellulose fibers are nontoxic and low-cost organic polymers in the form of polysaccharide, which consists of hundreds to thousands of glucose units $(C_6H_{10}O_5)_n$. It is an abundant lignocellulosic biomass which is found mostly in forestry wood, agricultural residues, industrial wastes, and municipal solid waste [9]. Cellulose consisted of active hydroxyl functional groups (–OH), which can easily develop desirable hydrogels with tailored properties and product structure by chemically modifying the functional groups or using various types of synthesis technologies. Thus, the utilization of green cellulose materials for hydrogels can overcome the limitation of synthetic hydrogels, with enhanced properties that satisfy the requirement particularly in food and biomedical industry [10].

In this chapter, different hydrogel preparation technologies for synthetic and natural hydrogels will be discussed. In addition, focus toward the cellulose-based superabsorbent hydrogel was highlighted with a closer discussion on different kinds of stimuli-responsive cellulose-based hydrogels. The relationship between cellulose structure with hydrogel characteristics (mechanical strength, viscoelasticity, stress-strain, and swelling ability) was covered in this study. Last but not least, application of cellulose-based hydrogels and cross-linking mechanism was also discussed herein.

2 Synthesis and Properties of Hydrogel by Various Polymerization Reaction System

Based on the classification, hydrogels are divided into three groups: synthetic, natural, and hybrid (a combination of synthetic and natural) [2]. The raw materials used to synthesize these three groups of hydrogels are either hydrophilic monomers or hydrophobic monomers. Basically, synthetic polymers possess hydrophobic features in nature with a stronger chemical interaction as compared to natural polymers. Thus, the stronger bonding of synthetic polymers always shows a poorer degradation as compared to natural polymers, with a higher durability [2, 8]. Thus, the challenges to develop hydrogels with both biodegradability and durability are the key requirements for various market demands. Various types of hydrogel preparation techniques are reported to cater to the desirable property range of hydrogels, which includes (i) chemical cross-linking, (ii) physical cross-linking, and (iii) other newly emerging technologies [6]. These processes involve the cross-linking of natural/synthetic polymer chains by different interaction such as electrostatic forces, hydrogen bonds, covalent bonds, hydrophobic interactions, or chain entanglements. The

Table 1 Examples of polymers, initiator, and cross-linkers for hydrogel production

Synthetic [12]	**Natural** [13, 14]
Poly(hydroxyethyl methacrylate) (PHEMA) Poly(vinyl alcohol) (PVA) Poly(ethylene glycol) (PEG) Poly(acrylic acid) (PAA) Poly(methacrylic acid) (PMAA) Polyacrylamide (PAM)	Alginate, fibrin, agarose, chitosan, gelatin, silk, carrageenan, hyaluronic acid, collagen, cellulose, protein/peptides, dextran, matrigel, starch
Initiator [15–19]	
Ammonium persulfate Benzoyl peroxide Ammonium persulfate-tetramethylethylenediamine (APS-TMEDA) Ammonium persulfate-sodium sulfite-Mohr's salt 1-[4-(2-hydroxyethoxy)-phenyl]-2-hydroxy-2-methyl-1-propane-1-one (Irgacure D-2959)	
Cross-linker [11, 20, 21]	
N,*N*′-methylenebisacrylamide (MBAm or MBAA) Pentaerythritol tetraacrylate (PETRA) Ethylene glycol dimethylacrylate (EGDMA) Ethylene glycol diacrylate (EGDA) Poly(ethylene glycol) diacrylate (PEGDA) Ethylene glycol dimethacrylate (EGDMA)	

cross-linking is a stabilization process of liquid polymers, where the freely flowing chains were turned into multidimensional polymeric network in the form of a gel. In general, hydrogel preparation usually involved the use of material, such as monomers/polymers, initiator, and cross-linker (Table 1). The presence of water or other aqueous solutions acts as diluents, in order to control the heat generated during polymerization and tuning the final properties of hydrogels. Additional purification step is required to remove impurities (e.g., unreacted monomers/polymers, initiators, cross-linkers, by-products) especially for chemical synthesis process [11].

2.1 Chemical Synthesis Methods

Chemically cross-linked hydrogels are known as permanent or chemical gels, where the polymeric network is formed via the covalently cross-linked of monomers precursors/polymer chains. The chemical gels reached an equilibrium swelling state under optimized polymer-water interaction parameter and the cross-link density. Thus, chemical gels are considered as 'strong gels' with good mechanical strength and durability [6].

In general, the formation of chemical cross-linkage in chemical gel involves grafting of monomers on the backbone of the polymers or usage of a cross-linking agent to interact between polymer chains. The interaction process occurred either by (i) reaction between activated functional groups of natural/synthetic polymers (e.g., –OH, –COOH, and $–NH_2$), (ii) using small molecular weight of cross-linker

(e.g., formaldehyde, epoxy compounds, dialdehyde), (iii) using photosensitive agents (e.g., gamma and electron beam polymerization), and (iv) initiation with an enzyme [5, 22]. All the mentioned chemical polymerization approaches are categorized into three groups, which included aqueous solution polymerization, inverse-phase suspension polymerization, and irradiation polymerization (Table 2). The differences among the above polymerization approaches are listed in Table 3.

2.2 Physical Synthesis Methods

Physically cross-linked hydrogels are known as reversible or physical gels. It is present in three-dimensional network via polymeric molecular entanglements and/or secondary interaction including ionic, hydrogen force or hydrophobic interactions. Physical gels are divided into two groups, which are strong physical gels and weak gels. The strong gels provide permanent physical interaction between polymer chains under certain experimental conditions. It shows similar characteristics as chemically cross-linked gels. Examples of strong physical bonds are lamellar microcrystals, glassy nodules, or double and triple helices. In contrast, physical gels with temporary connections between polymeric chains can lead to a reversible process. This cross-linkage leads to finite lifetimes of products and continuously restructuring ability. Examples of weak physical bonds are hydrogen bond, block copolymer micelles, and ionic associations [2, 6].

Generally, the dissolution of physical gel is inhibited by physical interaction between polymer chains without the presence of cross-linking agents. Some of the cross-linking agents contain toxicity which affect the purity of substances (e.g., drugs, cell, proteins, etc.) to be entrapped in gels, as well as the need for further removal before application, particularly in the food and personal care industries. However, these physical interactions are reversible, which are easily decomposed under the physiological environment (such as temperature, pH, or electric field) or application of stress. Thus, the physical gels are considered biodegradable and biocompatible [5]. There are several methods for the preparation of physically cross-linked hydrogels, which include crystallization, amphiphilic graft and block copolymers, ionic interaction, complex coacervation, hydrogen bonding, and protein interaction. The roles and examples of physical hydrogels are summarized in Table 4.

2.3 Newly Emerging Approaches

The existing technology for hydrogel production, such as cross-linking copolymerization, cross-linking of reactive polymer precursors, and cross-linking via polymer-polymer reaction, is still rendering limited criteria during the process and features of hydrogels. Several studies have reported difficulty in controlling the detailed structure (chain length, sequence, and three-dimensional structure) due to the presence of side reaction, and unreacted pendant groups and entanglements occur. In addition,

Table 2 Methods for different chemical cross-link hydrogels

	Methods	Roles	Examples	Reference
1.	Aqueous solution polymerization	Reaction between ionic and neutral monomers with multifunctional cross-linking agent Polymerization is initiated thermally by UV irradiation or redox initiator system Aqueous solvent serves as heat sink for polymerization process (e.g., water, ethanol, water-ethanol mixtures, and benzyl alcohol)		
(a)	Radical polymerization	Known as chain-growth polymerization or anionic or cationic polymerization The process involves initiation, propagation, and termination steps Generation of free-radical activities induces the addition of monomers in polymer chains	Poly(*N*-isopropylacrylamide) Poly(sorbitan methacrylate) Poly(*N*-vinyl-2-pyrrolidone)	[23] [24] [25]
(b)	Chemical reaction of functional groups	The cross-linking involves functional group (–OH, –COOH, $–NH_2$) of hydrophilic polymers with polyfunctional cross-linking agents		
	(i) Aldehydes	Hydrophilic polymers having –OH groups form cross-link through cross-linking agents – aldehydes (e.g., glutaraldehyde)	Polyvinyl alcohol (PVA) cross-linked with glutaraldehyde hydrogels	[26]
	(ii) Addition reaction	Bis or higher-functional cross-linkers may be used to react with functional groups of hydrophilic polymers through addition reactions	Cross-linking glycidyl methacrylate derivatized dextran (Dex-GMA) and dithiothreitol (DTT)	[27]
	(iii) Condensation reaction	Reaction occurs between the functional group of –OH and $–NH_2$ with carboxylic acids or derivatives to form polyesters and polyamides	Zinc phthalocyanine-PEG-alginate copolymer	[27]

(*continued*)

Table 2 (continued)

	Methods	Roles	Examples	Reference
(c)	Enzyme-induced cross-linking	Enzymes act as a catalyst in cross-linking by cleave or form a chemical bond with polymer chains without interference with other chemical functional groups in polymer molecules For example, horseradish peroxidase, transglutaminase, tyrosinase, phosphopantetheinyl transferase, and lysyl oxidase	Enzymatic cross-linking of a nanofibrous multidomain peptide hydrogel	[28]
2.	Inverse-phase suspension polymerization	Monomers and initiator are dispersed in the nonpolar solvent (e.g., *n*-hexane, toluene) as a homogeneous mixture (water in oil system) Continuous stirring and utilization of low hydrophilic-lipophilic-balance (HLB) suspending agent/surfactant to maintain the dispersion of mixture The final hydrogel products present in the form of powder or microspheres (beads) with desirable sizes	Polymerization of highly hydrophilic monomers, such as salts of acrylic and methacrylic acids, as well as acrylamide For example, poly (methacrylic acid-co-partially neutralized acrylic acid) hydrogels prepared using SPAN 80 as the dispersant, heptane as the organic phase	[29]
3.	Irradiation polymerization	High-energy electromagnetic irradiations (e.g., gamma, x-ray, and electron beams) are applied as an initiator/cross-linker to induce the formation of radicals from hydrophilic polymer chains for the cross-linking process The process is initiator-free and render high purity of hydrogels	Gamma-radiation water-soluble polymer blends based on poly(vinyl alcohol) (PVA) and poly (ethylene glycol) (PEG)	[30]

Table 3 Comparison between three polymerization approaches

Polymerization type	Characterization
Microwave irradiation polymerization	High efficiency, fast heat, and clean (mass shape products)
Inverse-phase suspension polymerization	Higher costs, complex, and unstable (particle products)
Aqueous solution polymerization	Lower cost, easy control, and stable (mass shape products)

the produced hydrogels are of poor mechanical properties and slow or delay in response times to external stimuli [1]. Thus, process modification is necessary in order to control the polymerization and improve the characteristic of hydrogels (better mechanical properties, viscoelasticity). Several novel technologies for the hydrogel production were presented in Table 5.

3 Cellulose-Based Superabsorbent Hydrogels

Owing to the hydrophilic characteristic performance, superabsorbent hydrogels have a high capacity for water uptake, which can absorb, swell, and retain aqueous solutions up to hundreds of times from their own weight (dry sample). Since most of the superabsorbent hydrogels are produced from synthetic polymers (acrylics), the tendency for replacing these synthetics with greener alternatives is more than overwhelming due to the poor degradability and biocompatibility of synthetic superabsorbent [10]. Thus, as an alternative to a greener route, cellulose-based superabsorbent hydrogel was invented. Cellulose (abundant biomass, biocompatibility, biodegradable, nontoxic, low cost and renewable, abundant hydroxyl groups) can be used to produce superabsorbent hydrogels easily with fascinating structures and properties which will be discussed in detail in this section.

3.1 Cellulose Structure and Biodegradability

The biodegradability characteristic for cellulose has been broadly investigated because of its capacity of molecular weight reduction, lower mechanical strength, and high solubility aspect. The great biocompatibility of cellulose, cellulosic, and cellulose disintegration has provoked the extensive utilization of cellulose-derived materials in biomedical utilizations. Moreover, the chemical alteration and cross-linking of water-solvable cellulosic material with bioresorbable component are able to produce degradable, absorbable, and resorbable cellulose-derived materials. In addition, cellulose and its subordinates are ecologically well disposed, as they are degradable by a few microscopic and macroscopic organisms that are present in

Table 4 Methods for different physically cross-linking hydrogels

	Methods	Roles	Examples	Reference
1.	Crystallization	The gelation process involves the formation of microcrystals in the polymer structure due to the cycle of freeze-thawing	**By homopolymer systems**: Polyvinyl alcohol and calcium alginate gel rendered touch and elastic behavior after repeated freeze-thaw process **By stereocomplex**: The presence of stereoisomers with opposite chirality (e.g., L-lactic acid and D-lactic acid) with high molecular weight	[31] [32]
2.	Ionic reaction	Polymers with ionic groups formed cross-linking with the presence of di- or trivalent counterions (metallic ions) Cross-linking occur under mild condition: physiological pH and room temperature	Polyelectrolyte solution (e.g., Na^+ alginate$^-$) with a multivalent ion of opposite charges (e.g., Ca^{2+} and $2Cl^-$)	[33]
3.	Block and amphiphilic graft copolymers	Self-assemble characteristic for amphiphilic (both hydrophilic and hydrophobic) graft and block polymers The copolymers may consist of hydrophobic chains with hydrophilic grafts (or water-soluble polymer backbone)	Poly(lactide-co-glycolide) (PLGA) and polyethylene glycol (PEG) copolymers favor for drug delivery system PEG and polybutylene terephthalate (PBT) copolymers Hydrophobized polysaccharides (e.g., dextran, chitosan, carboxymethyl-curdlan, and pullulan)	[34] [35] [36]
4.	Hydrogen bonding	Formation of hydrogen bonding occurs between polymers carrying carboxyl groups (–COOH) Protonation favorable in low-pH condition	Hydrogen-bounded carboxymethyl cellulose (CMC) Carboxymethylated chitosan (CMC) hydrogels Xanthan-alginate Poly(acrylic acid)- and poly (ethylene oxide)-based hydrogel Poly(acrylic acid) (PAA) and poly(methacrylic acid) (PMAA) with polyethylene glycol (PEG)-based hydrogel	[36]

our surrounding [44], which can disintegrate cellulose into cellulose-specific enzyme (i.e., cellulase) [45].

3.2 Water-Soluble Cellulose Derivatives

Most of the water-soluble cellulose derivatives are obtained via the surface modification of cellulose with the etherification process (reaction between hydroxyl groups of cellulose with the organic compounds, e.g., methyl and ethyl units). Subsequently, cellulose-based hydrogels are either reversible or stable, which can be formed by cross-linking between aqueous solutions of cellulose ethers, such as methylcellulose (MC), hydroxypropyl methylcellulose (HPMC), ethyl cellulose (EC), hydroxyethyl cellulose (HEC), and sodium carboxymethylcellulose (CMCNa), which are among the most widely used cellulose derivatives. The chemical structure of such derivatives is shown in Table 6. It is worth highlighting that all these polymers have shown a wide application as thickeners and/or emulsifying agents in the food, pharmaceutical, and cosmetic industries, due to their non-toxicity and low cost. Water-soluble cellulose derivatives are mostly biocompatible which can be used as thickener, binding agents, emulsifiers, film formers, suspension aids, surfactants, and more. They have been used to fabricate cellulose-based hydrogels through physical cross-linking, chemical cross-linking, and irradiation cross-linking which have been discussed above.

Table 5 Methods for different novel technologies

Methods	Roles	Examples	Reference
Solid-liquid interface technology	Polymerization occurs by immersed agarose gel rod loaded with acetic acid in the cellulose solution, to form onion-like and multilayered tubular cellulose-based hydrogels Controllable size, layer thickness, and interlayer space of the multilayered hydrogels Hydrogels render good architectural stability, solvent resistance, high compressive strength, and excellent biocompatibility	Multilayered tubular cellulose hydrogels	[41]
Electrospinning technique	Well-aligned, highly ordered, and covalently cross-linked polyacrylamide (PAM) hydrogel microfiber produced by using electrospinning techniques This technique is able to generate ordered structures from nanoscale to microscale fibers for biological muscle application	Highly aligned and covalently cross-linked polyacrylamide hydrogel microfibers	[42]
Microwave technology	Cross-linking approach assisted by microwave led to strong irradiation penetrating ability, faster heating, and a cleaner process Poly(vinyl alcohol) with either poly(acrylic acid) or poly (methyl vinyl ether-alt-maleic anhydride) forms cross-linking without the use of monomers, thus avoiding the purification step of unreacted species	Combination between poly (vinyl alcohol) with either poly(acrylic acid) or poly (methyl vinyl ether-alt-maleic anhydride)	[43]

3.3 Cellulose-Based Hydrogels and Cross-Linking Strategies

Hydrogels can be divided into those formed from natural polymers and those formed from synthetic polymers. On the basis of the cross-linking method, the hydrogels can be divided into chemical gels (covalent bond), physical gels (molecular self-assembly through ionic or hydrogen bonds), and irradiative cross-linking (formation of covalent bonding between polymer chains).

3.3.1 Physical Cross-Linking of Cellulose Derivatives

In the family of thermos-reversible gelling polymers for hydrogels, hydrophobically modified cellulose is one of the largest members. When hydroxyl groups are substituted partly by methyl groups or hydroxypropyl groups, some hydrogen bonds are prevented, and the resultant derivatives become water soluble [46]. Methylcellulose (MC) aqueous solutions possess the unusual properties in forming reversible physical gels, due to hydrophobic interactions when heated above a particular temperature [47]. On the other hand, hydroxypropyl methylcellulose (HPMC) has a higher gelation temperature than MC, which forms firmer gels with equivalent substitution and molecular weight. Evidence have indicated that the gelation of HPMC cellulose derivatives resulted from the removing of water molecules from methoxylated regions of the polymer [48]. Sammon's group [48] successfully modified hydroxypropyl methylcellulose with 9.1% hydroxypropyl and 29.3% methoxyl at 4 °C for 24 h. In addition, Sekiguchi et al. [49] discussed the hydrophobic interactions and hydrogen bonds contributed to thermally reversible

gelation of methylcellulose aqueous solution. They were successfully modified cellulose acetate with dimethyl sulfoxide (DMSO) under a reaction condition of 60 °C and 1-h process. Subsequently, the sample underwent the methylation process (methylene chloride) and was further washed with deionized water.

As reported by Joshi et al. (2008), methylcellulose (MC) in cold deionized water shows a higher gelation rate at higher concentrations by using heating-cooling cycles. Initially, dried methylcellulose mixed with deionized water and heated till the temperature at 95 °C. The sample was allowed to cool down to 22 °C for at least 24 h, and finally the sample was maintained at a temperature of 4 °C. As a result, the gelation rate during the second heating-cooling cycle is higher than that in the first cycle [50].

Hydroxypropyl methylcellulose (HPMC) is a methylcellulose modified with a small amount of propylene glycol ether group attached to the anhydroglucose of the cellulose. Weiss' group [51] has developed a series of biomaterials based on HPMC. The first generation of injectable calcium phosphate ceramic suspensions is composed of a mixture of HPMC solution and biphasic calcium phosphate granules. The aggregation and gelation behavior of HPMC (19–24% methoxyl and 7–12% hydroxypropyl) aqueous solutions is concluded as follows: (i) polymer reputation increases due to thermal motion, which led to a weaker network; and (ii) above 55 °C, the polymer chains become more hydrophobic, and polymer clusters start to form [52].

The second generation of hydrogel products that can suppress the long-term flow by easily controlling the cross-linking of silated HPMC (Si-HPMC) has been developed by Vinatier's group [53] in 2009. Basically, Si-HPMC powder was solubilized in NaOH for 2 days. The solution was then sterilized by steam (121 °C, 30 min). To allow the formation of a reticulated hydrogel, the solution was finally mixed with *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) buffer. The resulted Si-HPMC is nontoxic and biocompatible so that it can be widely used in biomedical areas, such as scaffolding for cell culture and cartilage model, and implanted in bone defects [54]. In addition, Si-HMPC-based hydrogels are developed as a scaffold for the 3D culture of osteogenic cells, which would be suitable for both in vitro culture and in vivo injection. The results from the mineralization assay and gene expression analysis of osteoblastic markers and cytokines indicate that all of the cells cultured in 3D into this hydrogel exhibit a more mature differentiation status from cells cultured as a monolayer on plastic. This Si-HPMC hydrogel is well suited to support osteoblastic survival, proliferation, and differentiation as it is used as a new scaffold and represents a potential basis for an innovative bone repair material [55].

3.3.2 Chemical Cross-Linking of Cellulose Derivatives

The stable structure and effective swelling of cellulose-based hydrogels often require a chemically cross-linked network. Some difunctional molecules are employed as the cross-linker for cellulose or its derivatives to covalently bind different polymer molecules in a three-dimensional hydrophilic network [46].

Sannino et al. [45] exploited the superabsorbent hydrogels based on cellulose through cross-linking carboxymethyl cellulose (CMC) and hydroxyethyl cellulose (HEC) with a cross-linking agent such as divinyl sulfone (DVS). Then sodium hydroxide (NaOH) and poly(ethylene glycol) (PEG) which acted as spacers between cross-links were added into the solution. These polyelectrolyte hydrogels display a high sensitivity in sorption capacity with variations of the ionic strength and pH of the external solution. Besides, the superabsorbent hydrogels are also developed to treat edemas for body water elimination. If hydroxypropyl cellulose (HPC) hydrogels are synthesized at certain temperatures in the single-phase regime, they remain nonporous, whereas when cross-linked in the biphasic regime, it will turn to microporous structure. Additionally, Hirsch and Spontak [56] reported the dynamic mechanical properties and swelling capacities of these hydrogels as a function of cross-linking temperature. The results showed that the HPC hydrogels when cross-linked with ammonia (NH_3) and epichlorohydrin (ECH) had excellent ability to absorb anionic dye with maximum adsorption capacity of 2478 (g/kg) which can be achieved at pH 3.96.

In 2008, Demitri et al. [57] reported the preparation of HEC and CMCNa hydrogels with citric acid as a cross-linker, which can overcome toxicity and material costs, as compared to divinylsulphone or with a carbodiimide cross-linking agent. Briefly, CMCNa and HEC (3:1) were mixed with citric acid which acts as a cross-linking agent. Results indicated that the swelling ratio of hydrogels depends on the reaction time and citric acid concentration, when the swelling degree reaches 900 with 3.75% of acid.

3.3.3 Irradiative Cross-Linking of Cellulose Derivatives

Irradiation is a useful method for the formation of covalent bonding between polymer chains. This method is advantageous because of the high purity of the hydrogel product without the use of toxic cross-linkers, thus enlarging the applications in food and pharmaceutical industries. However, only a small fraction (17–30%) of gel aggregates (lumps) can be obtained by γ-ray irradiation at a dose of 20 kGy from 20 wt% of biopolymer solutions (such as cellulose/ionic liquid/water, CMC, and carboxymethyl chitosan (CMCT) aqueous solutions), with the assistance of generated hydroxyl radicals [58, 59].

The electron beam (EB) irradiation in the vacuum seems to be able to increase the gel yield (the gel fraction reached up to 55% at 20 kGy and increased with the irradiation dose). Petrov group [60] successfully obtained an opaque spongy material via UV irradiation from 3 wt% of aqueous cellulose polymers (HPMC, HEC, and MC) with (4-benzoylbenzyl) trimethylammonium chloride (BBTMAC) as a photo initiator. At high energy doses and low polymer concentration (10 wt%), the degradation of the polymer chains competes with cross-linking, thus resulting in the destruction of network structure and a decrease in tensile strength. The occurrence of degradation was due to EB irradiation (higher radical number created in the system) or irradiation in an oxygen-free atmosphere to avoid the generation of oxides and peroxides.

4 Stimuli-Responsive Cellulose-Based Hydrogels

The smart hydrogel can be categorized as physical or chemical stimuli-responsive hydrogels. Physical stimuli (temperature, electric or magnetic fields, and mechanical stress) will affect various energy sources and alter molecular interaction at a critical onset point. However, the chemical stimuli (pH, ionic factors, and chemical agents) will change the interaction between polymer chains and solvent at the molecular level. Thus, the responsive cellulose-based hydrogels found a new generation of smart materials to be used in numerous fields (biomedical devices, scaffolds for engineered tissues, biosensors, and actuators).

4.1 pH-Responsive Hydrogels

pH-responsive hydrogels are produced of polymeric backbones with the ionic pendant groups that can accept or donate protons in response to an external pH change [46, 61]. The acid- or basic-side functional groups in polyelectrolytes undergo dissociation in a similar way as the acidic or basic groups of monoacids or monobases. The ionization on polyelectrolytes, however, is more difficult due to electrostatic effects of other adjacent ionized groups. So, the apparent dissociation constant (*K*a) may be different from that of the corresponding monoacid or monobase. When the macromolecules are constituted by a huge amount of ionizable groups, such polymer is called polyelectrolyte. Hydrogels constituted by polyelectrolytes are, often, sensible to pH changes, which makes the hydrogel to swell (if the side functional groups are in an ionized state) or to collapse (if the side functional groups are not ionized). The process of swelling/collapsing of pH-sensitive hydrogel is reversible and may have strong applications in the pharmaceutical field because hydrogels can protect a given encapsulated drug from hostile environments, e.g., the presence of enzymes and low pH in the stomach region. A drug that can suffer degradation at acidic conditions can be transported through the gastric tract and be released in the colon if it is encapsulated in an appropriated pH-sensitive hydrogel. Hydrogels can also control drug release by changing the gel structure in response to environmental stimuli. Hydration under alkaline pH favors enzyme access to the hydrogel and its later enzymatic decomposition with the ensuing delivery of the drug entrapped in the hydrogel [61].

4.2 Temperature-Responsive Hydrogels

Chemically cross-linked thermosensitive hydrogels undergo volume change rather than sol-gel transitions. Certain molecular interactions, such as hydrophobic associations and hydrogen bonds, play a vital role in the abrupt volume change of these hydrogels at the critical solution temperature. In a swollen state, water molecules form hydrogen bonds with polar groups of polymer backbone within the hydrogels

and organize around hydrophobic groups as iceberg water. At critical solution temperature, hydrogen bonding between the polymer and water, when compared with polymer-polymer and water-water interactions, becomes unfavorable. This forces the quick dehydration of the system, and water is released out of the hydrogel with a large gain in entropy, resulting in the shrinkage of the polymeric structure. Temperature-sensitive hydrogels will have a small variation in temperature which induces a phase transition, and therefore shrinking or expansion of the material is observed. This is because chemically cross-linked thermosensitive hydrogels undergo a volume change rather than sol-gel transitions. Theoretically, certain molecular interactions (hydrophobic associations and hydrogen bonds) play a vital role in the abrupt volume change of these hydrogels at a critical solution temperature. As a result, an abrupt transition in the 3D matrix occurs: water-solvated macromolecule quickly dehydrates and changes to a more hydrophobic structure.

4.3 Ionic Strength-Responsive Hydrogels

The swelling, loading, and releasing-solute capabilities of hydrogels are, sometimes, dependent on the ionic strength (IS) of the external fluid. Due to the diffusion and convection, an osmotic pressure is produced via the difference in the ionic concentration of the exterior solution and interior hydrogel, thus, causing the swelling and shrinking of the cellulose smart hydrogel [46].

4.4 Solvent-Responsive Hydrogels

The response to solvent is also a very important issue on stimuli hydrogels. Several aspects are exploited in this way. The change from hydrophilic to hydrophobic solvent (or the reverse) is a common strategy to induce the shrinking or expansion of a three-dimensional network [46].

4.5 Other Responsive Hydrogels

Other than stimuli-responsive cellulose-based hydrogel, there are a few different strategies for visible stimuli, for example, ultraviolet-visible, magnetic field, mechanical stress, and others to generate changes in hydrogels. As specified, a few frameworks have been produced to join more stimuli-responsive structure in the polymer systems [62]. As stimuli-responsive cellulose-based hydrogel is actively developing, there is a pattern in growing new smart hydrogel to be responsive not only to stereotype stimuli but also to machine and analytical device that have a more responsive characteristic.

5 Structure Property Relationships in Hydrogels

Generally, hydrogels consist mostly of 60–90% fluid and 10–30% polymer [63]. Due to its characteristic properties such as swell ability in the water, high water content and elastic nature similar to natural tissue, biocompatibility, and lack of toxicity, hydrogels have been utilized in a wide range of biological, medical, pharmaceutical, and environmental applications [64]. Moreover, to achieve a successful network of hydrogels, it must consider its chemical cross-linking, physical entanglement, ionic bond, and hydrogen bond [65]. In a broad sense, it shows that the hydrogels are categorized into chemical gels when the cross-links of hydrogen bonds in the main chains are replaced by the stable covalent bonds [66] and into physical gels when the links are held together by secondary weak bonds such as ionic bonds, hydrogen bonds, van der Waals and electrostatic interactions, or molecular entanglements [65, 67].

A different type of preparation method for hydrogels is another parameter to classify the hydrogels, which includes (i) homopolymer hydrogels, (ii) copolymer hydrogels, (iii) interpenetrating polymeric hydrogels, and (iv) multi-polymer hydrogels [7]. The homopolymer hydrogels referred to as polymer networks are composed only of one type of hydrophilic monomer, while the copolymer hydrogels are composed of two types of monomers, where at least one is hydrophilic monomers [7]. Meanwhile, the interpenetrating polymeric hydrogels are hydrogels that are prepared by swelling a network without any chemical bonds between them, such as a swelling process of polymer 1 in monomer 2, to make an intermeshing network of polymer 1 and polymer 2 [68]. Last but not least, the multi-polymer hydrogels indicate that hydrogels consist of a combination of more than three types of monomers [68]. Different types of hydrogel lead to different characteristic features, which included structure parameters, mechanical properties, and swelling effect.

5.1 Structural Parameters

Theoretically, several parameters of hydrogel structures are intensively discussed in many studies which are (i) polymer volume fraction in the swollen state ($V_{2,\,S}$), (ii) average molecular weight between cross-links (M_e), and (iii) correlation length (ξ) also known as the network mesh (or pore) size [68]. The equilibrium polymer volume fraction in the gel ($V_{2,\,S}$) is the ratio of the polymer volume (V_p) to the volume of the swollen (V_{gel}) and the reciprocal of the volume swelling ratio (Q):

$$V_{2,S} = \frac{V_p}{V_{gel}} = Q^{-1} \tag{1}$$

Besides, the polymer volume fraction in the swollen state can also be determined by the equilibrium swelling experiments when the average molecular weight between cross-links (M_e) is theoretically related to the degree of cross-linking (X):

$$(M_e) = \frac{M_0}{2X} \tag{2}$$

where M_0 is the molecular weight of the repeating unit of a polymer.

The correlation length or the network mesh size (ξ) indicates the distance between the consecutive junctions, cross-links, or tie points. All the network parameters can be measured through a range of experimental techniques or calculated by the application of the network deformation theory [68].

5.2 Mechanical Properties

At present, there are a few methods available for characterizing the mechanical properties of hydrogel constructs. The mechanical properties of hydrogels are very difficult to describe and understand its structure. Besides, its mechanical behavior can be studied by using theories to analyze its polymer structures and to determine the effective molecular weight between cross-links and to provide information about the number of elastically active chains and cyclization versus cross-linking tendency [68].

5.2.1 Dynamical Mechanical Analysis

The dynamical mechanical analysis is characterization method for hydrogels to provide information related to the viscoelastic behavior of hydrogels by measuring the response of a sample when it is deformed under periodic oscillation (stress or strain) [68]. Based on the dynamic experiment, the material is subjected to a sinusoidal shear strain (or stress):

$$\gamma = \gamma_0 \sin(\omega t) \tag{3}$$

where γ_0 is the shear strain amplitude, ω is the oscillation frequency (which can also be expressed as $(2\lambda\ gf)$ where f is the frequency in Hz), and t is the time. The mechanical response shows that the shear stress (σ) of viscoelastic materials is intermediate between an ideal pure elastic solid (in phase with the deformation) and an ideal pure viscous fluid (90° out of phase with the deformation). Therefore, it is out of phase with respect to the imposed deformation as expressed by:

$$\sigma = G^*(\omega)\, \gamma_0 \sin(\omega t + \delta p) \tag{4}$$

And consequently

$$\sigma = G^*(\omega)\gamma_0 \sin(\omega tg)\cos(\delta) + G''(g\omega)\, \gamma_0 \cos(\omega t)\sin(\delta) \tag{5}$$

and if it is defined

$$G' = G^* \cos(\delta)$$

$$G''(\omega) = G^* \sin(\delta) \tag{6}$$

we get:

$$\sigma = G'(\omega)\gamma_0 \sin(\omega t) + G''(g\omega)\,\gamma_0 \cos(\omega t) \tag{7}$$

where G′(ω) is the shear storage (or elastic) modulus and G″(ω) is the shear loss (viscous) modulus. G′ is referred to as the elasticity or the energy stored in the material during deformation, whereas G″ gives information about the viscous character or the energy dissipated as heat. The dependence of the elastic and viscous moduli upon frequency is called mechanical spectra. The combined viscous and elastic behavior is given by the absolute value of complex shear modulus G*:

$$\mathrm{B}^*(\omega) = \sqrt{\mathrm{G}'^2\mathrm{G}''^2} \tag{8}$$

or by the absolute value of complex viscosity η* defined as:

$$\eta^*(\omega) = \sqrt{\frac{\mathrm{G}'^2 + \mathrm{G}''^2}{\omega}} \tag{9}$$

On the other hand, the ratio between the viscous modulus and the elastic modulus is expressed by the loss tangent:

$$\tan\,\delta = \frac{G'}{G''} \tag{10}$$

where J is the phase angle. The loss tangent is a measure of the ratio of energy lost to the energy stored in the cyclic deformation.

Theoretically, the ratio between the stress and strain may depend both on time and stress. The ratio will only depend on time if the deformations are kept small in order to obtain a liner material behavior. To determine the region of linearity, the preliminary strain sweep tests at fixed oscillation frequency are performed. Specifically, the dynamic moduli are monitored while logarithmically varying the strain amplitude, γ_o.

5.2.2 Viscoelastic Properties

According to Borzacchiello et al. [68], the mechanical spectra analysis can clearly distinguish the concentrated (entangled) polymer solutions and gels based on the concentration and its frequency. For the concentrated solution at low frequency, the solution presents a viscous behavior ($G'' > G'$), while at high frequency, it shows an elastic behavior ($G' > G''$). The transition between viscous and elastic behavior is indicated by the cross point of G′ and Gil curves, as a function of frequency, occur at a given value of the frequency (f^*). Besides that, the common behavior of the concentrated solution when at low frequency shows that the solution behaves as a viscous liquid which the polymer chains are able to achieve the equilibrium configuration through the Brownian motion within the time scale of the experiment. Meanwhile, when at high frequency, the chains cannot be detached during the

short period of oscillation, and it behaves as a temporary cross-linked network to accommodate stress by network deformation and elastic behavior ($G' > G''$). The crossover frequency (f^*) depends on the intrinsic rate of disentanglement of polymer chains.

5.2.3 Stress-Strain Behavior

Hydrogels consist of a water-swollen network of cross-linked polymer chain which can be considered in a rubber state. This rubber state condition allows them to respond to external stresses with a rapid rearrangement of polymer segments. The mechanical stress-strain properties of hydrogels in this rubber-like behavior correspond mainly to the architecture of the polymer network. Besides, to generate an equation of rubber elasticity, the relationship of network characteristics, mechanical stress-strain behavior with the classical and statistical thermodynamics, and phenomenological approaches must be used and considered. Based on the classical thermodynamics, the state equation for rubber elasticity is shown below:

$$f = \left(\frac{\delta U}{\delta L}\right)_{T,V} + \left(\frac{\delta U}{\delta L}\right)_{L,V} \tag{11}$$

where f is the retractive force of the elastomer in response to a tensile force, U is the internal energy, L is the length, V is the volume, and T is the temperature.

Other than that, for elastomeric materials, the change in length is not internally driven by retractive forces. Indeed, for those materials, the bonds are not stretched with a change in L, but an increase in length will decrease the entropy due to the changes in the end-to-end distances of the network chains. The entropic model for rubbery elasticity is the most reasonable approximation for hydrogels while the entropy is full with 90% of the stress. The retractive force and entropy are related through the Maxwell equation:

$$-\left(\frac{\delta U}{\delta L}\right)_{T,V} = \left(\frac{\delta U}{\delta L}\right)_{L,V} \tag{12}$$

By expressing the retractive force using the statistical thermodynamics, it can be assumed there is no volume change upon deformation. The free energy change on straining the polymer chains is due to the restraints placed on the configurational rearrangements and is considered to be totally entropic in origin [8]. It is, therefore, possible to write the equation of state for rubber elasticity as follows:

$$\tau = \left(\frac{\delta A}{\delta \lambda}\right)_{T,V} = \frac{\rho RT}{\bar{M}C}\frac{\bar{r}_0^2}{\bar{r}_f^2}\left(\lambda - \frac{1}{\lambda^2}\right) \tag{13}$$

where τ is the shear stress per unit area, ρ is the density of the polymer, M_c is the average molecular weight between cross-links, and λ is the extension ratio. The quantity, $\bar{r}_0^2 / \bar{r}_f^2$, is the ratio of the end-to-end distance in a real network versus the

end-to-end distance of the isolated chains; it is generally approximated as 1 when it is unknown. From Eq. 13, it can be deduced that the stress is directly proportional to the number of network chains per unit volume (i.e., ρM_c). The equation assumes that the network is ideal in that all chains are elastically active and contribute to the elastic stress and network imperfections such as cycles, chain entanglements, and chain ends which are not taken into account [33–35]. To correct the chain ends:

$$\tau = \frac{\rho RT}{\bar{M}c} \frac{\bar{r}_0^2}{\bar{r}_f^2} \left(1 - \frac{2\bar{M}c}{\bar{M}n}\right)\left(\lambda - \frac{1}{\lambda^2}\right) \tag{13}$$

where M_n is the average molecular weight of the linear polymer chain before cross-linking. The correction can be neglected when $M_n \gg M_C$. From the constitutive equation, the modulus can be expressed as:

$$G = \frac{\rho RT}{\bar{M}c} \frac{\bar{r}_0^2}{\bar{r}_f^2} \left(1 - \frac{2\bar{M}c}{\bar{M}n}\right) \tag{14}$$

and the force per unit area as:

$$\tau = G\left(\lambda - \frac{1}{\lambda^2}\right) \tag{15}$$

The rubber elasticity theory predicts the nonlinear stress-strain behavior. The theory predictions describe the experimental results fairly well at low extension but are less accurate at higher elongations.

5.3 Swelling Properties

Swelling properties of hydrogels are important both dynamically and at equilibrium. The polymer chains in hydrogels can be obtained via either by physical or chemical stabilization of aqueous solutions, and thus, it is considered as one molecule regardless of its size [45]. A small change in environmental condition may trigger fast and reverse changes in the hydrogel. Hydrogels have the ability to sense changes in environmental parameters like pH, temperature, electric signal, and the presence of enzyme and other ionic species which may change the hydrogel physical texture. Apart from that, this swelling behavior of hydrogels can be determined by the several parameters which are the polymer volume fraction in the swollen state ($V_{2,\,S}$), the number average molecular mass between cross-links (Mc), and the mesh size (ξ) [69]. Besides, the equation of hydrogel volume in the dry state (V_d) and hydrogel volume when swollen to equilibrium (V_s) are shown below as (16) and (17), respectively:

$$V_s = \frac{m_{a,s} - m_{h,s}}{\rho_h} \tag{16}$$

$$V_d = \frac{m_a - m_h}{\rho_h} \tag{17}$$

where (m_a) is the mass of the initial dry polymer in air (m_h) is the mass of the dry polymer in a swelling medium, $m_{a,\ s}$ is the mass of the swollen hydrogel in the air after reaching equilibrium swelling, $m_{h,\ s}$ is the mass of swollen hydrogel in a swelling medium after equilibrium swelling, and ρ is the density of swelling medium. The mass of hydrogel in a non-solvent can be measured by placing the sample in a stainless steel mesh basket suspended in swelling medium before swelling measurements are made and after the equilibrium swelling is achieved. The polymer volume fraction of the hydrogel in swollen state ($V_{2,\ S}$) is calculated from the swelling data by using the following relationship:

$$\left(V_{2,S}\right), = \frac{V_d}{V_s} \tag{18}$$

where (V_d) is the volume of the dry polymer and (V_s) is the volume of the hydrogel after equilibrium swelling. The determination of swollen hydrogel volume (V_s) requires the placement of hydrogel sample in the buffer and allows it to attain equilibrium.

6 Synthesis and Characteristics of Cellulose-Based Smart Superabsorbent

Throughout the years, the "superabsorbent polymer" has been developed and widely used in various areas due to its extraordinary properties [70, 71]. Due to its superior characteristics such as excellent hydrophilic properties, high swelling ratio, and improved biocompatibility, this superabsorbent hydrogel shows a high potential to attribute in many industries such as sanitary, agriculture, biomedical, food packaging, pharmaceuticals, and others [72, 73]. Generally, most of the superabsorbent hydrogels are produced from synthetic polymers (acrylics acid), and for the past several years, researchers have focused its attention to replace synthetic polymers with "greener" alternatives due to poor degradability and biocompatibility of the synthetic superabsorbent [10]. Cellulose is one of the carbohydrate polymers with the most inexhaustible resources on Earth. This type of biopolymer is biocompatible, biodegradable, and nontoxic and is a low-cost material. Besides, cellulose consists of an abundance of hydroxyl groups that will interact between the hydrogen bond, which contributes to the cellulose's mechanical strength, molecular structures, and its properties [10]. Additionally, the advantages of cellulose-based superabsorbent hydrogels give superior characteristics such as high absorbency, high strength, good salt resistance, excellent biodegradable ability and biocompatibility, and other special functions that promise a wide range of applications in many fields [10, 65].

According to Sannino et al. [45] and Fekete et al. [74], the superabsorbent hydrogels were synthesized by both chemical and physical methods. The chemical

method involves the synthesis processing of cellulose-based superabsorbent hydrogels via covalent linkages, and this includes aqueous solution polymerization, inverse-phase suspension polymerization, and even microwave irradiation pathways [3]. Most of the cellulose-based superabsorbent hydrogels are synthesis via aqueous solution polymerization due to lower production cost, better control for heat of polymerization, and more convenience as compared to other methods. Besides, this method is mainly attributed to free-radical-induced polymerization, which monomers are polymerized through the action of initiators in the aqueous medium condition that is safe and harmless [10]. Other than that, the physical synthesis methods refer to the molecular assembly cross-linked by hydrogen bonds or ionic bonds between the polymers or by the interaction between the polymers. These physical cross-link techniques include freeze/thaw cycle technology and hydrogen bond cross-linking, which are also adapted in some cases [75]. Among the methods that are used for the preparation of cellulose hydrogels, physical approach is the best choice of process due to its simple pathway with zero solvent for environmentally friendly purposes [10].

7 Synthesis and Applications of Macro- and Nano-hydrogels

7.1 Synthesis Routes of Macro- and Nano-hydrogels

Recently, the synthesis of hydrogels by using biocompatible/biodegradable polymers in macro- and nanometer range is getting much attention. Among the research conducted are for the application in catalysis, electronics, bio-sensing, drug delivery, and nano-medicine [76]. The incorporation of nanoparticles or macro-particles with various structures and morphologies into the polymeric hydrogel matrix can be considered as a facile and effective way to obtain enhanced characteristics of hydrogels, which is similar to the particle strengthening effect in polymer bulk matrix [77]. For instance, the macro- and nano-sized hydrogels produced a higher area/volume ratio that significantly modifies the mechanical, thermal, and catalytic properties. As reported by Feeney et al. [78], under IUPAC classification, the micro-hydrogel is defined as a particle of hydrogel of any shape with an equivalent diameter of 0.1 to 100 μm. For nano-hydrogel, it is defined as a particle of hydrogel of any shape with an equivalent diameter of 1 to 100 nm. Generally, micro- and nano-hydrogels can be produced by several methods such as self-assembling, suspension, emulsion, precipitation or dispersion polymerization, micro-molding, droplet generation, microfluidics, and others [76].

7.2 Potential Application Fields

According to the Global Industry Analysts, Inc. report, the global superabsorbent hydrogel consumption was around 2.3 million metric tons in 2015, and it is expected that the global demand will continue to rise and reach 3.48 million metric tons in

2020 [79]. The rapid growth and demand for hydrogels were reflected on the developing markets and its different applications. On the other hand, Transparency Market Research reported that the global superabsorbent hydrogel market was valued at US$ 10084.9 million in 2016 and was predicted to reach US$ 17487.6 million by 2024. This large market suggests a strong tendency to develop novel superabsorbent hydrogel materials with higher water absorbency and excellent mechanical properties. This section discusses about the highly potential applications of cellulose-based superabsorbent hydrogels, which range from the conventional use of hydrogels in agriculture and personal health care to the more innovative biomedical applications. In fact, there are a number of hydrogel products that have either been commercially available or are in the progress of development. Cellulose-based superabsorbent hydrogels act as promising biomaterials for hydrogel products which show the greatest significance for various fields of application and thus are extensively studied in industrial and academic research.

7.2.1 Agriculture and Horticulture

Hydrogels have been widely proposed over the last 40 years for agricultural and horticulture usage. There is an increasing interest in using superabsorbent hydrogels in agriculture and horticulture due to several reasons, which includes ameliorating the water availability for plants, increasing the water holding properties of growing media (soilless or soils substrates), optimizing the water resources, and reducing the water consumption. Due to its unique properties, several possible agricultural applications of hydrogels have been defined.

During the swelling of hydrogel, it turns the glassy material to a rubber-like state, which is able to store water even under compression. However, the swollen hydrogel can slowly release its absorbed water via a diffusion-driven mechanism when there is a humidity gradient between the outside environment and the inner part of the material. Generally, the water molecules loaded in the polymer network can be released in a sustained and controlled manner through diffusion. In order to make the cultivation possible in the arid, desert, and drought-prone areas (especially in South America, Africa, and west of Asia), where there is always a lack of sufficient available water resources, the dry hydrogel (i.e., xerogel) which is in the form of granules or powder is envisaged to be mixed with the soil in proximity of the plant root area. In addition, the hydrogel is possibly charged with the plants, pharmaceuticals, or nutrients [45]. When the cultivation is watered (by either rain or irrigation), the water is absorbed and retained by the water, which can avoid the rapid water loss after watering due to drainage and evaporation. When the soil is in dried condition, the hydrogel will release the stored water and loaded nutrients in a continuous manner via diffusion mechanism as needed, keeping the soil or the substrate in the humid state over long periods of time [57]. On the other hand, this process allows a high saving of water as well as the redistribution of the water resources that is available for cultivation in other applications. A further advantage of using this novel material in the agricultural application is related to its swelling effect in the soil. Basically, the dry form of hydrogel granules which is almost similar in size with the

substrate granules is able to increase in size after swelling, thus increasing the soil porosity and providing a better oxygenation to the plant roots.

Unfortunately, most of the acrylate-based superabsorbent products available in the market are non-biodegradable, and some concern about toxicity was raised for agriculture application [57]. This is harmful to cultivation and human consumption; thus, it should be avoided. As a result, the concern of the public and researchers toward the biological system and environment issues has led to an increase in demand for cellulose hydrogel-based products. Several studies have been conducted toward the manufacturing of biodegradable nature hydrogel-based superabsorbent. So far, the development of environmentally friendly cellulose-based hydrogels fits perfectly in the current trend as an alternative to replace the conventional acrylate-based superabsorbent hydrogels. Such studies have been conducted and patented by Sannino and coworkers [80, 81], in which degradable cellulose-based superabsorbent hydrogels have been successfully invented. It is worth mentioning that the obtained hydrogels exist in the form of powder or a well-defined-shaped bulky material with the strong memory of its shape after swelling. Such hydrogels are capable of absorbing up to 1 l of water per gram without releasing it under compression and are able to charge with nutrients and to be released under a controlled kinetic [82]. Researches on the development of novel and green superabsorbent hydrogels for agriculture and horticulture have been further extended to recent years. In 2014, Li et al. [83] studied the effects of superabsorbent polymers on a soil-wheat (*Triticum aestivum* L.) system as a soil additive to increase crop yield and reduce the loss of soil water. The authors investigated the changes of crop yield, soil microbial activity, and water content between the modified soil and original soil; the results showed that the addition of superabsorbent hydrogels into the soil is able to improve the soil conditions with better crop yield and reduced detectable adverse effects on the soil microbial community. Besides that, Demitri et al. [57] proposed that the use of large-scale hydrogel might have an innovatory impact on the optimization of water resource management, especially in the agriculture field. The preliminary results revealed that the produced polyelectrolyte cellulose-based hydrogel could significantly increase the water retention capability of the soil and allow for the continuous release of water for a prolonged time effectively; thus, no additional watering is needed for the plants and soil. In fact, the proposed hydrogel potentially acts as an efficient storage and water reservoir in agriculture. A similar finding has been supported by Salmawi et al. [84], in which the superabsorbent hydrogel produced from acrylic acid and carboxymethyl cellulose with clay montmorillonite by gamma irradiation showed a higher percentage of swelling in distilled water and could act as a water-managing material in dried and drought-prone areas.

Pesticides are the most cost-effective way to control the growth of pest and weed. It is known that the cellulose-based superabsorbent hydrogels are used as pesticide carriers for special interest in terms of both sustainable and economic development. Hydrogels can be impregnated with fertilizer components such as nitrogen compounds, potassium ions, and soluble phosphate. Encapsulating the pesticides or herbicides into the cellulose-based superabsorbent hydrogels could be used to reduce the release rate of these herbicides [85]. This is because the chemical trapped

in a polymer network is normally unable to wash out immediately by water but is gradually released into the root zone before being absorbed by plants. Compared to those of conventional polymers such as poly(acrylic acid), polyacrylamide, polymethacrylic, cross-linked poly(vinyl alcohol), pectin, chitosan, and carboxymethyl cellulose, which normally have severe limitation such as rapid biodegradability in soil, cellulose-based superabsorbent hydrogel is able to increase the water capacity of soil, at the same time minimizing the water loss through evaporation and seepage [86]. In the mixture with other active substances, it can be used as the polymer matrix to transfer bioinsecticides or herbicides, which is mainly designed to control, for example, proliferation of insect larvae into the soil. In general, the superabsorbent and fertilizers are combined via two methods, which have been well described in the literature [87, 88]. In the first approach, fertilizers are blended with cellulose superabsorbent hydrogels. In the second methodology, fertilizers are added to the reaction mixture and polymerized in situ in order to be entrapped in the superabsorbent. Results verified that these two procedures always result to a higher release rate.

Furthermore, the role of hydrogels as horticultural substrates enhances the soil water capacity. During rainfall or irrigation, the hydrogels bind the water in the soil to prevent it from seeping into deeper layers [89]. Up to date, researchers have proposed the combination of inorganic clays, such as bentonite, kaolin, montmorillonite, etc., into pure cellulose superabsorbent hydrogels with the intention of improving the hydrogel strengths and swelling property and reduced production costs. In recent years, a study conducted by Bortolin et al. [90] has proven that polyacrylamide/methyl cellulose/montmorillonite nanocomposite superabsorbent hydrogels have presented a synergistic effect by rendering high fertilizer loading and the slow release of fertilizers. The results revealed that the produced cellulose-based hydrogels effectively reduced the loss of nitrogen by volatilization of ammonia.

In summary, the main advantages of cellulose superabsorbent hydrogels are controlled by the release of water, increase of soil porosity, long time maintaining soil humidity, and better oxygenation of plant roots. On the other hand, this type of hydrogels is biodegradable and low cost, has high holding capacity, and is an eco-friendly resource. Its application helps to reduce irrigation water demand, minimizes the plants death rate, increases the growth rate of plant and improves fertilizer retention in soil [91, 92].

7.2.2 Personal Health Care

Superabsorbent polymers have been introduced for various hygienic applications such as disposable diaper and feminine napkin industry for about 30 years ago due to their excellent water retention and the ability to retain the secreted liquids under pressure. In 1978, the commercial production of superabsorbent polymers began in Japan for the production of feminine napkins. This is considered to be the first generation of commercial superabsorbent hydrogels that has been successfully marketed [3]. Previously, the commercial superabsorbent hydrogels were made through alkaline hydrolysis of starch-graft-polyacrylonitrile in the 1970s. However,

Table 7 Water absorbency of different types of common absorbent materials [93]

Absorbent material	Water absorbency (wt%)
Superab A-200	20,200
Cotton ball	1890
Wood pulp fluff	1200
Soft polyurethane sponge	1050
Facial tissue paper	400
Whatman No. 3 filter paper	180

the high expenses and inherent structural weakness (lack of sufficient gel strength) had contributed to the major factors of its market defeat [93]. Further development of superabsorbent materials is being employed in baby diapers in France and Germany in the 1980s. In 1983, the low-fluff diapers which contained about 5 g super-absorbent polymers were launched. This was followed by the introduction of superabsorbent diapers with a thinner layer in several Asian countries, Europe, and the United States. The thinner layer of diapers and nappies was mainly due to the replacement of bulkier cellulose fluff with superabsorbent polymers that can retain much liquid more effectively [94].

Continuous development of superabsorbent materials has led to a new generation of high-performance diapers. It was worth noting that the diapers not only become thinner but have also improved the retention performance significantly which has proven to be beneficial in reducing diaper rash and leakage [45]. The results showed that premium diapers have the leakage values below 2%, while the average weight of a typical medium-size diaper was further decreased by 50%. This was advantageous in terms of economic sense and environmental issues due to the reduced packaging cost. Compared to superabsorbent polymers, traditional absorbent materials (such as polyurethane sponge and tissue papers) will not be able to hold most of the absorbed water when these materials are squeezed. As a result, superabsorbent polymers caused a huge revolution in the personal health-care industries over these years. Table 7 shows the water absorptiveness of some common absorbent materials using the commercially available superabsorbent polymers.

Making recyclable and disposable products such as napkins, diapers, hospital bedsheets, and sanitary towels is one of the important targets for the modern industry due to environmental awareness of society. Therefore, an innovative idea to this issue has recently been proposed, which involves the production of cellulose-based hydrogels with fully biodegradable properties. At present, the superabsorbent hydrogels contained in sanitary napkins are mostly derived from polymerized acrylamide or acrylic acid, which is a costly process, and the final product is environmentally unfriendly and poorly degradable [10]. Due to these reasons, some novel types of hydrogels composed of a mixture of hydroxyethyl cellulose and sodium carboxymethyl cellulose cross-linked with divinyl sulfone have been innovated. This hydrogel material is able to swell like conventional superabsorbent polymer, which exhibits higher water retention under centrifugal loads and swelling kinetics due to the capillary effects and the resulted introduction of microporous structures into hydrogel [45].

In order to establish more innovative methods for developing novel and new hydrogel products, many attempts have been made, which possess better swelling capabilities and are able to retain more fluids absorbed under the existence of external pressure or applied restraining force. Liu et al. reported a novel tactics for the production of eco-friendly superabsorbent hydrogels incorporated with flax yarn waste for sanitary napkin applications [95]. Their study proved that the product obtained exhibits from several outstanding properties such as excellent biodegradability, superabsorbent, and good in retention of artificial blood solution as compared to the currently commercialized, marketed sanitary napkin products. A similar study has been reported by Zhang et al., in which a flax cellulose-based superabsorbent composite was synthesized by the free-radical graft copolymerization of acrylic acid and acrylamide [96]. The results revealed that the yielded composite material attained the best water absorbency of urea. Most importantly, they found that 46.6% of the remaining residue after buried in soil after 90 days presented an excellent biodegradability. In modern times, a lot of convenient and comfortable disposable health-care products made up of hydrogels have been reported in literature; however, biodegradable health-care products have either not been commercially available or been industrialized [10]. In reality, more than 90% of superabsorbent composites are landfilled or incinerated after usage. This will cause serious environmental problems, undesirable water-keeping capacity, and higher cost that limit its practical applications [97]. Hence, continuous effort needs to be done in order to convert the cellulose-based superabsorbent hydrogels into the core layer of health-care products.

Further developments in the personal health-care area are expected with the formulation of the superabsorbent hydrogel materials containing enzymes and other additives in order to prevent unpleasant smells or infections. Furthermore, considering the scale of production of these materials is prerequisite as there is a clear need for environmentally friendly hygiene products that undergo biodegradation. Thus, it has a high value in the development of novel, green superabsorbent hydrogels by minimizing the consumption of chemicals or improving the degradability of disposed hydrogels. In this context, recent innovations about the cellulose-based hydrogels have move toward the implementation of an environmentally sustainable production process [98] as well as utilization of the nontoxic cross-linking agents during the process [72].

7.2.3 Water Treatments

Rapid industry developments had caused a series of severe problems to the surroundings and the environment, such as water contamination. The release of wastewater that consists of heavy metal ions into the local waterway or environment can be harmful to plants, humans, and animals. Pollution resulted from heavy metals has been accorded more attention due to the increase in awareness regarding the hazardous effects of heavy metal ions in the environment. A number of technologies have been established for water treatments, which mainly include chemical oxidation, adsorption, pressurized membrane-based separation, etc. However, several disadvantages such as high energy consumption and the pollution caused by

traditional materials have been reported. Therefore, research-scholars have shifted their attention to the cellulose-based superabsorbent hydrogels.

Zhou and coworkers [99] prepared a novel magnetic hydrogel bead in order to remove Pb^{2+} from the polluted streams. The authors blended the chitosan with carboxylated cellulose nanofibrils, amine-functionalized magnetite nanoparticles, and poly(vinyl alcohol) by using instantaneous gelation method. This novel magnetic hydrogel beads can be used to absorb Pb^{2+} metal ion in sewage effectively, which are mainly attributed to the various carboxylate groups on the carboxylated cellulose nanofibrils as well as the abundant amino and hydroxyl groups on the chitosan [69]. Tripathy et al. [100] examined the metal ion sorption behavior of cellulose-based superabsorbent hydrogels (sodium carboxymethylcellulose-g-*N*-vinylformamide) to the selected metal ions including Hg^{2+}, Pb^{2+}, Zn^{2+}, Ni^{2+}, and Cu^{2+}. They found that the values of the percent ion uptake were 8.7, 9.0, 9.8, 11.5, and 13.8 at the maximum values, respectively. On the other hand, a study reported by Kamel et al. [101] proved that the cyanoethyl cellulose-based superabsorbent hydrogels were capable of the adsorption of copper (II) ions from aqueous solution effectively. The authors reckoned that metal ion removal mainly depends on the protonation and deprotonation properties of its acidic and basic groups, specifically pH value. A similar finding has been reported by Abdel-Aal's group [102] in which the metal ion absorption capacities increased with the increase of pH values. They prepared the maize starch-acrylic acid hydrogels by radiation grafting technique, and the obtained hydrogels were used to remove the heavy metal ions (Fe^{3+}, Cr^{3+}, Pb^{2+}, and Cd^{2+}) from wastewater. Hashem et al. [103] reported three types of hydrogels which were prepared via graft polymerization of acrylonitrile into maize starch and ceric ammonium nitrate which were used as the initiator. The study has proven that the prepared hydrogels could be used for the removal of Hg(II) ions from aqueous solutions with the maximum adsorption capacity of 1250 mg/g. The adsorption data agreed with the Freundlich and Langmuir isotherms.

Apart from the metal ion pollution, increasing oil contamination and oil spills from the industrial wastewater have become a new source of water pollution. In order to be cost-effective and an energy-efficient oil separation, Rohrbach's group [104] has fabricated the nanofibrillated cellulose-based superabsorbent hydrogel as the filter for water/oil separation. The fabricated filter possesses oleophobic and hydrophilic properties, resulting in an increase in filter life and reduced negative impact toward the environment while showing the efficiency of more than 99% under gravitational force. Basically, cellulose nanofibril-based aerogels have been of great interest as absorbent materials owing to their biodegradability, high absorption capacity, large surface area, and low density. In addition, the hydrophobic aerogels have been designed to contribute excellent absorption tendency for various oil from water [105].

7.2.4 Biomedical (Controlled Drug Delivery, Scaffolds for Regenerative Medicine, Wound Dressings)

In 1960, poly-2-hydroxyethylmethacrylate was used as a synthetic biocompatible hydrogel for the application of contact lens. Wichterle and Lim reported the

cross-linked poly-2-hydroxy-ethylmethacrylate hydrogel using ethylene glycol dimethacrylate as a starting material [106]. The hard contact lenses are primarily made up of hydrophobic materials such as poly(hexa-fluoroisopropyl methacrylate) or poly(methyl methacrylate), while soft lenses are based on hydrogels [107]. Usually, contact lenses are classified as soft or hard, according to their elasticity. Albeit the hard lenses are longer lasting compared with soft lenses, they tend to be poorly accepted by the users and require a lengthier adaptation period. Many efforts are made to obtain lenses with good oxygen permeability. For this purpose, several hydrophilic monomers are proposed including methacryloylamino-4-t-butyl-2-hydroxycyclohexane, 4-t-butyl,2-hydroxycyclohexyl methacrylate, and 4-t-butyl,2-hydroxycyclopentyl methacrylate with hydroxyethyl methacrylate and *N*-vinyl-2-pyrrolidone. After that, a significant progress has been accomplished, and a diverse range of polymers have been used for the fabrication and synthesis of hydrogels for various applications.

The cellulose superabsorbent hydrogels have gained noticeable interests in the application of controlled drug delivery system. This is due to their remarkable characteristics such as versatility and flexibility in fabrication; high tunability in the chemical, physical, and biological properties; variety in composition; excellent biocompatibility; and high moldability in shape [108]. One of the most notable characteristics of hydrogels is the highly porous structure, which permits a depot maintaining a high local concentration of an active pharmaceutical ingredient or drug at the targeted tissues over a long period, ranging from hours to weeks [109]. The transportation capability of high porosity of hydrophilic/hydrophobic molecules is important for a hydrogel-based drug delivery system. The drug diffusion and release behavior via the polymer network can easily be adjusted by manipulating the cross-linking density in the gel matrix and monitoring the porosity (i.e., mesh size) of hydrogels [109]. Also, the porous structure allows the drugs to be loaded and then released continuously. So far, the drug can be loaded into a hydrogel followed by releasing to the targeted place through several mechanisms: swelling controlled, chemically controlled, diffusion controlled, and environmentally responsive release. He et al. [41] fabricated the multilayered tubular and onion-like cellulose-based superabsorbent hydrogels for the first time. Their results indicated that the multilayered superabsorbent hydrogels are important and have a great potential application in the biomedical field due to its non-cytotoxicity, good architectural stability, good biocompatibility, and solvent resistance against acetone, ethanol, dimethylacetamide (DMAc), and sodium hydroxide aqueous solution.

It is known that the drug release rate is highly dependent on the network parameters (i.e., mesh size and degree of cross-linking) as well as the water content of the swollen hydrogel [110]. In the typical matrix systems, the drug is dissolved or dispersed uniformly throughout the 3D structure of the hydrogel. The drug is released through the macromolecular pores or mesh, and the initial release rate of drug is proportional to the square root of time. Depending on the structure of the hydrogels used, the chain dissolution takes place along with the swelling process due to the physical nature of the hydrogel network; thus, the release of drug results from the complex combination of diffusion, swelling, and erosion mechanisms. When

using hydrogels to modulate the bioactive molecules and drug release, the loading of the drug is performed either during network formation or after cross-linking [111]. Moreover, the bioactive molecule can be physically or covalently linked to the polymer network and further tune the release rate. It is important to note that the cross-linking reaction has to be conducted under mild conditions in order to prevent the denaturate of loaded bioactive molecule. Although hydrogel formulations for transdermal and oral delivery can be non-degradable, the direct delivery of drugs to different body interest sites requires the hydrogel biodegradation. This is to avoid foreign body reaction, and further surgical removal is necessary [45]. At present, injectable hydrogel formulations are mostly appealing and still under investigation. Recently, a new and novel injectable cellulose nanocrystal-reinforced superabsorbent hydrogel has been developed by Yang's group [112] which could maintain their original shape for more than 60 days when immersed in 10 mM phosphate buffered saline or purified water and exhibits the excellent storage modulus. These properties make nanocellulose-reinforced injectable hydrogels a high potential interest for various biomedical applications such as tissue engineering matrices or drug delivery vehicles.

In the last decade, the use of excellent biocompatibility cellulose hydrogel and its derivatives as biomaterials for the design of tissue engineering scaffolds has received increasing attention. Regenerative medicine is an interdisciplinary research which deals with the induced regeneration of organs and tissues in vivo, by means of a scaffolding template or material that support and guide the cells during the synthesis of new tissues. In other words, it involves the replacement or improvement of specific organs or tissues using engineered materials and synthetic strategies. Basically, the superabsorbent hydrogels can be altered by using linker molecules that enable covalent or non-covalent molecular interactions between the hydrogel matrix and its surroundings in order to enhance the mechanical performance and tissue-/cell-adhesive properties [3].

For an ideal tissue regeneration, the generated scaffold has to be biodegradable with a reasonable biodegradation rate that matches with the biological process of the body. Practically, a slow degradation process is often favored to minimize the risk of premature resorption of the scaffold. Due to the bio-durability of cellulose, it is a suitable candidate for the design of tissue engineering scaffolds. However, it is known that a too slow degradation or a bio-durable material may cause the undesired biological responses in the long term, such as foreign body reaction, which limits the applications of cellulose in regenerative medicine. In fact, several studies [113, 114] have been conducted to prove the potential application of cellulose-based hydrogels for inducing the regeneration neural tissues, cartilage, and bone. A final remark about the development of regenerative medicine concerns the important role played by the scaffold porosity, which enhances the infiltration, attachment, and survival of cells within the scaffold. Owing to its nano-dimensional mesh structure [110], the superabsorbent hydrogels are usually employed to the small tissue defects while failing in larger implants. Several novel techniques for producing porous hydrogels had been summarized in several review papers [3, 45] and might be of great value in improving the regenerative potential of cellulose-based superabsorbent hydrogels.

In addition, there has been considerable interest in using cross-linked carboxymethyl cellulose (CMC) as tablet disintegrants. In order to achieve this, the cellulose superabsorbent hydrogels in powder form is mixed well with other excipients and thus is compressed to a tablet. Sadly, the cellulose-based superabsorbent hydrogel tablets may get soften at high-humidity condition, and thus, it may have an instability concern to the moisture-sensitive drugs [115]. Tissue engineering is the latest application of hydrogels which is mainly served for three purposes including as delivery vehicles for bioactive substances (for encapsulation of secretory cells and promotion of angiogenesis), as space-filling agents (to prevent adhesion, employed for bulking and as biological glue), and as three-dimensional structures that organize cells and present stimuli in order to ensure the development of a required tissue in the body (i.e., smooth muscle, bone, and cartilage) [111].

Superabsorbent hydrogels are widely applied in the wound treatment. During the wound healing, several processes including inflammation, autolytic debridement, granulation tissue formation, and reepithelialization are normally involved. Large wounds result in high risk of infection as well as loss of large amounts of fluids. Therefore, suitable wound dressings are designed to promote healing while protecting the wound from further infection. For an ideal wound management product, it should have numerous properties such as being able to absorb excess toxins and exudate, preserve the wound from external infection, prevent excess heat at the wound, maintain good moisture between the dressing and wound, have good permeability to gases, be easy to remove without further trauma to the original wound, and be supplied completely sterile [116]. It is known that a moist environment encourages rapid healing; therefore, the hydrogels in the form of sheets or amorphous state are optimal candidates for the development of wound dressings [117]. Basically, amorphous hydrogels are physically cross-linked, and their viscosity will be decreased when absorbing the physiological fluids. Amorphous-state hydrogels are generally reapplied daily, while the sheet structure hydrogels are usually changed 2–3 times weekly [3]. The hydrogels may be packaged in foil packets or in tubes and can reinforce with a polymeric mesh or gauze for the ease of removal and to prevent gel liquefaction. The advanced dressings are aimed to keep the moist environment at the applied site, allowing the fluids to remain close to the wound rather than spread to the healthy, unaffected skin areas [118]. The significance of the moist condition around the wound as a factor accelerating the healing process was first observed in 1962 by Winter [119] but only has received much attention recently.

Besides that, hydrogels are used as moist dressings, debriding agents, and components of pastes for wound care. Yet, they do not prerequisite wound fluids to convert into gels and, thus, are suitable for dry wounds [120]. It is worth mentioning that the superabsorbent hydrogels are able to provide non-adherent dressings which can be easily detached from the wound bed without further hurt. A further advantage of hydrogel is the transparency properties as the user can easily monitor the condition of wound healing. In recent year, the antimicrobial agents, such as silver ions, have been included in the formulation of hydrogel dressing production, as shown in Table 8. Bacterial cellulose has been extensively

Table 8 Commercially available hydrogel for application of wound dressings [45]

Hydrogel wound dressing	Producer	Composition
IntraSite™ Gel	Smith & Nephew	Propylene glycol, water, NaCMC
Aquacel Ag™	ConvaTec	NaCMC, silver ions (1.2%)
GranuGel™	ConvaTec	Water, NaCMC, propylene glycol, pectin
Purilon Gel™	ColoPlast	Water, calcium alginate, CMC
Silvercel™	Johnson & Johnson	Calcium alginate, silver ions (8%), CMC

investigated for wound healing due to its high purity and excellent water retention capacity, and a series of bacterial cellulose-based wound dressing are currently marketed [121].

8 Formation Mechanism of Cellulose-Based Hydrogels

In general, there are three main types of hydrogel-forming mechanisms: chemical cross-linking, ionotropic cross-linking, and complex coacervate formation. The mechanism for the formation of hydrogels (gelation behavior) has a direct and significant impact on the methods used to fabricate the hydrogel component for tissue engineering. Certain gel-forming processes resulted in the rapid prototyping fabrication process, while the slower fabrication techniques (i.e., porogen leaching) are suitable for robust hydrogels, which normally require more time to develop [122]. All hydrogels possess physical attraction between macromers due to the presence of hydrogen bonding and entanglements among one another [20]. Unfortunately, these physical interactions are strong enough only for the formation of a weak gel but not strong enough for tissue engineering applications or layer-upon-layer fabrication. Therefore, a hydrogel is usually intended for tissue engineering applications which must be strengthened through additional chemical cross-linking or electrostatic interactions.

In the current era, chemical cross-linking is the highly resourceful method for the formation of hydrogels having an excellent mechanical strength. Cross-linking is responsible for the three-dimensional network structures of hydrogels and their physical properties (i.e., swelling and elasticity) that are attributed to the presence of chemical or physical cross-links within polymer chains. The cross-linking level of the hydrogels is also vital because the physical states of the hydrogels can be altered by changing the cross-linking level [123]. In this process, a cross-linking agent is added to a diluted hydrophilic polymer solution, and the polymer must have a suitable functionality to react with the cross-linking agent. This process is applicable for preparation of hydrogels from synthetic and natural hydrophilic polymers [124].

Ionotropic hydrogels are formed from the electrostatic interactions between polycations and anions or polyanions and cations. For instance, chitosan is a polycationic polymer comprised of glucosamine residues, which form a firm ionotropic hydrogel upon addition of phosphate ions and which are positively charged above its isoelectric point [11]. Another example is alginate, a polyanionic

polymer containing glucuronic and mannuronic residues, which will form a firm ionotropic hydrogel with calcium ions [125]. Usually, these hydrogels are able to form a firm hydrogel upon cooling; therefore, it is particularly useful for use in rapid prototyping fabrication techniques or for in situ tissue engineering [126]. Normally, ionic cross-links are beneficial for biomedical applications due to its self-repair properties. Thus, it is proposed to be used as cartilage tissue scaffolds which consist of epoxy amine polymers and gellan gum (a water-soluble anionic polysaccharide) [127].

Complex coacervate hydrogels (as referred to polyelectrolyte complexes or polyion complexes) are formed upon mixing of a polycation and a polyanion with one another (i.e., poly(L-lysine) and alginate) or with an amphoteric polymer (i.e., gelatin and chondroitin sulfate) [20, 128]. This approach is based on the principle that the opposite charges of the polymers stick together to form either soluble or insoluble complexes, depending on the pH and concentration of the solutions [38]. Hydrogels can be produced by a variety of cross-linking methods as well as agents. However, most of the cross-linking agents are toxic and must be eliminated from the hydrogel before contact with the body or cells.

9 Conclusion

Considering the desirable features of hydrogels in terms of biocompatibility, biodegradability, high water content, controllable swelling behavior, low cost, hydrophilicity, and non-toxicity characteristics, cellulose-based superabsorbent hydrogels that are made from natural biomass resources are drawing attention to both industrialist and academicians. These types of novel hydrogels are potentially used for a variety of industrial applications such as drug delivery system, agriculture, tissue engineering, water engineering, hygiene products, wound dressing, and more. In this chapter, we had summarized several polymerization reaction systems that were widely used for the superabsorbent hydrogel production. In addition, stimulate-responsive cellulose-based hydrogels established a new generation of green materials to be applied in several fields, such as pharmaceutical and medical systems. According to different applications, these materials are able to respond to various internal and external stimuli and are sensitive to the changes of temperature, pH, ionic strength, and solvent system. Undoubtedly, superabsorbent hydrogels derived from cellulose and cellulose derivatives offer abundance of promising opportunities in various industries' usage.

10 Outlook/Future Scope

This chapter discusses the current progress of cellulose-based superabsorbent hydrogels from different aspects. Generally, cellulose-based superabsorbent hydrogels possess several favorable properties such as biocompatibility, biodegradability, hydrophilicity, transparency, low cost, and non-toxicity. Therefore, these

bio-based materials offer a wide variety and diverse range of applications for agriculture and horticulture, water treatments, personal health care, and biomedical industries. Nevertheless, some of the novel applications need to be explored, such as electronics, catalysis, capacitors, dye-sensitized solar cells, plugging agent, biosensor, and fire control. Up to date, the established conventional hydrogel-based product could not meet the requirements of the present day and thus the future development on superabsorbent hydrogels by emerging natural biomass resources (cellulose or cellulose derivatives) with the intention of achieving the demands for different product requirements. From the economic and application point of view, the performance of superabsorbent hydrogels (e.g., distinctive mechanical strength, antimildew properties, swelling capability, and electrochemical properties) can be further improved in order to expand to more industrial field. As a result, intense research on the production of cellulose-based superabsorbent hydrogels has to be conducted continuously. It is worth mentioning that cellulose fibers are low cost and is an environmentally friendly material, which is the suitable alternative of petroleum-based materials. Up to date, many hydrogel-based drug delivery devices and scaffolds have been designed, studied, and patented; however, not much of the products are able to reach commercialization stage. On the other hand, commercial hydrogel products for tissue engineering and drug delivery are still limited. It is believed that the limited commercial products with hydrogels in these areas are due to high production costs. Furthermore, advanced technologies need to be further developed in order to produce superabsorbent hydrogels with intrinsic and unique properties. Most important is an in-depth study on the reaction mechanism, and swelling kinetics of superabsorbent hydrogels originated from interdisciplinary angles is needed for deeper investigation.

Acknowledgments The authors are grateful for the financial support from the University of Malaya: SATU Joint Research Scheme (ST015-2017) and Postgraduate Research Grant Scheme (PPP) (PG249-2016A, PG253-2016A).

Abstract

In recent years, renewable/biodegradable polymer-based hydrogels have attracted great interest in the field of hydrogel research and development. The reasons of this interest are their applications in versatile fields including personal care products; drug delivery systems; wound healing; tissue engineering; industrial, pharmaceutical, and biomedical, agricultures; water treatments; food packaging; etc. Other important reasons are the problems caused by synthetic sources to the environment. Therefore, it is our demand to develop natural materials that can be biocompatible and biodegradable with the environment, and important efforts are focused on finding alternatives to replace the synthetic one. Furthermore,

renewable hydrogels display unique properties such as biodegradability, biocompatibility, stimuli-responsive characteristics and biological functions. Natural hydrogels are often based on polysaccharide or protein chains. Due to the hydrophilic structure of polysaccharides, they have a good property to form hydrogel. There are various polysaccharides like starch, cellulose, sodium alginate, chitosan, guar gum, carrageenan, etc. that have been focused and used for the preparation of environmental friendly hydrogels. Among them, cellulose and its derivatives revealed distinctive benefits because they are the most abundant natural polysaccharide having low cost and better biodegradability and biocompatibility. Protein chains, which form natural hydrogels, are collagen, silk, keratin, elastin, resilin, and gelatin. On the other hand, many synthetic polymers/copolymers also form hydrogel like poly(vinyl alcohol), polyacrylamide, poly(ethylene oxide), poly(ethylene glycol), etc. Synthetic polymer-based hydrogels have one benefit of chemical strength than natural counterpart due to the slower degradation rate of the hydrolyzable moieties. However, biorenewable polymers usually present higher biocompatibility compared to synthetic polymers, as they undergo enzyme-controlled biodegradation by human enzymes (e.g., lysozyme) and produce biocompatible by-products. This chapter focused on the advantages of biorenewable hydrogels over synthetic (acrylate- and acrylamide-based) hydrogels.

Renewable hydrogels · Synthetic hydrogels · Biopolymer · Polysaccharide · Protein chains

1 Introduction

In nature, polymers are extensively distributed, and they are derived from renewable sources and commonly termed as natural polymer [1]. These natural polymeric materials show a huge variety of chemical structures, diverse physiological functions, and other biological properties. For example, they have physiological properties like tissue; they are bioactive, degraded by naturally occurring enzymes, have less inflammatory response, etc. Consequently, hydrogels prepared from renewable sources/polymers are gaining a great interest. Hydrogels can be defined as a three-dimensional network of polymer chains (may contain inorganic/organic cross-linker), which is hydrophilic in nature and can absorb huge amounts of water or biological fluids. Hydrogels from polymer become the fast developing group of materials due to their wide range of application in different disciplines, especially pharmacy, medicine, agriculture, and environment. At the end of 1960s, Wichterle and Lim first reported about the hydrogel preparation [2], and subsequently these incredible materials emerged as an indispensable part in different fields of applications. In 1980, Lim and Sun developed hydrogels of calcium alginate microcapsules and used in cell encapsulation [3]. Again, at the end of 1980s, another important work was done by Yannas and coworkers with natural polymers [4]. They prepared

hydrogels by incorporating natural polymers (e.g., collagen and shark cartilage) and applied them for artificial burn dressings. Renewable or biodegradable hydrogels also have similarity with natural living tissue more than any other type of synthetic biomaterials. They have high water absorption capacity and soft consistency and resemble to natural tissue [5]. Their biocompatibility related to high water content of these materials. Hydrogel-forming polymers do not dissolve in aqueous solution at physiological conditions. Nevertheless, they swell substantially in water or biological fluid [6] and exhibit amazing ability (>20%) to absorb water into their network structure. Hydrogels exhibiting a phase transition behavior with changing external conditions like pH, temperature, ionic strength, and electric currents are called stimuli-responsive/smart gels [7]. Hydrogels with 3D hydrophilic networks can absorb large amounts of water as they are insoluble in water. This property attributes to their good blood compatibility and keeps a firm amount of structural integrity and elasticity [7]. Due to these types of special properties, recently hydrogels are fast emerging group of materials, achieving extensive application in the fields of personal care products; drug delivery systems; wound healing; tissue engineering; industrial, pharmaceutical, and biomedical; agricultures; water treatments; food packaging; etc. [5, 8–15].

Based on network formation hydrogels can be of three types:

(a) Physical hydrogels – usually formed by electrostatic interactions between oppositely charged biopolymers.
(b) Chemical hydrogels – can be prepared by applying inorganic/organic cross-linkers to covalently bridge biopolymers at reactive sites.
(c) Interpenetrating polymer networks (IPN) – these are physical entanglements of polymers which form a distinct network as shown in Figs. 1 and 2.

Natural or synthetic polymers can be used to prepare physical and chemical hydrogels. The network formation of molecular association occurred, even though they form mixed organization of free domains (Fig. 1) [16]. Weak interaction forces like hydrophobic interactions, ionic interactions, or hydrogen bonding are responsible for the formation of physical hydrogels [9]. It is also called reversible or pseudo gels because it can be degraded or disintegrated in water and easily melts on heating. On the other hand, in chemical hydrogels network formation occurred by covalent bond formation, and therefore it is also called irreversible or permanent gels (Fig. 1) [17]. They cannot be dissolved or disintegrated in water or aqueous solutions. Another type of hydrogel, "IPN," can be defined as a physical blend of cross-linked polymers, where a minimum of one polymer needed to be synthesized and/or cross-linked within the instantaneous presence of the other. Without breaking the chemical bonds, these blends cannot be separated [18, 19]. IPN hydrogels can be classified again in three types according to the method of preparation such as (i) simultaneous IPN [18] (Fig. 2a), (ii) sequential IPN (Fig. 2b), and (iii) semi-IPN [18, 19]. If a linear polymer (synthetic or biopolymer) is entrapped in a matrix and form a semi-IPN hydrogel, then a fully IPN would be prepared later by a

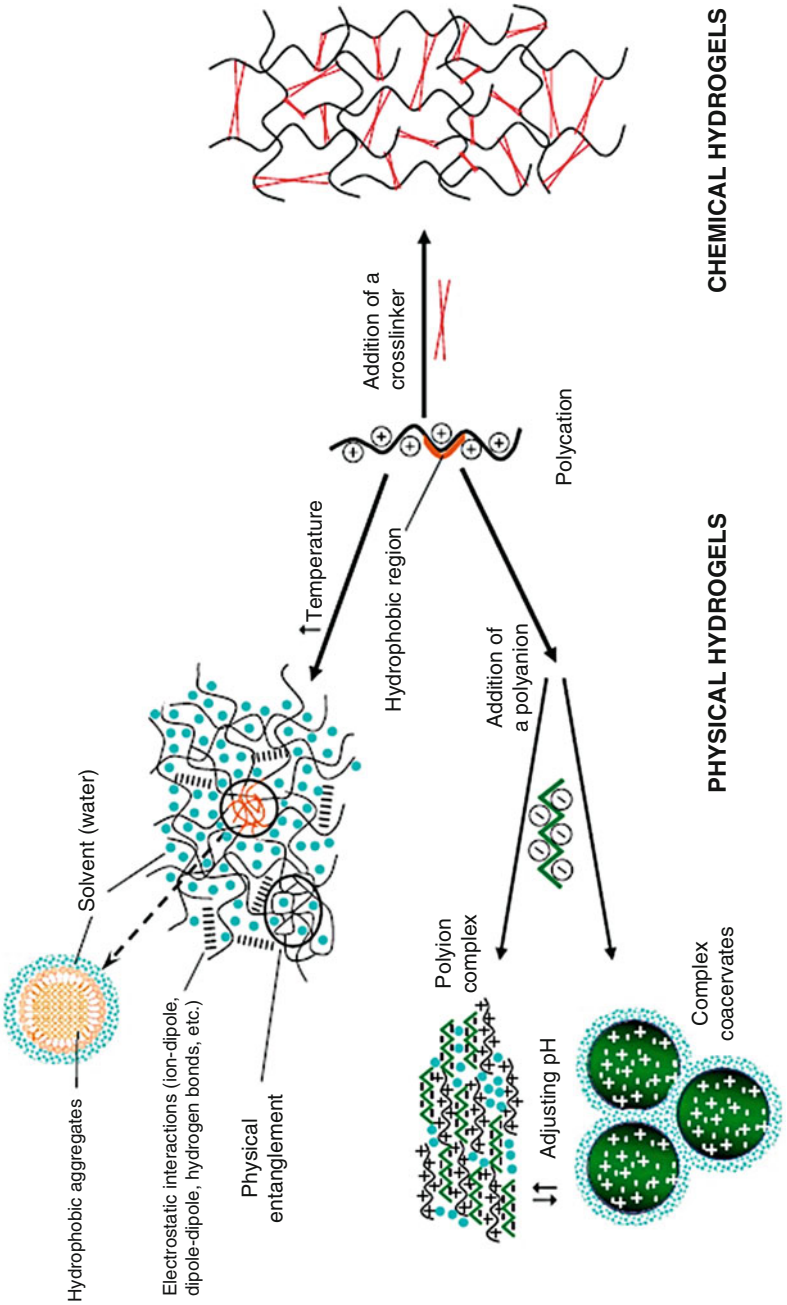

Fig. 1 Common mechanism for the formation of physical and chemical hydrogels. (Reprinted with permission from Ref. [15]. Copyright © 2017, Elsevier)

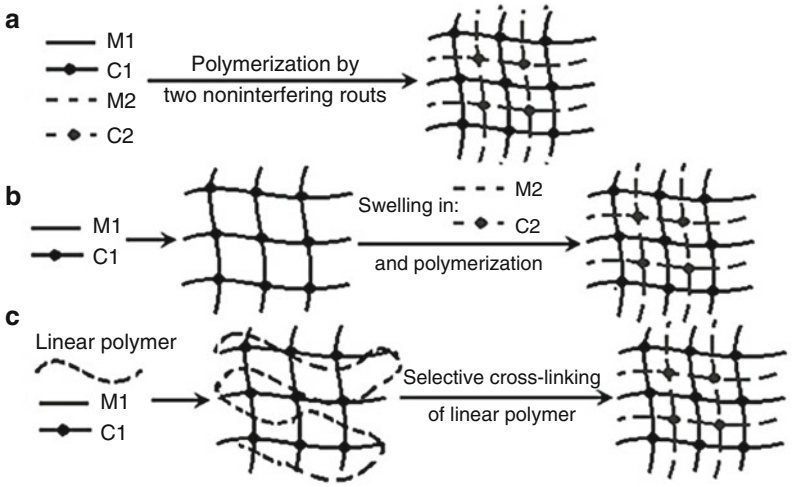

Fig. 2 Common mechanism for the formation of physical and chemical hydrogels. (Reprinted with permission from Ref. [15]. Copyright © 2017, Elsevier)

selective cross-linking of the linear polymer chains [20, 21] (Fig. 2c). Again, based on the preparation methods, this 3D structure of hydrogels could be divided into homopolymeric and copolymeric. These copolymeric thermoplastic biodegradable hydrogels also have been prepared for biomedical uses like drug delivery system [22, 23]. Another special type of hydrogel name is superabsorbent hydrogels. These are also hydrophilic networks capable of absorbing large quantity of water, have high swelling property, and can retain aqueous solutions up to hundreds of times their own weight [24–26].

As it was mentioned earlier, biorenewable hydrogels have many benefits over synthetic hydrogels and there are many reasons. Another important reason is the problems created by synthetic sources to the environment [27]. Hence, scientists are trying to develop natural materials to replace the synthetic one that can be biocompatible and biodegradable, which will not be harmful to the environment [28]. Among the different types hydrogel, renewable hydrogels show distinctive properties like biocompatibility, biodegradability, stimuli-responsive features, and biological functions [29, 30]. Natural or renewable hydrogels are usually based on polysaccharides or proteins. Polysaccharides can form hydrogel easily because of their hydrophilic chemical structure. There are many types of polysaccharides, which can be applied to prepare environmental friendly hydrogels such as cellulose, starch, chitosan, sodium alginate, guar gum, carrageenan [31–33], etc. Among them, cellulose and its derivatives revealed distinctive benefits because they are the most abundant natural polysaccharide having low cost and better biodegradability and biocompatibility [8, 34]. Proteins are another source of renewable hydrogels, prepared from natural extracellular matrix composed of isolated or enriched proteins. These hydrogels are favorable candidates as smart biomaterials due to their inherent

and controllable properties. They have excellent properties to be used in biomedical applications such as natural cell binding, cell degradable, and growth factor-binding sequences. Some of the examples of protein chains forming natural hydrogels are collagen, silk, keratin, elastin, resilin, and gelatin [35, 36]. On the other hand, various synthetic polymers/copolymers also form hydrogel such as polyacrylamide, poly(vinyl alcohol), poly(ethylene glycol), poly(ethylene oxide), etc. Compensating the limitations of synthetic polymer-based hydrogels, they have one advantage of chemical strength than natural one due to the slower degradation rate of the hydrolyzable moieties [37–39]. Conversely, biorenewable/natural polymers generally show higher biocompatibility, if we compare with synthetic polymers. Natural polymers also undergo enzyme-controlled biodegradation by human enzymes (e.g., lysozyme) and produce biocompatible by-products [40].

This chapter will be focused on details about the advantages of biorenewable hydrogels over synthetic hydrogels especially acrylate- and acrylamide-based hydrogels. Moreover, it will discuss about the renewable or biorenewable polymer-based hydrogels, their sources, preparation methods, types, properties, and applications. It will cover the information about newly developed biorenewable hydrogels. Furthermore, the advantages of biorenewable hydrogels over synthetic hydrogels especially acrylate- and acrylamide-based hydrogels will be discussed. Finally, future scope of these types of hydrogels is also described.

2 Renewable Hydrogels from Biopolymers

Renewable hydrogels, obtained from biopolymers, are the most widespread and effective materials because of their safety, biocompatibility, hydrophilicity, biodegradability, and wide applicability [41–43]. The demand of biopolymeric materials is increasing due to the problems caused by the use of different types of synthetic sources. Biopolymers are polymers produced from living organisms and are always renewable, because they are made from plant materials that can be grown indefinitely. Biopolymer contains monomeric units that are covalently bonded to form larger structures. There are three main classes of biopolymers: polynucleotides (RNA and DNA), polypeptides, and polysaccharides [44, 45]. Biodegradable natural polymers are mainly based on renewable sources such as starch, alginate, gelatin, chitosan, cellulose, etc. and can be produced naturally or synthesized from renewable sources. These biodegradable polymers have wide applications in a variety of fields such as agriculture, food industry, wastewater treatment, medicine, cosmetics, tissue engineering, drug delivery and wound healing, packaging industry, removal of heavy metals, and so on. Synthetic polymers including poly(vinyl alcohol), polyacrylamide, poly(ethylene oxide), and poly(ethylene glycol) have also been used for the formation of hydrogels [46]. But natural polymers usually show higher biodegradability and biocompatibility compared to synthetic polymers, as they undergo enzyme-controlled biodegradation by human enzymes like lysozyme that produces biocompatible by-products [47]. In the following sections, details about biorenewable hydrogels (polysaccharide- and protein-based) will be discussed.

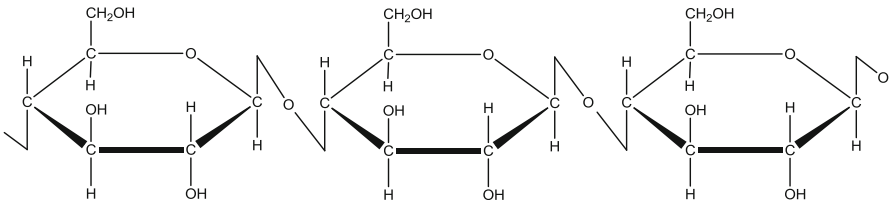

Fig. 3 Structure of cellulose

2.1 Polysaccharide-Based Hydrogels

Polysaccharides have hydrophilic structure which is a favorable property for the preparation of renewable hydrogels [48]. The ever-increasing interest to utilize renewable polysaccharide-based hydrogels as biomaterials has gained increased attention in many disciplines including biomedicine, bioengineering, pharmacy, chemistry, and materials science. Some examples of polysaccharide-based hydrogels are hydrogels made of alginate, cellulose, chitosan, starch, and guar gum. Preparation reactions for polysaccharide-based hydrogels can be classified into two main groups: (1) graft copolymerization of vinyl monomers on polysaccharide in the presence of a cross-linker and (2) direct cross-linking of polysaccharide [49]. Various kinds of polysaccharide-based hydrogels are discussed in the following sections.

2.1.1 Cellulose

Cellulose is the most abundant biopolymer on earth, thus having great potential in hydrogel preparation. From a chemical point of view, cellulose is a polydispersed linear homopolymer that consists β-(1→4)glycosidic-linked D-glucose units, which gives rise to a linear syndiotactic polymer with hydroxyl groups arranged in an equatorial disposition (Fig. 3). The main source of cellulose is the main constituent of the cell walls of plants. Cellulose is traditionally used as a raw material for the production of paper, paperboard, fiberboard, textile fibers, stabilizer, thickener, gelling agent, etc. [50].

Cellulose-based hydrogels, obtained from different low-cost routes, have excellent biodegradable and biocompatible properties. Such bio-friendly behavior makes cellulose-based hydrogels appealing for smart application in a variety of fields. Cellulose-based hydrogels can be obtained from cellulosic (native cellulose and its derivatives) via cellulose dissolution and physical as well as chemical cross-linking strategies. Composite hydrogels with specific properties can be prepared by using cellulose in conjunction with natural and/or synthetic polymers. The major advantage of cellulose-based hydrogels is that they are easily modifiable and have good transport properties. In view of expanding the scope of hydrogel applications, it is important to take full advantage of the unique structure as well as physical and chemical properties of hydrogels to develop novel materials with promising new features. Several approaches were developed to prepare cellulose-based renewable hydrogels.

Hydrogels Prepared Directly from Native Cellulose

Cellulose hydrogels can be prepared from a cellulose solution through physical cross-linking due to hydroxyl groups, which can easily form hydrogen bonding linked network. The main limitation of cellulose hydrogels is the low solubility of cellulose in both water and most organic solvents due to the hydrogen-bonded structure [51]. This problem can be avoided by using new solvents such as *N*-methylmorpholine *N*-oxide (NMMO), ionic liquids (ILs), alkali/urea (or thiourea) aqueous systems, dimethylacetamide/lithium chloride (DMAc/LiCl) system, etc. to dissolve cellulose, providing great opportunities for the preparation of cellulose hydrogels. Moreover, bacterial cellulose (BC) is also a strong candidate for the fabrication of cellulose hydrogels. Nowadays cellulose hydrogels are the ideal materials for tissue engineering applications [52].

Hydrogels from Cellulose Derivatives

Water-soluble cellulose derivatives are mostly biocompatible which can be used as thickener, binding agents, emulsifiers, film formers, suspension aids, surfactants, lubricants, and stabilizers, especially as additives in food, pharmaceutical, and cosmetic industries. Selective cellulose ethers such as methyl cellulose (MC), hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and carboxymethylcellulose (CMC) have been used to fabricate cellulose-based hydrogels through physical cross-linking and chemical cross-linking method.

Cellulose-Polymer Composite Hydrogels

To obtain new structural materials, blending of different polymers is an extremely attractive, inexpensive, and advantageous method [53]. Cellulose (or its derivatives) has created novel materials when blended with natural biodegradable polymers, such as chitin, chitosan, starch, alginates, and hyaluronic acid [23, 54–56] to fit the special applications, such as blending with chitosan for heavy metal removal, with starch for foods, and with alginates for tissue engineering. Poly(vinyl alcohol) (PVA) is also a good candidate for the preparation of hydrogels. Several methods are used to prepare cellulose-PVA hydrogels including chemical agents, electron beam, irradiation, or physical thermal cycling. For biomedical applications, physical cross-linking has the advantage than PVA gels cross-linked by either chemical or irradiation techniques because physical cross-linking method avoids residual amounts of toxic chemical cross-linker and shows higher mechanical strength [57].

Cellulose-Inorganic Hybrid Hydrogels

Due to potential applications in electric, optical, magnetic, and biological fields, polymeric-inorganic hybrid materials have attracted increasing attention in recent years [58]. Introduction of inorganic into cellulose hydrogel networks is an effective way to develop materials with high functionality. For instance, hydrogel made from calcium phosphate and Si-HPMC is used as an injectable and self-cross-linkable bone substitute and also developed for filling bone defects.

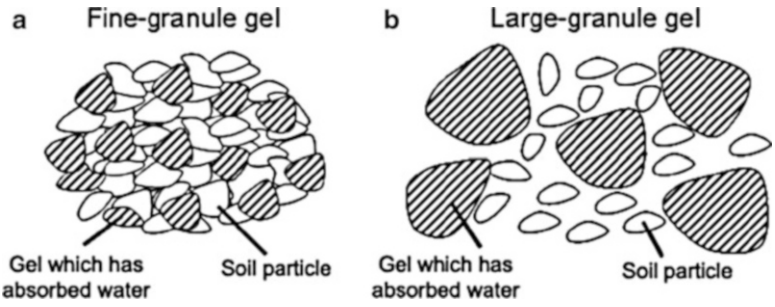

Fig. 4 Spatial distributions of hydrogels and soil particles [8]

Prospects for Applications of Cellulose-Based Hydrogels: There is an increasing interest in using cellulose-based superabsorbent hydrogels in agriculture. This is mainly due to the necessity of decreasing water consumption and boosting water resources in agriculture. Sannino and coworkers recently developed a novel class of totally biodegradable and biocompatible microporous cellulose-based superabsorbent hydrogels [59–62] which are able to absorb up to 1 L of water per gram of dry material (Fig. 4).

Due to the industrial development, the serious threat of heavy metal ions to the environment is a precise concern worldwide. Heavy metals are the most common pollutants found in wastewater and can be accumulated in the environment and living tissues. These heavy metals cause various diseases and disordering of living organisms even at a trace level [63]. Thus, it is indispensable to remove harmful heavy metals from aqueous solutions. Recently, cellulose-based renewable hydrogels have wide application for the removal of heavy metals from the aqueous solution. For example, Xiong Chen and his coworkers [64] prepared cellulose/graphene oxide hydrogel, a highly efficient bioadsorbent using NaOH/urea aqueous solution (Fig. 5). The hydrogel showed high efficient regeneration and high adsorption capacity for Cu^{2+}, Zn^{2+}, Fe^{3+}, and Pb^{2+}.

Moreover, cellulose-based hydrogels are appealing materials for a number of applications in vivo [62, 65] due to the intrinsic biocompatibility of cellulose. Also, Sannino and coworkers reported the development of cellulose-based hydrogels from the aqueous mixtures of NaCMC and HEC, which have been shown to be tempting for the production of dietary bulking agents [66, 67]. In particular, cellulose-based hydrogels obtained from nontoxic cross-linking agents are particularly attractive for this kind of application.

In another work, Sannino et al. reported that cellulose-based hydrogels cross-linked with hyaluronic acid [66] induce a good proliferation of keratinocytes, following a scratch wound model in in vitro culture. A few studies show that cellulose-based hydrogels are potentially useful for inducing the regeneration of bone, cartilage, and neural tissues [68, 69].

Tissue engineering is the most recent application of cellulose-based hydrogels. J. J. Marler et al. reported the cellulose-based hydrogels which are used as scaffolds

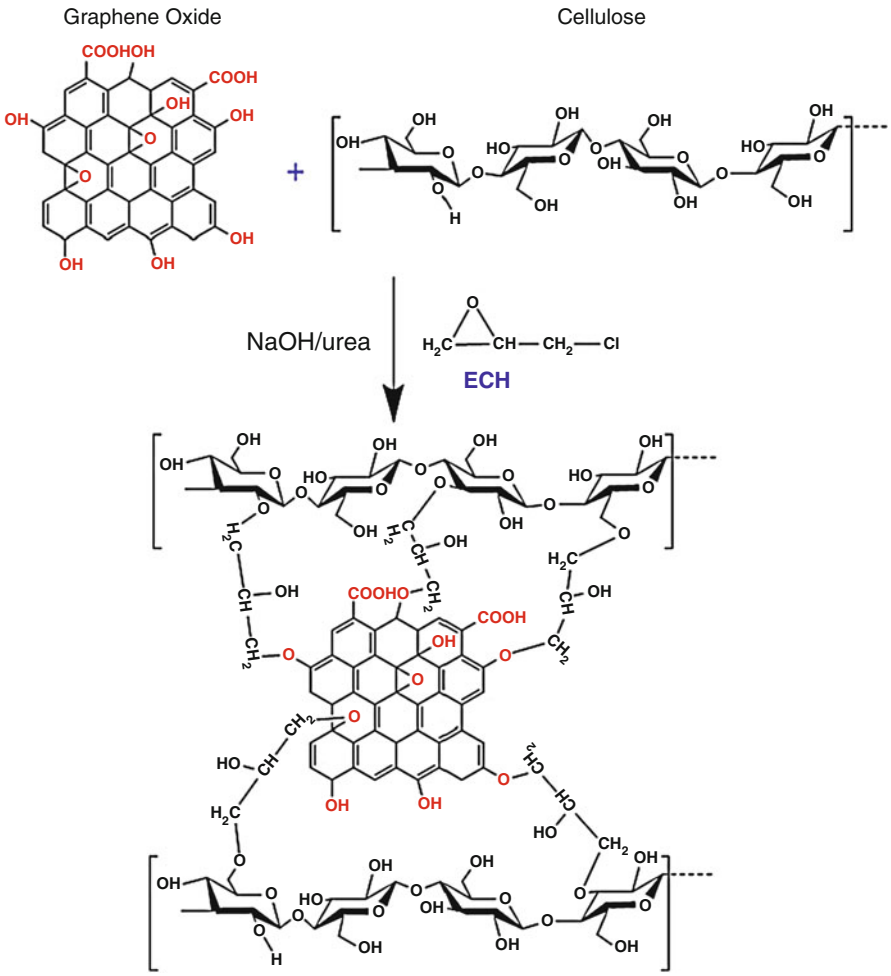

Fig. 5 Proposed mechanism for cross-linking reaction of epichlorohydrin with graphene oxide and cellulose [64]

to mimic many roles of extracellular matrixes. These scaffolds provide space and nutrients for new tissue formation and potentially control the structure and function of the engineered tissue in situ or in vitro [70]. The scaffolds also serve as a temporary, artificial, extracellular matrix in order to support the cell attachment [71, 72]. Hydrogel scaffolds are at or near clinical uses in engineering many tissues in the body including cartilage, bone, muscle, skin, fat, artery, ligament, tendon, liver, bladder, and neurons [73]. Several studies report the applicability of cellulose-based materials for culturing cells and for implantation such as bone regeneration [74, 75], hepatocyte culturing for an artificial liver [76], expansion of progenitor hematopoietic cells in culture [77], and suppression of matrix metalloprotease action in wound healing [78].

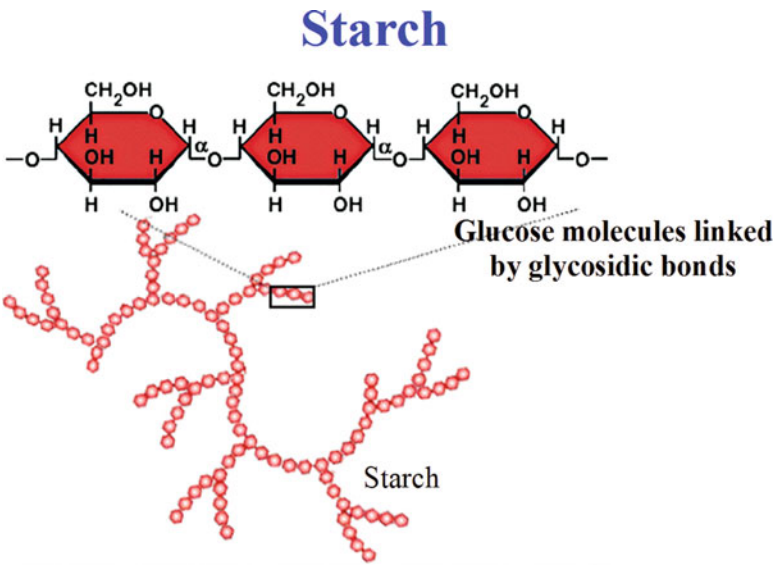

Fig. 6 Structure of starch

As we know cellulose itself has no antimicrobial activity to prevent wound infection. For that reason, to achieve antimicrobial ability, few researchers impregnated ZnO or Ag nanoparticles (NPs) into the cellulose gel system [79, 80]. Furthermore, due to their high absorbency, porous structure, rich functional groups, and relatively low crystallinity, cellulose-based hydrogels have attracted special attention for water purification through adsorption.

2.1.2 Starch

Starch is the most abundant storage polysaccharide which is composed of linear amylose and branched amylopectin (Fig. 6) and is considered the main form of stored carbohydrates in plants such as rice, potatoes, or corn [81]. Starch has gained more attention for developing renewable hydrogels by mixing with other natural or synthetic sources because of its complete biodegradability, low cost, nontoxicity, and renewability. Recently, it has been reported that starch-based polymers have better application in packaging, drug delivery systems, and tissue engineering scaffolds [82]. But the application of starch film is restricted because of its poor process ability, dimensional stability, low shear resistance, high tendency toward retrogradation, and high moisture sensitivity. This restriction has led to the necessity to associate starch with either biopolymers or synthetic polymers to preserve the biodegradability of the final product [83].

Prospects for Applications of Starch-Based Hydrogels: Recently, much attention has been given in developing starch-based renewable hydrogels [84, 85]. To retain large amounts of water, starch-based renewable hydrogels have been used for a variety of applications in the medical and pharmaceutical industries.

Viyoch et al. [86] reported the preparation of an injectable thermosensitive hydrogel for chondrocyte delivery by mixing starch and chitosan. They found that the presence of starch in the chitosan system could raise the average pore size and water absorption of the hydrogels that can be suitable for cartilage tissue engineering.

Pereira et al. [87] reported biodegradable hydrogel based on starch/cellulose acetate blends, produced by free-radical polymerization and used as biodegradable bone cements or drug delivery carrier. Fekete and coworkers [88] reported the synthesis of starch/carboxymethylcellulose superabsorbent hydrogels by gamma-irradiation technique that exhibits good swelling properties but lower sensitivity to the presence of salts or the pH of the soil. Also, Baran et al. [82] prepared starch-chitosan hydrogels by reductive alkylation cross-linking method for biomedical application.

Due to the increase in awareness about the hazardous effects of enhanced levels of heavy metal ions in the environment, pollution by heavy metals has been recently given more attention [89]. As we know, activated carbon is used as adsorbent for the removal of heavy metal ions because of its extended surface area, high adsorption capacity, and microporous structure. However, activated carbons are found to be commercially expensive, which has led to a search for cheaper adsorbents. Hashem et al. [90] reported the preparation of three types of hydrogels through the graft polymerization of acrylonitrile onto maize starch where ceric ammonium nitrate was used as the initiator. The hydrogels were used to remove Hg (II) ions from aqueous solutions. In another research, Chauhan et al. [91] prepared poly-carboxylated starch-based hydrogels as Cu^{2+} ion sorbents by the free radical initiation, and *N,N′*-methylenebisacrylamide was used as a cross-linker. The studies showed that the maximum adsorption capacity of 128.26 mg/g was obtained within 2 h at 40 °C with 7 pH and a Cu^{2+} ion concentration of 50 ppm. The possible interaction of Cu^{2+} with polycarboxylated starch-based hydrogels is shown in Fig. 7.

Superabsorbent hydrogels prepared from starch can also be utilized for electric cable production to prevent penetration of water in the cable through the junction when the outer coating of the cable is damaged. Such a special type of water-blocked telecommunication cables and water-blocked yarns was invented by Schoeck et al. [92] using a starch superabsorbent hydrogel.

2.1.3 Alginate

Alginates are binary, natural linear polysaccharide and copolymers of (1→4) linked β-D-mannuronic acid (M) and α-l-guluronic acid (G) monomers of widely different compositions and sequences (Fig. 8). The most common source of alginate is the cell wall of brown algae including *Laminaria hyperborea*, *Laminaria digitata*, *Laminaria japonica*, *Ascophyllum nodosum*, and *Macrocystis pyrifera*. For commercial purposes, alginates are extracted from seaweed [93]. Due to its biocompatibility, low toxicity, relatively low cost, and mild gelation, alginates have been widely used for many years as a potential biomaterial for many biomedical applications such as tissue engineering, wound healing, cartilage and bone regeneration, protein delivery, in vitro cell culture, antibacterial films, drug delivery [94], etc. Although alginate has a strong potential to be used in various applications, it usually lacks the desired

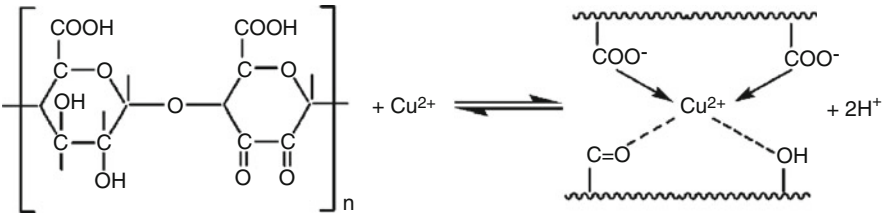

Fig. 7 Possible interactions in Cu^{2+} ion sorption. (Reprinted with permission from Ref. [91]. Copyright © 2017, American Chemical Society)

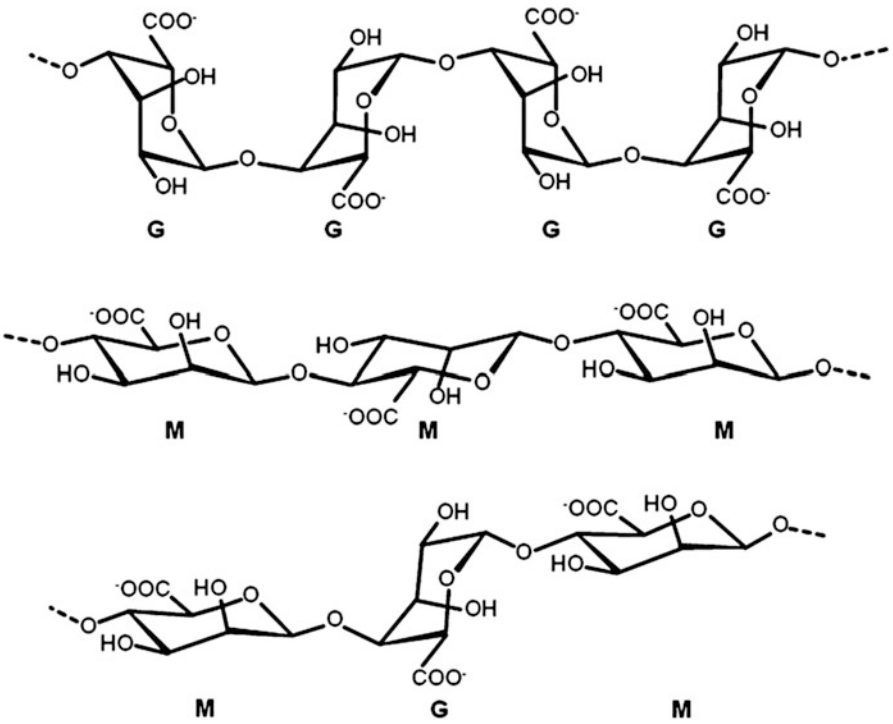

Fig. 8 Chemical structures of G-block, M-block, and alternating block in alginate. (Reprinted with permission from Ref. [95]. Copyright © 2017, Elsevier)

mechanical strength and thermal properties. For that reason, alginate is often associated with natural as well as synthetic polymers to improve the mechanical and thermal properties.

Prospects for Applications of Alginate-Based Hydrogels: Alginate-based hydrogels are considered one of the most biocompatible materials [96] and have been found applicable in several pharmaceutical and biomedical systems. For instance, they have been widely used in tissue engineering and controlled drug delivery of molecules or proteins [97, 98], cell encapsulation system [99], and

scaffolds for tissue or organ regeneration [100]. Alginate-based hydrogels are prepared by cross-linking method because cross-linked polymers have better mechanical strength than natural polymers. Several researchers developed alginate-based hydrogels using various approaches. Zhao et al. [101] reported the preparation of Janus alginate hydrogel particles with magnetic anisotropy for cell encapsulation. Navratil et al. [102] reported the preparation of alginate hydrogel by ionotropic gelation for entrapment of microbial cells for the production of fermented beverages.

Drug delivery carriers and tissue engineering systems have attracted a lot of interest during the past decades. Due to biocompatibility and low toxicity of alginate, the need for alginate-based hydrogels in tissue engineering and drug delivery is enormous and of great clinical significance. For instance, Wang et al. [103] prepared three-dimensional alginate scaffolds cross-linked with calcium ion using microfluidic method which is used for tissue engineering.

We know that sodium alginate is one of the most abundant and naturally occurring polysaccharides. Due to its biocompatibility, biodegradability, high hydrophilicity, and mechanical strength, sodium alginate has received considerable attention for its use in pharmaceutical dosage forms, particularly as a vehicle for controlled drug delivery. Kulkarni et al. [104] reported an interpenetrating hydrogel membrane using sodium alginate and poly(vinyl alcohol) for the controlled release of prazosin hydrochloride through the skin. Moreover, El-Sherbiny and Smyth developed a semi-IPN hydrogel microsphere from sodium alginate and poly(ethylene glycol)-graft-*n*-phthaloyl chitosan [105] which entrapped up to 90% of the drug with promising in vitro sustained release profiles.

Recently, a novel hydrogel system based on oxidized alginate covalently cross-linked with gelatin (ADA-GEL) has been recently developed by Detsch et al. [106] and utilized to design tissue engineering scaffolds, in which cell growth, proliferation, and migration were observed. Xu and coworkers [107] developed a hydrogel composed of alginate and chitosan, cross-linked by calcium chloride and/or sodium sulfate for colon-specific drug delivery. Bunaprasat et al. [108] reported the development of porous polycaprolactone-alginate scaffolds for cartilage tissue engineering. Furthermore, alginate-cellulose hydrogels that are prepared by solvent casting method have found applications in biomedical field especially cell proliferation and tissue generation.

Alginate-based wound dressings such as hydrogels, sponges, etc. are promising substrates for wound healing applications. Alginate/aloe vera hydrogel films prepared by solvent casting method were reported by Pereira et al. [109] for wound healing applications (Figs. 9 and 10). Balakrishnan et al. showed that an in situ-forming hydrogel wound dressing can be prepared from gelatin and oxidized alginate in the presence of small concentrations of borax [110].

2.1.4 Chitosan

Chitosan is a unique bio-based polymer that is an important derivative of chitin (found in the skeleton of crustaceans, such as crab, shrimp, lobster, etc.). It is obtained by partial deacetylation of chitin using a chemical method or by enzymatic hydrolysis [111] (Fig. 11). It is the second most abundant natural polysaccharide next to cellulose and composed of (1→4)-2-acetamido-2-deoxy-β-D-glucan

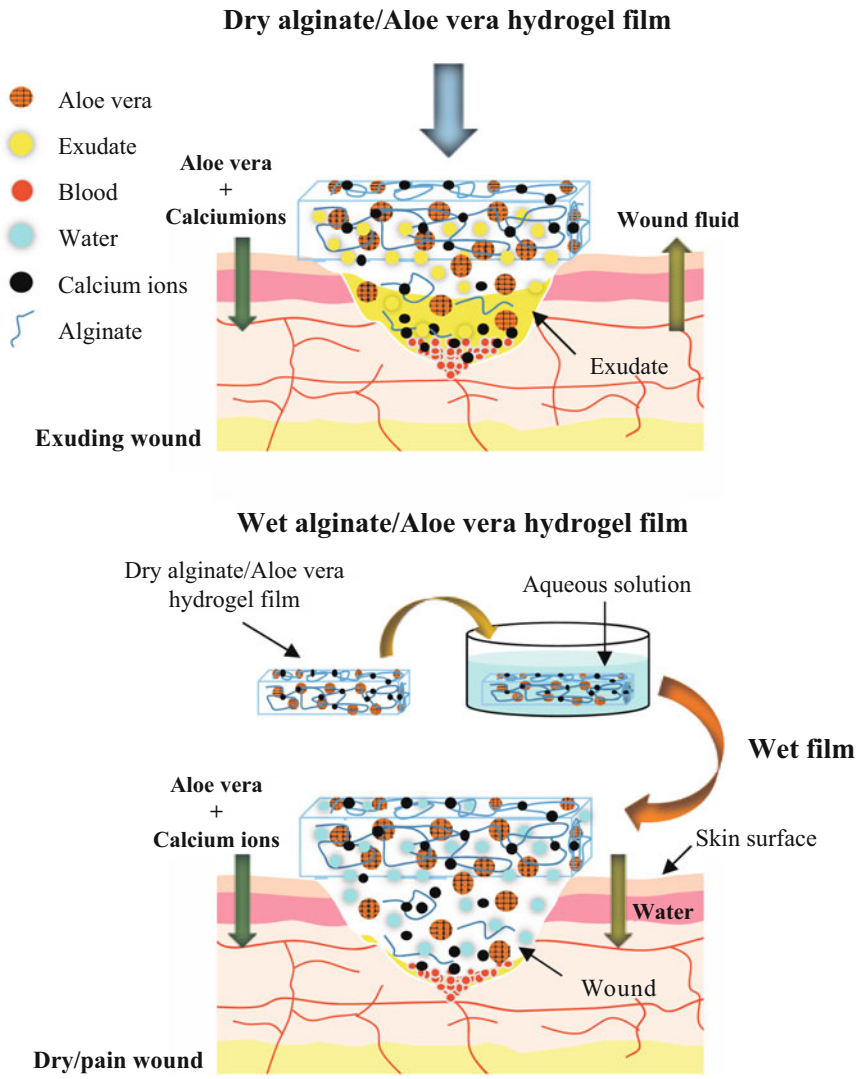

Fig. 9 Application of the alginate/aloe vera hydrogel films into exuding and dry wounds. (Reprinted with permission from Ref. [109]. Copyright © 2017, Elsevier)

(N-acetyl D-glucosamine) and (1→4)-2-amino-2-deoxy-β-D-glucan (D-glucosamine) units [112]. The high availability of chitosan and its biocompatibility and biodegradability have enhanced interest in its use as a hydrogel with potential applications in tissue engineering, biosensors, drug delivery and wound healing, wastewater treatment, removal of heavy metals, and so on [113, 114]. Chitosan has been combined with a variety of natural as well as synthetic polymers to form hydrogels which have potential applications in the fields mentioned above.

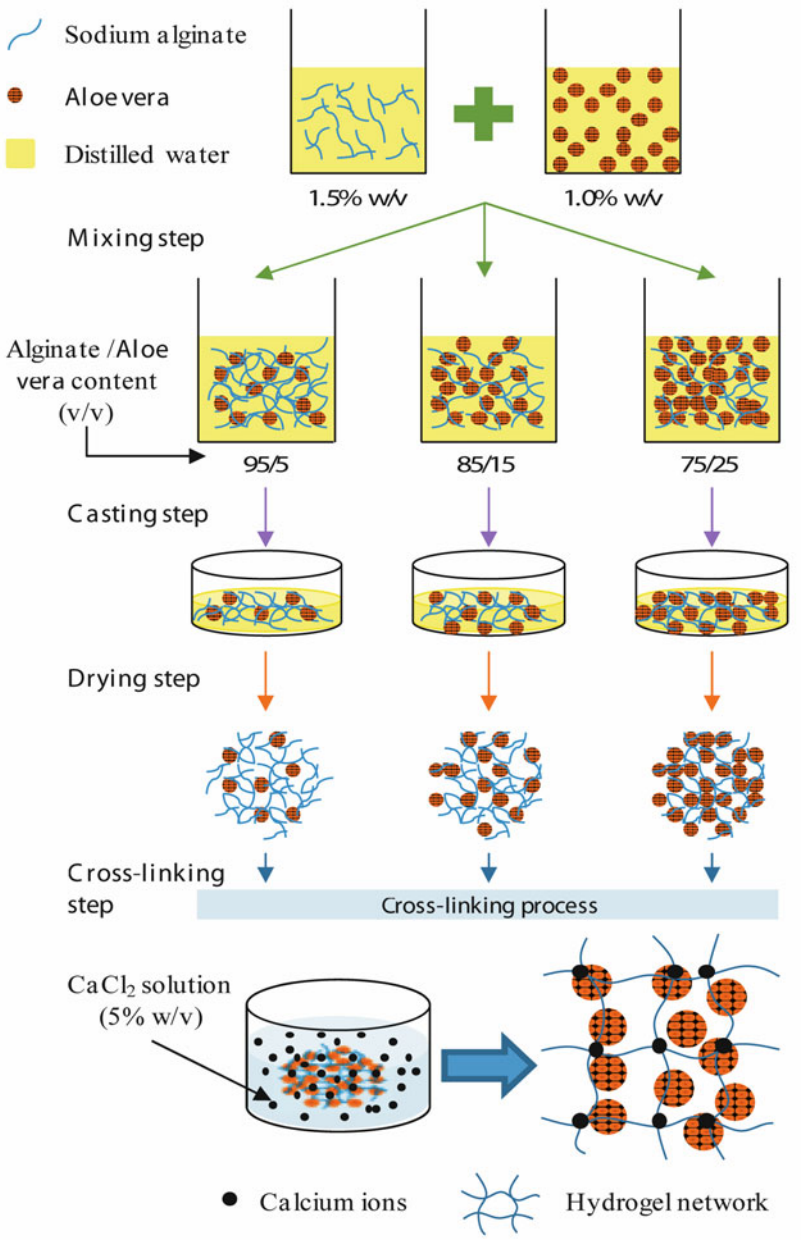

Fig. 10 Production of alginate/aloe vera hydrogel films. (Reprinted with permission from Ref. [109]. Copyright © 2017, Elsevier)

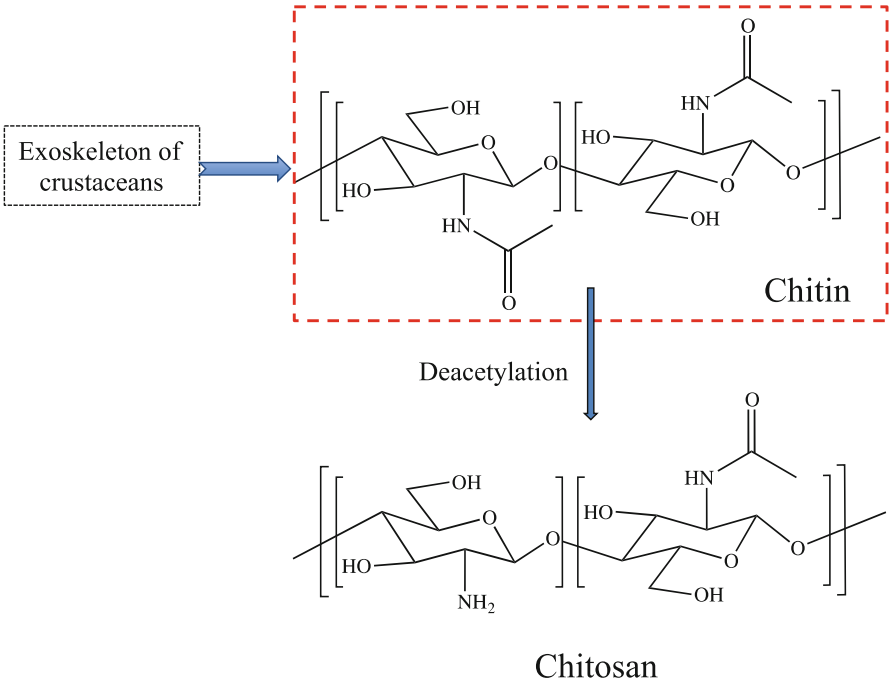

Fig. 11 Chitin is extracted from crab shell from which chitosan is made by deacetylation

Prospects for Applications of Chitosan-Based Hydrogels: Hydrogel based on chitosan and its chemically modified forms are investigated for the delivery of drug to specific sites of the body such as the oral cavity, stomach, small intestine, and colon. Chitosan has cationic nature due to the presence of amine group and therefore can adhere to negatively charged biological surfaces as a bioadhesive material that provides localized drug delivery [115]. Due to its biocompatible and biodegradable property with a structure that could be modified easily, chitosan has been used as drug carrier for different routes of administration.

A novel pH-sensitive hydrogel bead composed of N-succinyl-chitosan and alginate was developed by Dai and coworkers [116]. Chang et al. [117] reported amoxicillin-loaded pH-sensitive hydrogels composed of chitosan and poly (g-glutamic acid) for the treatment of *Helicobacter pylori* infection in the peptic ulcer disease. Interpenetrating polymer networks (IPN) of chitosan and poly(ethylene oxide) have also been developed for the treatment of *Helicobacter pylori* [118].

The high water absorption and mucoadhesive potential of chitosan facilitate its use in nasal drug delivery application. For instance, Nazar et al. [119] reported the synthesis of N-trimethyl chitosan chloride and formulated it into a hydrogel with poly(ethylene glycol) and β-glycerophosphate for nasal drug delivery. Moreover, a thermosensitive in situ gel system was prepared by mixing chitosan and poly(vinyl alcohol) for the nasal delivery of insulin [120]. In another study, Wu et al. [121]

prepared thermosensitive hydrogel by simply mixing quaternized chitosan and poly(ethylene glycol) with a small amount of a- and β-glycerophosphate for nasal drug delivery.

Chitosan in topical form is used for wound healing. The major use of chitosan hydrogels for wound healing is using these systems as wound dressing and hemostatic agent to promote the process of wound healing. A series of hydrogels from an aqueous solution of gelatin and carboxymethyl chitosan were prepared by radiation-induced cross-linking at ambient temperature for wound healing [122]. Also, Tran et al. [123] reported an in situ-forming rutin-releasing chitosan hydrogel as an injectable dressing for wound healing.

The hydrogels derived from chitosan have been the most widely used biomaterials for tissue engineering. As tissue and organ loss or damage is a major human health problem, tissue engineering is one of the available therapies to treat such kind of damage. Hong et al. developed a novel injectable scaffold by combining collagen-coated poly-lactide microcarriers and a cross-linkable chitosan hydrogel loaded with cartilage tissue of rabbit ear for cartilage regeneration [124]. Another novel thermosensitive hydrogel composed of chitosan and pluronic was developed by Park et al. as an injectable cell delivery carrier for cartilage regeneration [125]. Tang et al. [126] prepared injectable hydrogels composed of chitosan and methyl cellulose for cartilage tissue regeneration. The obtained hydrogel resulted in good cell viability and proliferation.

Water contamination is a pervasive and extremely serious global problem owing to the rapid development of the modern industry. Among contaminants, heavy metals are the most harmful ones due to their hazardous effects on the environment. Different methods have been proposed for the treatment of water and industrial wastewater containing heavy metals. Among them adsorption is the easiest and cost-effective way. Due to the pore-forming ability, high adsorption capacity, and three-dimensional cross-linked structure of chitosan, chitosan-based hydrogels have been the most widely used adsorbents to remove heavy metals from wastewater. Some investigations have reported about using chitosan in hydrogel structure for pollutants and heavy metal removal. Wu et al. [127] reported the preparation of porous chitosan-tripolyphosphate beads by the ionotropic cross-linking and freeze-drying that were used for the removal of Cu^{2+} ion.

In another study, Li et al. [128] prepared hydrogel beads from cellulose and chitosan that show high adsorption capacities for Cu^{2+} ion. Wang and his coworkers [129] reported chitosan-poly(vinyl alcohol) hydrogel adsorbent for the removal of Hg(II) ion. Also, chitosan-graft-γ-cyclodextrin (Ch-*g*-γ-CD) was synthesized using persulfate/ascorbic acid which was used for Cd(II) removal [130].

2.1.5 Guar Gum

Guar gum is a hydrophilic and nonionic galactomannan polysaccharide derived from the seed endosperm of the plant *Cyamopsis tetragonolobus*. It is a biodegradable, nontoxic, cheap, and easily available renewable raw material that can be widely used in pharmaceutical formulations, textile, petroleum, paper, explosive, cosmetic, food, toiletry industries [131], etc. Chemically, guar gum has a linear chain of

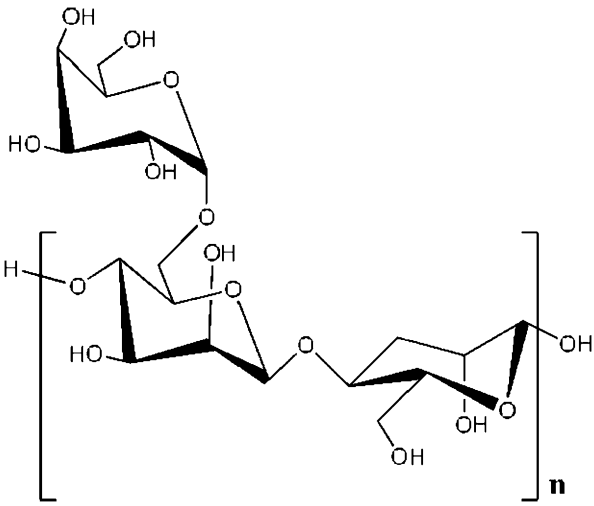

Fig. 12 Structure of guar gum [132]

(1→4)-linked β-D-mannopyranosyl units with (1→6)-linked α-D-galactopyranosyl residues as side chains with mannose: galactose ratio is approximately 2:1 (Fig. 12) [132]. The guar gum has the unique property of absorbing large quantities of water, resulting in dispersions of extremely high viscosity that makes guar gum the most applicable natural polymer nowadays. However, due to uncontrollable rate of viscosity, uncontrollable rate of hydration, instability of its solution for a long time, and susceptibility to microbial contamination restricts the use of guar gum in pharmaceutical industries. To overcome these drawbacks, a lot of research has been done to modify guar gum as hydrogel by changing their physical and chemical properties by grafting, blending, and compositing with synthetic as well as natural polymers. Some of the guar gum derivatives are carboxymethyl guar gum, hydroxymethyl guar gum, hydroxypropyl guar gum, acryloyloxy guar gum, methacryloyl guar gum, sulfated guar gum, guar gum esters [132–134], etc.

Prospects for Applications of Guar Gum-Based Hydrogels: In recent years, biopolymeric hydrogels have been receiving much more attention because of the enhanced properties over purely synthetic hydrogels [135–137]. In the pharmaceutical sector, guar gum-based hydrogel was used for the controlled release of drugs in the gastrointestinal tract, as well as carrier for colon-targeted drugs in the treatment of colorectal cancer [138, 139]. For example, Kabir and his coworkers prepared hydrogel from guar gum with glutaraldehyde and phosphate using chemical cross-linking method to be used as carrier for colon-targeted and transdermal drug delivery [140]. Moreover, M. George et al. developed pH-sensitive alginate-guar gum hydrogel cross-linked with glutaraldehyde for the controlled delivery of protein drugs.

In another study, Fujioka et al. [141] reported the synthesis of novel super-absorbent hydrogels based on the reaction of guar gum and succinic anhydride, using 4-dimethylaminopyridine as the esterification promoter demonstrating maximum absorbency in pure water.

2.1.6 Carrageenan

Carrageenan is a collective term for linear sulfonated polysaccharide that can be extracted from red seaweed (Rhodophyta), such as *Kappaphycus alvarezii*. These natural polymers comprise of repeating units of (1,3)-D-galactopyranose and (1,4)-3,6-anhydro-α-D-galactopyranose with sulfate groups in a certain amount and position [142]. Carrageenan is hydrophilic in nature due to the presence of hydroxyl groups and sulfate groups in it. Because of its gelling ability, nontoxicity, biodegradability, and biocompatibility, carrageenan is a favorable biopolymer to form hydrogel. The properties of hydrogel made from carrageenan depend on the recovery method from seaweed [142]. Alkali treatment in carrageenan recovery from seaweed improved the strength of hydrogel obtained from carrageenan [143]. Carrageenans are widely used as agent for thickening and gelling in food and nonfood industries [144].

Prospects for Applications of Carrageenan-Based Hydrogels: Hydrogels derived from carrageenan were used for various applications. Few studies reported the preparation of carrageenan-based hydrogels by cross-linking with epichlorohydrin [145] and genipin [146] that were suitable for applications in biomedical fields. As glutaraldehyde is easily available and inexpensive, Distantina et al. [147] prepared hydrogel from carrageenan by using film immersion in glutaraldehyde solution followed by thermal curing method.

At present, industry which is a huge source of water pollution produces pollutants that are extremely harmful to people and the environment. Many industries like dye, textile, paper, and plastic facilities produce considerable colored wastewater. Dyes are the type of pollutant from industry that damages the environment. So, it is necessary to remove dyes from wastewater before being discharged into the environment. Carrageenan-based hydrogels were used to remove dyes from wastewater.

Due to its high viscosity and gelling abilities, carrageenan shows interesting properties for the development of a controlled release strategy. Santo et al. [148] developed carrageenan-based hydrogel beads for the controlled delivery of platelet-derived growth factor (PDGF-BB) in bone tissue.

To improve hydrogel properties, new hydrogels based on two or more natural polymers have been developed in the last few years. For instance, Soares et al. [149] developed a new hydrogel based on two natural polysaccharides, galactomannan and kappa-carrageenan. This hydrogel was stable with possible applications in biomedical (scaffold matrices for tissue engineering) and cosmetic fields.

2.2 Protein-Based Hydrogels

Natural protein polymers, i.e., collagen, silk, gelatin, etc., can be found in plenty and offer a renewable source for production of hydrogels. These biopolymers are characterized to possess unique mechanical and architectural properties due to their homogenous secondary structure containing repetitive amino acid sequence [150]. Protein-based hydrogels offer features such as low toxicity and great biocompatibility since their chemical and mechanical structure are similar to extracellular

matrix [151]. Protein-based hydrogels show great potential in cell encapsulations [152, 153] and tissue engineering applications [154, 155]. This part will discuss about the renewable protein-based hydrogel made from biopolymers.

2.2.1 Collagen

Collagen, most common protein in mammals, has a wide application in preparing natural biomaterials. Around 25% (of dry basis) of mammalian protein matter is composed of collagen [156]. There are 28 different types of collagen [157], and among them, type I is by far the most prevalent and popular in tissue engineering owing to its facile extraction process and versatility.

Collagen is composed of a right-handed triple helical structure with amino acid triplet sequence being repeated [158]. It gives the necessary structural support and the strength to various tissues of the skin, tendons, bones, etc. by acting as the provider for adhesion molecules and growth factors [159, 160].

The most common sources are bovine or porcine origin [161]. Discarded human tissue also can be taken as a good collagen source [162]. However, collagen from mammalian tissue may carry the possibility of immunogenicity and disease transmission [163]. Recombinant collagens have low yield and high cost. Furthermore, they are often not bio-functional due to the lacking of cofactors or enzymes [163]. Hence, animal is still the principle source of collagen.

Owing to the presence in tissues, collagen hydrogels are mostly used in medical and tissue engineering, including application in the myocardium [164] and intervertebral disc [165], as a substitution of the skin [166] and regeneration of cartilage [167].

Collagen hydrogel use is limited in daily occasion since they are mechanically less stable and their degradation is rapid [168, 169]. To improve its durability and mechanical strength, collagen hydrogels are blended with natural and synthetic polymers or changing their cross-link density [170]. The hybrid hydrogels have both the trait of bioactivity of collagen and tailor-made properties of the blended polymers. Alginate, glycosaminoglycans, dextran, etc. are combined with collagen to form stable hydrogels. Collagen-alginate-dialdehyde hydrogel showed potential for cell proliferation [171]. When collagen is copolymerized with glycosaminoglycans, the hydrogel formed showed a stiffer property with a lower degradation rate [4]. Collagen gels modified with aldehyde-functionalized dextran show compressive strength around 20 times higher than pure collagen hydrogels [172]. The compressive strength can be further improved by poly(vinyl alcohol) and collagen hydrogel, cross-linking with glutaraldehyde [173]. Functionalized silver nanoparticles can also improve the tensile strength further.

For wound healing, it is necessary for hydrogels to absorb exuding wound to a significant extent. Collagen hydrogels, functionalized with 4-vinylbenzyl chloride, glycidyl methacrylate, and methacrylic anhydride individually, have shown significant high swelling with their mechanical properties being competent and cytocompatible. The swelling ratios have been found to be around 707 ± 51–1996 ± 182 wt. %. Due to the stiffness given by the vinyl group, the blended collagen hydrogels showed such characteristics [174]. Collagen-based

hydrogel nanocomposites have also been used in wastewater treatment. To absorb metal ions or dyes, hydrogels should have both ionic and nonionic functional groups. For functional group addition, natural protein polymers are grafted with vinylic moieties.

2.2.2 Silk

Silks are nonmammalian protein biopolymer with high biocompatibility and tunable biodegradability [175]. Silk proteins created from the biosynthesis of epithelial cells of insects or spiders are spun into fibers that show high thermal stability and incredible tensile strength yet being elastic [176, 177]. Hydrogels produced from silk fibers are mostly used in tissue engineering and cell encapsulation [178, 179].

Sources for silk proteins are mainly from the domesticated silkworms (*Bombyx mori*) and spiders (*Nephila clavipes* and *Araneus diadematus*) [180]. Since cultivation of a large amount of spiders are difficult and the yield is less [176], commercialization of silk proteins is mainly generated from silkworms. Generally, silkworm's silk fibers are 10–25 micrometers in diameter (Fig. 13). However, to increase the availability, the production of spider silk from bioengineered bacteria, yeast, and insects is also being explored [181].

Of the two types of components of silkworm silk proteins, fibroins are mainly used in biomaterial production. Fibroins are the structural protein, whereas the other type, sericins, which are removed during processing, glues the fibroin fibers. The presence of sericins can cause hypersensitivity in vivo [183]. Silk fibroin polymers can be transformed into hydrogel in the presence of acid, ions, or other additives [184–187]. This gelation process is due to the inter- and intramolecular hydrophobic and hydrogen bond interactions [188, 189].

Hydrogel preparation can be done in several methods (Fig. 14). They are sub-categorized mainly by physical or chemical processes. Application field of silk hydrogels is vast. Hydrogel from silk fibroin and doxorubicin, a chemotherapeutic agent, showed excellent antitumor response, better than the intravenous dosage, and that the release of doxorubicin can be controlled by modifying different properties to minimize side effects [190].

Several blended or hybrid silk hydrogels have also been successfully prepared. Silk fibroins are blended with collagens, gelatin, chitosan, etc. to form hydrogels of different characteristics. For example, gelatin and silk fibroin composite hydrogels show greater thermal withstanding at 37 °C than gelatin hydrogel alone [191]. Genipin can be used as a cross-linker to silk fibroin and gelatin blend to stabilize [192]. Changing the ratio of silk fibroin to gelatin, structural and mechanical properties of the composite hydrogel can be modulated. For the fibroin and collagen hybrid hydrogel, it has been found to have increased thermal and mechanical stability than only collagen hydrogel [193]. Hydrogels made of alginate, a natural polysaccharide, dissolve in the absence of divalent ions, thus limiting their in vivo applications. But after blending with silk fibroin, the gelation kinetics along with tailorable mechanical and structural properties of the composite could be significantly improved [194]. Composite hydrogels of silk fibroin with other synthetic

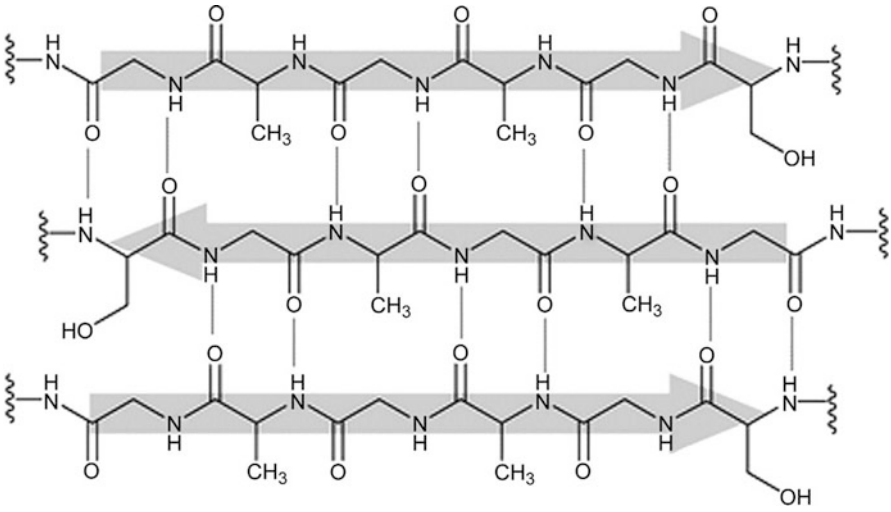

Fig. 13 Sequence of repeating amino acid units of silk. (Reprinted with permission from Ref. [182]. Copyright © 2017, Royal Society of Chemistry)

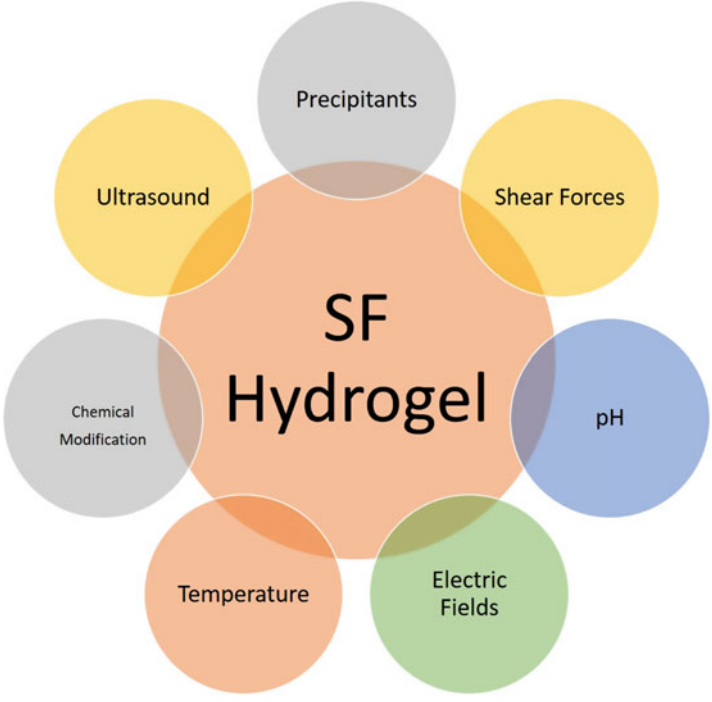

Fig. 14 Methods available for the fabrication of silk hydrogel

polymers are also being explored. Blend of silk fibroin with poly(ethylene glycol) in aqueous media and further cross-linking of the PEG macromere by means of ultraviolet rays produced a composite hydrogel that have a lower degradation temperature. In addition, due to the presence of PEG, water content of the hydrogel could also be increased. The composite hydrogel also showed increased tensile strength and elongation at break [195]. These blended hydrogels are mostly being used in biomaterials. Glycerol and silk fibroin blended hydrogels have showed a controlled release behavior of vitamin B1 derivative benfotiamine (BTMP) with the change in silk fibroin to glycerol ratio. The release of BTMP can be lowered by increasing the silk fibroin content or stiffness or glycerol content [184]. Genetically modified constructs of silk fibroin are also being studied to bring about unique characteristics. Such genetically engineered polymers have shown potential as matrices in cancer gene therapy [196].

2.2.3 Keratin

Keratin is a structural fibrous protein found in the outer layer covering of animal hairs, hooves, wool, feathers, and horns [197]. While there is an abundance of potential sources of keratin present, people often discard feathers, hairs, low-grade wools, and trimmings into waste streams.

Keratin is rich in cystine and shows good biocompatibility as well as biodegradability [199]. They have comparatively higher sulfur content. Keratin has both non-covalent and covalent interactions (disulfide bonds) (Fig. 15). These disulfide bonds help keratin to stabilize against proteolytic degradation. Furthermore, keratin compounds are not easily degradable in vivo since mammals do not produce keratinase, a keratin-degrading enzyme.

Since sources are abundant, the only cost at making keratin biomaterials comes at the processing. Extracting of keratin first starts with the breaking of disulfide cross-links between the cystines [200]. Two different methods for keratin extraction are common in which either oxidative or reductive solvents are used to create non-cross-linked keratins [201, 202]. With the oxidative solvent, cystine changes to keratose form (cysteic acid), and with reductive solvent, cystines are not affected and this form is referred to as kerateines (Fig. 16). These two forms show marked difference in degradability and mechanical structure. Although both can be used to make hydrogels, keratose can degrade relatively faster in vivo than keratin [203].

Keratin-based hydrogel scaffolds show prospect in regenerating peripheral nerves as well as promoting neuromuscular recovery [204]. Furthermore, keratin-based hydrogel was found to be neuro-inductive and promoting nerve recovery. Use of keratin hydrogel as hemostatic agent showed potential for reducing total blood loss [205]. Wool keratin hydrogels exhibited higher storage and loss modulus, i.e., faster swelling characteristics than collagen hydrogels [206]. Human hair keratin-derived hydrogel made by Ca^{2+}-induced polymerization method showed a branched and porous structure which was similar in performance to collagen hydrogels for cell viability and proliferation [207].

2.2.4 Elastin

Elastin is an extracellular matrix protein often found in connective tissues of vertebrates. It is responsible for the elasticity of the skin, lungs, and blood vessels. Elastin is biosynthesized from its monomer, tropoelastin, which has both hydrophilic and hydrophobic domains [208]. The water-soluble tropoelastin monomers first aggregate at physiological state, and then cross-linking of multiple tropoelastin with lysyl oxidase forms the insoluble elastin [209]. The insolubility of elastin hinders biomaterial processing and research. To overcome this, several techniques have been adopted such as solubilization, tropoelastin utilization, and recombinant proteins.

Solubilization can be done in two forms either with oxalic acid that produces alpha-elastin or with potassium hydroxide that produces kappa-elastin. Hydrogel made of α-elastin forms through the hydrophobic interaction. Further cross-linking gives structural stability and increases mechanical properties [155, 210, 211]. α-Elastin was chemically cross-linked with glutaraldehyde at high-pressure CO_2 to form hydrogel. It has been found that with the processing pressure increased from 30 bar to 150 bar, the swelling ratio was increased 60% (Fig. 17). This cross-linked hydrogel showed sensitivity toward temperature and salt concentration change

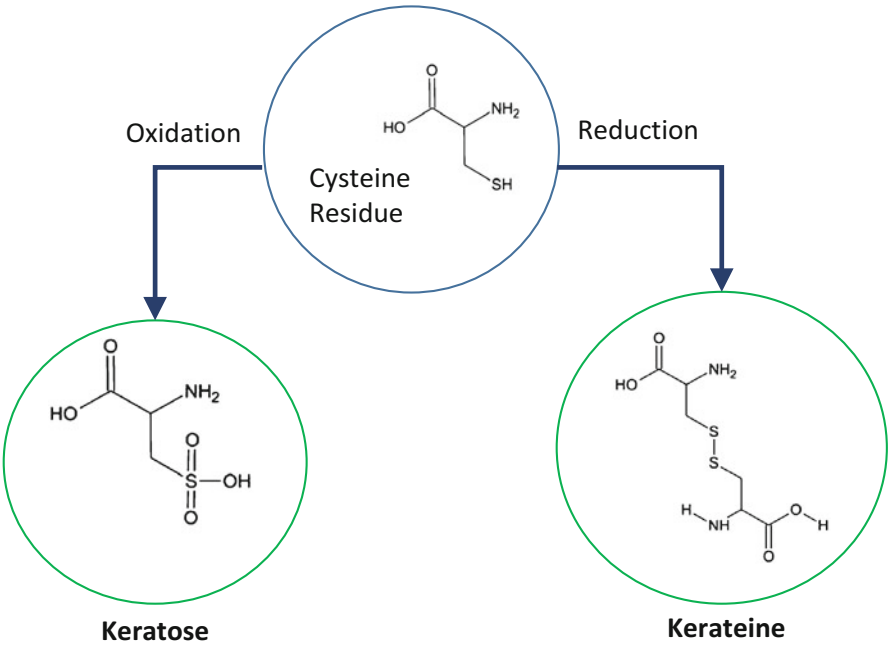

Fig. 16 Illustration depicting the process of extraction of keratose and kerateine

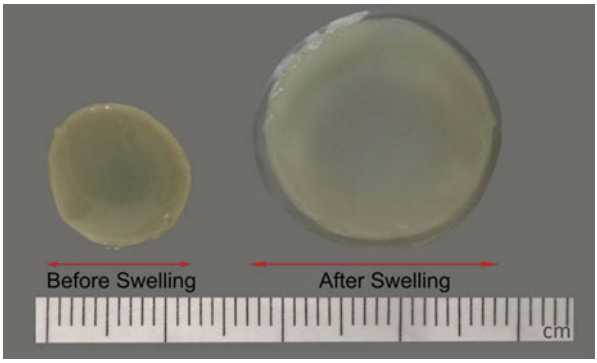

Fig. 17 Image depicting a comparison of before and after swelling of hydrogel produced at 60 bar with CO_2. (Reprinted with permission from Ref. [212]. Copyright © 2017, Elsevier)

[212]. Another hydrogel was prepared with high-pressure CO_2, cross-linking hexamethylene diisocyanate with α-elastin. The swelling ratio and porosity was also significantly improved which showed potential for tissue engineering [210]. Presently most of the elastin-based biomaterials are of elastin-like polypeptides and recombinant tropoelastin type. Mithieux et al. [213] prepared a biocompatible hydrogel by chemically cross-linking bis(sulfosuccinimidyl) suberate with recombinant human tropoelastin. The hydrogel supported in vitro epithelial and fibrosarcoma cell growth. It was also found that the hydrogel was well suited when implanted in the dorsum of guinea pigs.

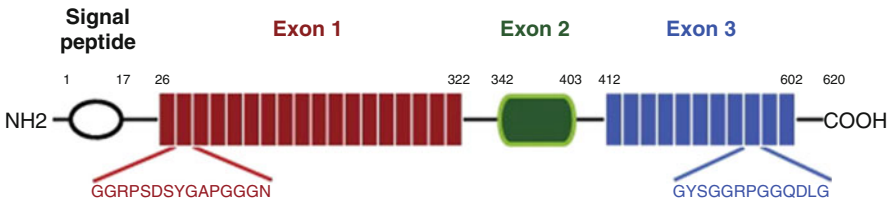

Fig. 18 Resilin gene sequence obtained from the *Drosophila melanogaster* (CG15290). (Reprinted with permission from Ref. [223]. Copyright © 2017, Elsevier)

Elastin-like polypeptides (ELP) are artificial polypeptides inspired by the disordered domains of tropoelastin [214]. Genetically modified ELPs are often used for tissue engineering. For example, ELP and poly(ethylene glycol) (PEG) were used to make a hybrid hydrogel that showed improved transparency, and when encapsulated with human fibroblasts, this hydrogel showed high viability [215]. Another study shows that ELP which was modified by the inclusion of thiols to allow disulfide bond formation formed hydrogel when exposed to UV light. This functionalized ELP showed potential as an in vivo hemostat. However, without denaturing, isolation of soluble elastin polypeptides is difficult and not suitable for mass production. To overcome this, sources like fish elastin are being explored to make elastin-based biomaterials [216].

2.2.5 Resilin

Resilin is a high resilient elastomeric protein found in insect cuticle, having high strain and low stiffness [217, 218]. Highly stretchable, resilins have elastic modulus of around 600–700 kPa. It has been shown that it can be stretched up to threefold to its original length before breaking [219]. Insect resilins are there to help insects take flight, jump, make sound, and expand exoskeleton [220, 221].

Resilin was first discovered in 1960 by Weis-Fogh [222]. Resilins are supposed to be highly disordered with presence of little to almost none secondary structures such as α helices or β sheets.

Most resilins are supposed to have three parts of exon where the first exon and third exon contain tyrosine residues which are probably responsible for cross-linking. These two exons also contain high glycine amount supposed to be involved in imparting flexibility. The second exon is known to bind chitin. This part allows the strong interaction between chitin and resilin when cuticle composite is being constructed [224, 225]. Exon I is more hydrophilic and aggregate to fibrillary structures in water, whereas exon II and exon III are relatively hydrophobic and form micelles. Dragonflies, however, do not have the chitin-binding domain in their resilin gene but just one exon [226]. Since there are not many viable ways to extract large quantities of resilin from natural sources, resilin genes have been expressed in recombinant forms. A tentative resilin gene (CG15920) was identified by Ardell and Andersen within *Drosophila melanogaster* (Fig. 18). Elvin et al. prepared a high resilient rubbery hydrogel by cross-linking a soluble protein found by cloning the first exon [227]. It has been found that resilience of around 92% was achieved in the

cross-linked resilin hydrogen with better elasticity than many other polymer hydrogels [228]. After this breakthrough, many genetically engineered resilin-like biomaterials have been studied. Charati et al. [229] removed the tyrosine with phenylalanine to enhance photochemical cross-linking. Qin et al. prepared hydrogels from exon I to exon III. The former showed a resilience of around 90%, whereas the latter showed only 63% [230]. Since resilin has great elastomeric properties, its application in cardiovascular tissue engineering is also being explored. Successful encapsulation of human aortic adventitial fibroblasts has been done in resilin-like polypeptides (RLP) and polyethylene glycol hybrid hydrogels [231]. RLP hydrogels cross-linked with tris(hydroxymethyl) phosphine showed potential for human mesenchymal stem cell encapsulation. The hydrogel could sustain its mechanical integrity and viability [232]. Hybrid hydrogel formed by ruthenium-mediated photo-cross-linking method combining regenerated silk fibroin with the recombinant resilin synthetic polymer synthesized from first exon (Rec 1) showed improved water uptake. Here the hydrogel showed improved storage modulus of around 6.56 MPa that is much higher than Rec 1 hydrogel [233].

2.2.6 Gelatin

Gelatin, a denatured protein obtained from thermal, physical, or acid and alkaline processing of collagen, has low immunogenicity, low cytotoxicity, and a great potential for biocompatibility [234–238]. Due to such properties, gelatin has been used in biomedical and pharmaceutical fields such as drug delivery, tissue engineering, biological glues [239], etc.

Source and type of collagen from which the gelatin is prepared will have influence on the properties of that gelatin. The amino acid sequence varies in sources. To elaborate, the contents of prolines and hydroxyprolines in collagens, influenced by temperature, vary from one source to another, hence the variation in gelatin properties such as denaturation temperature, thermal shrinkage, and melting temperature [240]. The sources of gelatin are mainly bovine hide and pigskin. Since mammalian sources contain transmittable diseases, other sources of gelatin are also getting popular, such as gelatin from fish sources [241]. Fish gelatins have found to have lower impact on humans than cowhide-sourced gelatins.

Gelatin hydrogel by physical cross-linking in water can be prepared above a certain concentration (around 2% w/v) and below 30–35 °C [243, 244]. That is when the gelatin-water mixture is above its gelling point temperature (around 30 °C), it exists as a sol. For the preparation of making hydrogel, the temperature is decreased below, and the gelatin monomers start to aggregate due to hydrogen bonding. The oligomers form a random conformation. At lower temperature, the hydrogen bonding shifts the random conformation to a structured one, resulting from single to triple helices which in effect make the sol-gel transformation (Fig. 19). These bonds are physical (hydrogen bonds and van der Waals), and hence the transformation is thermo-reversible [245, 246]. However, at temperature higher than 30–35 °C, these bonds are easily broken. So the resulting formation of gelatin, at higher temperature, has the possibility of change of shape as well as poor mechanical strength and low elasticity [247].

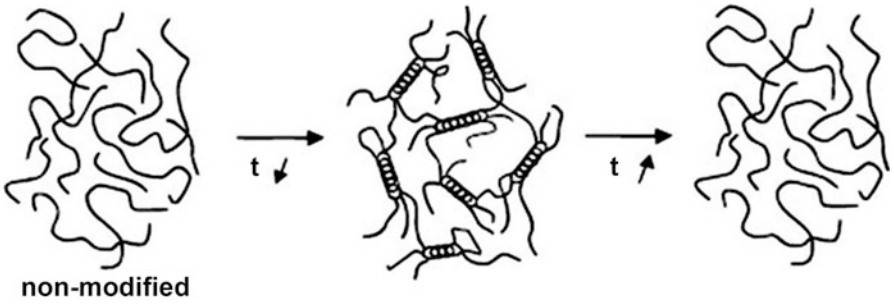

Fig. 19 Sol-gel transformation of gelatin. (Reprinted with permission from Ref. [242]. Copyright © 2017, American Chemical Society)

To use in biomedical applications with stable architectural and mechanical properties, gelatin hydrogels are covalently bonded with chemicals such as amide bond formation [248, 249]. Gelatins are often modified with methacrylate group. However, they possess short degradation time [250, 251]. To improve the degradation time and mechanical strength, photoreactive double bonds have been proposed to incorporate during hydrogel preparation [251]. Poly(lactic-co-glycolic acid) microsphere-incorporated gelatin hydrogel has shown to improve the tensile strength. To improve the elastic modulus, gelatin-poly(2-hydroxyethyl methacrylate) (PHEMA) hydrogels have been prepared. With the increase of PHEMA, the elastic modulus was found to be enhanced [252].

The potential of gelatin hydrogels for cartilage tissue engineering has been explored by modification of amino, hydroxyl, and carboxyl groups in gelatin molecules. Gelatin hydrogel has also shown potential as a drug carrier. Gelatin hydrogel incorporated with cellulose nanocrystals (CNC) has been reported to have greater sensitivity toward pH and temperature change [253]. Glutaraldehyde was used as the cross-linker to gelatin-CNC hydrogel due to its reactivity toward amine groups on gelatin.

3 Acrylate- and Acrylamide-Based Hydrogels

Acrylate and acrylamide are water-soluble synthetic monomers and are commonly used for synthesis of cross-linked polymeric hydrogel. There are several methods of preparing hydrogels from the acrylate and acrylamide monomers of which free radical cross-linking copolymerization is the most followed method where the hydrophilic monomers are reacted with cross-linkers [254].

Polyacrylamide- and polyacrylate-based synthetic hydrogels are synthesized mainly due to their responsiveness toward external stimuli such as pH, temperature, etc. pH-responsive hydrogels have either acidic or basic functional groups which accept or donate protons when there is a change in pH of the environment. Pourjavadi and Hosseinzadeh [255] synthesized a pH-sensitive hydrogel in two

stages. In the first stage, acrylamide and acrylonitrile were copolymerized using ammonium persulfate, and in the second stage, the copolymer was hydrolyzed and cross-linked. Steady swelling of the hydrogel with the increase of pH (from 1.0) occurred up to around pH 8.0 and decreased thereafter. Li et al. [256] prepared polyacrylamide-based pH-sensitive hydrogels that showed reversible swelling-deswelling behavior between pH 5.0 and 10.0. Swelling hindrance at low pH was attributed due to protonation of carboxylic groups present in the surfmar. One of the drawbacks of synthetic pH sensitive hydrogels is their non-biodegradability [257]. This could be a serious issue when the hydrogels are used inside the body for a prolonged period which can result in complications such as acute inflammation [258].

Thermosensitive synthetic acrylate- and acrylamide-based hydrogels are often in use for drug delivery; among them poly(*N*-isopropylacrylamide) (PNIPAAm) is the most common [257]. Tokuyama and Yazaki [259] prepared the PNIPAAm hydrogel using a novel circulation polymerization technique. In this process, pre-gel aqueous solution is added into moving silicon oil. Although PNIPAAm has widespread use as a temperature-sensitive hydrogel, it has certain restrictions owing to the limitation of biocompatibility of its monomers and cross-linkers used [257]. The hydrogel itself is non-biodegradable, and it activates platelets when in contact with blood [260]. Hence, use of such acrylamide-based hydrogel needs to be tested for toxicity.

Synthetic hydrogels are also applied in drug delivery. When loaded with caffeine, hydrogels synthesized from methyl methacrylate and *N*,*N*′-dimethylaminoethyl methacrylate copolymers showed release behavior at pH around 3–5 which helps the drug release in the stomach rather than on the mouth since the mouth has a neutral pH level [261]. Copolymer hydrogel of acrylamide and itaconic acid was prepared and studied for the controlled release of paracetamol [262]. Polymers such as poly(methacrylic acid-g-ethylene glycol) [P(MAA-g-EG)] have been investigated for synthesizing glucose-sensitive hydrogel that releases insulin. However, glucose-sensitive hydrogel response is quite slow and their original states are not totally acquired after response [257].

Feng et al. [263] synthesized a hybrid hydrogel made of polyacrylamide and multiwalled carbon nanotubes for increased mechanical strength. Another study showed the preparation of a hydrogel of higher strength without the use of any chemical cross-linkers. Here acrylamide monomers were copolymerized with sodium 9- or 10-acrylamidostearic acid monomers to produce the desired hydrogel [256]. Yang et al. [264] synthesized a hydrophobic hydrogel by micellar copolymerization of base monomers (acrylamide and acrylic acid) with a hydrophobic association monomer. However, a fast and responsive hydrogel is usually required to be thin and small [257]. So the synthesis of hydrogels having a fast acting quality while maintaining their mechanical strength is a challenge.

A number of synthetic monomers have been copolymerized with acrylate- or acrylamide-based monomers to produce hydrogels for different specific applications. A photochromic hydrogel (2-hydroxyl-ethyl methacrylate-N-vinylpyrrolidone-spironaphthoxazine) using HEMA (2-hydroxyethyl methacrylate) in polymeric form (PHEMA), copolymerized with *N*-vinyl-2-pyrrolidone (NVP), has found uses

as contact lenses [265]. Highly absorbent copolymer of acrylamide-crotonic acid, in the form of rod, containing ammonium nitrate and potassium nitrate fertilizer was synthesized for agricultural use [266]. Poly(acrylamide-co-acrylic acid) hydrogels have been used in gardens and fields for soil hydration. Kim et al. [267] showed that the commercially available polyacrylamide hydrogels are modified with ionic groups and that they have minimal effect on crop life and quantity. Furthermore, authors stated that such synthetic hydrogels are fragile and showed poor performance in the context of their effect on overall plant production.

4 Advantages of Renewable Hydrogels over Synthetic Hydrogels

Due to countless advantages of hydrogels prepared from renewable sources with special properties, their application fields are huge as mentioned earlier such as regenerative medicine, drug/gene delivery, stem cell and cancer research, wound healing, tissue engineering, agriculture, water treatment, hygiene products, etc. [268–270]. The benefits of renewable hydrogels produced from renewable sources over synthetic hydrogels are enormous. On the other hand, polyacrylamide hydrogels may degrade to acrylamide and become harmful for the living (Fig. 20). Although one school of thoughts believes that the polymer hydrogel is degraded to nontoxic forms other than acrylamide, there are several experimental findings to

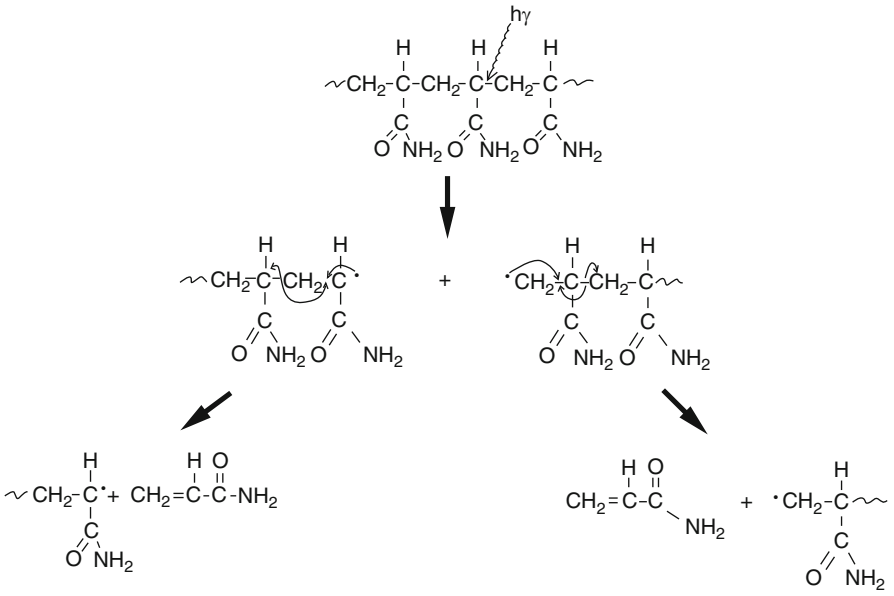

Fig. 20 Photolysis of polyacrylamide. (Reprinted with permission from Ref. [271]. Copyright © 2017, Elsevier)

prove otherwise. Smith et al. have showed that the polyacrylamide can degrade to acrylamide in the environmental condition. The researchers created an artificial environmental conditions and used ammonium concentrations and pH as parameters for the degradation of monomer/polymer. Energy from the light may break the polymers. Polyacrylamide has C-C, C-N, and C-H bonds. Crosby D.G. showed that sunrays have enough energy to break C-C bonds and thus may initiate a photolysis of polyacrylamide to form acrylamide [271]. Acrylamide is highly soluble and has the ability to translocate through various soil types. Acrylamide can cause neurotoxicity, genotoxicity, and skin irritation [272–274]. EPA has listed acrylamide as a probable carcinogen-causing compound [275]. Cationic polyacrylamides are toxic for aquatic environment and floc forming and should not be used.

Biocompatible and bioadhesive hydrogels can be prepared from renewable sources. Although most of the superabsorbent hydrogels are prepared from synthetic sources due to their lower price, the trend for replacing these synthetics with biorenewable alternatives is increasing due to the low degradability and biocompatibility of synthetic superabsorbent. One of the most important and most abundant renewable sources of hydrogel is cellulose, because it is biocompatible, biodegradable, nontoxic, and low-cost material. It has many polar hydroxyl groups, which can be applied to synthesize superabsorbent hydrogels simply with interesting valuable structures and properties. Nowadays, cellulose-based hydrogels are becoming universal and essential in many application fields [276]. By incorporating cellulose-based materials in the field of superabsorbent hydrogels, we can remove the limitations of synthetic-based superabsorbent hydrogels, and we can get products with outstanding properties [277].

But polyacrylamide hydrogels are proving to be less biocompatible than the natural renewable hydrogels. There are incidents that prove polyacrylamide hydrogel to be a less biocompatible hydrogel for human. Generally, polyacrylamide hydrogels are used as an injectable filler for soft tissue augmentation of different body areas. However, several cases of postinjection complications were recorded. Luo et al. [278] found that around 68% of 235 patients complain of pain after injecting polyacrylamide hydrogel for breast augmentation. Around 73% had multiple complications simultaneously and around 9% suffered distant gel migration. In addition, polyacrylamide deposits may worsen inflammation and infection in breast tissues by being a culture media [279]. Rong et al. [280] stated that a female patient complained of recurrent swelling and pain in temporal area after the polyacrylamide hydrogel injection. The female patient ultimately experienced leukocytopenia due to the dispersion migration of the hydrogel. Polyacrylamide may also cause complications such as acute inflammation and galactocele formation during breastfeeding [279]. Eon Rok Do showed that 10 years after injecting polyacrylamide hydrogel for breast augmentation, the patient developed lumps near the injected area [281]. Complications due to the injection of polyacrylamide hydrogels may include pain, abscess, host tissue rejection, inflammation, hematoma, etc. Delayed gel induration is also reported as a late onset of polyacrylamide [282]. Cheng et al. showed that postinjection complications may lead to breast cancer. The hydrogel may hinder the growth of fibroblasts resulting in apoptosis and hence a chance for developing cancer

[283]. Such complications show that polyacrylamide is not totally biocompatible. Furthermore, these complications may require complex surgeries and debridement procedures for cure.

5 Conclusion

This chapter presented a detail about the renewable polymer-based hydrogels, which exhibit biodegradability and biocompatibility and therefore suitable for applications in biomedical fields as well as other fields. Renewable polymers from different sources have gained a great attention of the scientists due to their intrinsic merits like low cost, eco-friendliness, biodegradability, etc. over the synthetic one during the last few decades. In this century, the demand of renewable materials is increasing in many diverse fields of basic research and different uses for the betterment of our environment. Hence, these materials are quickly developing as the sustainable replacements to non-biodegradable synthetic materials. Hydrogels from biopolymers are such kind of new materials. Throughout this chapter, it has been shown that polysaccharides have a variability and a versatility due to their special chemical structures, which is not found in other types of polymers. The uniqueness of the polysaccharides permits a very wide range of uses, and their applications can be further increased by finding new derivatives. As a result, hydrogel (from native and derived polysaccharides)-related publications and patents are increasing day by day. At the same time, renewable hydrogels from protein-based polymers are also increasing. They can form exceptional scaffolds for tissue engineering and repair due to their changeable mechanical and structural properties. Moreover, these hydrogel components are attractive for their structural tunability and precise biological functionality, and they are stimuli-responsive. Different types of synthetic hydrogels are being developed and scientists are trying to find their newer applications in biological fields. On the other hand, there are enough scientific evidences for the application of biorenewable hydrogels in the field of drug delivery and other biomedical applications. Finally, increasing the knowledge and the application of renewable hydrogels in nanoscience and nanotechnology is a potential area, which needed to be explored in the future.

6 Future Scope of Renewable Hydrogels

Among all of the renewable hydrogels, cellulose-based hydrogels are expected to be forerunners in renewable hydrogel research due to their large abundance and inherent mechanical properties. They have already showed their potentiality in waste treatment, agriculture, food packaging, and different industrial applications, where a huge amount of them are demanded. Moreover, as they are biocompatible and biodegradable materials, the importance of these hydrogels is huge in biomedical applications as well as where the environmental issues are concerned. The present trend in the development of cellulose hydrogels is to increase the safety of both the

final product and the manufacturing procedure by using nontoxic cross-linking agents or cross-linking treatments. Some hydrogels of cellulose derivatives have "smart" (sensitive to change environment like pH, ionic strength, temperature, etc.) behavior which is principally interesting for in vivo applications. Furthermore, the opportunity to functionalize cellulose-based hydrogels with bioactive and biodegradable extracellular matrix domains indicates that such hydrogels might be ideal stages for the design of scaffolding biomaterials in the arena of tissue engineering and regenerative medicine in the near future. Therefore, the advancement of the areas in chemical engineering, materials science, and biology is continuing, and it will be continuing and even larger development will occur in biomaterial research and application in the future.

Contents

Abstract

Hydrogels are polymeric three-dimensional networks able to absorb and release water solutions. Sometimes, this behavior is reversed in response to definite environmental stimuli, i.e., temperature, pH, ionic strength, etc. Such stimuli-responsive behavior makes hydrogels attractive candidates for the design of "smart" devices, applicable in a variety of technological fields. In particular, when concerning either ecological or biocompatibility issues, the biodegradability of the hydrogel network, combined with the control of the degradation rate, may add more value to the developed device. Development of new products and materials, particularly those which are based on renewable organic resources using innovative sustainable processes, represents an increasing interest in both academic and industrial research. Cellulose and its derivatives – with numerous

hydroxyl groups – have established to be flexible materials with unique chemical structure which provides a good platform for the creation of hydrogel networks with distinctive properties with respect to swelling ability and sensibility to external stimuli. Consequently, cellulose-based hydrogels are attractive materials, biodegradable, biocompatible, and low cost, which exhibit properties that make them promising in many applications, particularly in biomedical and environmental applications. This article reviews the design and the applications of cellulose-based hydrogels, which are extensively investigated due to cellulose availability in nature, the intrinsic degradability of cellulose, and the smart behavior displayed by some cellulose derivatives.

1 Introduction

The modification of natural polymers is a promising method for the preparation of new materials. Graft copolymerization of vinyl monomers onto natural polymers is an efficient approach to achieve these materials. Among these materials, hydrogels have attracted great attention due to their wide applications [1–7]. Hydrogels are three-dimensional (3D) materials with the ability to absorb large amounts of water while maintaining their dimensional stability and network structure. The amount of water absorbed in hydrogels is related to the presence of specific groups such as –COOH, –OH, $–CONH_2$, –CONH–, and $–SO_3H$.

The 3D structure of hydrogels in their swollen state is maintained either by physical or chemical crosslinking [8]. These crosslinking points within the network keep the three-dimensional integrity of hydrogels in their swollen state. In chemically crosslinked hydrogels, the linear polymer chains are covalently bonded with each other via crosslinking agents; different natural polymers, either of plant or animal origin, were used in preparation of hydrogels for different applications. Some of these hydrogels are conventional hydrogels such as those used in diapers. Whereas others are "smart," i.e., they show specific response toward certain stimuli. Thus, hydrogels can be classified according to different bases. Some of these bases are given in Fig. 1.

Indeed, the invention of smart hydrogels represents a great revolution in science. Due to many environmental concerns, polymers of animal or plant sources are now incorporated in the network structure. The natural polymers derived from animal or plants are given in Table 1. The substitution of petroleum-based products with bio-based materials is not an economical solution. Some of the possible solutions are blending biopolymers with synthetic polymers and reinforcing natural fibers with synthetic polymers (termed bio-composites), which are viable alternatives to glass fiber composites.

Among natural polymers, cellulose is the most abundant organic raw material and finds numerous applications in different areas as composite materials, textiles, drug delivery systems, and personal care products. Since it was first characterized in

1838 [9, 10] it has received a great deal of attention for its physical properties and chemical reactivity. Moreover, cellulose is an inexpensive, biodegradable, and renewable material. Many properties of cellulose, both physical and chemical, are significantly different from those of synthetic polymers. Despite all its well-established and interesting properties, cellulose lacks some of the versatile properties of synthetic polymers.

Modification of biofibers has motivated to increase their functionality and the scope of their use. Different chemical modifications are available, but the most predominant type is modification by graft polymerization which provides a

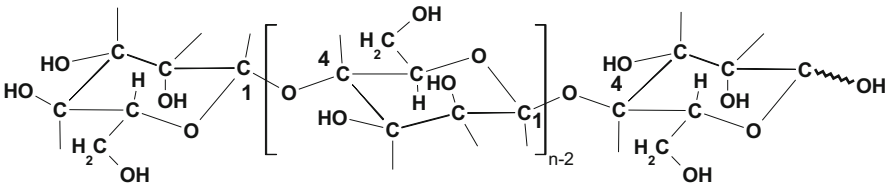

Fig. 2 Chemical structure of cellulose

means of altering the physical and chemical properties of cellulose and improving its functionality. With the recent progresses in polymer synthesis, new routes are now available for the production of functional and sustainable cellulose-based materials. In this chapter, the structure of cellulose and its reactivity, together with highlights of the recent advances in techniques for cellulose grafting, are considered.

1.1 Chemical Structure of Cellulose

The chemical and physical properties of the cellulose biopolymer are mainly dependent on its particular structure. The polymeric structure of cellulose was first verified by Staudinger in 1920. Understanding the structure of cellulose is very important in controlling its modification. Figure 2 shows the molecular structure of cellulose generated from repeating β-D-anhydroglucopyranose units that are joined together covalently through acetal functions between the equatorial group of the C4 carbon atom and the C1 carbon atom (β-1,4-glycosidic bonds).

The linearity of structure arises from the b-glucose link at C1–O–C4 to yield cellobiose units. This linear structure can contain up to 1000–1500 b-glucose units [11]. The degree of linearity enables the molecules to draw near together. Thus, cellulose has a high cohesive energy that is greatly enhanced by the fact that the hydroxyl groups are capable of forming extensive hydrogen bond networks between the chains and within the chains.

1.2 Cellulose Reactivity

The presence of three hydroxyl groups in each glucose residue gives cellulose high reactivity. In the most cases, the hydroxyl groups at the second and third positions act as secondary alcohols, while the hydroxyl group in the sixth position behaves as a primary alcohol (Fig. 3). These hydroxyl groups are principally responsible for the chemical reactions and chemical modification of cellulose.

As the DS indicates the average number of reactive groups in the molecule that have been substituted, one can say that the DS of the anhydroglucose unit

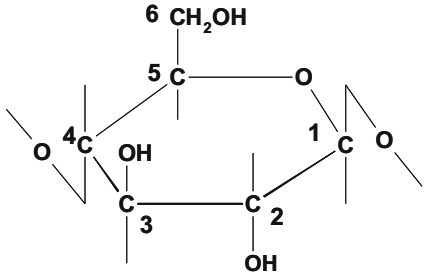

Fig. 3 The numbering system for carbon atoms in anhydroglucose unit of cellulose molecule

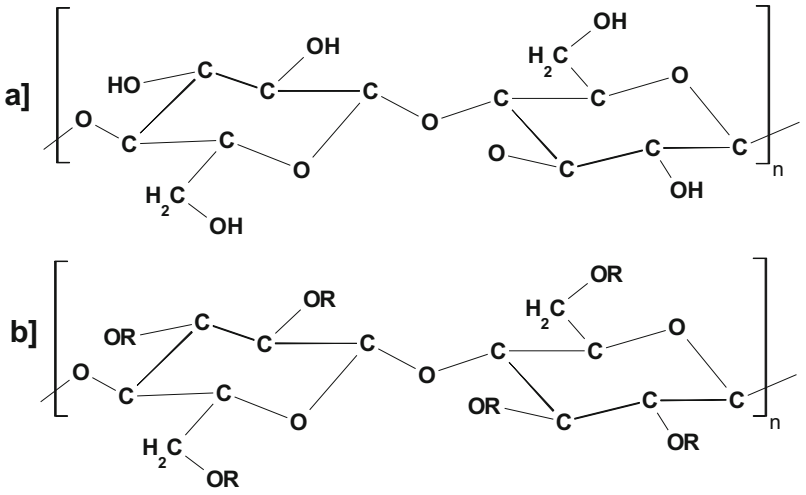
of the cellulose molecule is three [12]. However, the reaction of cellulose should not simply be considered as being that of a trihydric alcohol that is similar in its chemistry to trihydric sugar. This is due to that cellulose is a fiber-forming and a high molar mass substance. The reactivity of these three hydroxyl groups under is mainly affected by their intrinsic chemical reactivity, by steric effects that are produced by the reacting agent, and by steric effects that are derived from the supramolecular structure of cellulose. Generally, the relative reactivity of the hydroxyl groups can be expressed as OH–C6 $\gg$ OH–C2 $>$ OH–C3 [13, 14].

2 Chemical Modification of Cellulose

Cellulose is a distinctive natural polymer that possesses several attributes such as a fine cross section, the ability to absorb moisture, high strength and durability, high thermal stability, good biocompatibility, relatively low cost, low density, and good mechanical properties [14]. Yet, there are some drawbacks for cellulose. These include poor solubility in common solvents, poor dimensional stability, lack of thermoplasticity, and lack of antimicrobial properties. Thus controlled physical and/or chemical modification of the cellulose structure is necessary to prevail over such drawbacks [15].

Introducing functional groups into cellulose molecules through chemical modification is one of the key ways of adding new properties to the cellulose without destroying its many attractive intrinsic properties. For instance, the formation of cellulose nitrate involves the esterification of cellulose with nitric acid in the presence of sulfuric acid, phosphoric acid, or acetic acid. Currently, other commercially important cellulose derivatives include hydroxyl ethyl cellulose, carboxymethyl cellulose, etc. Some cellulose derivatives are given in Fig. 4.

The modification of cellulose with bi- or polyfunctional compounds to form crosslinked or network structure provides another possible attempt of modifying the structure of cellulose [16]. These methods can bring stability to the structure of cellulose and can induce crease-resistance (or “durable press” properties) to cellulose [17]. Among the methods of modification of polymers, graft copolymerization offers a smart and adaptable means of imparting a range of functional groups to



MC	R= H, CH_3
HPMC	R= H, CH_3, $CH_2CH_2CH(OH)\ CH_3$
EC	R= H, CH_2CH_3
HEC	R= H, CH_2CH_2OH
NaCMC	R= H, CH_2COONa

Fig. 4 (**a**) Repeating unit of cellulose "cellobiose." (**b**) Repeating unit of cellulose derivatives. The substituent group "R" is indicated for (MC), (HPMC), (EC), (HEC), and (NaCMC)

a polymer molecule. A graft copolymer generally consists of a long chain of one monomer, referred to as the backbone polymer (main chain) with one or more branches (grafts) of long sequences of a different monomer [18].

This chemical modification can provide polymeric materials with valuable properties and different chemical structures. It can also permits one to combine the best properties of two or more polymers in one physical unit This can be achieved by controlling some parameters such as the polymer types, the degree of polymerization and the polydispersities of the main chain and the side chains, the graft density (average spacing in between the side chains), and the distribution of the grafts (graft uniformity) [19].

The creation of cellulose graft copolymers is one of the key ways of modifying the physical properties and chemical properties of cellulose [19]. This involves modification of the cellulose molecules through the formation of branches (grafts) of synthetic polymers that impart specific properties onto the cellulose substrate, without destroying its intrinsic properties (Fig. 5). These grafts can be linked together via their functional groups to form a three-dimensional network structure known as "gel." Cellulose hydrogels will be discussed in more details in the next sections.

Cellulose acetate	Drug carrier system	[30, 31]

3 Cellulose-Based Smart Hydrogels

Because cellulose has many hydroxyl groups which can form hydrogen bonding linked network easily, various designations of cellulose-based hydrogels can be tailored. Water-soluble cellulose derivatives are mostly biocompatible which can be used as thickener, binding agents, emulsifiers, film formers, suspension aids, surfactants, lubricants, and stabilizers, especially as additives in food, pharmaceutical, and cosmetic industries.

Cellulose-based hydrogels can be obtained via either physical or chemical stabilization of aqueous solutions of cellulosics. Additional natural and/or synthetic polymers might be combined with cellulose to obtain composite hydrogels with specific properties [20, 21]. Some cellulose derivatives and their most common applications are given in Table 2.

Stimuli-responsive or smart hydrogels are those hydrogels that undergo reasonably large and abrupt changes in their network structure, swelling behavior,

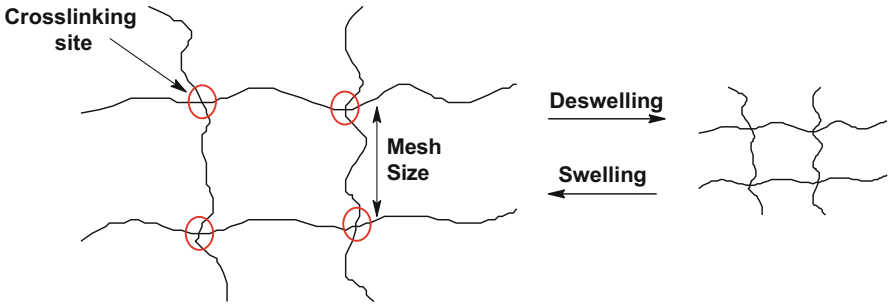

Fig. 6 Stimuli-responsive hydrogel

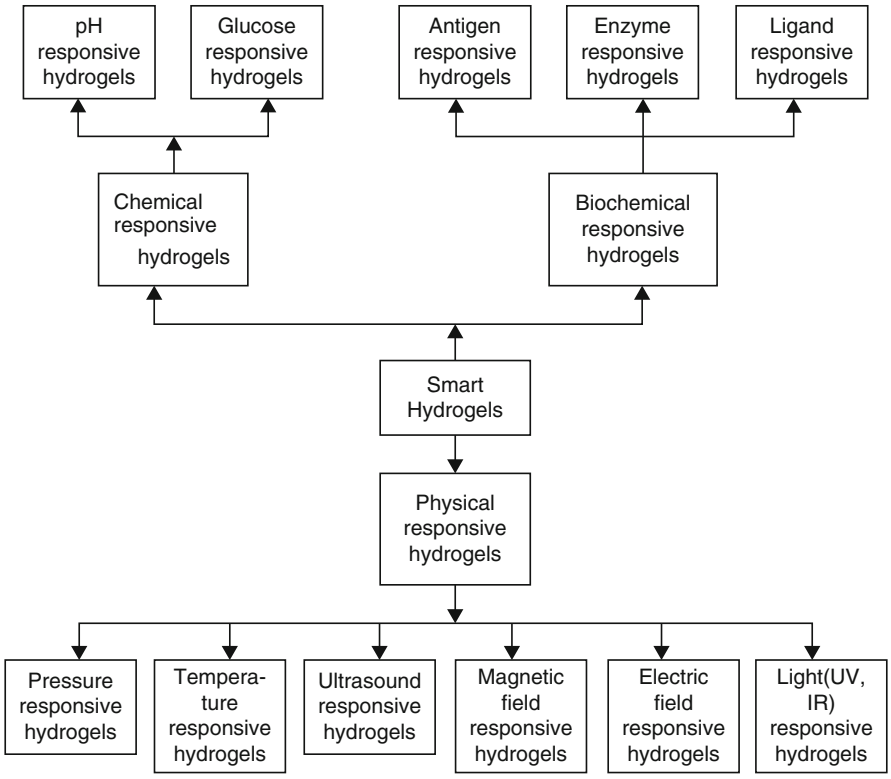

Fig. 7 Classification of smart hydrogels. (Modified from [34])

permeability, and/or mechanical strength in response to small environmental changes (Fig. 6). Stimuli-responsive hydrogels are also known as environmentally sensitive hydrogels [32, 33]. Stimuli-responsive hydrogels could be further classified as either physical or chemical stimuli-responsive hydrogels as shown in Fig. 7 [34]. Chemical

stimuli, such as pH, ionic factors, and chemical agents, change the interactions between polymer chains or between polymer chains and solvent at the molecular level, whereas physical stimuli, such as temperature and electric or magnetic fields, and mechanical stress will influence the molecular interactions at critical onset points.

3.1 Thermo-Responsive Cellulose-Based Hydrogels

Temperature-responsive hydrogels have gained considerable attention in the endless applications. Some molecular interactions, such as hydrophobic associations and hydrogen bonds, play a vital role in the immediate volume change of these hydrogels at the critical solution temperature (CST). In the swollen state, water molecules form hydrogen bonds with polar groups of polymer backbone within the hydrogels and arrange themselves around hydrophobic groups.

Physically crosslinked, thermo-reversible gels were prepared from water solutions of methylcellulose and/or hydroxypropyl methylcellulose (in a concentration of 1–10% by weight) [21]. The gelation mechanism involved hydrophobic associations among the macromolecules possessing the methoxy group. At low temperatures, polymer chains in solution are hydrated and simply entwined with one another. By increasing temperature, water of hydration is lost gradually, until polymer-polymer hydrophobic associations take place, thus forming the hydrogel network.

The glass transition temperature (Tg) was dependent on the degree of substitution of the cellulose ethers as well as on the addition of salts. A higher degree of substitution of the cellulose derivatives provided them a more hydrophobic character, thus reducing the glass transition temperature at which hydrophobic associations take place. A similar effect was noticed when adding salts to the polymer solution. This may be due to that salts reduce the hydration level of macromolecules by recalling the presence of water molecules around themselves. Both the degree of substitution and the salt concentration could be properly adjusted to obtain specific formulations gelling at 37 °C and thus potentially useful for biomedical applications [35–37].

Selective cellulose derivatives, including methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropylmethyl cellulose (HPMC), and carboxymethyl cellulose (CMC), have been used to construct cellulose-based hydrogels through physical crosslinking and chemical crosslinking. The mostly studied temperature-responsive hydrogels among cellulose derivatives were methylcellulose [38] and hydroxypropyl methylcellulose [39].

In the case of physical crosslinked gels, there is no covalent bonding formation or breakage, and the crosslinked network is formed through ionic bonding, hydrogen bonding, or an associative polymer-polymer interaction [40]. In general, chemical crosslinked hydrogels are prepared through crosslinking two or more kinds of polymer chains with a functionalized crosslinker [41] or under UV light [42]. However, physically crosslinked hydrogels are reversible [39] thus might flow under given conditions (e.g., mechanical loading) and might degrade in an uncontrollable manner. Due to such drawbacks, physical hydrogels based on MC and

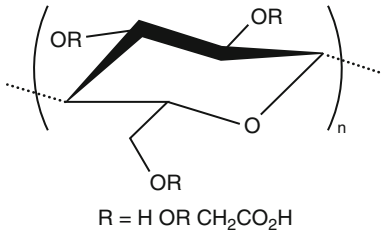

Fig. 8 Chemical structure of CMC

HPMC are not recommended for use in vivo. In vitro, MC hydrogels have been recently proposed as novel cell sheet harvest systems [43].

In agriculture, there is an increasing interest in using superabsorbent hydrogels. This is mainly due to the call for a reduction of water consumption and to optimize water resources in agriculture and horticulture and has a role in the endorsement of a novel advance of human habit and culture toward water, to be treated as a benefit to save and not as an excess to waste. During the swelling process of a superabsorbent hydrogel, the material changes from a glassy to a rubber-like state, which is able to pile up large amount of water and release the stored water under significant conditions. The controlled release system is formed from carboxymethyl cellulose (Fig. 8), a low-cost and completely biocompatible polymer that can be produced in a sustainable way from natural sources.

In this respect, Bao et al. [44] investigated the reaction process of cellulose-based inorganic/organic nanocomposite superabsorbent hydrogels by solution polymerization. First, potassium persulfate was used as an initiator to produce free radicals under heating, and then these radicals abstracted hydrogen from the hydroxyl groups on the cellulose substrate to create the alkoxy radicals. The alkoxy radicals attacked the acrylic monomers leading to chain initiation. Consequently, these small molecule radicals acted as free-radical donors to the neighboring molecules. Furthermore, in the presence of the crosslinker, *N*,*N*- methylenebisacrylamide (MBA), and a filler, inorganic sodium montmorillonite (Na-MMT), the chain propagation developed promptly. Finally, the reaction ceases by the coupling of macromolecules. The formation mechanisms of cellulose-g-poly(AA-co-AM-co-AMPS)/MMT superabsorbent hydrogel are shown in Fig. 9.

During or after preparation, the xerogel might also be loaded with nutrients and/or plant pharmaceuticals. When irrigating plants, the water is absorbed by the hydrogel, which then affected externally to release water and nutrients to the soil as needed, thus keeping the soil moist over long periods of time. This process is a highly water-saving process that the water is not lost soon after the watering due to evaporation and drainage and a redistribution of the water resources available for cultivation in other applications [45–47]. An extra advantage in using hydrogels in this application is related to the effect of the swelling itself on the soil. Indeed the hydrogel granules, which in the dry form have almost the same dimensions of the substrate granules, increase their dimension after swelling, thus increasing soil porosity and providing a better oxygenation to the plant roots (Fig. 10) [45].

This also suggests that large-granule hydrogels are likely to yield better results than fine-granule ones, if suitably mixed with the soil (indeed different spatial

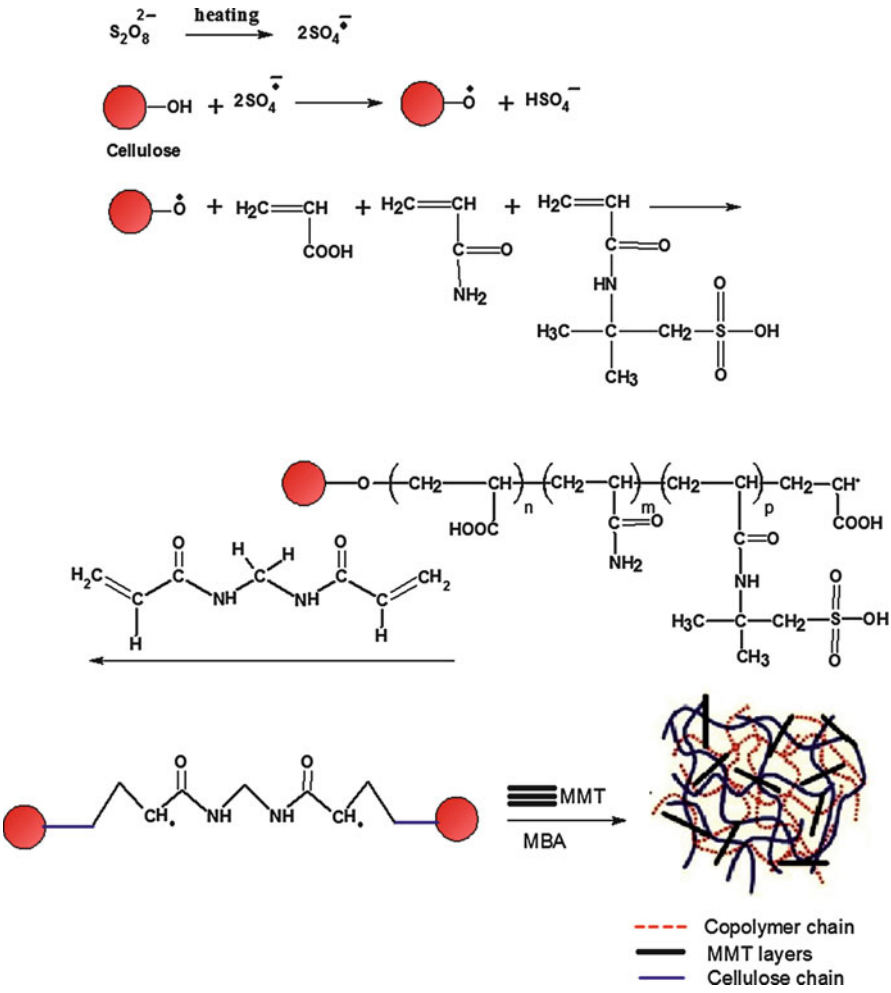

Fig. 9 Mechanism of formation of CMC-based superabsorbent hydrogels

configurations for the soil and hydrogel particles are possible, depending on their densities and the soil-hydrogel and hydrogel-hydrogel interactions).

Cellulose-based hydrogels fit perfectly in the current trend to develop environmentally friendly alternatives to acrylate-based superabsorbent hydrogels [48–50]. Sannino and coworkers recently developed a novel class of totally biodegradable and biocompatible microporous cellulose-based superabsorbent hydrogels [47]. In biomedical applications, cellulose derivatives are used in preparation of thermoresponsive hydrogels used in drug delivery systems, as found in dressing and in bioengineering.

In this respect, Trong et al. [51] prepared hydrogel membranes mainly composed of three kinds of latex particles within carboxymethyl cellulose (CMC) matrix for

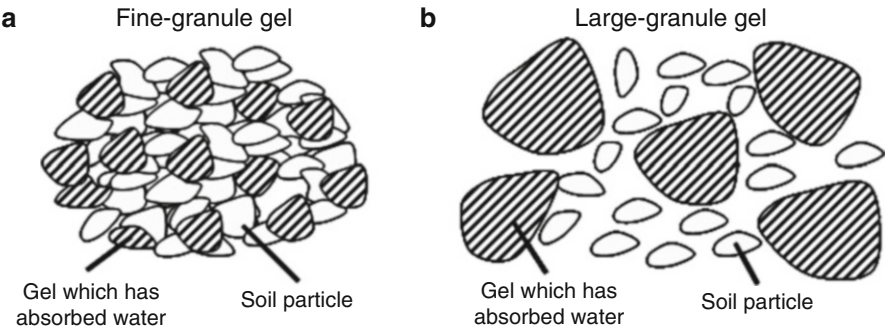

Fig. 10 Compactness of soil particles due to addition of hydrogels [45]

the purpose of transdermal drug release. To give a thermo-responsive behavior in swelling, poly(*N*-isopropyl acrylamide) latex and its copolymers were synthesized by polymerization of *N*-isopropyl acrylamide with different amounts of acrylic acid, in which lower critical solution temperature (LCST) could be modulated. Morphology, structures, and swelling capability of prepared hydrogel membranes were then examined. Caffeine, used as the model drug, was incorporated into membranes, and the drug release behavior at different temperatures was evaluated. These prepared hydrogel membranes have potential in the application of transdermal drug delivery system.

Recently, semi-interpenetrating polymer network (SIPN) strategy was employed to fabricate a kind of novel hydrogels composed of cellulose and poly(*N*-isopropylacrylamide) (PNIPAAm) in the presence of *N*,*N*-methylenebisacrylamide (MBAAm) as the crosslinker and benzoyl peroxide (BPO) as the initiator. The results from FTIR and TGA indicated that the network indeed existed in the SIPN hydrogels. The data from experiments, those associated to the swelling behavior of the hydrogels at different temperatures in particular, proved the thermal sensitivity of these hydrogels. The impact of crosslinker concentration on the hydrogel properties was discussed as well. The swelling ratio of hydrogels decreased with increasing the content of MBAAm. Besides, the loading and releasing behavior of the hydrogels was examined using dimethyl methylene blue as a model drug. These novel hydrogels combining the advantages of natural polymer with thermal-responsive behavior are of great potential to be applied to drug delivery and control release systems [52].

Mohammed and Kourosh [53] suggested the following mechanism for preparation of carbohydrate-based superabsorbent hydrogel (Fig. 11):

(a) Graft copolymerization of suitable vinyl monomer(s) on polysaccharide in the presence of a crosslinker
(b) Direct crosslinking of polysaccharide

In graft copolymerization, generally a polysaccharide enters reaction with initiator by either of two separate ways. First, the neighboring OHs on the saccharide units

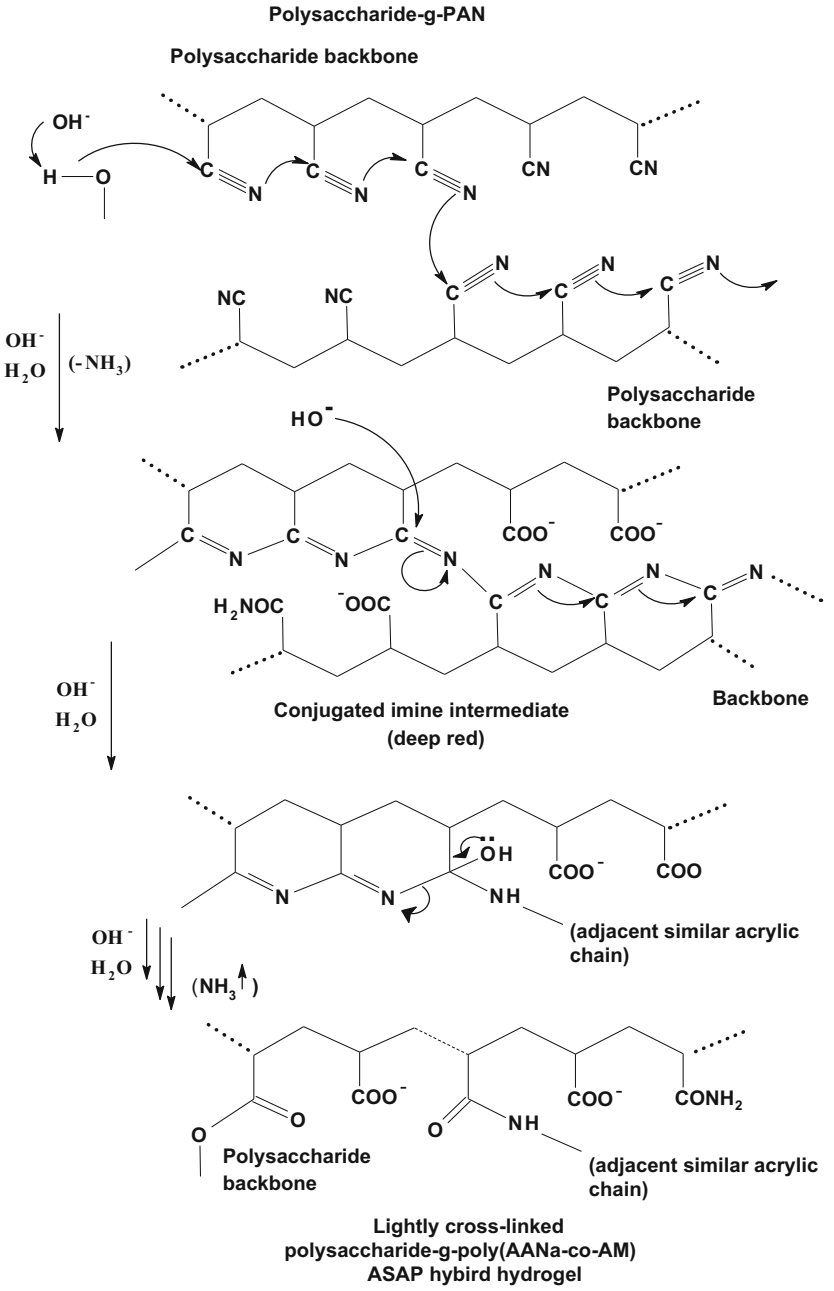

Fig. 11 The mechanism of preparation of polysaccharide-g-PAN copolymer superabsorbent

and the initiator (commonly Ce^{4+}) interact to form redox pair-based complexes. These complexes are subsequently dissociated to produce carbon radicals on the polysaccharide substrate via homogeneous cleavage of the saccharide C–C bonds. These free radicals initiate the graft polymerization of the vinyl monomers and crosslinker on the substrate. In the second way of initiation, an initiator such as persulfate may abstract hydrogen radicals from the OHs of the polysaccharide to produce the initiating radicals on the polysaccharide backbone.

Due to employing a thermal initiator, this reaction is more affected by temperature compared to previous method. In agriculture, polymer complexes of crosslinked carboxymethyl cellulose (CMC) and starch were synthesized to form superabsorbent polymers (SAP) and their performances as a water retaining aid for irrigation were assessed [54]. Starch from vegetables and chemically modified cellulose fibers were used as the basis for the polymer structure because of their biodegradability and the sustainability of their sources. These polymers were found to release the absorbed water at 34 °C, i.e., the LCST of *N*-isopropylacrylamide.

3.2 pH-Responsive Cellulose-Based Hydrogels

Variations in pH are known to occur at several body sites, such as the gastrointestinal tract [55], vagina [56], and blood vessels, and these can provide a suitable base for pH-responsive drug release. pH- sensitive polymers are polyelectrolytes that bear in their structure weak acidic or basic groups that either accept or release protons in response to changes in environmental pH. The pendant acidic or basic groups on polyelectrolytes undergo ionization just like acidic or basic groups of monoacids or monobases. However, complete ionization on polyelectrolytes is more difficult due to electrostatic effects exerted by other adjacent ionized groups. Most commonly studied ionic polymers for pH-responsive behavior include poly (acrylamide) (PAAm), poly(acrylic acid) (PAA), poly(methacrylic acid) (PMAA), poly (diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA).

In this respect, a new set of pH-, temperature-, and redox-responsive hydrogels were prepared from carboxymethylcellulose (CMC) and poly(*N*-isopropylacrylamide). Copolymeric (CP) hydrogels were synthesized by copolymerizing *N*-isopropylacrylamide (NIPA) and methacrylated carboxymethylcellulose; semi-interpenetrating network (SIPN) hydrogels were prepared by polymerizing NIPA in the presence of CMC. Two types of crosslinkers were used, viz., *N*, *N*′-Methylenebisacrylamide (MBA) and *N*,*N*′-Bis(acryloyl)cystamine (BAC), a redox sensitive crosslinker. The structures of the hydrogels were characterized by FTIR and SEM studies. The CP hydrogels were proved to be more porous than analogous SIPNs which resulted in higher swelling for the CP hydrogels. Swelling for both the hydrogels was established to increase with CMC content. While the swelling of SIPN hydrogels showed discontinuous temperature dependency,

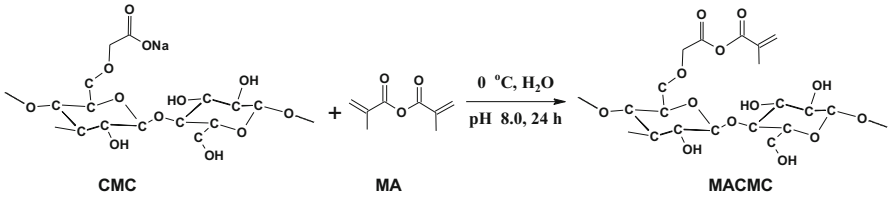

Fig. 12 Synthesis of methacrylated carboxymethyl cellulose sodium salt (MACMC)

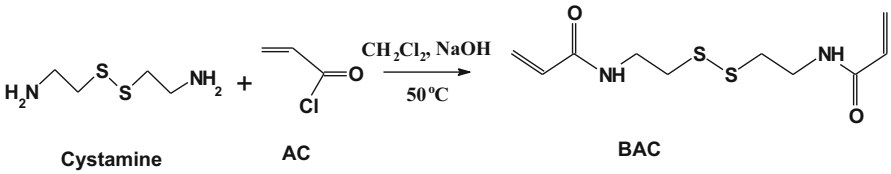

Fig. 13 Synthesis of *N*,*N*′-Bis(acryloyl)cystamine (BAC)

CP hydrogels showed gradual decrease in water retention values with increase in temperature. CBA crosslinked hydrogels showed higher swelling in comparison to BIS crosslinked hydrogels. Additionally, lysozyme was loaded in the hydrogels, and its in vitro release was studied in various pH, temperature, and in the presence of a reducing agent, glutathione (GSH). The release rate was found to be maximum at lower temperature, lower pH, and in the presence of GSH [57] (Figs. 12 and 13).

Furthermore, Lim et al. [58] prepared a novel pH-sensitive hydrogel with superior thermal stability, composed of poly(acrylic acid) (PAA) and cellulose nanocrystal (CNC). CNC was extracted from kenaf fiber through a series of alkali and bleaching treatments followed by acid hydrolysis. PAA was then subjected to chemical crosslinking using the crosslinking agent (*N*,*N*-methylenebisacrylamide) in CNC suspension. A disk shape hydrogel was obtained by casting the mixture onto a petri dish. PAA/cellulose hydrogel with the same composition ratio was also prepared as control. The effect of reaction conditions such as the ratio of PAA and CNC on the swelling behavior of the hydrogel obtained toward pH was studied. The obtained hydrogel was further subjected to different tests such as thermogravimetric analysis (TGA) to investigate the thermal behavior, Fourier transform infrared for functional group detection, and swelling test for swelling behavior at different pH. The crosslinking of PAA was established with FTIR with the the absence of C=C double bond. In TGA test, PAA/CNC hydrogel showed significantly higher thermal stability compared with pure PAA hydrogel. The hydrogel obtained showed excellent pH sensitivity and experienced maximum swelling at pH 7. The PAA/CNC hydrogel can be developed further as drug carrier.

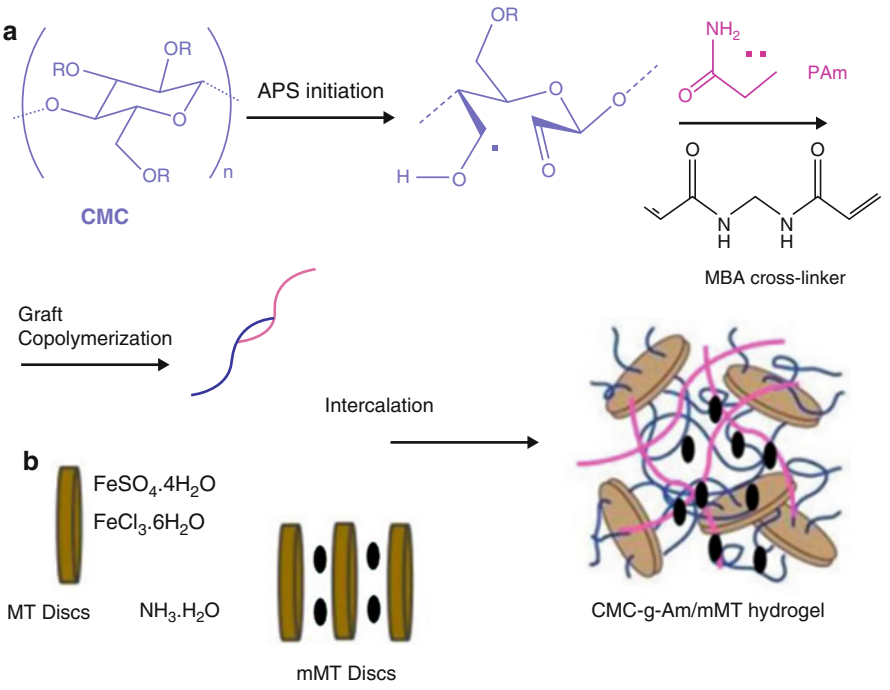

Fig. 14 Schematic representation for the synthesis of CMC-g-Am/mMT hydrogel [59]

Recently, Gholamreza et al. [59] developed magnetic/pH-sensitive nanocomposite hydrogel-based carboxymethyl cellulose-g-polyacrylamide/montmorillonite for colon-targeted drug delivery (Fig. 14).

3.3 Biodegradable Cellulose-Based Hydrogels

An important focus of the research in this field is the material's biodegradability. Modern superabsorbents are non-biodegradable acrylamide-based products. The renewed attention of institutions and public opinion toward environmental protection issues has awoken some producers to the development of biodegradable superabsorbents. Potential biodegradable cellulose-based superabsorbent, with sorption properties similar to those displayed for acrylate-based products, can be prepared by crosslinking reaction of cellulose polyelectrolyte derivatives, carboxymethyl cellulose (CMC), hydroxyethyl cellulose, etc.

Biodegradable superabsorbent hydrogels involve crosslinked poly (amino acid)s such as poly(γ-glutamic acid) and poly(aspartic acid) [60, 61] and crosslinked sodium salt of carboxymethyl cellulose (CMC). The crosslinking of CMC has been investigated with various methods, such as crosslinking agents [62] and ionizing irradiation [63, 64]. As concerns about environmental problems are rising today, various

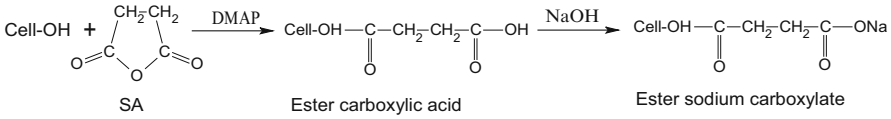

Fig. 15 Synthetic route of sodium carboxylate from cotton cellulose and SA [68]

naturally occurring polymers should be used instead of synthetic ones. Among them, cellulose exists most abundantly on the earth and is used for various applications. Cotton is one of the most accessible types of cellulose in our daily life and is produced in large amounts every year [65] One of the typical features of cotton cellulose is its extremely high molecular weight in the cellulosic family, over 1,000,000 [66]. Thus, cotton cellulose is a suitable starting material for superabsorbent hydrogels because the extremely high molecular weight of the polymer is one of the indispensable factors for attaining high water absorbency. The most representative cellulosic derivative containing sodium carboxylate is CMC, which contains it via an ether linkage [67].

The introduction of sodium carboxylate groups into cotton cellulose was investigated by esterification because esterification proceeds under milder conditions than etherification and ester linkages are more susceptible to hydrolysis and biodegradation than ether linkages [68] (Fig. 15). These features are suitable for the design of biodegradable superabsorbent hydrogels. Thus, the synthesis of superabsorbent hydrogels by the esterification of cotton cellulose with succinic anhydride (SA) was studied. It was found that a hydrogel could be obtained without any crosslinker when 4-dimethylaminopyridine (DMAP) was used as an esterification catalyst (Fig. 16).

Furthermore, Francesco et al. [69] evaluated a novel class of cellulose-based superabsorbent hydrogels, totally biodegradable and biocompatible, for agricultural use. Briefly, two cellulose derivatives, sodium carboxymethyl cellulose (CMCNa) and hydroxyethyl cellulose (HEC), were used for superabsorbent hydrogel preparation; citric acid (CA), a crosslinking agent able to overcome toxicity and costs associated with other crosslinking reagents, was selected in a heat-activated reaction. The objectives of their study were (1) to validate the ability of the hydrogel to modify the water retention properties of the growing media (soils and soilless substrates), (2) to investigate the effects on the growth of plants grown on media amended with the hydrogel, and (3) to find out the biodegradability of the prepared hydrogels. The applied tests revealed the absence of phytotoxicity of the hydrogel, and cultivation trials on cucumber (on soil) and sweet basil (in soilless conditions) showed a general overall enhancement of plant growth and quality when hydrogel was added to growing media. The tested hydrogel showed a high suitability for potential use in agriculture. The scheme for crosslinking reaction is illustrated in Fig. 17 [70].

Chunyu et al. demonstrated [71] two novel methods to prepare cellulose/PVA hydrogels with different functional properties via a green process. They introduced a series of hydrogels that were prepared from cellulose and PVA in NaOH/urea aqueous solution using both physical and chemical crosslinking methods. The

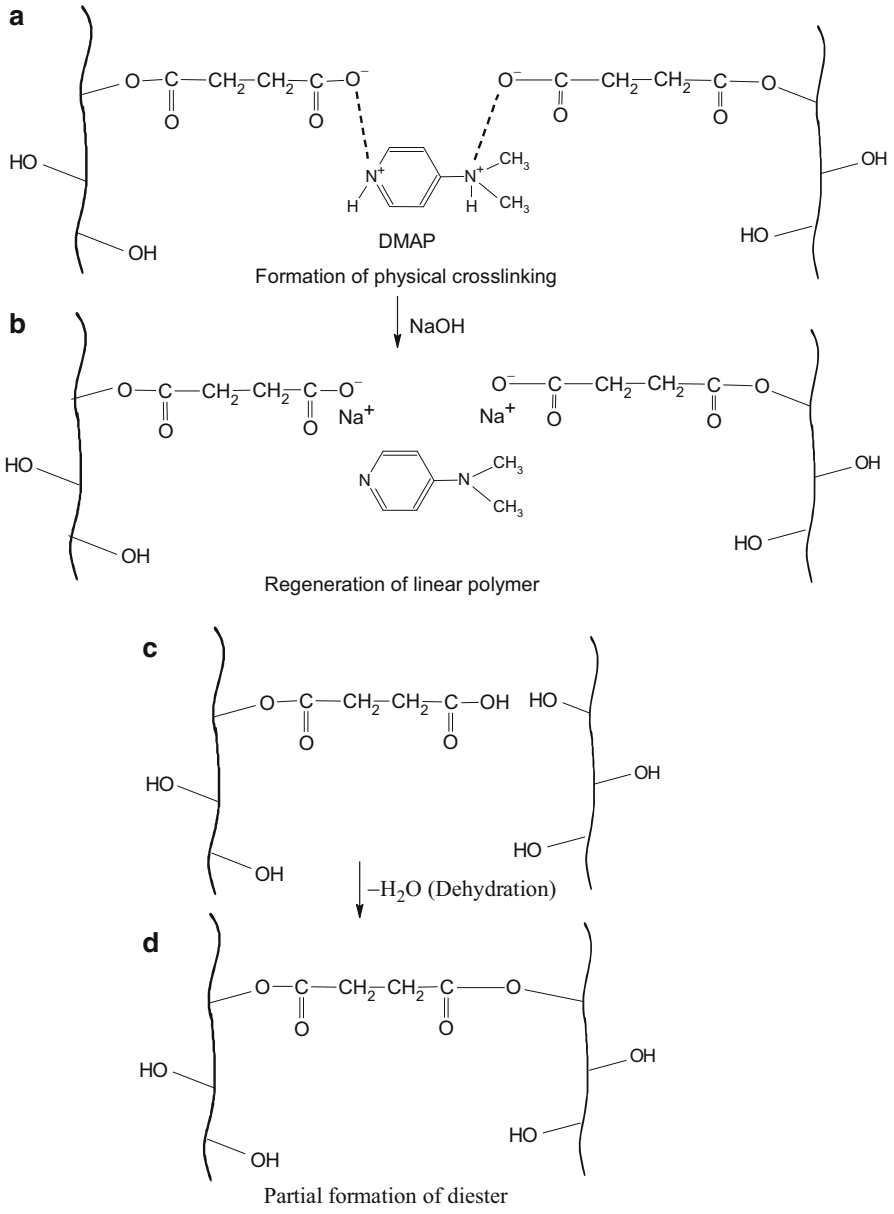

Fig. 16 Synthesis scheme of biodegradable superabsorbent hydrogel

hydrogels were secure and biodegradable materials. The results showed that all of the cellulose/PVA hydrogels exhibited homogeneous porous structures and a certain miscibility. The swelling degree and water uptake of the chemical hydrogels were markedly higher than those of the physical hydrogel (Fig. 18).

4 Conclusion

The green chemistry approach pushed researches and researchers toward replacing petroleum-based products with natural polymers for environmental concerns. In this respect, polymer networks of crosslinked cellulose derivatives were synthesized to form hydrogels for different purposes starting from sanitary pads and hygienic products to advanced applications such as biomedical field, drug delivery, pharmaceutical ground, and agriculture. In these specific applications, "smart" polymers are required to respond to different environmental changes to induce the required effect. These smart polymers are cheap, adaptable, and biodegradable so that extensive work is continued in order to introduce new generations of these materials to serve in different fields.

5 Future Perspectives

Shortage of fresh water resources is of worldwide concern. Efforts are directed to solve this problem by focusing on hydrogel industry. Hydrogels can be made by chemical modification of natural polymers such as cellulose, carboxymethyl cellulose, starch, guar gum, and so on. They can be used in water holding applications such as retained irrigation. They can be used as vehicles for delivering nutrients and pesticides to the root. Furthermore, they can be applied in wastewater treatment and removal of heavy metals. The new application of hydrogel utilization is in greenhouse industry where they regulate the amount of sunlight that can pass into the shelter and control the water loss.

Acknowledgments The authors express their gratitude for the Egyptian Petroleum Research Institute for supporting this work.

Abstract

Stimuli-responsive hydrogels can spontaneously change their physical and chemical properties in response to changes in the external environment, and they have potential applications in numerous fields as demonstrated in many reports. Cellulose is the most abundant polysaccharide in the natural world, and cellulosic polymers have been considered to be outstanding candidates as building blocks for stimuli-responsive hydrogels with great potential applications for absorption, separation, in the biomedical field, as well as other fields. The main purpose of this chapter is to demonstrate the significance of these materials and provide representative examples regarding the combination of stimuli-responsive hydrogels and cellulosic polymers. Inspired by the merits of both cellulose and stimuli-responsive hydrogels, in this chapter, we will also individually discuss some of the superior properties of stimuli-responsive cellulose-based hydrogels relative to a fossil-based hydrogel, including bulk hydrogels, microgels/nanogels, and injectable hydrogels that respond to stimuli such as heat, pH, ionic strength, light, electric field, magnetic fields, or shear, as well as their major applications. Furthermore, the typical strategies for the preparation of hydrogels (i.e., chemical cross-linking and physical cross-linking), as well as the mechanisms that drive the ability of these hydrogels to respond to various stimuli (i.e., heat, pH, light, special chemicals, electric fields, magnetic fields, and shear), will also be briefly presented in this chapter. This chapter might be useful for the development of novel stimuli-responsive cellulose-based hydrogels with high performance.

Stimuli-responsive · Cellulose · Hydrogels · Synthesis · Applications

1 Introduction

Stimuli-responsive behavior is a common phenomenon in the natural world. For example, the living cells in biosomes can change their chemical structures or functions by regulating their assembly behaviors and interfacial properties in order to maintain their biological lives [1]. Actually, many synthetic compounds can also mimic these behaviors, and they can undergo relatively dramatic physical or chemical changes in response to small external changes in the environmental conditions (e.g., temperature, pH, salt concentration, light, electric or magnetic fields, etc.).

Thus, this family of polymers is defined as "stimuli-responsive polymers" [2] (terms such as environmentally sensitive, "smart," or "intelligent" are also used).

A hydrogel (or gel, usually used interchangeably in food and biomaterials fields) is a three-dimensional (or cross-linked) network that is created from a class of synthetic and/or natural polymers [3]. Due to the presence of hydrophilic groups in their polymeric networks, hydrogels can absorb and retain a significant amount of water in aqueous environments [4]. Unlike other cross-linked resins, due to the water-containing network within hydrogels, they are usually soft and exhibit low surface tension that is similar to biological cells. Thus, hydrogels are widely used in drug delivery, for drug control release, for tissue engineering, as wound dressings, and in other fields [5].

The frameworks of stimuli-responsive hydrogels are constructed of stimuli-responsive polymer backbones, which provide the hydrogels with certain features in response to external stimuli. The typical responsive behaviors of hydrogels consist of (1) reversible/irreversible changes of the networks between homogeneous phase and phase separation (or transitions between swollen and collapsed phases) within a short time to change the hydrogels' physicochemical properties, (2) reversible/irreversible changes of the hydrogels' frameworks between cross-linked networks and flexible linear polymers (or sol-gel transitions), and (3) other reversible/irreversible changes in physical properties such as shape, size, optical properties, or dielectric properties. The stimuli responsiveness plays a pivotal role resembling that of a "switch, thus offering us an approach for regulating or controlling the hydrogels' physicochemical properties in various conditions. This switchable behavior provides these materials with numerous applications, such as intra- or extracellular stimuli-triggered drug release [6]; injectable scaffolds for tissue cultures [7]; the recycling of used sorbents for pollutants or water [8], or separation membranes [9]; sensors for minor changes in the surroundings [10]; microfluidics [11]; artificial muscles [12]; and so on.

Cellulose (Fig. 1a) and its derivatives are usually colorless, odorless, and nontoxic solid polymers with other promising merits such as excellent mechanical strength, biocompatibility, high sorption capacities, desirable hydrophilicity,

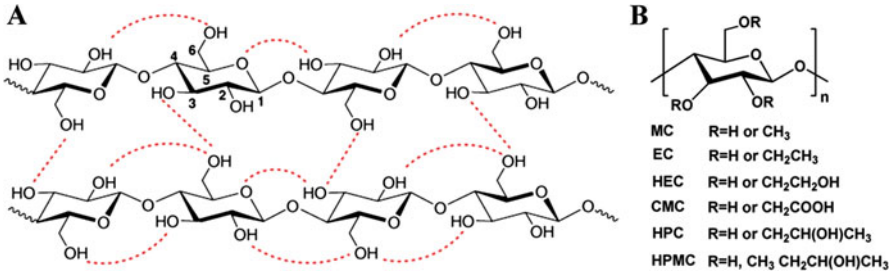

Fig. 1 (**a**) Molecular structure of cellulose illustrating the intermolecular and intramolecular hydrogen bonds [15]. (Copyright 2013 Society of Chemical Industry). (**b**) Structures of some common cellulose derivatives

desirable thermostabilization, and alterable optical appearance [13]. Cellulose can be readily obtained from plants, and this material accounts for one third of the dried weight of plants (PC). Additionally, cellulose can also be synthesized by algae, tunicates, and some bacteria (BC) [14]. The widely reported cellulose derivatives are MC, EC, CMC, HEC, HPC, and HPMC, the structures of which are shown in (Fig. 1b). The conventional applications of these cellulosic polymers have included the preparation of cellulose fibers and papers, and these conventional cellulosic products were usually produced via the viscose process, which consumes a lot of energy and creates pollution [15]. In recent years, stimuli-responsive hydrogels have been demonstrated to be useful and promising materials with potential applications in many fields. Meanwhile, with the rapid development of modern synthetic chemistry, numerous studies have focused on the incorporation of cellulosic polymers or cellulose crystals into stimuli-responsive hydrogels to improve their physicochemical properties. There are three main purposes for the conjunction of cellulosic polymers with stimuli-responsive hydrogels:

1. To Improve the Mechanical Properties
   Desirable mechanical properties are required for a swollen hydrogel, especially if it serves as a scaffold or barrier in the biomedical field. However, a highly swollen hydrogel, created from pure conventional fossil-based polymers such as polyacrylic acid, is always fragile, and it may fracture when it is subjected to an external force [16]. A promising method for improving the mechanical properties of a hydrogel consists of (1) preparing hydrogels with interpenetrating polymer networks (IPN) or semi-IPN structure [17], (2) incorporating other organic or inorganic additives into the hydrogel [18, 19], and (3) designing special structures to release the stress encountered by the network [20]. Cellulose usually serves as the dominant reinforcing phase in plants, and it was widely reported for its ability to serve as an organic additive to enhance the mechanical properties of hydrogels. The molecular structure of cellulose consists of a straight chain composed of β-(1→4)-linked $_{D}$-glucose units. Strong *intramolecular* or *intermolecular* hydrogen bonds exist between the neighboring hydroxyl groups (shown in Fig. 1a), which produce a composite structure bearing coexisting crystallized regions and amorphous regions. For example, the crystallinity of PC is usually in the range from 40% to 60%, but this value is over 60% for BC [21]. In comparison to some irregular fossil-based polymers with good solubility, bulk cellulose or molecular aggregates usually exhibit poor solubility as well as poor dispersity because cellulose molecules have ultrahigh tacticity. However, the native cellulose powder is still able to undergo disassembly and form nanoscale cellulose aggregates such as nanocrystals (with a specific area ~250 m^2/g), nanowhiskers, or nanofibers (with diameters in the range of 5–20 nm) in the presence of an inorganic acid. These cellulose-based nanoaggregates exhibit not only better water dispersity than native cellulose but also excellent mechanical performance due to their crystalline structure [22]. For example, the tensile strength of a cellulose nanofiber is over 7500 MPa, and its Young's modulus usually reached up to 140 GPa [23]. These cellulose-based

nano-aggregates are extraordinarily promising for their ability to improve the mechanical properties of hydrogels.

2. To Improve the Biocompatibility and Biodegradability
   Generally, hydrogels are considered as biocompatible materials. The undesirable allergies and inflammation caused by hydrogel implants can be effectively prevented because the adhesion of immunocyte or protein antibodies onto the surfaces of hydrogels can be avoided due to the excellent hydrophilicity and low surface tension of these materials. The incorporation of other biocompatible components into hydrogels can serve to inhibit undesirable stimulation caused by hydrogel implants. The cell viability results described in recent reports demonstrated that the biocompatibility of hydrogels can be effectively enhanced via the incorporation of cellulosic polymers [24, 25]. On the other hand, the biodegradability is also important because biodegradable hydrogels can be spontaneously decomposed into smaller molecules in physiological environments and thus easily excreted via sweat or urine instead of requiring removal by surgery, which may cause unnecessary tissue damage. It should be noted that the by-products produced from these degradation processes should be nontoxic to both humans and the natural environment. Generally, the degradation of fossil-based polymers only occurs under extreme conditions (i.e., intense heat or UV irradiation). The by-products that accompany the degradation process, such as organic acids, aldehydes, or alcohols, may be toxic to humans. In contrast, cellulosic polymers, in the presence of cellulase, can be rapidly decomposed into nontoxic glucose-based molecules under mild conditions. However, cellulose-based hydrogels cannot be digested or metabolized by the human body because it does not synthesize cellulase. The degradation of cellulosic polymers can only be effectively controlled by cellulase. Some researches have demonstrated that the degradation of cellulose-based hydrogels usually requires over 60 weeks to take place when they are exposed to physiological conditions [26]. Thus, cellulose-based hydrogels can be considered to be biodurable and can be used as biodegradation-controlled materials that are suitable for long-term service, as is the case with other fossil-based hydrogels.
3. To Decrease the Production Cost
   Fossil fuels have been considered as important strategic resources for many countries, particularly in recent years. The procedures for the mining, machining, and synthesis of fossil-based materials are usually cost-intensive and have large environmental footprints. The search for novel carbon resources is a critical issue for the sustainable development of human society [15, 27]. Cellulose, which is mainly generated by plants and organisms in nature at a scale of 1.5×10^{12} tons per year, is the most abundant renewable resource. However, in recent years, most of the cellulose produced was decomposed to CO_2 via metabolism of bacteria and fungi that exist in the air, water, and soil. Only 0.2% of cellulose was used for the industrial fabrication of materials such as paper and textiles [15]. The development and application of biomass materials has become increasingly important as researchers seek to reduce industrial costs and environmental risks.

4. Others
   As is the case with synthetic polymers, some cellulose derivatives can also reversely regulate their conformations under external stimuli. For example, MC, HPC, and HPMC exhibit thermo-responsive behavior resembling that of PNIPAAm and PEO-*b*-PPO-*b*-PEO (or Pluronic® F-127) [28–30]. Meanwhile, CMC exhibits well-defined pH-responsive behavior resembling that of polyacrylic acid (PAA). These cellulosic polymers with native responsive behaviors provide outstanding candidates as precursors for stimuli-responsive hydrogels. Furthermore, the backbones of cellulosic polymers usually contact active groups, such as hydroxyl groups in the HPC component and carboxyl groups in the CMC component. These active groups can not only react with cross-linking reagents to form a network, but they can also be modified with other pendent functional groups.

In this chapter, we will briefly introduce the general gelation strategies in Sect. 2 and the basic theories regarding stimuli-responsive behavior in Sect. 3. These discussions may be useful for improving the performance of cellulose-based hydrogels exhibiting with classic responsibility such as thermo- and pH-responsibility, and they may also provide some insight regarding the preparation of cellulose-based hydrogels with novel responsiveness to stimuli such as light, as well as electric and magnetic fields. In Sect. 4, great attention will be paid to the properties and applications of cellulose-based stimuli-responsive hydrogels with different responsive behaviors, with particular focus devoted to the significance of employing cellulosic polymers in stimuli-responsive hydrogels. Some relevant examples from the literature will also be briefly introduced in this section.

2 Classification of Gelation

Gelation (or a sol-gel transition) can be defined as the process through which a solubilized polymer with free macromolecular chains undergoes a collapse to a poorly dispersed network with contractive macromolecular chains. In this process, a solution of free macromolecular chains can be defined as a "sol," and a network of contracted and interconnected macromolecular chains can be defined as a "gel." The critical point of a sol-gel transition is defined as the "gel point" [31]. The hydrogels can be classified as physical gels or chemical gels according to the manner by which two neighboring polymer chains are linked.

2.1 Physical Gelation

Physical gelation is a "sol-gel" process, and it is usually triggered by the formation of temporary associations between free polymer chains. These associations can include the entanglement of coiled polymer chains, electrostatic forces between ionized groups or metal ions, the formation of crystallites between two or more polymer

chains, hydrogen bonding, clathration, aggregation due to the hydrophobic effect, and so on. Physical gelation is usually reversible because these temporary associations will dissipate when the hydrogels are exposed to external stimuli such as changes in the temperature, pH, ionic strength, solvent polarity, or stress. For example, the clear solutions of MC, HPC, and HPMC will spontaneously be converted into cloudy gels when they are subjected to an elevated external temperature. When the heat is removed, the cloudy gel will revert back to a clear solution [28–30]. The mixture of CMC and polyvinylamine can form an electrolyte hydrogel via electrostatic interactions between $-COO^-$ and $-NH_3^+$ at a certain pH value, and the electrostatic interactions can be disrupted via increasing the concentration of NaCl [32]. The cage-like macrocycle cyclodextrin, with its hydrophobic cavity, can serve as a supramolecular host to entrap hydrophobic guest molecules to form inclusion complexes, and this complexation behavior can be used to link the two polymers together via the threading of the polymer chains as guests through the macrocyclic host molecules. However, the linkage points can also be weakened via the addition of other guest molecules that have stronger binding affinities with these hosts [33].

2.2 Chemical Gelation

Chemical gelation is triggered via the formation of strong and stable covalent bonds, and this bond formation is usually irreversible unless they are subjected to extreme conditions or catalysts are added that facilitate the cleavage of these bonds. In order to form robust covalent bonds, di- or multifunctional molecules, aggregates of molecules, are usually incorporated as the cross-linking reagents to link the neighboring free polymer chains bearing active groups via the reactions between functional molecules and cross-linking reagents. The cross-linking processes are usually effectively achieved with the promotion of light, heat, catalysis, or radiation. The chemical reactions that are usually employed to cross-link polymers include radical polymerization between vinyl groups [34], condensation between amine and carboxyl groups [35], ring-opening reactions between epoxy and amine or carboxyl [36], coupling between two of thiol groups [37], Schiff's base reactions between glutaraldehyde and amine [38], click chemistry between azides and alkynes [39], or thiol-ene and other relevant reactions [40].

3 Responsive Mechanisms

3.1 Thermo-Responsiveness

Thermo-responsiveness can be defined as a spontaneous and reversible phase separation process that a polymer solution undergoes across a specific temperature value without any cleavage of covalent bonds. This particular temperature is defined as the "cloud point." Generally, under a constant pressure, it is not a fixed value because it

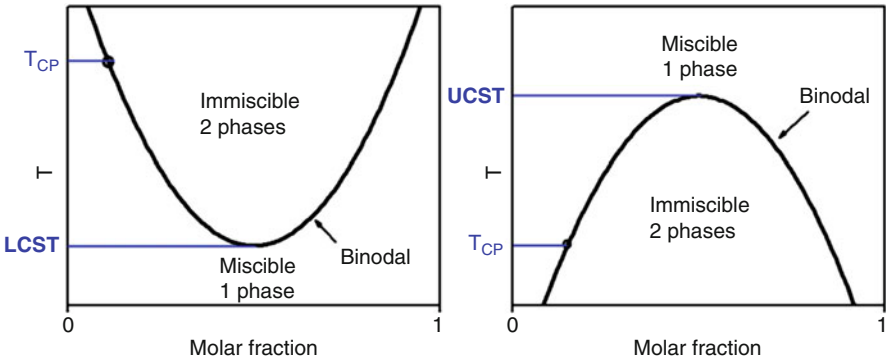

Fig. 2 Phase diagram for a polymer solution depicting an LCST (left) or UCST (right) [42]. (Copyright 2015 Elsevier Ltd)

mainly depends on the concentration of the polymer solution as well as other factors including the polymer's chemical structure, the ratio between the hydrophilic and the hydrophobic components of the polymer, the nature of the polymer and its molecular weight, or doses of additives in the polymer solution [41–43]. The lowest and the highest cloud points are, respectively, defined as the lower critical solution temperature (LCST) and the upper critical solution temperature (UCST, shown in Fig. 2). If the temperature of a polymer solution crosses the coexistence curve, the polymer solution consisting of one homogeneous phase will convert to a mixture composed of two miscible phases (often called "miscible-immiscible"). The most significant difference between the LCST and the UCST is the relative strength of the solvent effect and intermolecular interactions. The solvation that occurs between solvent molecules and polar groups in polymer backbones facilitates the dissolution of polymer chains, whereas the intermolecular interactions, such as hydrogen bonds or electrostatic interactions, facilitate the aggregation and precipitation of polymer chains.

3.1.1 LCST

LCST polymers are soluble when the external temperature is lower than their cloud point temperature (T_{cp}), while they are insoluble when the surrounding temperature is higher than T_{cp}. This behavior ascribes to the competition between solvent effect and intermolecular interactions. For example, PNIPAAm is the most famous LCST polymer that undergoes a phase transition at ~32 °C because the highly polar -NH- groups as well as the nonpolar -$CH(CH_3)_2$ groups both coexist in the backbone of PNIPAAm [44]. When the external temperature is below 32 °C, the solvation between water molecules and -NH- groups (or hydration in this case) is dominant, which overcomes the hydrophobic effect taking place on account of the -$CH(CH_3)_2$ groups. On the contrary, when the external temperature is above 32 °C, the hydration is weakened, and the hydrophobic effect is dominant; thus PNIPAAm chains tend to aggregate and form precipitates. In addition to PNIPAAm, some other synthetic

polymers also exhibit the LCST thermo-responsive behavior in pure water, such as PNVA derivatives [45], PVME [46], PNVCL [47], copolymer such as Pluronic® F-127 [48], etc.

3.1.2 UCST

In contrast with LCST polymers, UCST polymers are soluble when the external temperature is above their T_{cp}, while they are insoluble when the temperature is below their T_{cp}. When the external temperature is lower than the polymer's phase transition temperature, the dissolution of the polymer is inhibited because the *inter*- and *intra*molecular forces of UCST polymers are usually much stronger than those of LCST polymers. When the external temperature is higher than the polymer's phase transition temperature, the dissolution of the polymer is promoted because the molecular forces between the polymer chains are weakened, thus providing water molecules with an opportunity to interact with polar groups in the polymer chains. Generally, the UCST behavior can be regulated via alternatively changing the amount of polar groups on the polymer chains or by changing the molecular weight of the polymer. Only a few of polymers exhibit UCST behavior in water at temperatures in the range from 0 °C to 100 °C. Some representative UCST polymers, such as PNAGA [49], PDMAPS [50], PSPP [51], and PMAAm [52], all possess highly polar zwitterionic groups, which can help generate strong intermolecular interactions.

3.2 pH or Ionic Strength Responsiveness

Due to the existence of ionizable pendant groups or electrostatic groups in polymer chains, the "stretch-coil" behavior of a pH-responsive polymer mainly depends on the electrostatic interactions within the polymer chain or with other polymer chains. In the solution with an initial pH, the ionizable groups will not gain or lose protons; thus there are no electrostatic interactions between the polymer chains (possibly only hydrogen bonds exist). When the pH is changed, the polymer's dissolution in aqueous solution is promoted because protons will dissociate from, or absorb onto, the ionizable groups in the polymer chains. The resultant charges will enhance the polarity of the polymer chains, thus promoting the attachment of water molecules onto the charged groups to form hydrated ions. Meanwhile, the electrostatic repulsion also prevents the neighboring polymer chains from coming into contact with each other. In the case of a pH-responsive hydrogel, its swelling ratio will be further enhanced because the charged groups induce more water molecules to diffuse into the hydrogel's network to balance the difference in the osmotic pressure between the exterior and the interior of the hydrogel.

Hydrogels that exhibit ionic strength responsiveness usually also exhibit pH responsiveness. The hydrogel's swelling ratio will decrease when the ionic strength is increased. This behavior can be attributed to the following factors: First, the charged groups on the hydrogel's backbones will be partly screened by the counterions in water, and the electrostatic repulsion between the neighboring polymer

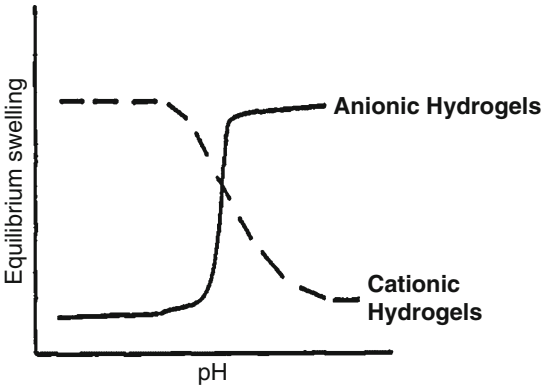

Fig. 3 Equilibrium swelling behaviors of anionic and cationic hydrogels. These behaviors are influenced by the ionic pendant groups. (Reprinted with permission from Khare et al. [53]. Copyright 2015 Elsevier B. V)

backbones is weakened. Second, increasing the ionic strength of the external solution will heighten the difference in osmotic pressure between the exterior and interior of the hydrogel, thus causing the water molecules within the hydrogel to migrate to the external solution to balance the osmotic pressures.

3.2.1 Anionic Responsiveness

Anionic polymers are hydrophilic when the pH value of the surrounding solution is higher than their pK_a. PAA, as a typical pH-responsive polymer with a pK_a of ~4.6, exhibits poor solubility in aqueous solution with a pH value that is below its pK_a. In this case, the *inter*- or *intramolecular* hydrogen bonds between neighboring PAA chains create the curled and aggregative conformation of the polymer chains. When the pH is above 4.6, carboxyl groups will gradually lose protons to form anionic carboxylates, which have better water-binding capabilities. The electrostatic repulsion between neighboring polymer chains also promotes the dissolution of PAA. Therefore, a PAA-based hydrogel will absorb water in an alkaline solution while releasing water in an acidic solution (shown by the dashed line in Fig. 3). However, it should be noted that the ionic strength responsiveness of a PAA-based hydrogel cannot be ignored especially in extremely alkaline solutions because a large number of cations, such as Na^+, may shield the carboxylate groups, which will restrain the water-absorbing capabilities of the hydrogel [54]. CMC is the most representative pH-responsive cellulosic polymer because its backbone contains many pendent anionic carboxylate groups as is the case with PAA. The hydrogels thereof exhibit both pH- and ion strength-responsive behaviors. In addition, various functional groups can be grafted onto CMC backbones due to the reactive nature of carboxyl groups.

3.2.2 Cationic Responsiveness

Cationic polymers exhibit good solubility in water when the pH value of the external environment is lower than the polymers' pK_a. PDMAEMA is a typical cationic polymer with a pK_a of 7.0–7.3 in aqueous solution [55] (in fact, PDMAEMA is a dual responsive polymer exhibiting both pH and thermo-responsiveness with an

LCST of ~31 °C [56]). When the external pH is lower than this range, the lone pair electrons in the sp^3 orbitals of the nitrogen atoms will accept protons to form $-NH_4^+$, which enhances the hydrophilicity of PDMAEMA. Thus, hydrogels that are based on cationic polymers will swell at low pH values and collapse at high pH values (shown by the solid line in Fig. 3). Besides PDMAEMA, other cationic polymers, such as PDEAEMA [57] and PAAm [5], also exhibit pH-responsive behavior.

3.3 Photo-Responsiveness

Light is much more readily manipulated than other stimuli such as temperature or pH. The incorporation of functional groups that were capable of absorbing light and transferring light to heat and thus trigger the thermo-responsive behavior of these hydrogels was reported during the preparation of the earliest photo-responsive hydrogels in 1990 [58]. However, the responsiveness was weak because this process required the conversion of "light to heat" that was thus accompanied by an elevated temperature. For pH- and/or thermo-responsive hydrogels, their responsive behaviors only depend on the physical changes within their frameworks. However, most photo-responsive hydrogels can change their physicochemical properties via photochemical reactions within their frameworks, and new chemical compounds are produced through this process. The rate at which a hydrogel responds to light stimuli is determined by the kinetics of the photochemical reaction, which relates to the reaction temperature or concentrations of the reactants/products, essentially absorbed intensity (I_{abs}), and overall quantum yield (φ). The prior parameter is primarily determined by the wavelength, concentrations of the reactants (as it is only effective at high concentrations), and the depth of light penetration. The latter parameter depends on the efficiency of the reaction and the fluorescent quenching effect of both the reactants and products. Photochemical reactions with high I_{abs} and φ facilitate rapid response rates and remarkable changes in the physicochemical properties.

3.3.1 Isomeric Responsiveness

Isomeric reactions are one of the most widely used physicochemical reactions for preparing hydrogels with photo-responsive properties. Among these reactions, the monomolecular *cis-trans* shift of azobenzene is the most representative isomeric reaction. Azobenzene can undergo a *trans*-to-*cis* transition at 360 nm, and the inverse transition takes place under light irradiation at a wavelength of 440 nm. It has been reported that azobenzene molecules existing as *cis* species are hydrophilic, whereas their *trans* forms are hydrophobic [59]. Furthermore, the stacking sequences between neighboring azobenzene molecules vary for azobenzene molecules with different forms because their *trans* isomers are positioned in the same plane with a length of 9 Å and their *cis* isomers are three-dimensional structures with a length of 5.5 Å (Fig. 4) [59, 60]. Azobenzene has frequently been incorporated into photo-responsive hydrogels and serves a critical role in the cross-linking process with neighboring polymer chains via the formation of supramolecular inclusion

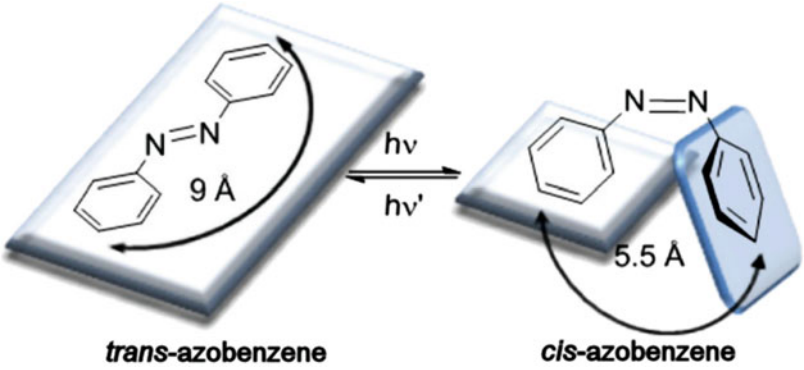

Fig. 4 Photoisomerization of azobenzene [59]. (Copyright 2012 Merino and Ribagorda; licensee Beilstein-Institut)

complexes with other cage-like molecules [61]. In addition, the light wavelength that triggers the conformation transition can be regulated via chemical modifications of the azobenzene molecules. Cyclization is another common isomeric reaction. For example, non-cyclized spirobenzopyran is a linear molecule bearing zwitterionic groups, which render it hydrophilic. However, upon exposure to light radiation, spirobenzopyran will be converted into a hydrophobic polymer because the self-cyclization takes place and the zwitterionic groups are consumed [62].

3.3.2 Covalent Responsiveness

The cleavage of covalent bonds within molecules usually leads to covalent-responsive behavior. In this responsive process, two new compounds will be created due to the cleavage of a covalent bond, or a new dimer will be created due to the formation of new covalent bonds. For example, a polymer containing *o*-methoxy nitrobenzene moieties can readily degrade into an oligomer when it is exposed to light irradiation at 350 or 750 nm [63]. In contrast, molecules containing coumarin or anthracene groups can form dimers via a reversible Diels-Alder reaction. These molecules can serve as cross-linkers to form chemical hydrogels [64, 65]. These reversible cross-linking processes may facilitate the preparation of injectable hydrogels capable of reversible "sol-gel" transition behavior.

3.4 Chemical Responsiveness

Chemical-responsive hydrogels can be defined as the hydrogels that can regulate their swelling properties or undergo a "sol-gel" transition in the presence of target molecules that act as triggers. The responsive mechanism may involve (1) binding of target molecules bearing particular functional groups onto the hydrogel's backbones, (2) the cleavage of covalent bonds caused by the incorporation of target molecules

(such as enzymes), and (3) the changes in the pH or temperature caused by a reaction between the target molecules.

3.4.1 Glucose Responsiveness

The glucose-responsive behavior proceeds via three mechanisms [66]. The first mechanism is based on the pH change that is induced by the decomposition of glucose in the presence of glucose oxidase (GOx). Glucose molecules diffuse from the external solution into the hydrogel's network and subsequently are converted into gluconic acids via reactions catalyzed by GOx. Thus, the phase transition behavior of the hydrogel is motivated due to the changes in the pH value in the presence of gluconic acids (the reaction shown in Fig. 5a). The second mechanism is based on the degradation of hydrogels due to the binding between glucose and

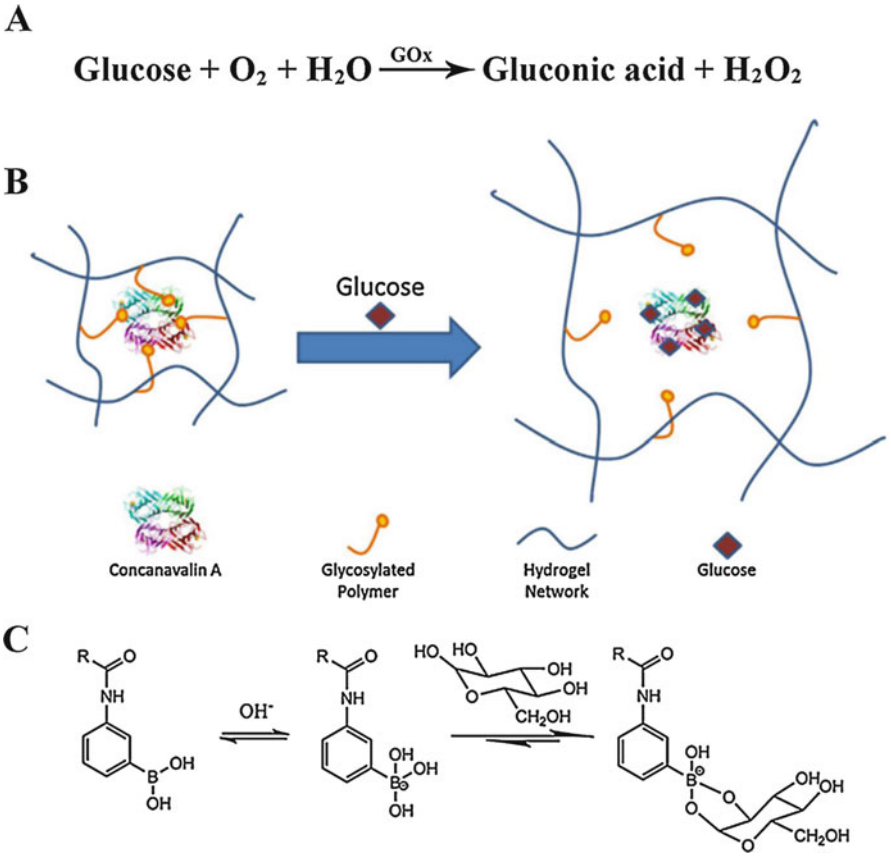

Fig. 5 (**a**) The reaction between glucose and oxygen catalyzed by GOx. (**b**) Illustration of the swelling mechanism of Con A-based glucose-responsive hydrogel. (**c**) Reaction between glucose and PBA [5]. (Copyright 2015 Elsevier B. V)

concanavalin A (Con A). The polymers bearing glycosylated backbones can bind with the neighboring polymers bearing Con A to form a cross-linked network due to the binding of the glycosyl moieties with Con A. However, the binding affinity between Con A and glucose molecules in external solution is higher than that between Con A and glycosyl moieties. Therefore, the binding between the glycosyl units and Con A will be disrupted, and the hydrogel subsequently undergoes a "gel-sol transition (as shown in Fig. 5b). The third mechanism is based on the changes in the charges caused by the binding of glucose with PBA. The PBA moieties on the backbones will bind with glucose to form cationic boron products (the reaction is shown in Fig. 5c) that increase the charge density within the hydrogel, resulting in the swelling of hydrogels.

3.4.2 Enzyme Responsiveness

Enzyme-responsive behavior can be understood as enzymatic decomposition. The enzyme-responsive hydrogels are cross-linked by peptide chains, and their peptide sequences can be recognized and subsequently digested by a specific enzyme, ultimately leading to the degradation of the hydrogels.

3.4.3 Alcohol Responsiveness

Some polymers, such as PNIPAAm, exhibit critical soluble behavior in mixtures of ethanol and water. This ethanol-responsive behavior is primarily determined by the concentration of ethanol. PNIPAAm has both lower and upper critical ethanol-responsive concentrations (usually, respectively, denoted as C_{E1} and C_{E2}), which are 16.7 and 51.9 vol.% in aqueous solutions at 25 °C (shown in Fig. 6). If the ethanol concentration is lower than 16.7 vol.%, the limited ethanol molecules are unable to disrupt the hydrogen bonds between water and -NH- groups in the PNIPAAm backbones. In this case, PNIPAAM is highly soluble in the aqueous ethanol solution. With an increasing ethanol concentration, the hydrogen bonds between water and the -NH- groups are gradually destroyed by ethanol molecules, and PNIPAAm undergoes a "coil-to-aggregate" phase transition. When the ethanol

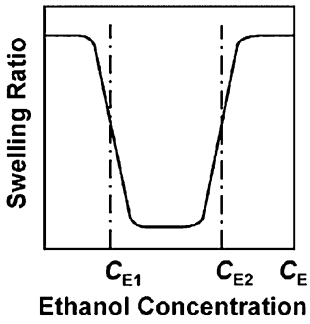

Fig. 6 Ethanol-responsive behavior of PNIPAM [67]. (Copyright 2012 American Chemical Society)

concentration is higher than C_{E2}, the -NH- groups effectively combine with ethanol molecules, thus causing the redissolution of PNIPAAm [67].

3.5 Electric Field Responsiveness

Electrolyte-based hydrogels usually respond to electric fields due to the fixed charges within their network structures. The responsive mechanism can easily be understood by considering sodium polyacrylate hydrogel as an example. In the absence of an electric field, the overall hydrogel is electroneutral. In this scenario the Na^+ ions with their positive charges act as counterions to the $-COO^-$ moieties and are partly bound with these groups via electrostatic interactions. Some Na^+ ions are also well-dispersed in water within the hydrogel's network. When an external electric field is applied to the hydrogel, the Na^+ ions begin to migrate toward the cathode, which results in an ionic gradient along the direction of the electric field, whereas the $-COO^-$ units migrate toward the anode because their motions are restrained by the cross-linked backbones of the hydrogel. Consequently, ion concentrations inside and outside of the gel are different. This difference between ionic concentrations creates an osmotic pressure difference between the anode- and cathode-facing sides of the hydrogel [68]. For anionic sodium polyacrylate hydrogel, the osmotic pressure on the anode-facing side is higher than that encountered on the cathode-facing side. In this case, water molecules tend to migrate from the cathode side to the anode side, which induces swelling of the hydrogel on the anode-facing side and shrinkage on the cathode-facing side. The opposite swelling/shrinking behavior in one region of the hydrogel thereby causes the overall structure of the hydrogel to become deformed. It should be noted that the electrolyte hydrogels only exhibit electric field-responsive behavior in a special pH range because the charged groups may be neutralized when the pH is changed. For example, hydrogels of sodium polyacrylate would lose their electric responsibility upon exposure to a strongly acidic environment [69].

3.6 Shear Responsiveness

Shear-responsive hydrogels can reversibly change their viscosity when an external shearing force is applied or removed. The shear-responsive behaviors can be classified as either shear thinning or shear thickening. In the case of shear thinning, temporary interactions that link the neighboring polymer chains together within a hydrogel, such as hydrogen bonds or electrostatic interactions, are unstable and can be provisionally destroyed by the application of a shear force. Thus the hydrogel will exhibit a reversible "gel-to-sol" phase transition [70]. In contrast, the latter case usually takes place in hydrogels which contain inorganic micro−/nanoparticles as part of their composition. The polymer chains binding with solvent molecules serve as dispersants to prevent the aggregation of micro−/nanoparticles.

Once the external shearing force is applied, the polymer chains are extruded out from the space between neighboring particles, and the hydrogel assumes a solid-like status [71].

3.7 Magnetic Responsiveness

Magnetic hydrogels are usually prepared via entrapping magnetic micro-/nanoparticles (such as γ-Fe_2O_3, Fe_3O_4, or $CoFe_2O_4$ nanoparticles) into the cross-linked networks [72]. For the bulk magnetic hydrogels that are exposed to an external magnetic field, the entrapped magnetic particles can change the distribution of the hydrogel's backbones, which will alter the properties of the hydrogel, such as the size, shape, or other physiochemical properties [73, 74]. In contrast with the hydrogel's polymer chains, the magnetic micro-/nanogels can migrate along the direction of the external magnetic field. However, strictly speaking, the migration of magnetic micro-/nanogels cannot be designated as typical magnetic-responsive behavior because the physiochemical properties of an individual particle are not changed during the magnetic migration. However, the external magnetic field may create other physical stimuli such as heat, which provide promising potential in thermal cancer treatment and targeted drug release.

4 Properties and Applications of Stimuli-Responsive Cellulose-Based Hydrogels

4.1 Thermo-responsive Cellulose-Based Hydrogels

4.1.1 Wound Dressings

Wound infection can often cause an injury to become more severe, increasing the risk of amputation and death [75]. Keeping a wound moist is a critical factor in allowing a wound to heal because moist conditions facilitate tissue restoration and limits the propagation of microorganisms. Additionally, these conditions can alleviate pain [76]. The ideal wound dressings should (1) adhere onto the surface of a wound for sufficient time without leading to abscission, (2) absorb the excess tissue fluid that exudes from the wound, (3) ensure the wound remains moist, (4) facilitate the transport of gas molecules, (5) protect the wound against heat, (6) readily detach from the wound when needed without inducing pain [77], and (7) have enough mechanical strength to avoid undesirable fracture in normal daily activities.

Physical hydrogels with appropriate LCSTs are considered to be the excellent candidates as wound dressings. First, polymer solutions that are initially at room temperature will undergo a "sol-gel" transition once they contact the surface of a wound with a higher temperature (such as 37 °C, which is encountered under physiological conditions). Subsequently, the polymer chains regulate their conformation to form a physically cross-linked hydrogel that covers the wound. Second, the hydrogels contain water molecules in their networks and can thus keep the

wound moist, while the excess tissue fluid from the wound can also be absorbed by the hydrogels. In addition, due to the continuous or semicontinuous pore structure that exists within hydrogel, gas molecules can freely pass through the hydrogel layer. Third, the hydrogel dressings can be easily removed in a pain-free manner via local cooling such as exposure to cold water when their removal is desired.

The incorporation of cellulosic polymers to the hydrogel's network is a promising method for preparing versatile and robust wound dressings. Firstly, cellulosic polymers contain numerous hydroxyl groups on their backbones, which facilitate the mucoadhesion of a hydrogel with epithelial tissue, because temporary interactions, such as electrostatic interactions, van der Waals forces, or hydrophobic effect, will occur between polar groups in the backbones of cellulosic polymers and the epithelial layer [78].

In addition, the mucoadhesion can be further enhanced by modifying the hydroxyl groups with other polar groups or polymer chains. Secondly, some cellulosic polymers, such as HPC, HPMC, and MC, exhibit distinct thermo-responsive behavior, which can be directly used as the matrix of a thermo-responsive hydrogel for a wound dressing. Meanwhile, the hydrogel's LCST can be regulated by changing the polymer's structure to satisfy a given requirement. Thirdly, the polar groups on cellulosic polymers facilitate the formation of a composite hydrogel bearing other polymers or small molecules such as antibiotics [79] or chitosan [80], which can inhibit the propagation of bacteria on the surface of a wound. Fourthly, some cellulosic polymers, such as CMC, can form weak electrostatic interactions with other charged components to enhance the hydrogel's mechanical properties. In addition, it is notable that BC-based hydrogel wound dressings have been demonstrated to have been shown to promote wound healing, possibly due to their distinctive 3D structure that resembles normal skin tissue [81].

4.1.2 Vaginal Drug Release

As of 2016, over 12 million people have died from acquired immune deficiency syndrome (AIDS) globally, and over 39.6 million people were infected by human immunodeficiency virus (HIV). Therefore, HIV infection poses a significant threat to global public security [82]. Sexual behavior is one of the critical routes for HIV transmission, especially from males to females. It has been verified that the risk of infection of women is eight times higher than men due to the physiological structure of the vagina [83].

Sustained drug release in the vagina is an effective method for preventing HIV infection. The ideal vaginal drug delivery platforms are expected to have the following properties: (1) excellent adhesion onto epithelial cells to avoid the unexpected leakage with the washing of vaginal fluid, (2) excellent biocompatibility and nontoxicity, and (3) facile private implantation.

Cellulose-based thermo-responsive injectable hydrogels are considered to be excellent carriers for anti-HIV drugs (generally, for vaginal drug release, pH responsiveness is also required as will be discussed in Sect. 4.2.2). First, injectable hydrogels can be easily injected into the vagina by the patient, and they usually undergo a "sol-gel" transition when they encounter the external conditions at the

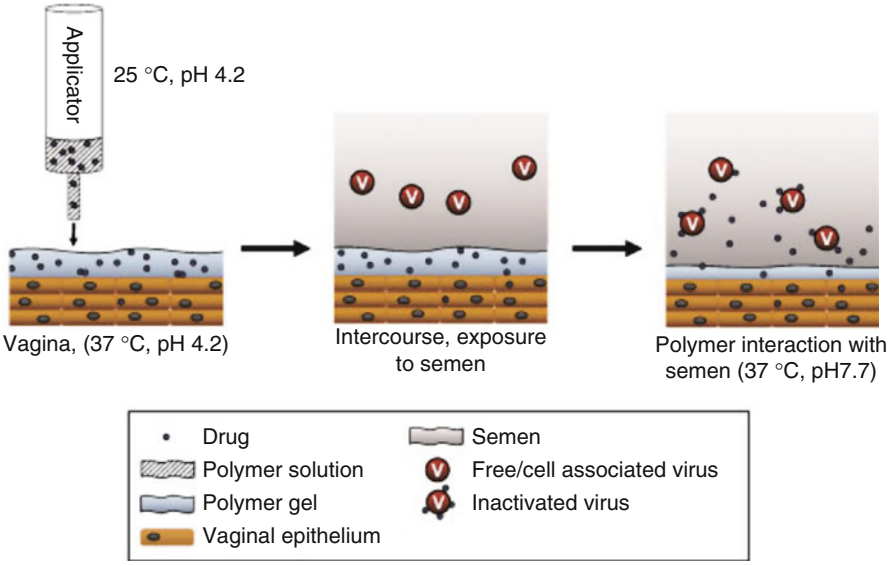

Fig. 7 Schematic depiction of the behavior of an LCST injectable hydrogel in response to the temperature and pH stimuli during vaginal drug release. Upon exposure to semen, the gel loses its mechanical properties and is converted to a liquid again, thereby releasing the entrapped drugs [87]. (Copyright 2006 Wiley-Liss, Inc. and the American Pharmacists Association)

injection site (shown in Fig. 7). Second, the fluid polymer solution will form a physically cross-linked gel and cover the epithelium because the temperature of the vagina is higher than room temperature. Meanwhile, as is the case with wound dressing hydrogels, the polar groups in the cellulosic polymers will facilitate mucoadhesion between the hydrogel and the tissue. Third, cellulosic polymers have been demonstrated to be nontoxic and biocompatible; thus some undesirable symptoms after the implantation procedure can be avoided. Thermo-responsive cellulosic polymers are suitable for use not only independently as drug carriers [84] but also in combination with other biocompatible polymers such as Pluronic® copolymers, to form composite hydrogel with better biocompatibility and mucoadhesion [85, 86].

4.1.3 Tissue Culture

The complete and effective repair of damaged tissues and organs is the ultimate aim of surgical operations. Usually there are two approaches that are employed to achieve this aim. One strategy is to completely replace the damaged tissues with synthetic materials. The other approach is to guide the histiocytes to propagate along with a predesigned shape and size via employing a synthetic scaffold [88]. The ideal scaffold materials are expected to exhibit the following properties:

1. Nontoxicity and biodegradability. The scaffold can be decomposed in a physiological environment when the damaged areas are adequately covered by regenerative histiocyte.

2. A continuous or semicontinuous porous structure, which serves as a passageway for the transport of metabolic wastes and nutrients.
3. Desirable surface physicochemical properties capable of facilitating the histiocyte propagation.
4. Readily machined into a particular shape or can mimic the natural texture of normal tissues.
5. Desirable mechanical properties that withstand normal daily activities [89].

Cellulose-based hydrogels with sol-gel transition behavior can provide suitable platforms for tissue cultures. First, cellulosic polymers have been widely used in tissue engineering due to their excellent biocompatibility and nontoxicity. Thermo-responsive polymers such as HPC, HPMC, or MC can serve as the matrices of hydrogel scaffolds. Polymer solutions can be selectively injected into an injured tissue at room temperature via a minimally invasive surgical operation. In response to the higher temperature encountered within the human body, the polymer solution will be converted to a gel and become deposited on the damaged tissue [90]. In addition, the polymer sols can also be pre-machined into a solid scaffold with various shapes using a mold. Second, the porous structure of the physical hydrogel facilitates the interchange of wastes and nutrients. Meanwhile, the pore size can be regulated by adding different amounts of pore-forming agents or adjusting the cross-linking degree. Third, the mechanical properties of the hydrogel scaffolds can also be regulated via (1) changing the cross-linking degree, (2) changing the concentration of the cellulosic polymer solutions, or (3) adding other components with better mechanical performance. Fourth, unlike crystalline native cellulose, mono cellulosic polymer chains can also partially degrade in less than 12 weeks in the absence of cellulase [91]. Fifth, the incorporation of nanofabricated cellulose and CNC can remarkably enhance the scaffold's mechanical properties due to their high crystallinity.

4.1.4 UCST Hydrogels

Cellulose-based hydrogels with LCST behavior have been widely used in various fields. However, the hydrogels with UCST properties also have some promising applications. In protein separation, for example, UCST polymers that form gels at elevated temperatures can capture proteins and release these proteins at low temperature because the UCST polymers undergo "gel-sol" transitions at low temperatures (shown in Fig. 8) [92]. UCST hydrogels can also be used in drug release. For example, drugs can be entrapped within the hydrogel at normal body temperature and freely diffused out from the hydrogel when the patient experiences a fever because the hydrogel networks become swollen at elevated temperatures [93]. Similarly, in tissue culture, a tissue sample can readily detach from a UCST physical hydrogel coating because the UCST polymers undergo a rapid "gel-to-sol" transition when the external temperature is slightly changed [94]. With the development of synthetic technologies, a growing variety of UCST polymers provide promising potential as cellulose-based hydrogels with advanced biomedical applications.

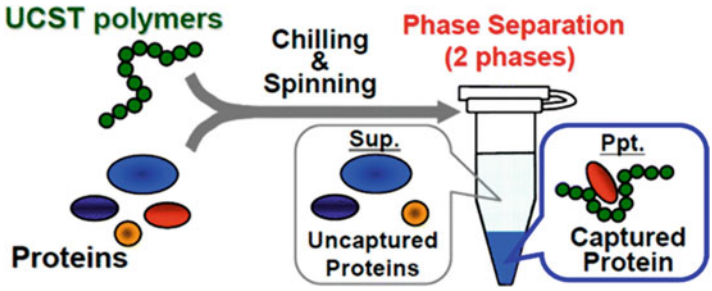

Fig. 8 Illustration depicting the use of UCST polymers for protein separation. The captured protein can be precipitated and collected, while the uncaptured proteins remaining in the solution are discarded [92]. (Copyright 2013 American Chemical Society)

Table 1 Locations within the body that exhibit a dynamic pH range during normal function or in response to a diseased state [95]

Location	pH
Blood	7.34–7.45
Stomach	1.0–3.0
Upper small intestine	4.8–8.2
Colon	7.0–7.5
Tumor, extracellular	6.5–7.2
Early endosome	6.0–6.5
Late endosome	4.5–5.0
Vagina	3.8–4.5
Inflamed tissue/wound	5.4–7.4

4.2 pH-Responsive Cellulose-Based Hydrogels

4.2.1 Oral Drug Release

Oral administration is the most widely used mode for disease treatment. However, the administration of a medicine at predetermined intervals usually leads to a sawtooth-like rather than a constant drug release profile. Thus, oral drugs with controlled release behavior have gained much attention in recent years.

A sustained-release tablet will pass through the mouth and stomach and finally arrive at the intestinal tracts. The active ingredient in the tablet will be constantly released to the intestine. The normal pH ranges encountered in different organs of the human body are listed in Table 1.

Due to the large difference in the pH between the stomach and intestine, the protection of tablets against corrosion by *succus gastricus* is a critical challenge faced in the field of oral drug release. The expected properties for an ideal hydrogel carrier for oral drug release should include:

1. An appropriate pH-responsive range to ensure that the active ingredients are released at the predetermined location.
2. Desirable biocompatibility and nontoxicity to prevent a rejection reaction by the intestines such as serious gastrointestinal peristalsis.

3. Desirable mucoadhesion to ensure that the tablets can constantly release drugs for a prolonged duration in the intestine without being excreted.
4. Desirable mechanical properties to withstand gastrointestinal peristalsis because the fracture of tablets may result in a sudden release of the drug.
5. Desirable chemical stability so that the tablet can resist corrosion by *succus gastricus*.

Based on the following considerations, pH-responsive hydrogels prepared from CMC exhibit great promise as potential carriers for oral drug release. First, CMC is a water-soluble polymer with desirable biocompatibility. The carboxyl groups in the backbone will result in the shrinkage of the hydrogel's network in the stomach because the pH value of *succus gastricus* is lower than the pK_a of the hydrogel's carboxyl groups. Thus, the drug molecules are protected by the collapsed hydrogel's network rather than being released into the surrounding solution. When the hydrogel enters the intestines, it will absorb water and become swollen because the pH value in the intestines exceeds the pK_a of the carboxyl groups. Thus the preloaded drugs in the hydrogel's network can freely diffuse into the intestines [96]. Second, CMC contains numerous carboxyl groups as well as many residual hydroxyl groups in its backbone, which facilitate the mucoadhesion of this hydrogel onto the intestinal epithelium. Third, anionic CMC backbones can establish electrostatic interactions with cationic polymers, such as chitosan, to enhance the hydrogel's mechanical properties and reduce the risk of a fracture-induced sudden release of the drug [97]. Interestingly, the incorporation of BC provides an effective method for enhancing the hydrogel's mechanical properties because the crystallinity of BC is much higher than that of PC [98]. Fourth, the CMC backbones can be rapidly cross-linked by metal ions, such as Fe^{3+} or Al^{3+}, instead of toxic organic cross-linkers such as glutaraldehyde [99].

Cationic hydrogels can also be used in oral drug release applications. For example, cationic hydrogels can serve as carriers for stomach drugs with poor water solubility, such as curcumin, to ensure they are released over a prolonged duration rather than prematurely excreted from the body [100]. In addition, cellulosic polymers with numerous hydroxyl groups can be quaternized to form cationic hydrogels. The positive charges in the networks can generate weak electrostatic interactions with sialic acid (*N*-acetylneuraminic) in gastric mucus, which can further enhance the residence time of the hydrogel-based drug carrier in the intestines [100, 101].

4.2.2 Vaginal Drug Release

As is the case with oral drug release, pH-responsive cellulose-based hydrogels can also be used in vaginal drug release. It is well known that the pH of semen is ~7.5, while the pH of vaginal fluid is in the range of 3.8–4.5. After sexual behavior, the vaginal fluid will be neutralized to ~7.0. Thus, some anti-HIV agents that have been preloaded in pH-responsive cellulose-based hydrogels can be spontaneously released after sexual behavior due to the variation in the pH value (shown in Fig. 7). In addition, as described in Sect. 4.2.1, due to presence of the ionic groups

on the backbones of cellulosic polymers, the mucoadhesion of these hydrogels will be further enhanced.

4.2.3 Pollutant Absorption

The major pollutants in wastewater that are drained from factories are dyes and heavy metal ions. Both of these pollutants are highly toxic to the human body, and they have been associated with cancers or skin irritation [102]. Generally, absorption is considered to have greater effectiveness for the treatment of dyes and heavy metal ions in comparison with chemical deposition or membrane technologies due to its high efficiency, easy manipulation, and less time consumption [103]. An ideal adsorbent is expected to exhibit the following properties: (1) environment friendliness, (2) affordability, (3) recyclability, and (4) high adsorptive capacity [104].

In comparison with their fossil-based counterparts, biomass-based absorbents have lower preparation costs and better environmental compatibility and biodegradability. As one of the most abundant biomass-based polymers, cellulosic polymers are well-suited for use in the treatment of dyes and heavy metal ions in wastewater. For example, anionic cellulosic hydrogels, such as CMC-based hydrogel, can absorb cationic heavy metal ions or dyes in alkaline media via electrostatic interactions. On the contrary, cationic cellulosic polymers, such as quaternized hydrogel, can absorb anionic heavy metal ions or dyes in acidic media (as shown in Fig. 9). Both of the aforementioned absorption phenomena may be reversible when the external pH is changed [105, 106]. In addition, the abundant -OH groups that are present on the polymer's backbone can be readily modified with other functional groups, which have the ability to selectively bind to particular molecules such as hormones and agricultural chemicals.

4.2.4 Wound Dressings

The faintly acid environment of human skin can inhibit the propagation of bacteria. However, after an injury, the pH of the damaged area will change to an alkalescent value (~7.4) because the tissue fluid and blood exuding from the wound provide ideal conditions for the propagation of bacteria, thus potentially leading to an infection. Therefore, pH-responsive cellulosic hydrogels can serve as wound dressings. For example, quaternized cellulosic hydrogels with excellent hydrophilicity can keep the surface of a wound moist. Meanwhile, cationic quaternary amine groups could inhibit the propagation of bacteria by destroying the bacteria cytomembrane [107]. Anionic cellulosic hydrogels can also be used in wound healing. For example, CMC polymer chains can be readily cross-linked in the presence of metal ions to form 3D networks. Some antibacterial agents such as Ag or ZnO nanoparticles can be entrapped within the networks to endow the hydrogels with excellent antibacterial activity [108, 109]. In addition, other functional molecules such as dextran can be incorporated into hydrogels, thus enabling neovascularization without adding other growth factors [110]. pH-Responsive cellulosic hydrogels can also serve as wound monitors if they are endowed with pH-responsive dyes. Small wounds could thus be detected as soon as possible to prevent infection and facilitate rapid healing (Fig. 10) [111].

(**b**) Desorption ratio of MB and OR II at different times (10 mg of adsorbents; 50 mL of distilled water at pH 3 (MB) or 11 (OR II); room temperature) [105]. (Copyright 2016 Elsevier Ltd.)

4.3 Thermo- and/or pH-Responsive Cellulose-Based Microgels/ Nanogels for Targeted Drug Release

Microgels/nanogels are cross-linked polymeric particles that are each composed of an independent 3D network. As is the case with bulk hydrogels, these micro- or nanoscale hydrogels also exhibit reversible "swell-collapse" behavior to regulate

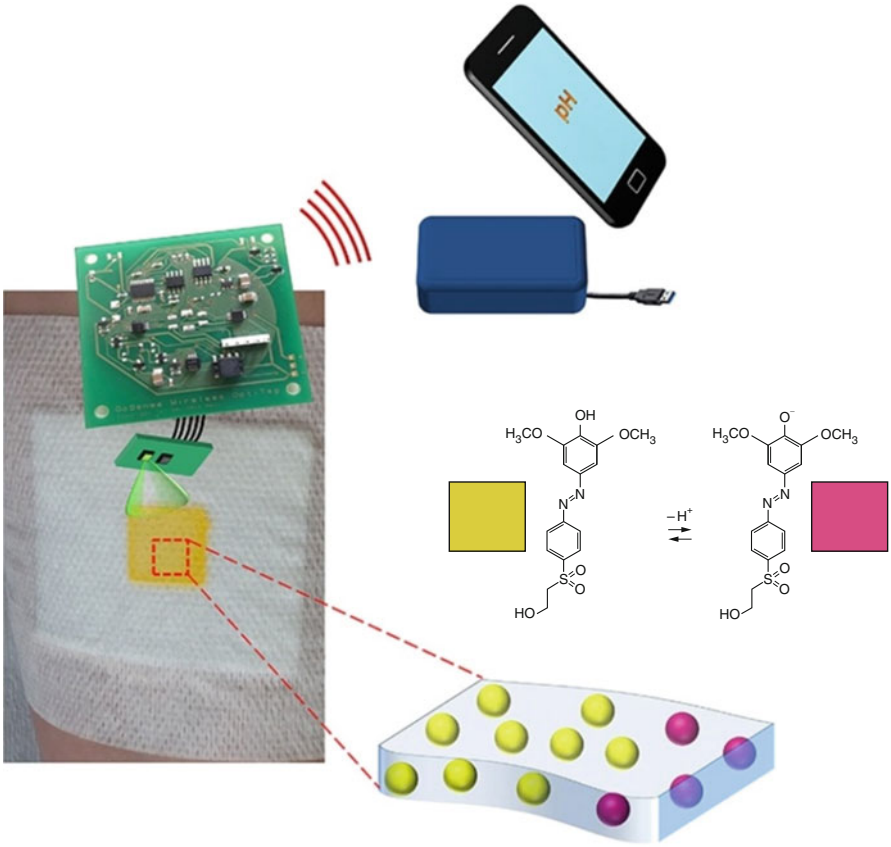

Fig. 10 Schematic diagram illustrating the operation of a wireless smart bandage. The pH-induced color change of cellulose particles that are covalently bound to the hydrogel is measured and sent by a remote unit. Insert is the chemical structures of the protonated and deprotonated forms of hydrogel and their respective color [111]. (Copyright 2017 Elsevier B. V)

their sizes when they are exposed to different stimuli. The diameters of these particles are usually in the nanometer or micrometer range. Microgels/nanogels can serve as conjugates, micelles, or vesicles that mimic microorganisms such as bacteria or viruses, to load molecules such as drugs, proteins, carbohydrates, or DNA/RNA, and transport these molecules into targeted sites within the human body [112]. Thermo- and/or pH-responsive microgels/nanogels are the most widely reported micro-/nanogel drug carriers. In comparison with oral tablets or intravenous injection, they can swell spontaneously, collapse, or disassemble to release drugs to the targeted sites of the human body when they are exposed to external thermal or pH stimuli. This mode of targeted delivery is promising due to the higher drug utilization ratio and the milder drug side effects [113]. In addition to the essential features such as biocompatibility and nontoxicity, the ideal microgel/nanogel carriers are expected to possess the following properties: (1) high drug loading capacities,

(2) desirable chemical stability and mechanical properties to avoid the disassembly or fracture during transport, and (3) sensitive response behavior to ensure rapid drug release in response to the relevant stimuli [114].

Polymeric microgels/nanogels are usually composed of both hydrophilic and hydrophobic polymers. The aforementioned properties are highly dependent on the structures of these hydrophilic and hydrophobic polymers [115]. Based on the following considerations, cellulosic polymers are suitable building blocks for the thermo- and/or pH-responsive microgels/nanogels. First, cellulosic polymers that contain both hydrophilic and hydrophobic groups can serve as surfactants to facilitate the particle formation. The hydrophilic groups such as carboxyl and hydroxyl moieties can improve the water dispersity of gel particles. Meanwhile, the hydrophilic and hydrophobic groups can both form strong intermolecular interactions such as van der Waals forces or associate via exhibiting the hydrophobic effect, to form the cores of the particles [116]. Second, some cellulosic polymers, such as HPMC, MC, HPC, or CMC with remarkable thermo- or pH-responsive behaviors, can be directly employed to create stimuli-responsive gel particles without the need for other fossil-based polymers. Third, some cationic or anionic drugs can form strong noncovalent bonds with the network's backbones via electrostatic interactions without exhibiting undesirable leakage. For example, when the external pH is 7.0, the positively charged anticancer drug doxorubicin (DOX) can associate strongly with the deprotonated backbones of CMC hydrogels. Once the pH is reduced to 6.2 (which is similar to the pH in tumor tissue), the adhesion of DOX will be weakened, which increases the release ratio (Fig. 11) [117]. Fourth, cellulosic polymers bearing numerous hydroxyl groups are excellent candidates for the preparation of amphiphilic graft copolymers with functional side chains, which can spontaneously assemble to form microgels/nanogels [118]. In addition, some reports have demonstrated that graft copolymers exhibited higher drug loading capacities and higher drug releasing ratios in comparison with linear copolymers. The size and structure of nanoparticles prepared from graft copolymers could be easily regulated via changing the structures of the graft copolymers [119–121].

4.4 Photo-Responsive Cellulose-Based Hydrogels

4.4.1 Photo-Reversible Superabsorbents

A superabsorbent is defined as a hydrophilic hydrogel that can absorb and retain extremely large amounts of water relative to its own mass. An ideal superabsorbent should be renewable and exhibit robust mechanical properties. The backbones of the network become fully stretched when the hydrogel is swollen, and the swollen hydrogel may be much more fragile than its collapsed counterpart. Thus, it is of critical importance to enhance the mechanical properties as much as possible to ensure their applicability. The incorporation of highly crystalline cellulose nanofibers is a promising method for improving the mechanical properties of a superabsorbent [122].

Meanwhile, a renewable superabsorbent is highly desirable for practical applications based on cost and environmental considerations. Therefore, a stimuli-

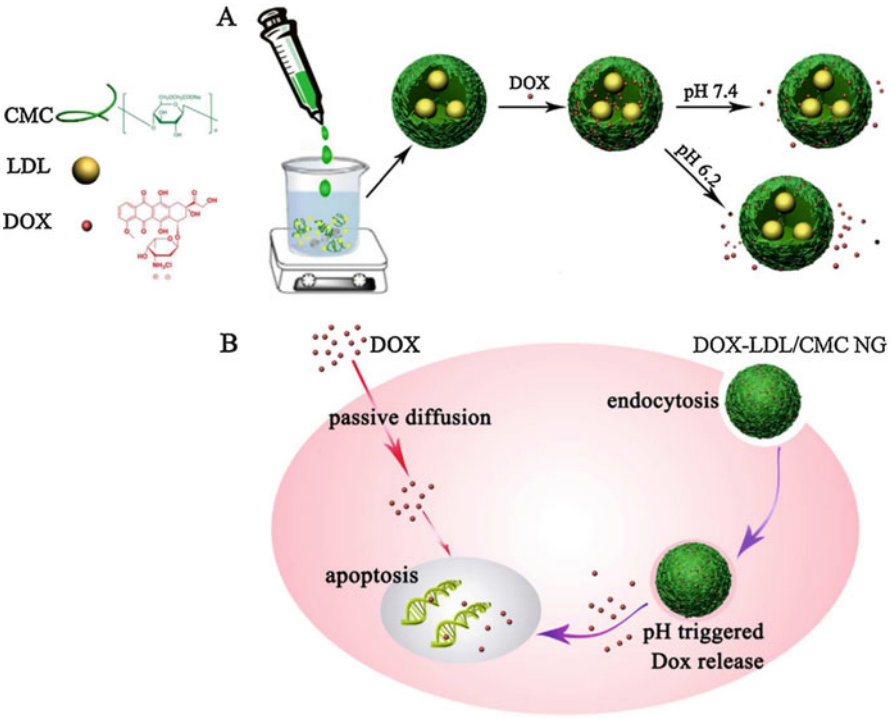

Fig. 11 (**a**) Illustration of the synthesis and structures of LDL/CMC nanogels, DOX loading, and pH-dependent drug release. (**b**) Schematic diagram showing the proposed model for intracellular delivery by DOX-loaded LDL/CMC nanogels to tumor cells [117]. (Copyright 2014 Elsevier B.V)

responsive hydrogel that exhibits reversible "swell-collapse" behavior would be a promising candidate for the preparation of renewable superabsorbents. In comparison to heat and pH, light is an easily manipulated physical stimulus for a renewable superabsorbent because it consumes less energy and chemicals. For example, in situations involving a superabsorbent composed of cellulose nanofibers, a TiO_2 coating exhibiting a photo-triggered "hydrophobic-hydrophilic" transition [123], or possessing a CF3AZO monolayer (Fig. 12) [124], can be deposited or grafted onto the surfaces of cellulose nanofibers. Upon exposure to light, the cellulose nanofibers become hydrophilic, and the superabsorbent thereof can readily absorb water. When the swollen superabsorbent is moved away from light, the cellulose nanofibers will be rendered hydrophobic, and the superabsorbent thereof expels water and thus regenerates itself.

4.4.2 Drug Release Based on Vesicles

Photo-responsive hydrogels can be also used as carriers for photo-triggered drug release thanks to the isomeric reactions of their photo-sensitive components. For example, drug molecules can be loaded into the cavities of vesicles, and the photo-

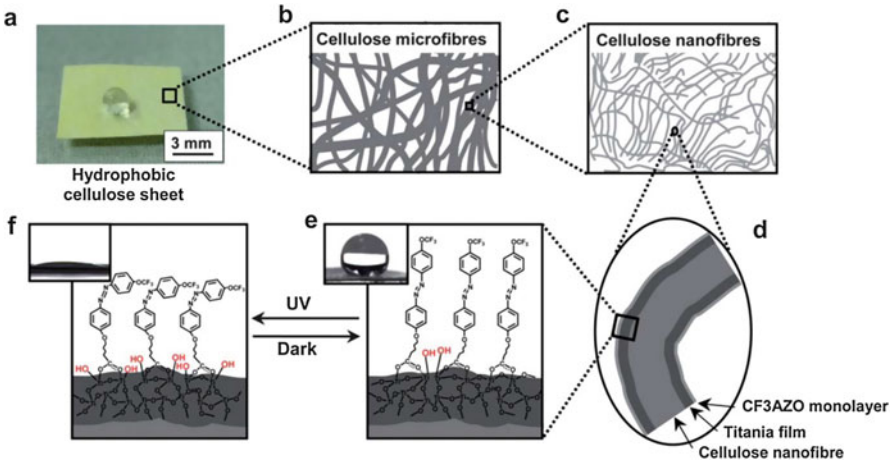

Fig. 12 Schematic illustration of the reversible wettability on the surface of filter paper that is coated by a titania/CF3AZO ultrathin film [124]. (Copyright 2011 The Royal Chemical Society)

responsive hydrogel can serve as the shell layers of these vesicles to prevent the escape of these drug molecules. The hydrogel shell layer can be cross-linked via supramolecular complexation between photo-sensitive guest molecules and cage-like host molecules. Upon exposure to light as a stimulus, photo-sensitive guest molecules can change their conformation and exhibit a lower binding affinity with the host, which provides opportunities for other small molecules to bind with the host molecules. Consequently, the hydrogel shell layer will disassemble, and the drugs within the inner cavity can be released (Fig. 13) [125]. It is also possible to synthesize a variety of derivatives of cellulosic polymers bearing both guest and host molecules via the functionalization of the numerous hydroxyl groups on the polymer backbone [125, 126]. However, light with short wavelengths (such as UV light) is usually unable to penetrate deeply into a material, which limits the applications of photo-responsive hydrogels that can only respond to UV light. Thus, the future studies should be focused on the development of visible or infrared light-responsive hydrogels, as these materials may have greater applicability for in vivo drug release.

4.5 Shear-Responsive Cellulose-Based Injectable Hydrogels

Injectable hydrogels, which are liquid in storage conditions, can be easily injected into target locations via noninvasive implantation. The liquid polymer solution will undergo a "sol-gel" transition via spontaneous physical or chemical cross-linking reactions upon exposure to external stimuli such as heat, pH, particular salt concentration, or shear force. With this in mind, injectable hydrogels are promising candidates for applications in targeted drug release, in cell delivery, or as tissue scaffolds [127].

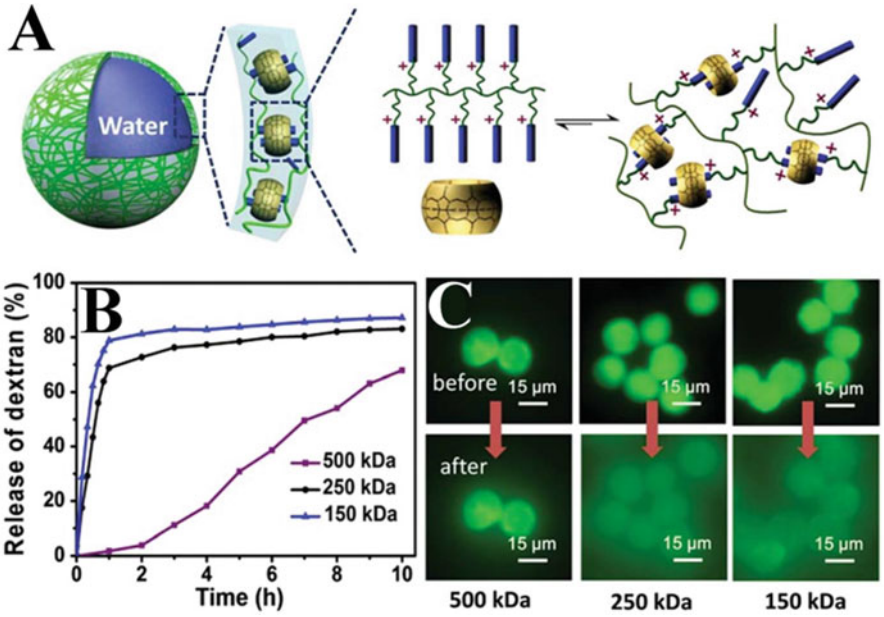

Fig. 13 (**a**) Scheme showing the generation of supramolecular polymer hydrogel shells at a water/oil interface. (**b**) Release profiles of FITC-dextran from microcapsules as a function of the rehydration time. (**c**) Series of fluorescence micrographs of microcapsules loaded with different molecular weight samples of FITC-dextran before and after 2 h of rehydration [125]. (Copyright 2015 The Royal Society of Chemistry)

Shear-responsive hydrogels with shear-thinning behavior are widely used as implantation materials in vivo. Shear-responsive hydrogels are stored in a liquid form. They will be converted to liquid polymer solutions upon the application of an external shearing force. These polymer solutions can be injected into the human body and become gels once again. In comparison to other stimuli-responsive injectable hydrogels, shear-responsive hydrogels have several advantages: (1) The "sol-gel" transition of a shear-responsive hydrogel can occur in an external environment so that the physicochemical properties of the hydrogel can be readily evaluated prior to injection [128]. (2) The gelation behavior of the polymer solution can be precisely controlled because the gelation only depends on the magnitude of the shearing force rather than other complex physical conditions in vivo, such as the pH or the ionic strength [129]. (3) An injected polymer solution can rapidly undergo gelation in the target location instead of spreading to adjacent tissue due to the absence of shearing force [130, 131].

An ideal injectable shear-responsive hydrogel should possess the following properties: (1) All of the components of the hydrogel should be biodegradable and nontoxic, including their by-products after degradation. (2) The required strength of the shearing force triggering the "gel-sol" transition should be within a reasonable range. (3) The viscosity of the hydrogel should decrease rapidly upon the application

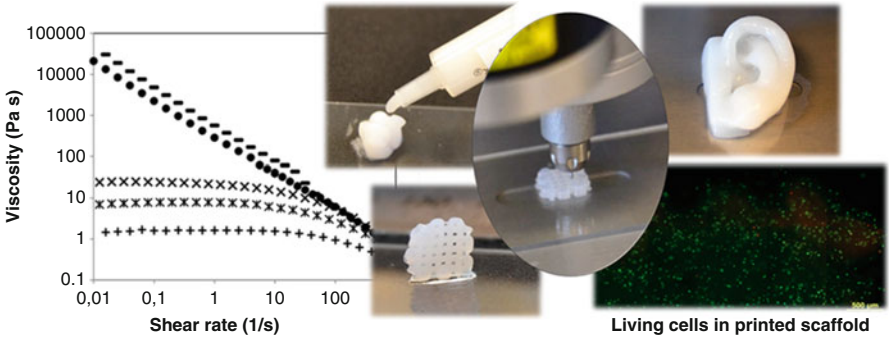

Fig. 14 (Left) Flow curve of a bioink denoted as ink9010 (•), which contains 2.25% nanofibrillated cellulose and 0.25% alginate. (Right) 3D printed small grids and a model of a human ear after cross-linking treatment and the representative images showing dead and live cells in 3D bioprinted constructs after 7 days of incubation in culture media [133]. (Copyright 2015 American Chemical Society)

of a shearing force, and the gelation should also be rapid when the shearing force is withdrawn. (4) The structure and the functions of the hydrogel should be easily regulated. (5) The fabricated hydrogel should exhibit desirable mechanical properties. (6) The hydrogel's biodegradation process should be easily controlled [5].

Shear-responsive hydrogels are promising candidates for applications in drug release, in tissue engineering, and as wound dressings. As discussed earlier, cellulosic polymers have been widely used as building blocks of hydrogels for use in the biomedical fields. For example, cellulosic polymers serve as the backbones that can be modified with cage-like host molecules and guest molecules. The resultant graft copolymers can be spontaneously cross-linked via supramolecular complexation. Drugs can be loaded into the hydrogels and subsequently delivered to a target location when an external shearing force is applied [132]. Furthermore, some biocompatible polymers, such as sodium alginate, can form injectable hydrogels with nanofibrillated cellulose via electrostatic interactions. The resultant injectable hydrogel can serve as a bioink for the fabrication of 3D-printed scaffolds (Fig. 14). The mechanical properties of the resultant scaffolds can be dramatically enhanced through the incorporation of nanofibrillated cellulose [133].

4.6 Electric Field-Responsive Cellulose-Based Hydrogels

4.6.1 Actuators

Electric field-responsive hydrogels can be used as actuators to convert electrical energy into mechanical energy. Muscle fibers are one of the most common examples of actuators, which can become swollen or collapse in response to the application of electric voltage stimuli by neurons. As discussed in Sect. 3.5, electrolyte hydrogels can mimic this behavior via bending or a change in shape upon undergoing morphological transitions in an electric field. They are promising building blocks for the

fabrication of artificial muscles and underwater soft robots [134, 135]. An ideal hydrogel actuator should exhibit the following properties:

1. Excellent mechanical properties to ensure that the actuator can undergo repeatable stretching/shrinking transitions and fine/gross motor movements.
2. Excellent sensitivity to small voltages. In addition, the driving voltage should be below the standard potential at which water undergoes hydrolysis (~1.23 V) to prevent an undesirable electrolysis from occurring and altering the physicochemical properties of the aqueous solution [136].
3. The hydrogel's responsive behavior should be readily adjusted via changing the magnitude of the voltage.

Ensuring that the mechanical properties are suitable is the primary issue regarding the application of an actuator. It has been demonstrated that the incorporation of cellulosic polymers can remarkably enhance the mechanical properties of an actuator. For example, the Young's modulus of an electric field-responsive hydrogel can increase by more than 60% with the incorporation of 1.4 wt% of CMC [136]. On the other hand, cellulosic hydrogels bearing ionic moieties, such as CMC [68] and sulfonated CNC [136], can remarkably enhance the hydrogel's electric responsive behavior due to the presence of ionic moieties in their backbones.

4.6.2 Drug Release

CMC-based electric field-responsive hydrogels can be also used in controlled drug release applications. With the migration of protons within the hydrogel toward the cathode side, the hydrogel will accumulate a negative charge, thus causing the osmotic pressure to increase. Water molecules begin to diffuse into the hydrogel, thus facilitating the release of the drug by the swollen hydrogel with fully stretched networks (Fig. 15) [137]. Although the application of an electrical field to human patients presents a challenge, transdermal drug delivery has been performed via topical electric field techniques such as iontophoresis and electroporation. It has also been demonstrated that electric field-responsive hydrogels can be implanted under the skin and successfully used for pulsed drug release over a prolonged duration [138, 139].

4.7 Magnetic Cellulose-Based Nanogels/Microgels for the Adsorption of Pollutants

The major application of magnetic nanogels/microgels is pollutant treatment. Nanogels/microgels that are loaded with magnetic nanoparticles can migrate along with the direction of a magnetic field and deposit at a particular side of a magnetic field gradient. All of the deposited gel particles can be collected and washed for subsequent use, which reduces the cost of pollutant treatment as well as the risk of residual nanomaterials being released into the natural environment [140]. Usually, the magnetic nanoparticles are incorporated into networks via blending or in situ

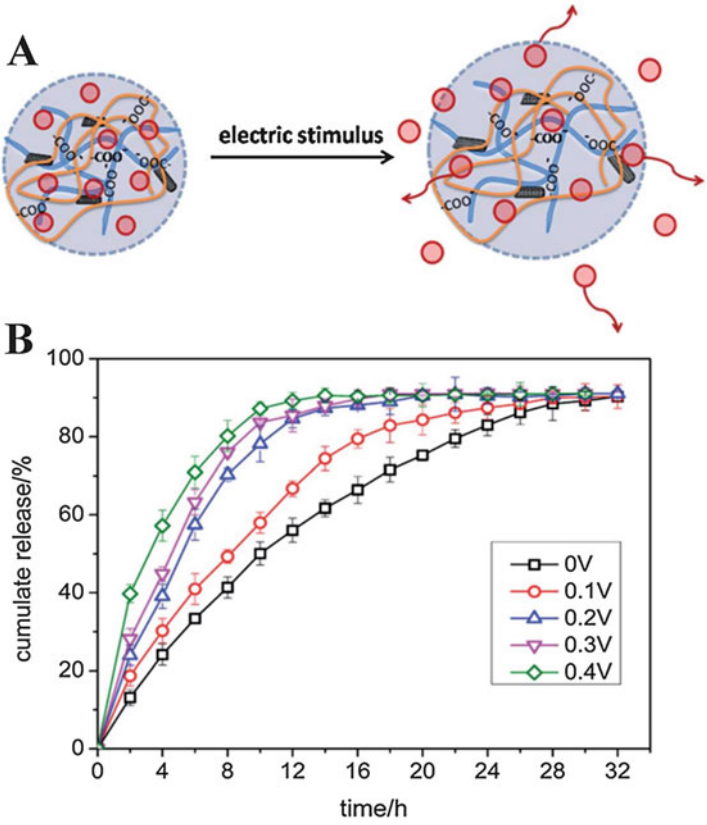

Fig. 15 (**a**) Schematic illustration of electric field-responsive release of ibuprofen molecules from BC/SA/MWCNTs 0.25% hydrogels. (**b**) Amounts of ibuprofen released from BC/SA/MWCNTs 0.25% hydrogels at time *t* at various electric voltages at 37 °C [137]. (Copyright 2015 The Royal Society of Chemistry)

formation. A high loading of magnetic nanoparticles is usually necessary because the rate at which magnetic gels migrate is primarily dependent on the degree of magnetic nanoparticle loading by the gel. However, magnetic nanoparticles may sometimes detach from the gel network and diffuse into water during usage, which will inhibit the magnetic migration. Thus, the two critical parameters for the application of nanogels/microgels are (1) the stability of the magnetic nanoparticles during the usage as well as (2) the loading degree of the magnetic nanoparticles in the gel network [72].

Based on the following three considerations, cellulosic polymers are suitable precursors for matrices of magnetic nanogels/microgels. First, a cellulosic polymer matrix facilitates the immobilization of magnetic nanoparticles, and the detachment of these nanoparticles can be prevented because the cellulose backbones contain many polar groups that interact strongly with the magnetic nanoparticles [141].

Second, any residual nanogels/microgels that are released into the environment can be decomposed by microorganisms in the natural world due to the biodegradability of the cellulosic polymer matrix, which helps minimize the environmental footprint of these materials. Third, cellulosic polymers are abundant and cheap, which facilitates the large-scale fabrication and application of magnetic nanogels/microgels. In addition, the carboxyl groups of CMC can serve as the active sites for the in situ formation of magnetic nanoparticles. The numerous active hydroxyl groups in cellulose can potentially be modified into other functional groups, such as vinyl groups, to form robust covalent bonds with magnetic nanoparticles, thus preventing their detachment.

Another promising application of magnetic cellulose-based nanogels/microgels is their 3D assembly in tissue engineering. For example, nanogels/microgels could be assembled in predesigned arrangements orders, and their stacking sequence could be easily controlled via regulating the direction of a magnetic field. This may be a promising strategy for the preparation of highly ordered hydrogel materials with well-defined structures and advanced functionality [142].

5 Conclusion

Stimuli-responsive hydrogels have been widely used in numerous fields, such as targeted drug delivery and controlled release, mass separation, soft machines, sensors and/or actuators, scaffolds for tissue engineering applications, and so on. The incorporation of cellulose into stimuli-responsive hydrogels helps to enhance the mechanical properties of the hydrogels, improving their biocompatibility, biodegradability, and mucoadhesion and also provides a facile means to synthesize gels. Cellulose-based stimuli-responsive hydrogels can serve as the key components of membranes, bulk hydrogels, microgels/nanogels, and injectable hydrogels. The properties of hydrogel-based materials that are used in these fields are significantly improved via the use of cellulose as a component. Cellulose-based stimuli-responsive hydrogels have excellent potential for use in drug delivery/control release, wound dressings, scaffolds for tissue engineering, absorbent materials, and actuators.

6 Future Outlook

Cellulose-based stimuli-responsive hydrogels combine the features between cellulose chemistry and stimuli-responsive materials. Therefore, the development of cellulose-based stimuli-responsive hydrogels is highly dependent on advances made in these two fields. Some of the following challenges may need to be addressed and investigated further in order to facilitate potential applications of cellulose-based stimuli-responsive hydrogels in the future.

1. The regioselective reactions for preparing cellulose derivatives are still limited, and more investigations remain necessary. The exhilarating results in this field facilitate the combination of cellulosic polymers with other novel stimuli-responsive groups or polymers. Some novel cellulose derivatives may exhibit improved biocompatibility, mucoadhesion, or distinctive responsive behaviors when compared to conventional cellulose derivatives.
2. Nanofabricated cellulose and cellulose nanocrystals can greatly enhance the mechanical properties of hydrogels. Their surface modification technologies and their morphology regulation will demand much attention because addressing these challenges may enable researchers to greatly enhance the mechanical properties of hydrogels. In addition, the dispersity of crystalline cellulose in water as well as its miscibility with other functional polymers warrants attention.
3. In comparison to other polysaccharides, i.e., chitosan and dextran, the biodegradability of cellulosic polymers, especially for nanofabricated cellulose and cellulose nanocrystals, still requires improvement. Notable examples include achieving control over their degradation rate and behavior in physiological environments.
4. The most prominent merit of cellulose-based materials is their low cost. An amount of cellulose-based stimuli-responsive hydrogels with novel functions and complicated structures have been successfully prepared and applied in the laboratory. However, their preparation cost is still an area of concern and is an important factor for their large-scale fabrication and application in the future.
5. Thermo- and pH-responsive hydrogels are currently the most widely studied classes of stimuli-responsive hydrogels, and the further studies should be devoted toward the development of hydrogels with narrow and accurately defined response ranges. Furthermore, their response regions should be easily regulated to facilitate their use in many fields.
6. Light is an easily manipulated physical stimulus compared to heat and pH. However, the application of UV light-responsive hydrogels in vivo is usually limited. Future research should be focused on the development of hydrogels that can respond to visible and infrared light.
7. Compared to heat and pH stimuli, non-contacting stimuli, such as light, electrical fields, and magnetic fields, have greater potential because they can be easily controlled and adjusted in terms of time and space. However, these stimuli have received relatively little attention.

Acknowledgments We thank Dr. Ian Wyman for proofreading this paper.

Abstract

In an enzymatically responsive system, a suitable enzyme is used as a stimulus for a control release or delivery at a specifically targeted site where that enzyme is designed in such a way that can work at certain controlled conditions (such as temperature, pH). Enzyme-responsive hydrogels prepared from cellulose along with other materials have suitable macromolecular networks and can work in controlled environment. Specifically designed enzymatic stimuli-responsive system, one of the highly explored techniques, popularly explored to add a triggerable agent (such as a polymer or a lipid) that can encapsulate the active component in a protective manner. Usually, this active agent is responsive to degradation or swelling when it reaches at the target site. An enzymatic stimulus-responsive system is highly attractive field of research due to its many potential applications (e.g., in controlled release, drug delivery, and other areas of life and material sciences). This chapter gives a brief overview on the design and uses of enzyme-responsive hydrogels based on cellulose and other polymers for their various applications in different fields including in controlled drug delivery and other areas of biomedical and material sciences.

Cellulose · Hydrogels · Enzyme · Enzyme-responsive hydrogels · Stimuli-responsive hydrogels · Drug delivery · Biomedical

1 Introduction

Hydrogels are substances that absorb significant quantities of water, and usually they are prepared from natural materials. They are widely studied all around the world for their enormous biomedical applications [1–4]. The attractive characters of hydrogels stimulate scientists for continuous investigation on novel biomaterials for their potential industrial applications. Hydrogels have the capability to absorb large quantities of water due to their three-dimensional polymer networks, and this morphological structure also modifies their characters to allow them to be soft and pliable as well as to retain structural water which makes them suitable for many conventional and potential biomedical uses. Recently, hydrogels are popular for a variety of biomedical

applications [5–12]. Because of the high water content of hydrogels, they are compatible to most of the living tissues, and their viscoelastic nature also contributes to reduce the damage to the surrounding tissue when implanted in the host system [13–15]. Besides this, the mechanical characters of hydrogels are parallel to those of soft tissues which are particularly attractive for tissue engineering applications. Bioactive materials are frequently used for hydrogel synthesis, and these materials can interact with the host tissues to assist and improve the healing process as well as to mimic functional and morphological properties of organ tissues [13–18]. Hydrogels can also be made by using biomaterials along with smart materials in order to offer natural adaptations (e.g., sensing devices, controlled actuations, regulation of target functions, control in feedback systems). This type of stimuli-responsive hydrogels is capable to adapt with the required changes in their surrounding environmental stimuli (for instance, surrounding composition, presence of enzyme, temperature, pH, light) [19–28]. Smart hydrogels are attractive for their practical and potential uses as biomimetic materials and for their applications in biosensors, processors, and also in activators for electrical responses [29–33]. As for example, the frequent uses of electroconductive hydrogels (such as in bio-recognition membranes for implantation of biosensors, fabrication of drug-eluting devices based on electrically stimulated hydrogels, and also in low interfacial impedance layers of neuronal prostheses based on hydrogels) have been successful to open new horizons in the fabrication of devices for biomedical detection purposes. One of the main reasons for this success is based on the fact that both biomolecular recognitions and responsive functions based on biomolecular targets and induced structural changes can be incorporated into the structural networks of hydrogels using meticulous preparation techniques and skillful design strategies [34–36]. In order for an effective therapeutic delivery, monitoring, and molecular imaging (using noninvasive techniques) to detect and treat different diseases, hydrogel-based drug delivery systems are popularly used since hydrogels provide the required feasibilities for the integration of smart systems and biomolecular imaging. As a result, this type of smart hydrogels can be used for self-regulation and controlling hydrogel-based devices for maintaining physiological variables (suitable for drug delivery and cell culture applications) [37, 38]. For drug delivery, hydrogel implantation can be carried out by preforming or injecting; however, the preformed hydrogels are usually processed by using active reagent in vitro before in vivo implantation. In biological sciences hydrogels are widely used in different areas, because both the intracellular cytoskeleton and extracellular matrix (ECM) are compatible with gel-phase materials. For example, biological gels can be designed to show responsive characters when they are exposed to suitable changes in their environment using different methods including specific enzymatic processes that involve adaption and reorganization of gel structures [39–47]. Both adaption and reorganization are very important to different processes within cell cultures (e.g., differentiation and cell division). Thus, the production of synthetic mimics of hydrogels is critically important as they can be used to measure and direct different biological processes. Enzyme-responsive hydrogels can be applied to mimic biological matrices, and different enzymatic processes have the feasibility to fabricate enzyme-assisted assembly of gels with precisely controlled characters [48–50].

Hydrogels have been widely used for various applications for a long time. For example, since the 1960s, synthetic hydrogels have been applied in biomedical uses,

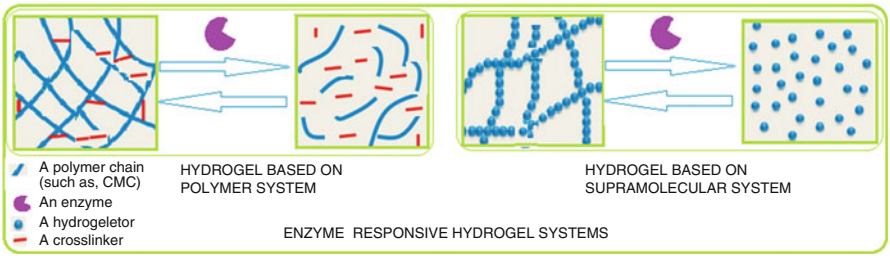

Fig. 1 A schematic representation of an enzymatic stimulus-responsive system

which at that time Wichterle and Lim illustrated the use of biocompatible hydrogels prepared by cross-linking poly(hydroxyethylmethacrylic)acid [poly(HEMA)] in contact lenses [49]. In 1980 naturally derived hydrogels (such as based on alginates) were reported and used to encapsulate pancreatic cells [50], which was then followed by the application of shark collagen in the dressings of burn wounds [51]. Both synthetic and natural materials are frequently used in hydrogel formations; however, currently hybrid systems are being rigorously investigated for their vivid benefits [52]. In previous studies on hydrogels, mostly structural properties of hydrogels that can effectively match natural tissues were used to be studied most rigorously; however, this focus has been shifted to the synthesis of materials that can match structurally and chemically as well as have the capability to mimic aspects of biological gels. As for instance, hydrogels are being designed in such a way which can retain short peptides, sugars, or other biomolecules in order to facilitate suitable interactions with biological systems. Recent progress in this field is mostly focused on the control degradation using enzymatic action to design biomaterials [48]. The application of enzymes in the fabrication of materials is significantly important because of their selectivity and synthetic capability under mild conditions [48]. Synthetics gels can be divided into two groups considering the chemical nature of their networks; they are (a) polymeric hydrogels and (b) supramolecular hydrogels (Fig. 1). Typically, polymeric hydrogels are covalently cross-linked networks that illustrate swelling characters because of the absorption and ability to trap water in their structures [49]. However, supramolecular hydrogels generally show reversible, non-covalent molecular interactions (such as hydrogen bonding, pi stacking, electrostatic and hydrophobic interactions, van der Waals forces) between self-assembling molecules (also termed as hydrogelators) to form nanofibers. Depending on their surface chemistry, these nanofibers are entangled into 3D networks that provide the capability to trap water and form hydrogels [52, 53]. This chapter briefly presents selective aspects of enzyme-responsive hydrogels and their applications in specific areas.

2 Enzymatic Stimuli-Responsive Hydrogels

Environmental stimuli-responsive materials have the capability to change form and/or function when exposed to environmental stimuli (or cues); some of the widely used environmental stimuli include pH, temperature, light, and electric fields

[49–51]. Suitable portable electronic devices based on stimuli-responsive materials have variety of applications in different branches of science and technology as well as in every-day life. These materials are highly sought for many advanced applications in a variety of areas (e.g., in electronics [52], healthcare [53, 54], and energy creation and storage) [55]. The stimulus or trigger used for induction on the stimuli-responsive materials causes a change or a combination of different changes on the characters of the exposed material which is a very important part of the responsive material technology suitable to design many controlled features of certain material properties. Enzymes have some sort of decisive control on different processes of living organisms, and thus enzymatic stimuli-responsive materials can be used to design a wide range of materials including artificial biological materials to perform desired activities [56, 57]. Enzyme-responsive materials (ERMs) change their functionality when they are exposed to the action of a particular enzyme or a combination of enzymes. Enzyme-responsive hydrogels are usually designed and synthesized for enzyme-responsive materials [4, 58–62]. The practical use of enzyme-responsive materials is a gradually increasing phenomenon in light of the inspiration for biologically compatible synthetic technologies to mimic natural environments. For example, in biological systems enzymes take part in a plethora of biochemical reactions which have effective influences on different nanoscale processes which include (a) protein expression, (b) formation of cellular adhesions, (c) signal transduction, and (d) macroscale processes such as (a) cell movement and (b) muscle contraction [57, 63]. In enzyme-responsive materials, enzymes control the specificity, selectivity, and the catalytic efficiency of the host materials [63–65]. Figure 1 shows a schematic presentation of enzyme-responsive materials based on polymeric (in the left side) and supramolecular hydrogels (in the right side). Enzymatic processes may be exploited in both the degradation and the controlled assembly of hydrogel materials. Recent investigations illustrated that the stem cell growth and differentiation (in addition to biochemical signals) are strongly influenced and show sensitivity toward suitable physical stimuli that exist within the range of their surrounding environment [56].

Enzyme as a stimulus is very often used to perform a certain piece of work in order to control material properties. A wide range of enzyme-responsive materials are used to carry out different ranges of selective activities. For example, different enzymes are used in enzyme-responsive materials where some of the most frequently used enzyme classes include (a) proteases, (b) kinases, (c) phosphatases, and (d) endonucleases. Proteases and endonucleases are capable to cleave peptides and oligonucleotides, respectively; they have their usual applications in the degradation or disassembly of enzyme-responsive materials. In addition, they are also capable to cleave functional groups from enzyme-responsive materials which make the materials suitable for a variety of sensing applications. On the contrary, enzymes with covalent bond formation capability (e.g., transglutaminases) can be applied for enhancing the structural strength of enzyme-responsive materials by allowing the formation of cross-links within the material [48, 56–59]. Generally, sophisticated methods are used to apply the hydrolytic properties of proteases and endonucleases as enzymatic triggers for initiating overall changes on the properties of the enzyme-

responsive materials. Additionally, phosphatases and kinases are also frequently used because of their complementary catalytic actions. For example, kinases are popular enzymes for phosphorylation of molecules during the presence of adenosine-5′-triphosphate and phosphatases are used for dephosphorylation reaction. Antagonistic interplay of this type of enzymes provides the scope of designing reversible enzyme-responsive materials with dynamic properties. The level of enzymatic interaction between enzymes and different enzyme-responsive materials is sometimes distinctly different from enzymatic reactions which involve solubilized substrates. As for instance, the usual use of kinetic models for stating the enzymatic conversion of solubilized substrates (such as Michaelis-Menten kinetics) cannot be employed for enzyme-responsive materials when the materials are significantly large in size (and show relatively lower mobility compared to that of the enzyme). Most enzyme-responsive materials (such as hydrogels, surfaces, particles) where the enzymes are expected to move toward the substrates show similar behavior. Moreover, it is also possible that aspects relating to diffusion kinetics where substrates bound to other materials may also exhibit a difference in characters than from the properties of solubilized substrates with respect to enzyme specificity and steric effects. As a result, for designing efficient enzyme-responsive materials, different important factors are usually considered, some of which are (a) the chemical and physical characters of the material, (b) the concentration of the enzyme present in substrate/material, and (c) the method in which the substrate is anchored to the material [64–66]. In addition, a longtime goal of the research activities on hydrogel is focused on the way to develop stimuli-responsive hydrogels with potential controls on external features relating to cell encapsulation or release of actives. Stimuli-responsive smart or intelligent hydrogels are those gels which may display property or functionality changes in response to variations in the external environment. Typically, these changes in their surroundings involve solvent polarity, temperature, pH, supply of electric field, light, etc. [4, 59]. More generally, materials based on stimuli-responsive technologies are increasingly attracting attention due to their potential applications in everyday life, offering improvements in many technologies [48, 60, 61]. There are excellent reviews on this topic that discusses the design, advantages, and challenges of stimuli-responsive hydrogels [56, 62]. In cellular environments, most stimuli-responsive mechanisms take place under the control of enzymes [63]. Compared with physical or conventional chemical stimuli (e.g., pH, temperature, ionic strength, ligand-receptor interactions), enzymatic regulation of material properties shows much promise because it enables responsiveness to biological signals, which are highly selective and involve catalytic amplification to enable fast response times [64]. Both polymeric and supramolecular hydrogels are useful [65] which can be used to degrade matrices in a controlled fashion using suitable methods, such as by incorporating enzyme-responsive materials into the structural compositions of the hydrogels. So, by doing this it is possible to design hydrogels with the capability of controlling degradation by using different ways including the breaking of chemical cross-links (polymeric hydrogels) or controlled disassembly (supramolecular hydrogels) (Fig. 1). As it is possible to carry out enzymatic degradation selectively and precisely using suitable techniques and

materials, enzyme-responsive hydrogels are highly attractive field of current active research for their huge application potentials in different areas of science and technology [66, 67].

2.1 Biocatalytic Assembly of Supramolecular Polymer-Based Enzyme-Responsive Hydrogels

In general, dynamic processes in biological systems can be controlled by two spatially confined molecular mechanisms; they are (a) catalysis and (b) molecular recognition. The working principles are a bit different for the biological system compared to that of other traditional methods usually used to control supramolecular synthesis that typically uses the change in one or more of the environmental conditions (e.g., pH [68], temperature [69], solvent polarity [66], and/or ionic strength [67]). For over the last two decades or so, enzymes have been popularly used for direct supramolecular assembly [48, 70, 71] due to a number of reasons including the relative ease in biocatalysis. Some advantages of biocatalysis performed in this way are (a) easy responsive assembly under constant, physiological conditions [72], (b) exploitation of biocatalytic reactions particularly relating to certain cell types or diseased states [64, 73], (c) easy inherent catalysis involving molecular amplification (turnover numbers approx. 10^3–10^7) that facilitates fast response time, (d) new tools for bottom-up nanofabrication by taking advantage of the ability to spatially and kinetically control the self-assembly process [72–74], and (e) thermodynamical control systems with routes toward the discovery of peptide-based nanostructures by using reversible exchange of amino acid sequences in dynamic peptide libraries. Additionally, biocatalytic self-assembly forms gelators by using enzymatic reactions (either through hydrolysis or condensation of precursors) followed by the self-assembly of these molecules to form supramolecular structures. These assemblies, in turn, entangle to form different nanostructures (such as 1D, 2D, or 3D nanostructures) (Fig. 2) through different non-covalent interactions that include (a) π-π interactions, (b) hydrogen bonding, and (c) electrostatic interactions [75–79].

2.2 Designing Enzyme-Responsive Materials

Generally, a wide range of issues are properly considered for the design of high-quality enzyme-responsive materials very selectively, and two of them are briefly included here.

2.2.1 Operational Capability

Enzyme-responsive materials are expected to maintain enzymatic activity under specific operational conditions or given environmental conditions (such as aqueous environments at neutral, basic, acidic pH, other selected ionic conditions). Particular types of synthetic materials (e.g., polymers or inorganic particles) sometimes can

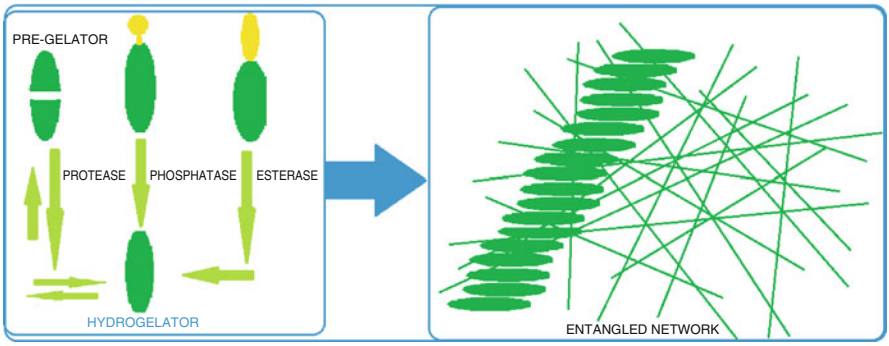

Fig. 2 Schematic illustration of enzyme-assisted self-assembly. The enzyme action results in the formation of hydrogelators which are able to self-assemble to form supramolecular structures and then entangle to form a network

work under this type of environmental condition. As for instance, poly(ethylene glycol) [66], dextran [67, 70], amylose [80], gold [81, 82], and silica [71, 72] nanoparticles and selected peptide-based materials [73, 74] are successfully used to design environmental stimuli-responsive materials.

2.2.2 Meeting Specific Design Requirements

Environmental stimuli-responsive materials are expected to carry out enzymatic activity and other stipulated functions by fulfilling certain design requirements. Some of these requirements include (a) the presence of an active enzyme-sensitive part, (b) translation of enzymatic action of the enzyme-sensitive part to the rest of the material, and (c) sufficient contribution for an effective change in the overall character of the material.

2.3 Specific Characteristics of Enzyme-Responsive Materials for Market Applications

2.3.1 Typical Natures of Enzymatically Responsive Systems

Enzymes have one of the unique control mechanisms usually observed within natural substances in order to regulate the complex biological processes which are by far not matched by the artificially developed systems. As a result one of the main objectives to design enzyme-responsive materials is to synthesize suitable materials with capabilities to replace or at least a comprehensive interaction with natural biological systems. The strength of enzymatically controlled material characteristic depends on the feasibility to design the required material response which is totally influenced and controlled by the biological systems present in the surrounding environment for an ultimate goal to assimilate the environmentally responsive materials into a biological process. However, due to biological complexity, there are tough challenges to develop enzyme-responsive materials with tremendous

application potential to carry out particular jobs on cue when prompted by an enzyme. Enzyme-responsive systems have been widely used in different areas of science and technology including (a) enzyme diagnostic systems [56, 86], (b) drug delivery systems [9, 74, 83–88], and (c) different areas of regenerative medicine [74]. For example, in order to detect different enzymes and their enzymatic activities, different types of enzyme-responsive particles have been developed. Additionally, because of aggregation or dispersion of particles and also due to a particular type of control, the quenching activity of quantum dots, usually the detection of enzyme, depends on the change in magnetic or spectroscopic characters [56, 89] where some of these systems are sensitive even in low level of enzyme concentration [9]. Enzymatic stimuli-responsive hydrogels are frequently used for targeted drug delivery, while the strength of enzymatically controlled drug delivery depends on the ability to allow drug release when it is required in the presence of specific enzymes. Higher levels of specific enzymes are related to different diseases; hence suitable markers and stimuli for the spatially and temporally targeted delivery of therapeutics are important. Thus, for a simultaneous treatment of the diseased tissue and the measurement of the effect of the treatment, the impact of environmentally responsive hydrogels, especially enzymatic stimuli-responsive hydrogels, has many special significance. As for instance, regenerative medicine constitutes a wide range of biomedical research where enzymatic stimuli-responsive materials are frequently used along with the association of many functional polymers or nanomaterials or biomaterials. Some specific applications out of many other important uses of enzymatic stimuli-responsive materials and enzymatic stimuli-responsive hydrogels include (a) applications of enzymatic stimuli-responsive materials or enzymatic stimuli-responsive hydrogels in the formation and degradation of hydrogels as artificial cell supports [74], (b) the enzymatic control of surface properties to control cell response [9, 85], and (c) the enzyme-triggered release of bioactive molecules (such as growth factors) [48, 53–55, 58, 59].

2.3.2 Matching Enzymes and Materials to Specific Applications

Selection of right enzymes or ESM exerts challenges during the design of environmentally responsive materials; however, different model enzymes are sometimes conveniently used to illustrate the mechanism of an ERM. This type of system is useful when the material used can show good performance under the specific conditions present in its surrounding environment. The target enzymes should have the ability to affect only the ESF in the material in order to leave the rest of the material unchanged for minimizing the chances of non-specific responses. Additionally, different strategies which have been developed for realizing the same material response should be reflective of the need to have a versatile repertoire of ERMs that can be adapted for a particular application. Undesirable effects of the biological environment on the material should be avoided, apart from some responsiveness characters, such as response to the marker enzyme and inertness of the environmentally responsive materials to other components present in the system (such as other enzymes, pH, and temperature). In this context, many ERMs have been synthesized and developed that have the capability to respond to an enzyme

with a high specificity to a particular substrate [26, 90]. On the contrary, when enzyme-responsive materials are unable to display the required specificity to a particular enzyme, they have limited application potential. For enzyme-responsive materials where longer peptide or DNA sequences are used that may be recognized by other enzymes and to ensure high impact applications of ERMs, these types of issues need to be resolved. For example, several ERMs with simple ESF (di- or tripeptides that are only sensitive to very specific enzymes) or intentionally broad enzyme specificity have been reported to perform well in in vitro studies that include the formation of supramolecular hydrogels inside cells and polymer hydrogel degradation [26–28, 66, 87, 91].

2.3.3 Choosing the Enzyme Response Mechanism

In case when a particular type of mechanism employed to translate enzymatic action into a material, response has to be tailored to the enzyme catalytic action if a target enzyme has been selected for a specific application. Since both bond formation and cleavage have been employed to date, the bond cleavage has been the more popular choice for existing ERMs. Besides this, some new methods have been applied in order to have opposite material responses with the similar type of enzymatic reaction, for example, enzymatic cleavage of peptide sequences on metal nanoparticles has been used to cause both aggregation and dispersion of the particles [28, 30]. In addition, current trends to enhance different targeted properties of enzyme-responsive materials are more focused on relatively higher dynamic or reversible systems that illustrate a shift from a single-time use of enzyme-responsive materials. Moreover, the introduction of functional characters with a capability to be controlled reversibly and/or on an on-demand basis is another level of progress for a relatively more precise type of incorporation of ERMs into a biological system. Different targeted applications where phosphatases and kinases play significantly important roles are useful for this due to their natural design to catalyze opposite reactions. Reversible enzyme-responsive materials are usually based on a phosphatase/kinase system, although nucleases and ligases perform similar functions (cleavage and bond formation between nucleotides); one example of an enzyme-responsive material is well known where the DNA strands are chemically reconnected after enzymatic cleavage [26–28, 40].

2.3.4 A Brief Discussion on the Enzyme Kinetics of Enzyme-Responsive Hydrogels

A full understanding on enzyme-substrate interactions and the manipulations of these interactions relating to enzymatic control on the suitable drug delivery systems based on enzyme-responsive hydrogels requires a basic understanding on certain aspects of enzyme kinetics, which is briefly outlined here in Fig. 3. The enzyme and substrate must interact to bind together for a conversion of a substrate (S) into a desired product (P), and in that stage the substrate gradually starts to convert into to the product by the enzymatic reaction depending on a range of influencing factors (such as temperature and pH of the surrounding environment, nature of the substrates and enzymes used, amount of both substrates and enzymes used, time of enzymatic

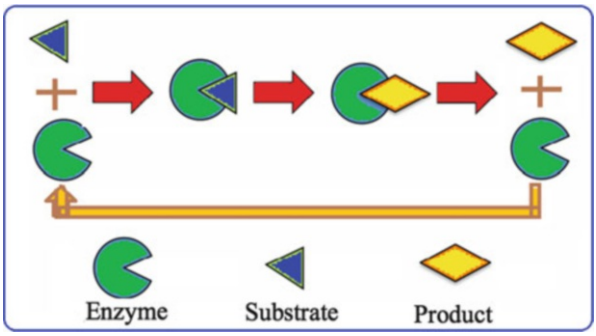

Fig. 3 A schematic representation of enzyme-substrate interactions and the manipulations of these interactions relating to enzymatic control on the suitable drug delivery systems based on enzyme-responsive hydrogels

reaction, etc.). At the final stage, the product is released by the action of enzyme (as demonstrated in Fig. 3). Figure 3 also demonstrates the mechanism by which enzyme specificity occurs using the "lock and key" mechanism. In this case, each enzyme has an active site (termed as lock) to which substrates of proper conformation (termed as key) must bind together and interact to cause a change in chemical structure. However, this change in chemical structure contributes to regulate the specificity of the enzymes in such a way to ensure that only specific substrates with the proper conformations have the capability to bind to the lock and undergo enzymatic conversion into product [27, 28, 92]. For instance, Fig. 3 exhibits a circular substrate would not be converted to product as it would not properly fit in the triangular lock.

2.4 Selective Examples of the Synthesis of Enzyme-Degradable Self-Assembled Hydrogels

Nowadays hydrogels are rigorously studied due to their different applications in various areas of science and technology; some applications include well-defined controlled release of bioactive molecules (such as proteins) and encapsulation of living cells. Biodegradability of hydrogels is one of the very interesting features of controlled drug delivery systems where the original three-dimensional structure has the capability to be disintegrated into nontoxic substances to ensure biocompatibility of the gel. Chemical cross-linking is a frequently used popular method to synthesize mechanically robust hydrogels, but the cross-linkers used in hydrogel preparation require to be extracted from the hydrogels before any suitable application because of toxic nature of the used cross-linkers. In this context, physically cross-linking techniques are preferred alternatives for preparation of hydrogels. Additionally, enzymes are also used for cross-linking to perform specific operations where most of the enzymes are usually used for biodegradation. The generation of a range of star-shaped block copolymers composed of a biocompatible poly(ethylene glycol) (PEG) core tethered to a polyalanine (PAla) shell that possesses the capability to (reversibly) self-assemble in water is a very interesting and important way of producing biodegradable hydrogels. The hydrogels formed in this way offer a

hydrophilic environment that is compatible to different biological processes involving proteins and are able to withhold albumin for prolonged periods before its triggered release following the targeted material degradation by a proteolytic enzyme (such as elastase). Thus, the hydrogels prepared in this way provide a promising opportunity to deliver proteins (and inhibitors, to some extent) in response to a proteolytic enzyme overexpressed in chronic wounds [27, 28, 46–48, 88, 92].

3 Applications of Enzyme-Responsive Systems

3.1 Biomedical Applications of Enzyme-Responsive Hydrogels

Enzyme-responsive hydrogels especially based on peptide self-assembly are attractive biomaterials because of their huge application potentials where some of the principal uses include (a) cell culture, (b) drug delivery, (c) biosensing, and (d) proving the scope for a dynamic control and regulation of cell fate by using systems with intracellular operation capability. So, in brief, the potential biomedical applications of enzyme-responsive hydrogels include (a) control and direction of cell fate, (b) imaging and biosensing, (c) controlled drug release, and (d) applications in cell scaffolds and tissue engineering [93–107]. Regenerative medicine, is a fast-growing area of science and technology. Different researcher groups are constantly working in different issues where devising and upgrading useful techniques and methods for repairing diseased or injured tissues are continuously investigated. Currently, stem cells are being rigorously studied because of their different aspects relating to embryogenesis, homeostatic turnover, and normal tissue repair. In order to realize the potential, stem cell-based therapies are still required to meet criteria in a clinical setting because of different issues including (a) number limitation, (b) immunogenicity, (c) tumor formation, and (d) ethical considerations surrounding their usages. Additionally, the stem cell differentiation mechanisms are complicated and very difficult to understand; hence expanding stem cell numbers and predictably directing their commitment to a desired lineage is very challenging (particularly, to devise tissue regeneration strategies). Different research groups are engaged with continuous research activities to realize the full potentials of enzyme-responsive hydrogels for tissue engineering applications particularly in the area of regenerative medicines [93–107].

3.2 Application of Enzyme-Responsive Hydrogels in Drug Delivery and Bioelectronics

Usually, enzyme-responsive materials have an enzyme-sensitive part along with another part that can direct or control the level of interactions in order to lead macroscopic transitions. Enzyme-responsive materials have many advantages over pH- and temperature-responsive materials, and all these types of materials can be used for stimuli-responsive hydrogels using suitable chemistry and methods. When

an enzyme-responsive hydrogel is applied on a target substrate, the catalytic action of the enzyme on the substrate can lead to different changes that include (a) changes in supramolecular architectures and (b) swelling/collapse behavior or the surface transformation of the substrate. In addition, the sensitivity of the enzyme as a stimulus is unique as enzymes are highly selective in their reactivity and they have the capability to operate under mild conditions present in vivo (a vital case for many biological pathways). The stimulus does not need to be added externally but can be supplied by the biological environment itself as many enzymes are already present in the body. When the naturally present enzyme matches with the triggering enzyme of the responsive material-based hydrogel system, it is more effective for particular type of uses such as controlled drug delivery in a particular location. Both enzyme-responsive materials and hydrogels produced by using them are important for drug development. For example, peptide-based nanocapsules and nanoparticles and hydrogel based on these products are useful for the delivery of bioactive molecules due to its cleavability by protease [107, 108]. Besides this, enzyme-responsive materials and hydrogels produced by using these materials are also suitable to apply in the fabrication of smart antibacterial devices [109], where the principal idea of smart antibacterial devices is based on the release of an antibacterial agent by the presence of the bacteria themselves [5–9].

3.3 Enzyme-Responsive Hydrogels for Biocomputing

Enzyme-responsive hydrogels are useful tools for their potential applications in bio-based computing systems that have wide scale uses in biomedical applications (such as monitoring wound healing and other physiological monitoring). For example, quick and accurate detection of injury (more specifically in accidents or battle fields) is challenging which is further complicated by time and logistics required to deliver emergency medicines. In addition, injuries that cause internal bleeding (particularly, when the effected individual fails to provide any information about his own conditions due to the severity of the accident) expose terrible challenge to diagnose the exact problems, and this type of situations requires advanced diagnostic measures in order to determine the injuries to the soft tissues with a sufficient reliability. In typical cases, pieces of sophisticated diagnostic equipment are usually used to study these conditions; some examples include (a) magnetic resonance imaging and (b) electromyography, which are costly and time-consuming. Besides this, there are many issues to operate these pieces of sophisticated equipment in the actual situation when the delivery of an immediate therapeutic intervention is vitally important. Moreover, in situations where such imaging equipment or laboratory tests are unavailable or impossible to timely deliver the results, the diagnosis is generally carried out by a medical professional using different physical tests. But this technique sometimes can lead to misdiagnosis leading to inaccurate treatments that may encumber the healthcare provider with an extra burden on the patient. In such situations, effective diagnostic tools which can be reliably used to rapidly detect to devise a plausible targeted treatment are most likely to offer great promise that can

contribute to enhance the prognosis of injury (such as in accidental or battlefield conditions). Most recently, biochemical computing technology based on sophisticated enzyme-based cascades has been drawing active research interest to develop systems that can rapidly and reliably work in the diagnosis of injuries and provide useful information to prescribe appropriate emergency medicine to save lives. In this type of systems, leverage from Boolean principles is used to emulate electronic logic gates in the biochemical domain. Enzyme-based logic gates have promising capability to integrate complex patterns of biological and chemical inputs in order to provide required information for relatively rapid diagnosis on a real-time scenario. This type of advanced diagnostic systems can be engineered and leveraged to realize desired diagnosis objectives and to provide required treatment for accidental injuries in an autonomous fashion which have potentials to develop an integrated "Sense-Act-Treat" field [74, 87, 88, 106].

3.4 Smart Bandage and Wound Healing

Enzyme switchable systems have the potential for biomaterial-based display applications with potential uses in a wide range of applications including in smart bandage systems for monitoring the state of injuries and wounds. For example, switchable biomaterials such as enzyme-responsive hydrogels have the potential for producing biomonitoring devices that benefit from lightweight form factors and have the feasibility to make conformal contact with the body. Additionally, a smart bandage can be designed to detect and monitor tissue wounds in vivo, and a flexible electronic device can be used to develop noninvasive maps of pressure-induced tissue damage or even provide some information when a noticeable damage is difficult to observe visually. For example, it has been reported that by using impedance spectroscopy across flexible electrode arrays in vivo on a rat model, the frequency spectra of impedance measurements showed a correlation in a robust way with the state of the underlying tissue across multiple animals and wound types. In addition, tissue damage has also been detected by using the impedance sensor and represented visually as a wound map that helped to identify regions at risk of developing a pressure ulcer which contributed to allow intervention. So, these results illustrate the feasibility of an automated, noninvasive "smart bandage" for early monitoring and diagnosis of pressure ulcers and for improving patient care and outcomes where enzyme-responsive hydrogels can be used [87–90, 108].

3.5 Enzyme (Such as Elastase)-Responsive Hydrogel Dressing for Chronic Wounds

Chronic wounds exert an expensive economical and clinical problem by causing the deaths of millions every year where the overexpression of enzyme (such as elastase) is a main factor that prolongs the normal wound repair process within chronic wounds. Many active research groups are engaged to overcome this situation, as

for instance, specific research activities are employed for designing hydrogel-based responsive chronic wound dressing systems. In this case, polymers such as PEGA (polyethylene glycol acrylamide) in the form of particles are used to prepare hydrogels for mopping up excess elastase by exploiting polymer collapse in response to elastase hydrolytic activity within sample fluids for mimicking the environment of chronic wounds. Besides this, many other investigations have focused on the functionalization of PEGA particles by enzyme-cleavable peptides (ECPs) with charged residues in order to control polymer swelling with a consequent elastase entrapment to cause a cleavage of the charge balance changes [74, 87, 88, 110].

3.6 Complex Bioactive Fiber Systems Incorporating Enzyme-Responsive Systems by Means of Electrospinning

Enzyme-responsive hydrogels have the potentials for producing complex bioactive fibers using different techniques including electrospinning. Generally, enzyme-responsive systems have a wide range of biomedical applications including in the production of complex bioactive fibers for a variety of applications in different areas of life sciences. As for instance, the prolonged life expectancy is a direct contribution of welfare and medical developments, and this prolongation often leads to an increased physical stress on the human body that sometimes requires to replace nonfunctional and damaged tissues or organs. Artificial complex electrospun bioactive fibers have many applications in tissue engineering. During tissue engineering, in vitro cell culture is usually carried out in an artificial three-dimensional scaffold, and there are different ways of doing this. For example, modern approaches toward three-dimensional scaffolds using bioactive interfaces are frequently used in tissue engineering that also provides the opportunity to use bio-integrated and biomimetic systems. Advanced understanding on how materials passively interact or actively communicate with biological systems via designed material-biology interfaces requires precise methods for fabricating macroscopic and nanostructured materials. Recently, modern materials and technology platforms have been developed for producing bioactive scaffolds for serving a number of purposes including for providing spatial control of mechanical, chemical, and biochemical signals at the bio-interface together with the tailored pore architecture and surface topology. Enzyme-responsive hydrogels or enzyme-responsive systems can be used to establish straightforward approaches to fabricate complex structures using electrospinning in order to produce structurally and chemically bioactive fiber suitable for relatively easier cell infiltration due to the scope for a control of the mesh porosity of the electrospun scaffolds. These electrospun scaffolds also provide the scope for direct crystallization of fibers suitable to be used for the investigation of the cell ingrowth for biomedical applications. Additionally, these types of electrospun bioactive fibers can further be functionalized for the decoration of the fiber surface using biomolecules (such as peptides and sugars) or other functional materials to serve specific purposes suitable for control delivery or other related biomedical applications. Additionally, electrospun bioactive fibers have promising biomedical

applications to replicate features of the natural extracellular matrix (ECM). However, most of the electrospun scaffolds are either nondegradable or degrade hydrolytically, whereas natural ECM degrades proteolytically, often through matrix metalloproteinases (MMPs). There are reports for the synthesis of reactive macromers that contain protease-cleavable and fluorescent peptides and are able to form both isotropic hydrogels and electrospun fibrous hydrogels through a photoinitiated polymerization. In addition, biomimetic scaffolds are susceptible to protease-mediated cleavage in vitro in a protease dose-dependent manner and in vivo in a subcutaneous mouse model using transdermal fluorescent imaging to monitor degradation. This type of systems has many biomedical applications [74, 88, 95–99, 105–109].

4 Perspectives and Trends in Future Developments

One of the main strengths of enzyme-responsive materials compared to other stimuli-responsive materials clearly depends on their ability to interact with a biological environment with the same communication mechanism used by nature. In principle, enzyme-responsive materials have the ability to perform their functions with high specificity to their target enzymes. These functions are not largely undisturbed by the multitude of other processes in the biological environment. Until today, research activities on ERMs are principally aimed at developing of enzyme-responsive mechanisms and the translation into a material response. Over the last couple of decades, notable development has been realized in the form of new translational mechanisms and the incorporation of ESFs into artificial materials. Although the high attraction of enzyme-responsive systems to act dynamically and on more than one enzymatic stimulus has been recognized, this area of ERM development still holds great potential to develop new materials with unprecedented possibilities. Enzyme-responsive systems are widely studied for their potential uses in the fabrication of next-generation biological devices. For example, different areas of biomaterials widely use functionalized hydrogels for their huge potentials in different areas of biomedical applications including in cell culture [53, 54] and biosensing [55] platforms. Hydrogels are popularly used in instructive matrices for stem cell growth. In addition, the incorporation of biochemical signals that have matrix protein-specific peptidic motifs (such as fibronectin-derived arginine-glycine-aspartic acid or RGD) which can be used to facilitate cellular adhesion is particularly important. As for instance, the mechanical [57] (such as gel stiffness) and structural/topographical factors [111] of the cell-contacting matrix have special impact on biochemical signals produced from the hydrogels, and they can be regulated to control different features of hydrogels' structure in order to have control of cell fate when these hydrogels are used in cell culture or similar areas. Besides this, the preparation with particular definitions of physical characters and chemical composition may need new synthetic protocols in order to control different properties that include (a) stiffness, (b) gel network structure, and (c) chemical functionalization.

Enzymatic fabrication techniques are useful to achieve some of these goals [48, 58, 74, 87].

In addition, mimicking biological systems is a hot topic for current active research as an effort to have more decisive control over the bottom-up fabrication process. Very often different aspects of biological systems are effectively influenced and controlled using different spatially confined molecular mechanisms, some of which include (a) catalysis and (b) molecular recognition. Thus, enzymes have been used as important tools to regulate suitable nanofabrication methods with aims to develop relatively complex and highly selective next-generation biomaterials for a wide range of conventional and high-tech applications in various fields including in material and life sciences. Different important characters of enzyme-assisted formation and dismantling of supramolecular structures include (a) self-assembly under constant conditions, (b) spatiotemporal control of nucleation and structure growth, and (c) control of mechanical characters (such as stiffness). In addition, systems that assemble under thermodynamic control also show distinctive natures that include (a) defect correcting and (b) component-selecting abilities. Currently, more focus is concentrated on the effective design of suitable materials for specific applications that cover particular areas which include (a) cell culture, (b) drug delivery, (c) imaging, (d) biosensing, and (e) cell fate control. Dynamic processes in biological systems are usually controlled by enzymes. Ongoing extensive research activities aim to have better understandings of different processes at their molecular levels using enzymatic controlled self-assembly approaches. Some of the most challenging tasks in this context include (a) effectively controlling nucleation and structure growth, (b) regulating the access structures which represent non-equilibrium assemblies, and (c) producing asymmetric, dynamic, and multicomponent structures with expected functionalities and characters. An enzyme-responsive hydrogel has a wide range of continuous active research interests in order to form supramolecular structures and also to devise suitable ways to investigate the ability of these structures to perform specific activities, some of which include (a) recognition, (b) adaptation, (c) correction, and (d) interactions of the complex ways related to evolving behaviors [8, 9, 26–28, 38–41, 103–105].

5 Conclusion

Enzyme-responsive hydrogels prepared from cellulose along with other materials have suitable macromolecular networks and can work in controlled environment. An enzymatic stimulus-responsive system is a highly attractive field of research due to its many potential applications (e.g., in controlled release, drug delivery, and other areas of life and material sciences). This chapter has provided a brief overview on different selective features of enzyme-responsive hydrogels based on different polymers, and it has also stated various applications of enzyme-responsive hydrogels in specific fields including in controlled drug delivery and other areas of biomedical and material sciences. However, due to the limited scope available within the perimeter of this chapter, it is almost impossible to explain all features of different

enzymes usually used in the formulation of enzyme-responsive hydrogels. Efforts have been made to provide enough references which can be used to have more comprehensive information for advanced readers.

Cotton Cellulose-Derived Hydrogels with Tunable Absorbability: Research Advances and Prospects

11

Yang Hu, Rohan S. Dassanayake, Sanjit Acharya, and Noureddine Abidi

Contents

Abstract

Cotton is an important, worldwide cash crop and is considered as a ubiquitous resource offering the purest form of cellulose in nature. By far, the most industrially exploited natural resources containing cellulose are wood and cotton. Cellulose derived from either wood or cotton has the same chemical structure. Hydrogels are jellylike materials consisting of substantially hydrophilic cross-linked network filled with water. Upon replacing water with air, hydrogels are able to form aerogels. Cellulose and its derivatives can be used to prepare hydrogels with tailored absorbability and adsorbability. In the first section of

this review, we discuss recent progress in the dissolution of high molecular weight cotton-derived cellulose as the dissolution of cellulose is an important step in preparing cellulose-based hydrogels. In the second section, we focus on the preparation of various cotton cellulose-based hydrogels and their derivatives by physical, chemical, and photocatalytic processes and their current applications. The third section includes the preparation and application of cellulose-based aerogels, which are a specific dry form of hydrogels. Overall, this review covers recent research developments in cotton cellulose-based hydrogels and their broad spectrum of applications in agriculture, environment, energy, health, and medicine.

Keywords
Biopolymer · Cellulose · Hydrogel · Aerogels · Cotton

1 Introduction

Cotton is an agricultural crop that has fluffy staple fibers growing on a boll surrounding the seeds. The annual worldwide production of cotton is estimated to be 25 million tons, which makes cotton one of the leading cash crops in the world. The world's largest producer of cotton is China, while the United States of America is regarded as the largest exporter of cotton in the world [1]. Cotton fiber is almost pure cellulose, and it contains over 95% of cellulose [2]. The biological growth of cotton fiber leads to the formation of cellulose starting with the primary cell wall development after the day post-anthesis (dpa) followed by the secondary cell wall development around 21 dpa [2, 3]. The conventional textile industry mostly uses cotton fiber to manufacture a variety of textile products including clothing, terry cloth, bed clothes, upholstery, and medical gauze. Despite the very large production, the current cotton industry is facing multiple challenges due to declining market price and considerable use of regenerated cellulose fiber, rayon, and synthetic fibers such as polypropylene and polyethylene terephthalate in the textile industry. As a result, there has been an increased demand for adding value to cotton fibers by preparing novel cotton-based materials which could potentially increase profitability and competitiveness of cotton.

Gels are a solid jellylike materials with a continuous, interconnected, and three-dimensional (3D) polymeric network [4]. Hydrogels consist of hydrophilic polymeric chains and chemical groups that can hold and exchange a large amount of water with the environment [5]. When water inside the hydrogels is replaced by a continuous gas phase, hydrogels become aerogels. These aerogels exhibit a wide range of applications in oil absorbability, metal recycling, probiotics, and environmental clarification [6–8]. The most intriguing feature of hydrogels is their capability of water retention and exchange with the environment. This property makes hydrogels adaptable to many areas including industrial, agricultural, environmental, and biomedical. Recent trends indicate that hydrogels synthesized from synthetic materials are gradually becoming popular in replacing the natural hydrogels

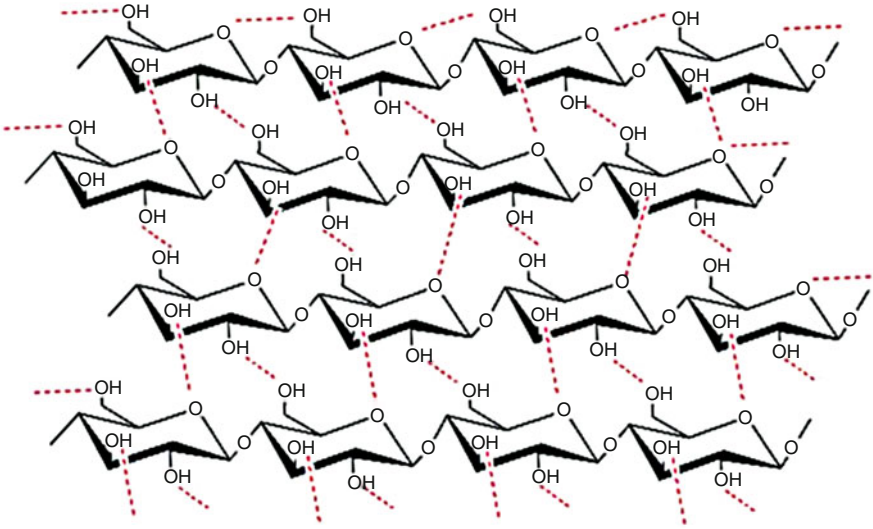

Fig. 1 Chemical structure of cellulose macromolecule with inter- and intramolecular hydrogen bonding

generated from biosynthetic polymers due to their long lifetime and more tunable capacity of water absorption. However, hydrogels prepared from biopolymers still play a pivotal role in agricultural, environmental, and biomedical areas that especially require renewability, biodegradability, and biocompatibility.

Cellulose is a carbohydrate polymer consisting of repeating β-D-glucopyranose molecules that are covalently linked through polycondensation reactions between two hydroxyl groups of two glucose units (Fig. 1), commonly known as β 1 → 4 glycosidic bond. Cellulose is found in plants, bacteria, marine animals (tunicates), and algae. Its chemical structure and composition remain unchanged irrespective of the source, while cellulose differs in its content, purity, and degree of polymerization. Wood and cotton are considered the most commercialized supplies of cellulose, while wood only contains 40% cellulose which is much lower than cotton [9, 10]. Due to the finer nanostructure, facile preparation, and broad availability bacterial cellulose has become an attractive research material in various fields [11–16]. The utilization of cellulose and its derivatives to prepare hydrogels for different applications has a long history [4]. The abundance of free hydroxyl groups in cellulose macromolecular structure allows the formation of many inter- and intramolecular hydrogen bonds and the semicrystalline structure makes cellulose highly reactive for advanced functionalization for superabsorbent hydrogels [17, 18]. Most of cellulose-based hydrogels are prepared from bacterial cellulose, wood cellulose, and its derivatives. However, only a few studies have been reported on the use of cotton cellulose for preparing hydrogels. This could be due to the fact that (1) cotton fiber almost entirely goes to traditional textile processing; (2) the difficulty in dissolution of cotton cellulose, and (3) most of the cellulosic materials available in the market

are derived from wood. Cotton cellulose has a high degree of polymerization (DP) (10,000–15,000) which makes it much harder to dissolve as compared to wood cellulose which has a relatively low DP (~300–1700) [9, 19–21].

This review discusses up-to-date research advances on the cotton cellulose-based hydrogels with tunable absorbability. Since the preparation of cellulose-based hydrogels involves cellulose dissolution, the first section of this review is focused on the dissolution of cotton cellulose and its derivatives. A diverse range of applications of cotton cellulose-based hydrogels is also discussed. The final section focuses on cotton cellulose-based aerogels and their current uses.

2 Dissolution of Cotton Cellulose and Its Derivatives

Most of the reported dissolution processes of cellulose carry limitations such as low cellulose solubility in terms of molecular weight and concentration, volatility, high cost, poor solvent recovery, high processing temperature, process instability, and environmental concerns [22]. Two industrial processes, viscose and lyocell, use raw cellulose derived mostly from wood pulp to produce regenerated fibers [23]. These industrial processes can also be applied to cotton cellulose, although cotton cellulose is not a popular feedstock to produce regenerated fibers [24]. Both viscose and lyocell processes are associated with several issues, such as generation of highly toxic carbon disulfide (CS_2), heavy metal compounds, hazardous by-products, unwanted side reactions, and harsh dissolution conditions [9, 25, 26].

2.1 Cotton Cellulose

Cellulose derived from wood remains the main source for the preparation of regenerated materials such as fibers and films in the industry [27]. However, the dissolution of cellulose from other sources including cotton has been investigated in numerous solvents along with the preparation of regenerated materials such as fibers, hydrogels, and aerogels [27–41]. Unlike other cellulose sources, native cotton cellulose is obtained in the form of fibers, which can be directly processed into yarn. However, a significant amount of cotton fibers is discarded as waste during ginning and carding processes. Therefore, there is a need to utilize the waste cotton as a source of cellulose to prepare various regenerated materials.

Cotton contains the purest cellulose among almost all other sources as shown in Table 1. The DP of cellulose varies upon the source and is described in Fig. 2 according to the type of extraction and purification. The cellulose content in cotton can reach over 99% after scouring and bleaching processes that remove non-cellulosic materials such as waxes, pectin, proteins, and inorganics. The DP of cotton cellulose in the natural state is higher than 10,000, while it is reduced to 1000–3000 or less in the preparation of cotton linters and cotton linter pulp [20]. Due to the high molecular weight, complex polymeric network, and non-covalent interactions among molecules, cellulose is generally inert to mild chemical

Table 1 Cellulose, hemicellulose, and lignin contents in wood and common agricultural residues [12]

Lignocellulosic materials	Cellulose, %	Hemicellulose, %	Lignin, %
Hardwood stems	40–55	24–40	18–25
Softwood stems	45–50	25–35	25–35
Cotton seed hairs	80–95	5–20	0
Nut shells	25–30	25–30	30–40
Corn cobs	45	35	15
Grasses	25–40	35–50	10–30
Paper	85–99	0	0–15
Wheat straw	30	50	15
Leaves	15–20	80–85	0

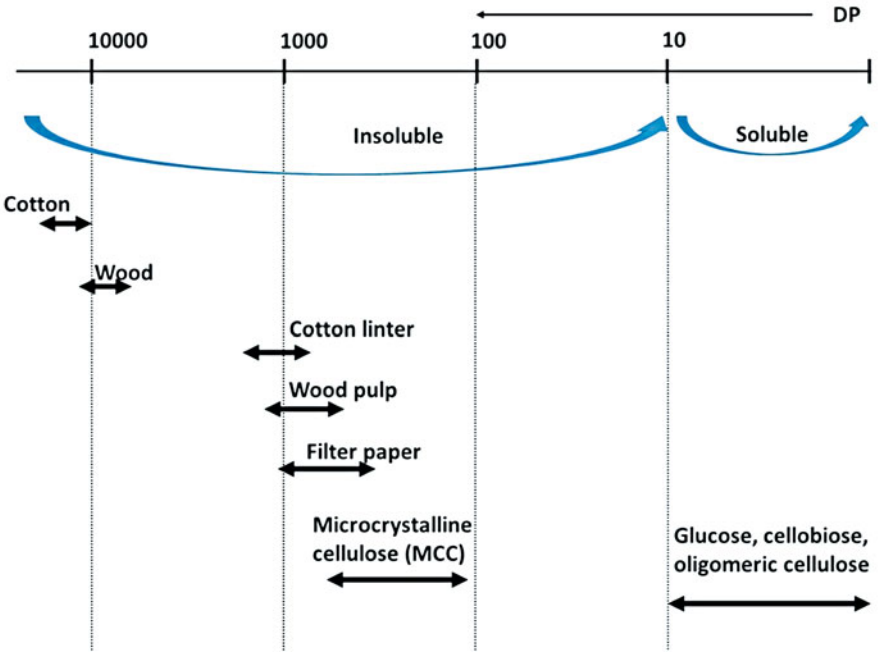

Fig. 2 Typical DP values of different cellulose substrates and their solubility [20]

processing. Therefore, it is hard to dissolve cotton cellulose in water and common solvents under mild conditions. The preparation of hydrogels generally requires the dissolution of cellulose as the first step to obtain homogeneous cellulose followed by mold casting and regeneration to obtain final hydrogel products [10]. Homogeneous dissolution of cellulose prior to the synthesis of hydrogels is required in order to achieve the desired homogeneous structure and superior features [26, 42].

Cost-effective and environmentally benign cellulose dissolution, in general, remains a challenge owing to its high molecular weight and high structural order.

The problem becomes more complicated with cotton cellulose because it possesses high molecular weight and structural order (high amount of crystalline cellulose) among all plant cellulose macromolecules. Since the molecular weight of a polymer is a key parameter in determining its solubility and is inversely related to the entropic driving force which contributes to the dissolution, cotton cellulose of high molecular weight inherently presents a low solubility [43]. Numerous studies have focused on both fundamental and applied aspects of cellulose dissolution. The majority of studies available in the literature use wood-based cellulose including microcrystalline cellulose (MCC) and wood pulps, which are different from cotton cellulose in terms of both molecular weight and crystallinity. These studies showed that different regenerated cellulose materials such as rayon and lyocell can be prepared from cellulose solution using different solvents [44, 45]. Since solvents effective for low molecular weight cellulose are not efficient on high molecular weight cellulose such as cotton under similar processing conditions, only few studies were focused on the dissolution of cotton cellulose in common cellulose solvents [46]. Decreasing the molecular weight of cotton cellulose by means of chemical and enzymatic pretreatments could enhance the solubility of cotton cellulose. Other pretreatments which facilitate the dissolution of cotton cellulose include treatment with sodium hydroxide, solvent exchange with acetone, and freeze-drying processes [10, 46, 47].

2.2 Dissolution of Cotton Cellulose in Different Solvents

2.2.1 Viscose Process

The "viscose" process ($NaOH + CS_2$) is the most dominant process employed by the industry to dissolve cellulose and produce commercially available regenerated cellulosic materials, such as rayon and cellophane [48, 49]. In the industry, high purity dissolving pulp is mostly derived from wood; only 10% of the dissolving pulp is produced from cotton [50]. In a typical viscose process, cellulose is steeped in sodium hydroxide solution to obtain an activated cellulose called soda cellulose, in which one of the three reactive hydroxyl groups on each glucose unit of cellulose is replaced by sodium ions. Then, the soda cellulose is mixed with carbon disulfide (CS_2) to obtain cellulose xanthate, derivatized cellulose. Cellulose xanthate is soluble in aqueous sodium hydroxide and can form "viscose" solution. Then in the coagulation bath, cellulose xanthate is converted back to cellulose in the shape of filaments and films from the "viscose" solution [9, 51, 52]. Studies were focused on new strategies to reduce the environmental impacts of the viscose process. Enzymatic pretreatment of cellulose (dissolving pulp) with endoglucanase and xylanase was reported to increase the reactivity of the dissolving pulps, and thereby the consumption of CS_2 can be reduced by 30% [53, 54]. Mechanical pretreatments such as grinding and PFI refining of cellulose were reported to enhance the reactivity of cellulose pulp in the viscose process [55]. The modified viscose process generates a soluble derivative called cellulose carbamate that is soluble in aqueous NaOH. Carbamate process is deemed more environmentally friendly as compared to the viscose process [9, 25, 30, 56] (Fig. 3).

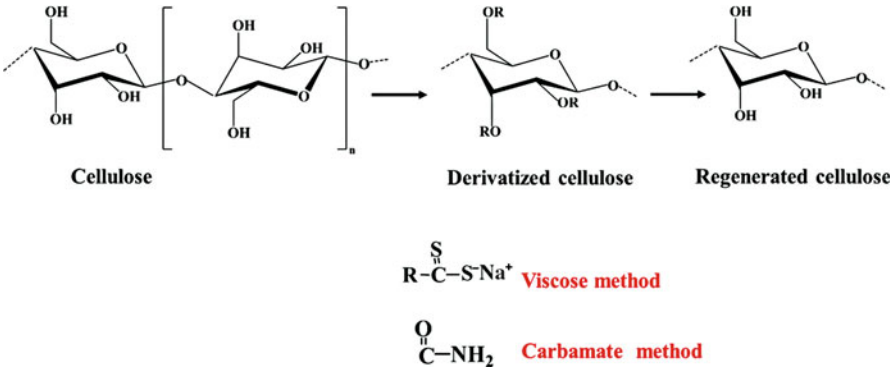

Fig. 3 Process principles in viscose and Carbamate processes [9]

Few studies were focused on the improvement of carbamate process using cotton linter cellulose. Yin et al. optimized the carbamation of cotton linter cellulose (DP ~520) with the aid of CO_2 supercritical dehydration of cellulose [57]. The study showed that CO_2 supercritical dehydration could yield cellulose carbamate of high nitrogen content, which positively correlates with the solubility of cotton cellulose in aqueous NaOH. In addition, the pretreatment of cotton linter cellulose (DP ~550) by means of microwave heating at 255 W for 2–5 min under catalyst-free and solvent-free conditions was conducive to the enhancement of nitrogen content of cellulose carbamates from 0.651% to 2.427% [58]. Fu et al. further optimized the carbamate process by improving the stability of the dissolved carbamate solution of cotton cellulose (DP ~790) by adding a small amount of ZnO in NaOH during the dissolution using conventional viscose method [56].

2.2.2 Aqueous Alkaline Systems

The potential of aqueous bases as cellulose solvents was reported as early as 1930, and it has been extensively studied since then [42, 47, 59–63]. Low molecular weight cellulose below 268,000 can be partially dissolved in aqueous NaOH of 7–10% concentration [64]. The formation of NaOH hydrates in water is the major driving force to break down the intra- and intermolecular hydrogen bonding of cellulose [65]. This system offers many advantages because of its low cost, minimal environmental issue, common chemicals, and facile dissolving process. However, NaOH/water system is unable to completely disrupt the semicrystalline region of cellulose, and the solubility is limited to cellulose of relatively low molecular weight. The improvement of cellulose dissolution in this system includes mechanical/physical, chemical, and enzymatic pretreatments of cellulose. Ball milling and steam explosion followed by grinding of wood cellulose pulp have been reported to enhance the solubility of cellulose in this system [47, 66]. Enzymatic pretreatments of cotton linter cellulose (DP ~850) could remarkably increase the solubility of cotton linter cellulose from 30% to 60% and significantly decrease the dissolution time [66]. Additionally, the use of additives in NaOH/water solvent

system, such as thiourea, urea, and polyethylene glycol, has been reported to enhance the dissolution ratio and the stability of the cellulose solution [28, 67–70]. For example, NaOH/ urea system was used to dissolve relatively high MW cotton cellulose (DP ~620) within 30 min at a concentration of 4.5% urea in NaOH [44]. Other bases, such as LiOH, KOH, and quaternary ammonium hydroxides, can also be used instead of NaOH to work with the additives to dissolve cellulose [48, 71–73]. One study reported that LiOH/urea/ H_2O system was more effective than NaOH/urea/H_2O system [28].

2.2.3 DMAc/LiCl System

N,*N*-dimethylacetamide (DMAc) combined with lithium chloride (LiCl) is a common and powerful solvent system for the dissolution of cellulose [74–76]. LiCl (8%) in DMAc (w/w) has been widely used. An activation procedure or a pretreatment is usually required especially for high MW cellulose such as cotton cellulose. The typical activation method involves solvent exchange where cellulose is first treated either in water, liquid ammonia, or NaOH, and then the solvent is exchanged to methanol, ethanol, or acetone to finally (dry) DMAc [77]. Heating or refluxing cellulose in DMAc or DMAc/LiCl has also been proposed to activate cellulose for better dissolution [78]. Although different mechanisms of cellulose dissolution in DMAc/LiCl solvent system have been proposed, most authors believe that the formation of Li^+[DMAc] macrocation is the driving force for the dissolution of cellulose where DMAc is considered a strong Lewis base and Li^+ is highly oxophilic cation [77, 79–83]. The native hydrogen bonding in cellulose is disrupted once the free Cl^- ions form hydrogen bonds with OH groups of cellulose in addition to the weak dipole-dipole interaction of macrocation via Li^+ with cellulose molecules (Fig. 4) [26, 76, 77, 84, 85]. A drawback of DMAc/LiCl solvent system is that a serious degradation of cellulose (loss of molar mass) may occur during the dissolution process by forming reactive intermediates at elevated temperature (>80 °C) [86].

2.2.4 Lyocell Process

Amine oxides constitute another important class of non-derivatizing cellulose solvents [87]. Among the amine oxides, *N*-methylmorpholine-*N*-oxide monohydrate

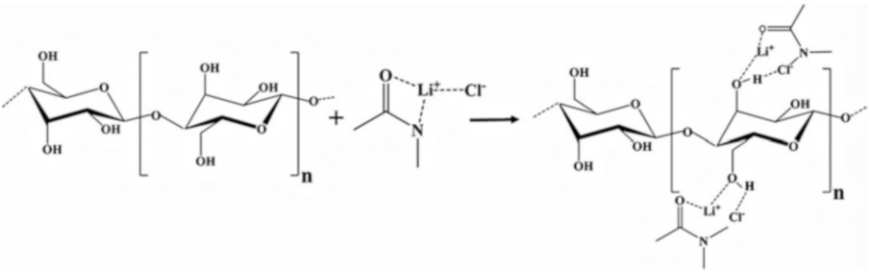

Fig. 4 Schematic of proposed hydrogen-bond breaking mechanism for cellulose dissolution in DMAc/LiCl [25]

(NMMO) is considered the superior cellulose solvent. The lyocell process is based on the use of NMMO as a solvent for cellulose. NMMO monohydrate at 13% concentration in water can dissolve cellulose without derivatization to achieve a solubility of 23% cellulose concentration at 80–120 °C [9, 88]. The mechanism of NMMO to dissolve cellulose is due to the formation of one or two hydrogen bonds between the oxygen of NO group and hydroxyl groups of cellulose caused by the strong dipolar character of the NO group [74, 87]. Lyocell offers several advantages over industrially predominant viscose process. It can directly dissolve cellulose in NMMO without extra activation and pretreatment. It does not need an intermediate transfer to cellulose derivatization, and it significantly shortens the production route and also eliminates the release of highly toxic CS_2. Additionally, the industrial recovery of NMMO can be as high as 99.7% [9]. Lyocell fiber also has advantages over rayon in many respects such as its strength in both wet and dry states, modulus of elasticity, absorbable behavior, gloss, and touch. However, the lyocell process suffers from some drawbacks including unstable regenerated fiber, unwanted side reactions, and excessive degradation [9]. Therefore, strategies have been applied to optimize the stabilization of the reaction and reduce the occurrence of unwanted side reactions [89].

2.2.5 Ionic Liquids

Ionic liquids (ILs) have emerged as promising non-derivatizing cellulose solvents with high potential to dissolve cellulose. ILs are generally asymmetrical organic salts that remain liquid at relatively low temperature (<100 °C). An IL usually consists of a bulky low charge density organic cation and a low charge density inorganic or organic anion [90–92]. Swatloski and coworkers first reported several ILs capable of dissolving cellulose, and a large variety of ILs has been developed and specifically applied to the dissolution of cellulose since then [90, 93, 94]. ILs exhibit many advantages over other cellulose solvents such as thermal and chemical stability, negligibly low vapor pressure, high efficiency of cellulose dissolution, and recyclability. In addition, a large variety of possible ion combinations allows tailoring ionic liquid solvents with specific properties for specific purposes. The number of potential ion combinations available is estimated to generate 10^{12} of ILs [93, 95]. The most efficient ILs reported for the dissolution of cellulose are mainly composed of a salt with halide, phosphonate, formate, or acetate as an anion and imidazolium, pyridinium, choline, or phosphonium as a cation [96–103]. As compared to NMMO and DMAc/LiCl, ILs have exhibited a capability of dissolving high molecular weight cotton linter (DP ~4745) [96]. Some cellulose pretreatments, such as mechanical ball milling, ethanol treatment, ultrasonic irradiation, and microwave irradiation can promote the dissolution of cellulose [104]. The dissolution of cellulose in ILs depends on the disruption of hydrogen bonding of cellulose chains by both anions and cations from ILs (Fig. 5). Anions and cations play a significant role during the dissolution. For example, imidazolium-based ILs dissolve cellulose by means of interaction of hydrogen bonding between the anions of the ionic liquid and the hydrogen of the C3...OH and C6...OH groups in cellulose. Meanwhile, acidic protons of the cations, especially the H2 proton in the imidazolium ring of the cation,

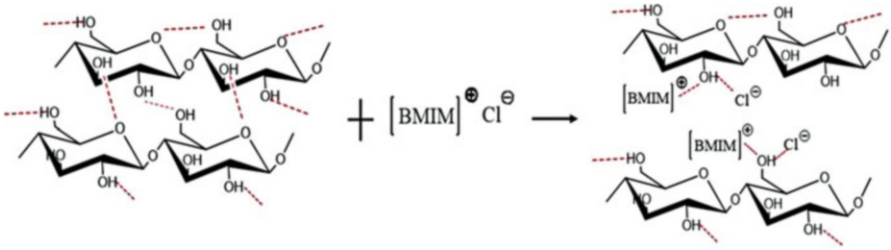

Fig. 5 Proposed cellulose dissolution mechanism in 1-butyl-3-methylimidazolium chloride [95]

form hydrogen bonding with the oxygen at C2. . .OH and the ring oxygen (O5) of cellulose [95, 105, 106]. Despite the great potential of ILs as cellulose solvents, ILs have not been applied to industrial applications yet. High production cost, high viscosity, high hygroscopic property, and reduction in dissolution ability and processing difficulties due to long-term dissolution are drawbacks of ILs [26, 107]. Efforts have never been stopped for exploring new ILs and improving the process of ILs to dissolve cellulose. A recently synthesized ionic liquid, 1,5-diaza-bicyclo [4.3.0]non-5-enium acetate ([DBNH][OAc]), was employed in the development of a process called Ioncell-F to produce regenerated cellulose fiber with properties comparable to lyocell [44, 45].

2.3 Other Methods for Preparing Cellulose-Based Hydrogels

Other methods for preparing cellulose-based hydrogels consist of synthesizing water-soluble cellulose derivatives and then forming hydrogels by means of physical, chemical, and radical cross-linking. Water-soluble cellulose derivatives contain methyl cellulose (MC), carboxymethyl cellulose (CMC), hydroxypropyl cellulose (HPC), and hydroxypropyl methylcellulose (HPMC) [4]. Generally, water-soluble cellulose derivatives have a low molecular weight (DP $<$100), and the substitution of hydroxyl groups on the cellulose macromolecular chain is more than 1.0 degree of substitution (DS) [9, 108]. These features make water-soluble cellulose derivatives quite easy to dissolve in water and other common solvents to prepare hydrogels. Most of water-soluble cellulose derivatives require that cellulose be well-dissolved or swollen prior to the modification, and they are produced from cellulose derived from wood because of the low molecular weight and abundant commodity of wood cellulose available. However, a few studies use cotton cellulose derived from waste cotton fabric, cotton by-products, and absorbent cotton that present low molecular weight to synthesize water-soluble cellulose derivatives [109–111].

Physical cross-linking is not involved in the covalent bonding. Cellulose derivatives are simply dissolved in water at a relatively high concentration under different conditions (heat or stir) to form hydrogels by means of ionic bonding, hydrogen bonding, and molecular interaction between polymeric chains [112–114]. Chemical and radical cross-linking of cellulose derivatives to form

hydrogels are achieved through covalent bonding by functionalized cross-linker or self-induced bonding by light, heat, and pressure [115, 116]. For example, cellulose from cotton waste textiles was carboxymethylated and cross-linked by divinyl sulfone to form superabsorbent hydrogel using NMMO to dissolve cellulose. The resulting CMC products exhibit a high binding capacity of 541 g/g and a rapid absorption rate within 60 min when the sample is immersed in water [117].

3 Applications of Cotton Cellulose-Based Hydrogels

Most of cellulose-based hydrogels have been used in agricultural, environmental, health, and medical areas depending on their super-absorbability and tunable absorbency. Cotton cellulose is not the major feedstock for making hydrogels, and only cotton cellulose products, including linter, linter pulp, and waste with low molecular weight, have been explored to prepare various hydrogels for diverse applications. This review discusses only the applications of hydrogels derived from cotton cellulose.

3.1 Applications in Agriculture

Superabsorbent hydrogels with self-tunable absorbency have been used in agriculture as soil additives or water reservoirs to meet the requirement of reducing water consumption and optimize the utilization of water resources [118]. Synthetic polymers such as sodium polyacrylate exhibit excellent water retention and discharge under specific conditions. However, they are not biodegradable or degrade too slowly, which may affect the overall soil quality [119]. Cellulose and its derivatives have an advantage over synthetic polymers due to their biodegradability and biocompatibility. The natural degradation of cellulose-based hydrogels in the soil could be a nutrition source for most plants. For example, during the whole lifetime of hydrogels, hydrogels are first able to store water from the environment when a rain event occurs and switch the appearance of hydrogels from glassy to a rubberlike state. The water discharge occurs when the soil dries and the rate of water release from the hydrogels can be controlled by controlling the functional groups of cellulose-based hydrogels [120]. A typical illustration is shown in Fig. 6 demonstrating the process of restoring and discharging water periodically fulfilled by cellulose-based hydrogels. The large-granule cellulose gel shown in Fig. 6 is better than the fine-granule gel because larger-granule gel can maintain better soil porosity that allows the air to flow. Water and nutrients can also permeate the thick soil layer and diffuse well around the root.

There are only a few examples using cotton cellulose to prepare hydrogels as soil additives for adjusting water requirement. Kono and coworker reported a superabsorbent hydrogel prepared from cotton cellulose with a high DP of 2400 [121]. The authors used LiCl/*N*-methyl-2-pyrrolidone (LiCl/NMP) to dissolve cotton cellulose followed by esterification of the dissolved cotton cellulose using 1,2,3,4-butanetetracarboxylic dianhydride (BTCA). Then the esterified product was

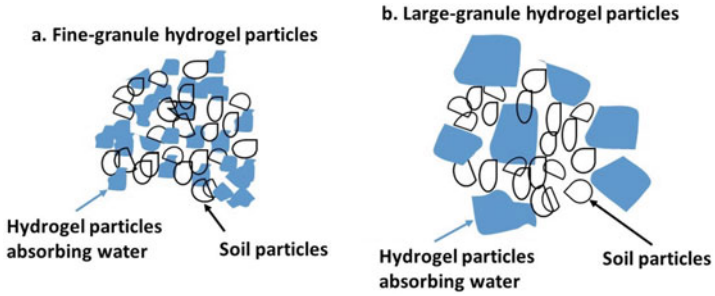

Fig. 6 Cellulose-based hydrogels: (**a**) fine-granule gel and (**b**) large-granule gel [120]

converted to sodium carboxylates in aqueous NaOH. The final hydrogel product demonstrates its potential in water retention and discharges in the soil with an excellent absorbency of 720 times of its dry weight and a good biodegradability. Cross-linked CMC prepared from cotton linter pulp and cross-linker (epichlorohydrin) was also reported [122]. Cotton linter was first swollen and then carboxymethylated followed by cross-linking. The resulting cross-linked CMC hydrogel exhibited an improved swelling behavior, which is sensitive to a change in the pH variation. This hydrogel may satisfy different soil pH requirements under different environments.

3.2 Environmental Applications

Cellulose-based hydrogels as pollutant adsorbents can remove heavy metal ions, dyes, and pesticides from water [123]. The absorbency of cellulose-based hydrogels can be easily tailored by using different cellulose derivatives. For example, cellulose grafted with acrylonitrile is a good adsorbent of Cr^{5+}, and oxidized cellulose-based hydrogel is considered a good absorbent for Hg^{2+} with an adsorption capacity of 258.75 mg/g at 30 °C and pH 4.0 [124]. The preparation of hydrogels from these cellulose derivatives requires the dissolution of cotton or wood cellulose, modification of cellulose by specific functional groups, and then formation of hydrogels by means of physical or chemical cross-linking. In addition, hydrogel composites prepared from cotton cellulose and functional additives also play a role in the removal of heavy metal ions. Zhou and coworkers developed a fixed-bed column filled with cellulose/chitin hydrogel beads for the removal of a number of heavy metal ions in a broad range [125]. A mixture of 4% cellulose solution prepared in DMAc/LiCl and 2% chitin solution prepared in NaOH/thiourea was used to coagulate and prepare composite hydrogel beads. The assembled bed with hydrogel beads could perform four cycles of adsorption/desorption to reach an adsorption efficiency of Pb^{2+} more than 70%. The cellulose/chitin beads also exhibited an excellent recycling capability. Beads treated with 0.1 M HCl can restore the regeneration efficiency up to 99%.

The removal of dye and pesticides can be achieved using cellulose-based hydrogel prepared from cotton cellulose modified with functional groups to synthesize super-adsorbent hydrogels or cellulose nanocrystals (CNCs) hydrogel composites. Zhou and coworker synthesized a super-adsorbent cellulose-graft-acrylic acid hydrogel using commercial cotton linter powder for the removal of methylene blue (MB) dyes from wastewater [126]. The resulting hydrogels exhibited excellent MB adsorption capacity of 2197 mg/g, and nearly 70% MB in weak acid solution could be removed during the desorption process. In addition, CNCs/alginate hydrogels beads were used for MB removal up to 97% efficiency [127], as well as CNCs-reinforced polyacrylamide-methylcellulose hydrogels were found highly effective for agricultural applications as an adsorbent for insecticides or as a carrier for agrochemical controlled release [128].

3.3 Applications in Health and Medicals

Cotton cellulose has a long history of application in health and medical areas. A great amount of traditional medical gauze tape and bandage is employed every day in hospitals, although modern gauze tape made of synthetic fibers gradually becomes popular due to its versatile properties such as self-adhesion and antibacterial. Therefore, it is not necessary to dissolve cotton cellulose to prepare cellulose-based hydrogels for this type of applications. However, when advanced applications are required, such as diapers and wound healing contact films, cellulose-based hydrogels are required. Two kinds of cellulose samples including cotton linter pulps and wood pulps are the major feedstock needed for the preparation of cellulose-based hydrogels [129] for health and medical uses. Diapers were the first cellulose-based super-absorbent, initially used in the healthcare industry in 1982 in Japan [120]. They were made from cellulose acrylate which is mostly used as a major functional compound in disposable diapers [130]. In recent years, a new generation of diapers with advanced functions has emerged. Peng and coworker synthesized multifunctional cellulose-based superabsorbent hydrogels by means of cross-linking and quaternization of cellulose in NaOH/urea solution [129]. The resulting hydrogel exhibited a high swelling ratio of 984 g/g and a good antimicrobial property against *Saccharomyces cerevisiae*.

Regarding wound healing and drug delivery, cellulose-based hydrogels play a key role as well. In addition to the traditional use as wound dressing materials, regenerated fibers made of cotton cellulose solution can be obtained by means of electrospinning or wet-spinning approaches. Various modifiers and chemicals can be added during the regeneration of dissolved cotton cellulose to exhibit versatile features of liquid exchange and drug delivery [131]. Further research reported that functionalized cellulose-based hydrogels may work as a temporary skin substitute to compensate the dysfunction of wound tissue, such as providing moisture to wound bed, as well as absorbing wound exudates [132, 133]. However, due to its non-biodegradation in the body, cellulose-based hydrogels are constrained to the long-term use as skin substitutes for chronic wound healing (e.g., second-degree

burn and above). Hu and coworkers performed considerable work to prepare cellulose-based hydrogel bioabsorbable by means of enzymatic incorporation to cellulose-based hydrogels [12, 134]. For drug delivery, a superabsorbent hydrogel synthesized from cotton cellulose and succinic anhydride exhibited an excellent water retention capacity of 400 times its dry weight [111]. This hydrogel can be degraded completely after 25 days, which is a good candidate for a drug carrier vehicle to transfer and release effective ingredients in the body.

4 Cotton Cellulose-Based Aerogels

Aerogels are organic, coherent, highly porous, spongelike, or skeleton-like solid materials formed by the solidification of a colloidal gel network followed by replacing the liquid in the gel with one continuous gas or air [135, 136]. Generally, the preparation of aerogels is completed by removing the liquid from a hydrated interconnected gel network to leave a gaseous phase via freeze-drying or supercritical drying operations, and inversely the process of reabsorbing the liquid makes the aerogels become hydrogels again [135, 136]. When the liquid in the gel is water, aerogels may be deemed as pre-hydrogels. Most of the hydrogels require dehydration or remain a low hydrous level materials to ensure the best absorbability of liquids. Of course, some hydrogels need to maintain a high hydrous level to discharge the desired liquids to the environment, such as hydrogels used for wound healing that require keeping the wound moisture for tissue cell growth [12, 133]. Therefore, this section describes aerogels with super-absorbability and tunable absorbency.

Cellulose-based aerogels possess diverse characteristics including ultralight weight, high internal surface area, 3D porous structure, low density, high rigidity, low dielectric permittivity, and thermal conductivity [137, 138]. Cellulose aerogels are usually prepared from long-chain fibers and their depolymerized forms. The depolymerized forms of long-chain cellulose fibers are mainly microcrystalline cellulose (MCC) and nanocrystalline cellulose (NCC). Acid hydrolysis of native long-chain cellulose fibers derived from wood, cotton, and bacteria can yield low molecular weight cellulose products like MCC and NCC with a DP of 100–1000 [9, 139–142]. Cellulose aerogels prepared from NCCs have attracted special interest due to their enhanced mechanical performance with high axial Young's modulus in the range of 110–220 GPa [143]. NCC can also be used to prepare aerogels with ultralow densities below 5 mg/cm^3, exceptionally high 3D nanostructured porosity in excess of 99%, and high internal surface areas [144]. Figure 7 shows a digital photograph and a scanning electron microscopic (SEM) image of cotton cellulose-derived monolithic nanoporous aerogels. Over the past few years, cellulose-based aerogels have been considered for diverse applications including wastewater treatment and dye removal [6, 126, 145], membranes [146–148], biomedical [148, 149], gas adsorption [150], energy absorbers [151, 152], oil sorbents [153, 154], insulation materials [152, 155], and supercapacitors [156, 157].

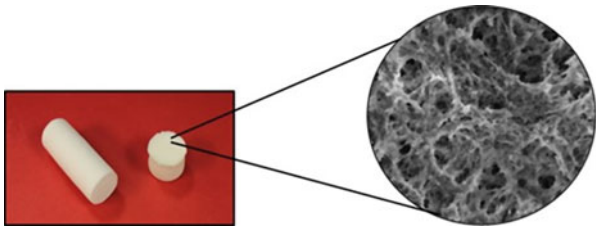

Fig. 7 Digital photograph of cotton cellulose-derived monolithic nanoporous aerogels. (Inset: SEM image of the aerogel at a magnification of 500 nm)

Although cotton contains over 90% of cellulose, there is a scant information in the literature about the uses of cotton cellulose-based aerogels. In this section, we report on the preparation of cotton cellulose-based aerogels and their current applications.

4.1 Preparation of Cotton Cellulose-Based Aerogels

The preparation of cotton cellulose-based aerogels involves five main processes: scouring and bleaching, dissolution, gelation, regeneration and solvent exchange, and dehydration. Scouring and bleaching processes remove noncellulosic materials including pectin, wax, lignin, hemicellulose, and pigments of cotton. The next step is the dissolution of pure cotton cellulose in a suitable solvent. This cellulose solution can be used to cast materials with different shapes such as films, fibers, monoliths, films, or dense powders. Then, the gelation process is facilitated at higher temperatures (50–60 °C) where the particles dispersed in the solution evolve to form a continuous three-dimensional (3D), interconnected, rigid, wet gel-like polymer network extending throughout the solution. The regeneration and solvent exchange step lead to the hydration of gels. This step involves the immersion of the cellulose gel solution in a coagulating bath and frequent replacement of the coagulating bath until the solvent exchange is complete. The final drying step is the removal of solvent inside the hydrated gels without any structural collapse. Figure 8 shows the general schematic representation of the preparation of cellulose aerogels from raw cotton.

4.2 Applications of Cotton Cellulose-Based Aerogels with a Good Absorbency

4.2.1 Oil and Solvent Spillage Cleanup

Oil spillage has become a serious environmental concern worldwide due to the rapidly increasing use and transportation of oils and accidental oil leakage and spillage. Those spillages can cause severe pollution of natural water resources including underground water streams and coastal waters and consequently affecting both human and animal health. Currently used technologies for the removal and separation of oil spillage include chemical treatments [158], bioremediation [159],

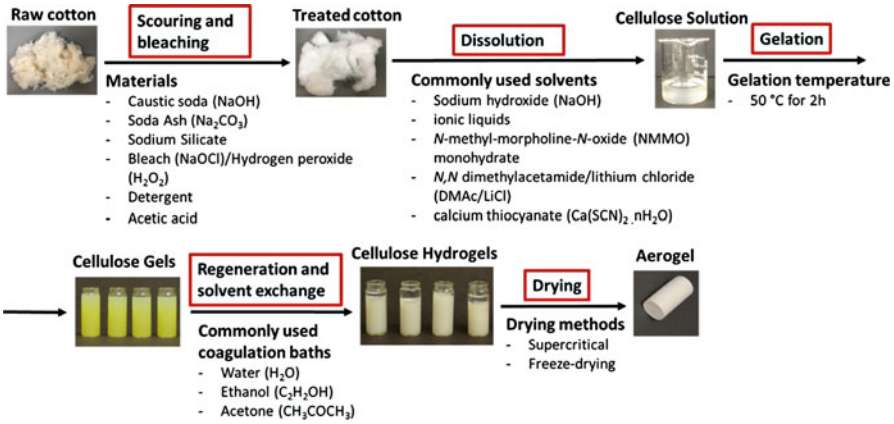

Fig. 8 Schematic illustration of the preparation of cellulose aerogels from raw cotton

and physical methods [160]. Among these, adsorbents used in physical methods are considered as one of the most efficient and effective approaches. Recently, cellulose-based aerogels have been investigated as suitable sorbents for removal of oil due to their natural abundance, sustainability, low cost, and environmental benignity. Cheng and coworkers reported on the utilization of pure cotton aerogels and cotton cellulose aerogels derived from pure cotton and cellulose fiber from paper waste for the adsorption of oil and organic solvents [161]. Cotton cellulose-based aerogels showed a better performance over pure cotton aerogels because of the synergistic effects of two different cellulose fiber sources. The adsorption capacity of the composite aerogel is 72.3 and 94.3 g/g for machine oil and dichloromethane, respectively. Wan et al. investigated the waste motor oil adsorption capacities of cotton cellulose-based aerogels modified by methyltrichlorosilane (MTCS) [162]. These MTCS-modified cotton cellulose aerogels exhibited an adsorption of approximately 14 times of its dry weight. Wang and coworkers also demonstrated the adsorption of diesel oil onto cotton-derived carbon fiber aerogels grafted with nitrogen-doped graphene [163]. Bi et al. investigated the adsorption of oil and organic solvents onto aerogels prepared from twisted carbon fibers (TCF) derived from cotton fibers [164]. They reported adsorption capacity in the range of 50–190 times the initial weight of TCF aerogels with excellent reusability.

4.2.2 Removal of Organic Pollutants and Heavy Metals

With the rapid industrialization and urbanization, a variety of industrial effluents containing organic and inorganic pollutants are discharged into natural water supply. Among those, pollutants such as organic dyes and heavy metal ions are extremely stable and persistent environmental contaminants and could not be eliminated naturally. Therefore, these pollutants pose a major threat to human health as well as aquatic ecosystems. Different approaches including chemical precipitation and adsorption, advanced oxidation and reduction, biological degradation, coagulation

and flocculation, membrane separation, ultrafiltration, and photocatalytic and sonochemical degradation have been employed for the removal of organic dyes and heavy metals [165]. The adsorption technique is considered to be the most efficient physiochemical approach due to its low operation cost and simplicity. Cellulose-based aerogels have been extensively investigated as adsorbents for the removal of organic contaminants and heavy metals. Chen and coworkers studied the removal of organic pollutants (phenol (PhOH), aniline ($PhNH_2$), methyl orange (MO), methylene blue (MB), rhodamine B (RhB), and Victoria blue (VB)) and heavy metal ions (Pb^{2+}, Co^{2+}, Cd^{2+}, and Sr^{2+}) using cotton-derived porous carbon (CDPC) and cotton-derived porous carbon oxide (CDPCO) aerogels [166]. They reported maximum adsorption capacity of 1519 and 1020 mg/g of MB for CDPC and CDPCO. The maximum Pb^{2+} adsorption of 111.1 and 21.2 mg/g was achieved for CDPC and CDPCO, respectively. Li et al. showed the maximum monolayer methylene blue (MB) adsorption of 101.23 mg/g for carbon fiber aerogels prepared from waste cotton [167]. Zhou et al. reported maximum MB adsorption capacity of 2197 mg/g for cellulose-graft-acrylic acid (C-g-AA) hydrogels derived from cotton linters [126]. Melone and coworkers reported on the preparation of ceramic aerogels via one-pot method by mixing aqueous hydrogels of cotton cellulose with titanium dioxide (TiO_2) or TiO_2/silicon dioxide (SiO_2) solutions and subsequent freeze-drying [168]. The calcined ceramic aerogels showed pronounced adsorption and photodegradation efficiency toward MB and RhB dyes.

4.2.3 Energy Storage and Carbon Dioxide Adsorption

The development of energy storage systems such as batteries and supercapacitors has continued to evolve over the last few years due to the variable production of energy from some renewable energy technologies. The energy storage systems have great potential for providing a stable energy supply and ensuring that the supply of energy matches the demand. Recently, supercapacitors have been developed as one of the most promising energy storage devices for their faster charge-discharge rates, excellent stability and cyclic retention, higher power, and minimal charge separation. Carbon materials such as graphene, activated carbon, carbon nanotubes, and carbon aerogels have been broadly used in supercapacitors [169, 170]. Carbon aerogels have advantages over other carbonaceous materials, including high surface area and porosity, excellent electrical conductivity, and high chemical and mechanical strength. Carbon aerogels derived from cotton cellulose have also been investigated for high-performance supercapacitor applications. Hu et al. reported the supercapacitance of 225 F/g and excellent cycle life with 94% of capacitance retention after 5000 charge/discharge cycles for nitrogen-doped carbon aerogels prepared from cotton linters and ammonia as a nitrogen source [171]. They also reported CO_2 gas adsorption of 4.99 mmol/ g for their material. Nitrogen-doped graphene aerogels prepared from raw cotton and urea showed a specific supercapacitance of 107.5 F/g [163]. Tian and coworkers investigated the super capacitance properties of silver (Ag)/polyaniline (PANI)/cellulose aerogel nanocomposite prepared from cotton linter pulp [172]. They reported a specific capacitance of 217 F/g with capacitance retention of 83% after 1000 cycles.

4.2.4 Biomedical

Owing to their high surface area and porosity, interconnected 3D network, biocompatibility, biodegradability, relative abundance, and cost-effectiveness, cellulose aerogels have attracted tremendous attention in a variety of biomedical applications. The applications of cellulose aerogels include tissue engineering, biosensors, antimicrobial agents, ultrasound contrast agents, drug delivery, and disease diagnosis [173]. However, the use of cotton-derived cellulose aerogels in biomedical field has not been fully explored. Wansapura et al. reported on the preparation of cotton cellulose-cadmium-tellurium quantum dot aerogels and its antibacterial activity against gram-positive bacteria, *Streptococcus aureus* [174]. Edwards and coworkers reported on the utilization of nanocellulose aerogels in biosensing of proteases [175, 176]. They prepared peptide-nanocellulose aerogels (PepNA) derived from cotton as biosensors for detecting proteases and reported the detection sensitivity of 0.13 units/mL for human neutrophil elastase.

5 Conclusion and Prospects

Cotton is a worldwide industrial crop which inherits the purest form of cellulose in nature. Most of harvested cotton goes to textile industry to produce fabrics for clothing, tablecloth, medical gauze, and home decoration. Compared to wood cellulose, it is uncommon to use cotton cellulose as a major feedstock to produce hydrogels. Because cellulose dissolution is a prerequisite to prepare regenerated cellulose materials, the high molecular weight and high crystallinity combined with extensive hydrogen bonding of cotton cellulose are the major obstacles for converting cotton cellulose to hydrogel materials. New emerging solvents can effectively dissolve cotton cellulose which can subsequently be converted to various materials including cellulose hydrogels. This review summarizes the current research trends in cotton cellulose-based hydrogels with tunable absorbability and cotton cellulose-based aerogels and their diverse range of applications in agriculture, environment, energy, health, and medical fields.

Abstract

In this chapter, different adsorption mechanisms of cellulose hydrogel will be investigated. For this aim, computational simulation will be used. On an atomistic scale, cellulose hydrogel has different hydrogen bond properties. The OH groups can only act as hydrogen bond acceptors, but due to the negative charge density, there are still more water molecules assembled around adsorbents. Besides intermolecular hydrogen bonding, it has some hydrophobic properties. It means that some hydrophobic materials can be adsorbed on the surface of cellulose hydrogel at specific conditions. Most force fields for this simulation are empirical and consist of a summation of bonded forces associated with chemical bonds, bond angles, and bond dihedrals and nonbonded forces associated with van der Waals forces and electrostatic charge. Empirical potentials represent quantum mechanical effects in a limited way through ad hoc functional approximations.

Cellulose · Hydrogel · Adsorption · Computational simulation

1 Introduction

1.1 Computer Simulations of Cellulose

In the past, coordinates from electron diffraction were widely used as starting configurations for computer simulations of cellulose derivative. But one always has to bear in mind the problems connected with the interpretation of raw data. For example, it is very difficult to determine the chain alignment in cellulose crystals [1]. Meanwhile, in the case of native cellulose derivative, the parallel orientation is established, but this question is left unsolved for regenerated cellulose. Cellulose derivative If consists of parallel sheets of hydrogen-bonded chains. This was confirmed by several simulation studies [2].

Previous simulation of various systems, including glucose, cellobiose, and carbohydrates, has been undertaken. Some authors simulated crystal-like cellulose, but under unrealistic conditions, like mini-crystals with only monosaccharide residues and with vacuum boundary conditions. Aablo and French calculated the energies for various packings of cellotetraose molecules [3]. Intra-chain hydrogen bonding occurs between different intrasheet bonding in adjacent planes (a prime indicating a second glucose ring). The conformational space of cellobiose and higher oligomers under vacuum conditions with respect to glucosidic torsions was explored by Hardy using molecular mechanics, both for charged and uncharged models. In the uncharged case, the minima are in agreement with

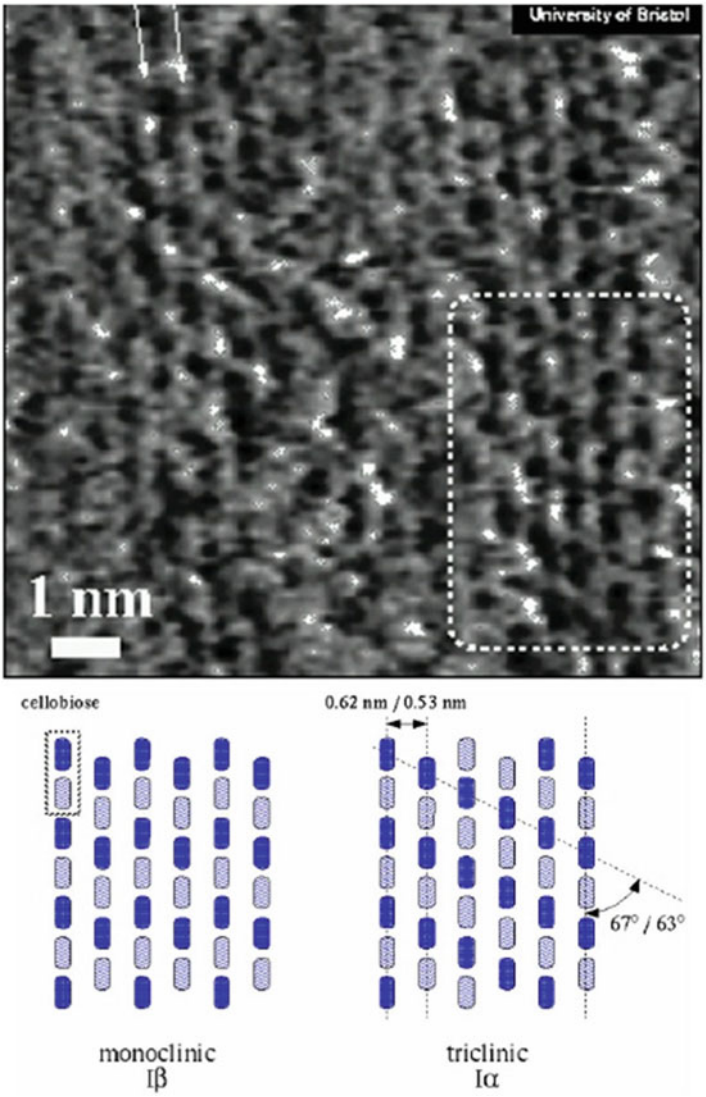

Fig. 1 A software zoom of an AFM image of microcrystalline valonia surface. The arrows point along the cellulose chain direction; the dotted box highlights an area with spots in the length of the cellobiose repeating interval. Bottom: The schematic diagram below shows the expected AFM pattern for monoclinic and triclinic surfaces of cellulose I. Each rectangle represents a single glucose unit [3]

experimental crystal structures of cellobiose and cellulose. However, in the charged model, the appearance of hydrogen bonding distorts this conformation, thereby leading to a new structure [3] (Fig. 1).

1.2 Crystalline Systems and Surfaces

All simulations known from literature deal with the non-orthorhombic unit cells by using monoclinic/triclinic periodic boxes, as implemented in molecular dynamics simulation packages like AMBER or GROMOS. Prework used the cellulose I crystal structure of Blackwell and Gardner, which is now considered to be wrong [4]. Other simulations suffer from a restriction to small systems or from the chosen force field, which does not allow full atomistic details. Recently Heiner performed united-atom simulations of If and If cellulose with the GROMOS force field starting from X-ray diffraction data of Sugiyama. The monoclinic system was built from an ff array of unit cells, the triclinic system from an ff array. Both runs extend over 1000 ns of simulation time. The experimentally observed energy difference between them was confirmed. Most surprising is the small tilt angle observed between glucose ring planes in crystal planes of the monoclinic phase. Alternating chains were termed even and odd; the different tilt angle with respect to the surface was attributed to better interplane hydrogen bonding. More details about the hydrogen bonding pattern were determined using radial distribution functions and energy calculations [2]. The only existing simulation of an cellulose surface was performed by Heiner. In the first paper, the crystal face and, in the second paper, both of them and surfaces were exposed to water. Only the topmost cellulose layers are structurally affected by hydration. The cellulose properties of the interface layers (which are in contact with the solvent) differ only slightly from that of the crystal's bulk. The odd/even duplicity is absent in the interface layers toward water for If and If cellulose, and there are changes in the hydrogen bond patterns, due to completion of cellulose-cellulose bonds with cellulose-water hydrogen bonds. The cellulose-water interface for both the monoclinic and triclinic crystals was classic [5]. From a comparison of the surface-water pair distributions, the monoclinic and the triclinic surfaces are found to be more hydrophobic than the monoclinic and triclinic surfaces. This becomes evident from the first hydration peak, which is repelled from the surface and more unpronounced. In their second paper, the authors focus on similarities and differences between different cellulose surfaces. They found the monoclinic and triclinic surfaces to be very similar. Likewise, the monoclinic surface is similar to the triclinic surface [6]. The latter surfaces are denser and more hydrophilic than the former two. As for f, the odd/even differences disappear on the cellulose-water interface [1] (Fig. 2).

1.3 Carboxymethyl Cellulose

Cellulose is further substituted to cellulose esters and ethers, by either reaction with acid anhydrides or halogen-carboxylate, respectively. An example for cellulose ether is carboxymethyl cellulose (CMC), which is gained by basic conversion of cellulose slurry with sodium chloroacetate or chloroacetic acid [7]. CMC is mass-produced, because of its versatile properties. It is used as thickener, former, or protective colloid. Consumer care products take advantage of its nontoxicity, and it is employed particular for foodstuff and as soil redeposition inhibitor [8]. CMC has a high affinity

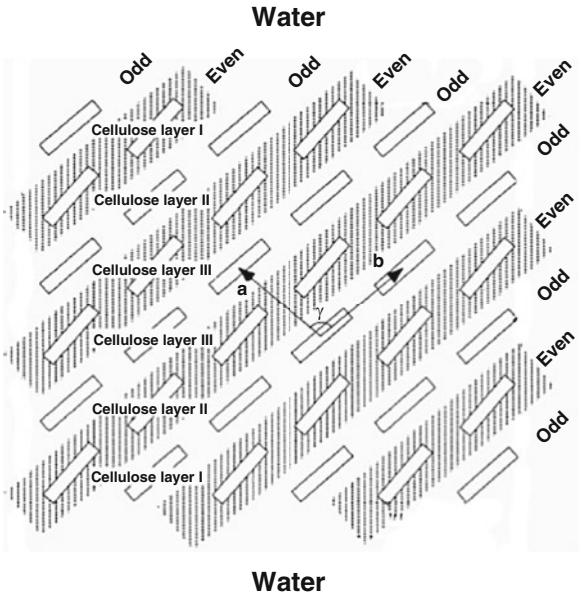

Fig. 2 Schematic picture of the simulation cell of Heiner, taken from. The sketch shows a monoclinic cellulose crystal, the 110 surfaces (top and bottom) exposed to water. Alternate even and odd 200 crystal planes are shaded white and gray. Glucose rings of even 200 planes are tilted with respect to the 200 planes and glucose rings of even planes [1]

to cellulose, and it is therefore a good coating for textiles. CMC coatings improve paper properties, like ink and surface gloss. Crude commercial-grade CMC is produced for detergents, for oil-drilling, or for the paper industry. Product properties of CMC are mostly determined by the degree of substitution (DS) and the substituent distribution within one anhydroglucose unit (AGU) and along the CMC chain. The degree of substitution ranges from zero (no substitution) to three (all three hydroxy groups of a glucose unit substituted). In the case of heterogeneous cellulose derivatization, statistical substitution patterns and polydisperse CMC are produced. The chemical characterization of CMC is almost restricted to the average degree of substitution, which is measured by titrimetric methods or chromatography where the persistence length of CMC is found by size exclusion chromatography to be 20 nm [9]. Owing to this, only little information is available on the interplay between the CMC structure (substitution pattern, degree of substitution) and its macroscopic properties. The actual substitution pattern of industrial cellulose derivatives can be rationalized by both kinetic and energetic arguments if cellulose is produced as alkaline slurry. Hydroxyl groups can only be carboxy-methylated if the bulk cellulose is swollen and hydroxyl sites are free from hydrogen bonding and accessible to the solvent and substituting agent. The carboxy methylation reaction takes place at the solvent-cellulose phase boundary [10]. From this, the dynamics of swelling and hydrogen bond cleavage are responsible for the degree of substitution and the

substitution pattern. The glucosidic linkage of CMC was hydrolytically cleaved, and on this way, information on the distribution along the backbone was lost. The same results can be found by high-pressure liquid chromatography, which allows separating and identifying differently substituted units. There are eight different substituted monomer units possible. CMC polyelectrolyte properties are only understood from a technical point of view. There is a good experience how to tailor a CMC through the production procedure to a certain property, like a high viscosity. The underlying molecular chemistry is still beyond our knowledge. The missing link between microscopic structure and macroscopic properties can be established by molecular dynamics simulations [11].

1.4 Nanocellulose

The various forms of nanomaterials that can be produced from cellulose are often collectively referred to as cellulosic nanomaterials or nanocellulose [12]. For example, the extraction of cellulose nanofibrils (CNFs) and cellulose nanocrystals (CNCs) from plants, bacteria, and some animals (e.g., tunicates) is leading to a wide array of worldwide research to use these nanomaterials in product applications [13, 14]. Examples include using CNFs as reinforcing agents in composites due to their high strength properties, relative low cost, and availability or CNCs due to their incredibly high strength (Fig. 3), renewability, lightweight, high surface area, and unique photonic characteristics [15]. As you will see when reading this book, research and development is currently taking place worldwide within academia, industry, and government agencies to study, characterize,

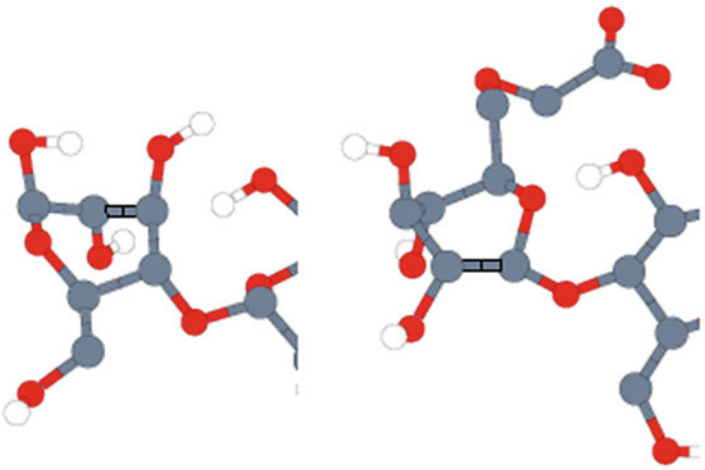

Fig. 3 Two terminal anhydroglucose units during the initial phase of a CMC I equilibration. The 4C1 conformation is lost and the OH oxygens take an axial position. Both rings are twisted neither in a proper chair nor boat form

and use these highly complex cellulosic nanomaterials. Nanocellulose in its various forms contains unique structures and self-assembly features that we can exploit to develop new nano-enabled green products. A specific example is the use of cellulosic nanomaterials in lightweight, high-performance composites. Such nanocellulose-enabled composites could eventually replace carbon fiber mats and strands by weaving cellulose-derived nanomaterials and fiber into mats. This could lead to replacement of the nonrenewable and fossil-based materials currently used to make automotive parts such as dashboards, seats, floor mats, and even body panels or frames. The world may not be ready yet to step back into a wooden airplane, but the day will come when aircraft will have wings and fuselage components containing lightweight, high-performance nanocellulose-enabled composites. Fiberglass is a common composite with which most people have experienced. It is used to manufacture diverse products including tool handles, sporting goods, bike frames, boats, and even the bodies of some sports cars. Fiberglass cannot be made transparent and is a heavy material for a composite. Replacing fiberglass mat with nanocellulose-containing mat could lead to new lighter-weight materials and the eventual replacement of nonrenewable products with sustainable and renewable cellulosic materials [14].

1.5 Polyelectrolytes

Polyelectrolytes play an important role in industrial chemistry. The fields of application range from tailor-made thickeners to paper finishing or ore preparation. Polysaccharide derivatives represent one interesting class of polyelectrolyte. In particular, cellulose products are important compounds [16]. For our simulation study, carboxymethyl cellulose (CMC) is chosen as an example for a polyelectrolyte derived from a natural polymer [17]. Aqueous CMC solutions exhibit valuable properties, like a wide range of viscosity, nontoxicity, and biodegradability. Particularly for the high-purity consumer-product market (cosmetics, food stuffs), CMC is used. However, pricing becomes more important in bulk applications (clay and ore treatment, oil-drilling). Hence, it is desirable to replace some of the high-cost high-selective chemicals with low-cost equivalents, like polypeptide, which is the prototype of medical synthetic polyelectrolytes. Polypeptide is the other polymer studied in this work. Most published works on aqueous CMC and polypeptide solutions were done experimentally using chromatography, C nuclear magnetic resonance, and rheological techniques [18]. Theoretical approaches are scarce. We are aware of only one paper, which treats CMC by the wormlike chain theory. This electrostatic theory successfully rationalizes some of the global properties of CMC, but as a rather generic approach, it does not allow for detailed predictions on an atomistic time and length scale. Similar restrictions apply also to Monte Carlo simulations of polyelectrolyte chains in a cell model, where the solvent is treated as a dielectric continuum. Especially local interactions such as hydrogen bonds (hydrogen bridges) are neglected in theories and non-atomistic simulations. With two or

three hydrogen bond donor groups per repeat unit and even more acceptor sites (including charged COOH groups), this type of interaction is likely to be very important for the behavior of CMC in water. Experimental techniques, on the other hand, suffer from different problems: NMR provides averaged local properties. Rheology derives and verifies scaling laws, but different polyelectrolytes lose their chemical identity and show the generic behavior of excluded volume chains. Atomistic molecular dynamics (MD) simulations cannot overcome all these problems, but they can provide some more detailed information [19].

Polypeptide is important for industrial applications because of good water solubility and as a (strong) model polyelectrolyte in science. Polypeptide is known for only weak adsorption to cellulose but binds with hydrophilic glass (SiO_2) surfaces. At high concentration, polypeptide forms networks, cross-linked by hydrogen bonds and entanglements. The water structure around the polyelectrolyte was investigated by Tsukida et al. using Raman spectroscopy. They found a high perturbation of water-water hydrogen bonds at a degree of neutralization below 10 and concluded that a certain amount of carboxylic groups enhances water-hydrogen bonds in the polymer vicinity. There is a minimal disruption of hydrogen bonds near a degree of neutralization. Even at higher ionization, polypeptide is assumed not to be fully stretched. The local conformation of polypeptide is assumed not to be dependent on ionization or salt concentration. Like in the case of CMC, no experimental method has been applied, which goes beyond a macroscopic view of PP. Methods applied to polypeptide are rheology, viscometry, light scattering, and calorimetric methods. The only simulation work was done by Ullner et al. This is a Monte Carlo study of one polypeptide chain in solution. But even though counterions are accounted for explicitly, the simulation is done in the generic cell model for polyelectrolytes [20]. However, there is some agreement that polypeptide behaves like a flexible coil in a “good solvent” instead of having rodlike structure. One aim of this thesis is to understand better the structural and dynamic aspects of the hydration of CMC and polypeptide and to compare the two polymers. To this end, we investigate both the chain properties and the interaction of chains with their immediate solvent environment. Atomistic simulation is confined to the study of small system sizes. However, in combination with coarse-graining methods, even some mesoscopic properties may be explored. Thus, a second goal of this study was to produce atomistic structural information, from which coarse-grained models of, e.g., polypeptide and the cellulose surface can be generated. The coarse-grained models can be used to study the adsorption of polyelectrolytes on cellulose beyond the size and time limitations of atomistic molecular dynamics [21].

2 Materials and Methods

Computer simulations came into fashion among scientists, as fast hardware became affordable. Early computer simulations were done on the MANIAC computer in Los Alamos by Metropolis and Rosenbluth. From this milestone in scientific computing, character and size of simulated systems changed. In the first

years, there was research to develop, validate, and try new methods, even with simple systems like hard spheres, where often a theoretical solution was already present. With the Lennard-Jones potential, it was possible to compare the outcome of simulations with experimental results. There was a need for a new method to simulate not only static properties (ensemble averages) but extend simulation to explore dynamical (transport) properties as well. Molecular dynamics (MD) is the new technique. If a given system follows Newton's equation of motion and we know one state of the system, then we can calculate every state of the system (both in the future and in the past). Classical particles are moved by integration of the system's equation of motion in time. By means of this, a molecular dynamics simulation is very simple; after initialization, the simulation cycles through successive molecular dynamics steps. For each step, the force is calculated, particle velocities plus positions are updated, and finally, properties of interest are sampled.

This was first done for hard spheres by Alder and Wrainwright and later by Rahman for Lennard-Jones particles. Later, the method was extended to molecular systems (by the introduction of bonds) and different algorithms devoted to handle different ensembles and conditions like nonequilibrium molecular dynamics. In particular, the Lennard-Jones potential has proven useful, and it is the most common model for nonbonded interactions.

The work of Rahman was pioneering, because it showed the benefits of molecular dynamics simulation over theoretical approaches, which often fail to describe. Moreover, MD is valuable also for nonideal, multiparticle systems. One recent example to show the versatility of the method is the dissipative particle dynamics method. Even if it is still based on the simple molecular dynamics scheme, it can be used for mesoscopic simulations through a modified equation of motion. The second route to handle large systems is to use more elaborated programs on multiprocessor computers. This enlarges the number of simulated particle from about on a workstation to several million particles on a supercomputer. To mention but a few trends in atomistic molecular dynamics, these are the calculation of free energy-related properties; the application to larger molecular systems, like polymers or biopolymers; the programming of user-friendly simulation programs to allow for easy standard calculations; and the development of new and better force fields. The last item development of force fields is very crucial. Although there exist a variety of different force fields, none of them describes all faces of a system completely. In consequence, there are many force fields available, and it is not always clear in advance, which one will give the best results to our questions. In other words, there is nothing like unique natural force fields for a given molecular or system: Even approaches with a high number of terms do not necessarily give good results [22]. The general layout is almost the same for all common force fields. They divide interactions into nonbonded (Lennard-Jones dispersion repulsion interaction, Coulomb electrostatic interaction) and bonded (bonds, angles, torsions, etc.) [23]. Some force fields employ special terms to treat hydrogen bonds or similar phenomena, but this is not very common, as a good description may be obtained by other terms as well.

2.1 Force Fields

While the kinetic part of the Hamiltonian uses only particle masses as parameters, the potential energy part is dealt with by a force field. The force field is the major choice or input of a simulation. It gives an expression for the potential energy as a function of particle coordinates (r). This expression consists out of different terms, which are usually chosen intuitively to mimic the nature of molecules. The splitting of the potential energy into a sum of bonds, angle, and other terms is arbitrary and only rejects a human understanding of chemistry. The second approach to a force field is the pragmatic, technical one, where terms are not even meant to have a special physical meaning but originate from some technical issue or procedure. To name but a few technical force field contributions, there are position restraint terms to keep atomic sites fixed in space or bond constraints to keep the distance between atoms constant. Nevertheless, the use of force fields instead of true electronic interactions has proven useful in lots of simulations from simple Lennard-Jones systems to much more complex molecular systems.

2.2 Nonbonded Interaction

The separation of a force field into distinct mathematical terms in molecular simulation is justified usually by computational convenience or reasons of transferability. There is no question that all interaction would have to be calculated by quantum mechanical methods. Unfortunately, this way is by far too time-consuming, even if fast semiempirical methods are employed. For systems with more than several thousand or even hundreds of thousands of atoms, it is inevitable to use a force field with pairwise additive terms. All electronic degrees of freedom are ignored, and every atom is taken as the position of its nucleus. Methods which rely on this statement are commonly summarized under the term molecular mechanics. Energy functions are called "effective potentials," as they try to incorporate many-body effects into a site-site potential. They do not resemble the potential as it would be correct for two interaction sites in vacuum but are representative for say two argon atoms in liquid argon. On one hand, this is an important breakthrough, as we do not bother about the explicit calculation of many-body terms, but on the other hand, this may reduce transferability of a parameter set, as there is an influence of the environment onto a single site's force field parameters. This leads to a rough categorization into force fields for inorganic (crystal) and for organic (soft) matter and for solutions, the latter one with a special emphasis on water as solvent. Some force fields are very biased toward aqueous solutions of (bio) organic compounds like DNA or carbohydrates. To achieve transferability, which is often considered a key property of force fields, the energy function is divided into several contributions. To name but a few, there is a bond term, often modeled by a spring, or a bond angle modeled by a harmonic angle

potential. Nonbonded interactions are divided into electrostatic and dispersion/repulsion (induced dipole, Pauli repulsion) contributions:

One example is the dispersion energy, which is often expressed as a (computationally cheap) Lennard-Jones potential, but some approaches use the Buckingham form, which models Pauli repulsion using an exponential function. Knowing the potential between two sites is only the first steps toward calculating the energy of a N-body system and all forces. Instead of using an order N double loop over all site-site combinations ij, the most efficient way is the use of a cut of rc together with a neighbor list to speed up the simulation by a factor of order N. This is a point where physical and technical issues meet and compete. From a physical point of view, one wants to take the cutoff as large as possible, but with limited computer resources, one should take it as short as possible.

2.3 Bonding Interaction

Bonding interactions are somehow better to understand, because their concept is rather intuitive. Usually they define some minimum energy state in terms of an equilibrium angle or bond distance. Deviations from this value impose an energetic penalty. The only exception are bond lengths, which if treated by a harmonic spring would require very tiny time steps and are thus not feasible. The bond vibrations of large molecules are of no interest. Therefore the harmonic bond potential is replaced with a rigid constrained bond, which on the one hand introduces additional calculations into the molecular dynamics simulation but on the other hand allows increasing the integrator's time step ft by one order of magnitude.

2.4 Constraint Dynamics

The SHAKE procedure of Ryckaert, Ciccotti, and Berendsen is one of the most explained and cited paper in molecular dynamics. The SHAKE method allows us to consider atomic connectivity without using harmonic bonds. Valence bonds vibrate at high frequency and impose a small integration time step to a simulation. SHAKE now alleviates this shortcoming by fixing (constraining) the distance r between two sites to a parameter value. This equality is usually written down in the form of a holonomic constraint.

First the unconstrained motion of all atoms is calculated and after the equation of motion is expanded by the introduction of a constraining force (as a Lagrange multiplier). The resulting equations of motions are now solved in an iterative fashion until all constraints k in the equation are within some tolerance. Our simulation packages use a special SHAKE algorithm, which performs well on vector machines like the Cray T or NEC SX.

2.5 Other Force Field Terms

Besides the nonbonded Lennard-Jones and Coulomb interaction and the constrained bonds, there are several other force field terms. They are computationally cheap and more generic as, for example, the nonbonded potential parameters. Examples include bond angles and bond torsions.

2.6 Periodic Boundary Conditions

Periodic boundary conditions are the way to generate pseudo-infinite systems, thus simulations which do not suffer from boundary or edge effects. Periodic boundaries are achieved by putting a grid of copies around the central simulation box. The algorithm ensures that no interatomic distance in one direction is larger than one box length (this holds strictly only for orthorhombic boxes). To calculate the force on a site in the central box, neighbors from the central and surrounding boxes are used, if they are within the cutoff distance. If one atom travels out of the central box, it reenters at the opposite side of the box. The internal coordinate format does not store these folded but unfolded coordinates, so that the folding is applied in the force loop. To avoid self-interaction, the box has to be larger than two times the cutoff.

3 Results and Discussion

3.1 Interactions and Force Fields

The actual parameterization of the GROMOS force field for carbohydrates has evolved since 2000 and was mainly tested on cyclodextrin, as well as on other sugars. Kroon-Batenburg, Bouma, and Kroon made use of the GROMOS parameter set for simulations of cellulose in solution and compiled an overview of different parameter sets in conjuncture with Ewald sums by Kouwijzer et al. One application of the GROMOS force field to crystalline cellulose was reported by Heiner, Teleman, and coworkers. Their simulations covered both the crystalline phase of cellulose and the interface with water. The successful simulations and the compatibility of the GROMOS force field terms in particular the treatment of electrostatics without an Ewald sum were decisive factors to choose the GROMOS force field. A second point is our interest in multicomponent, heterogeneous systems, with both a cellulose surface, a solvent, and a polyelectrolyte solute molecule. Our force field of choice should be able to give a good description for every component, not only of the sugar. So the use of a building block based and thus force field is sensible. However, there are plenty alternatives for carbohydrate force fields. Besides generic ones, like AMBER, CHARMM, and the OPLS, parameter sets, some authors developed special approaches for carbohydrates. Most of these expert models

have some special application in mind, like the exploration of anomeric equilibrium of sugar rings. An overview is given by French and in various articles published in a special issue Carbohydrate Modeling of the *Journal of Molecular Structure*. A recent approach was done by Neyertz et al. to develop a cellulose all-atom potential model from various origins (mainly from other sugar parameters and quantum chemistry). Despite the mixed sources, the Neyertz approach reproduces unit cell parameters, thermodynamic stability, and moduli in close agreement with experiment. Tests or applications for this force field in solution are not known yet. The authors develop the force field with PEO-cellulose interface simulations in mind. In contrast to the Neyertz model, the GROMOS approach is a so-called united-atom force field. Aliphatic oxygens are not modeled by an explicit interaction site. Only polar/OH hydrogens are explicitly treated. Aliphatic hydrogen atoms are accounted for by a change of the parameters for the parent carbons, which grow in size (+%) compared to all-atom force field (like AMBER) and get a higher minimal energy (+%). For organic materials, this has proven feasible if the stereochemistry at chiral centers is preserved using additional terms in the parameterization. The GROMOS force field tackles this by harmonic dihedral angles, which fixes four atoms in a given tetrahedral geometry. The major benefit is the reduced amount of computer time. However, for our cellulose-water systems, the savings are less pronounced. Even if the united-atom model removes one third of all atoms for a glucose ring (aliphatic hydrogens), there is still the large amount of polar hydrogen sites left.

Torsions in the GROMOS force field are considered by (a) the torsion potential and (b) modified interactions. United atoms separated by exactly three bonds interact through a reduced Lennard-Jones potential. For atoms other than united atoms, the interaction is not modified. The sum of both terms results in a physical torsional potential. There is usually only one torsional term for each bond i-j-k-l, but this rule is changed for sugar rings, where additional torsions guarantee for the correct ring puckering. All interactions are dealt with by some force field term (bonds, angles); all atom pairs with a topological distance greater than four bonds interact by unmodified nonbonded interactions. We make use of an effective model potential. This is because the parameter set is chosen to incorporate many-body effects by the physicochemical environment. For example, charges are taken to reproduce average polarization effects by the solvent. Because of this, we avoid mixing of different force fields and used SPC-water (simple point charge) throughout, where parameters harmonize well with the GROMOS cellulose force field. Furthermore, it is a rigid model, and it has the minimal number of sites, which makes it computationally efficient. The CMC and polypeptide force field terms were taken to be compatible with the cellulose parameters. Because of this, CMC and polypeptide are modeled with the GROMOS force field as well. The CMC parameterization is based on cellulose, with extra parameters for the CH–COOH group. The CH parameters were taken from an aliphatic sub-chain in the GROMOS force field, and the carboxylic group is an generic parameter set which is used for all kinds of carboxylic acids in the GROMOS handbook.

3.2 Computational Details: Polyelectrolyte in Dilute Solution

For the polyelectrolyte simulations in dilute solution (CMC and polypeptide with counterions but without a surface), a single oligomer was solvated in about (see below for exact numbers) water molecules. The water configuration has been prepared from a cubic centered lattice by an equilibration run of 1000 ps until density converged. The initial polyelectrolytes' configurations were generated from a Z-matrix for a linear molecule. The sodium counterions were placed into the simulation box at random but not closer than 5 nm to any atoms of the solute. All coordinate sets were joined together, and overlap was removed by either f removing water molecules, closer than 9 nm to any of the solute atoms, or f pushing overlapping water molecules away from the solute: All water molecules in the vicinity of the solute are moved away from the polyelectrolyte along a solute water vector r, defend for every water molecule. The displacement vector starts at the polyelectrolyte site, which is closest to the water oxygen and ends at this oxygen. The length of the vector is scaled by an exponential decay function (jrj = c); c was chosen by trial and error to be nm. Water molecules far apart from the solute are hardly displaced at all (Figs. 4 and 5).

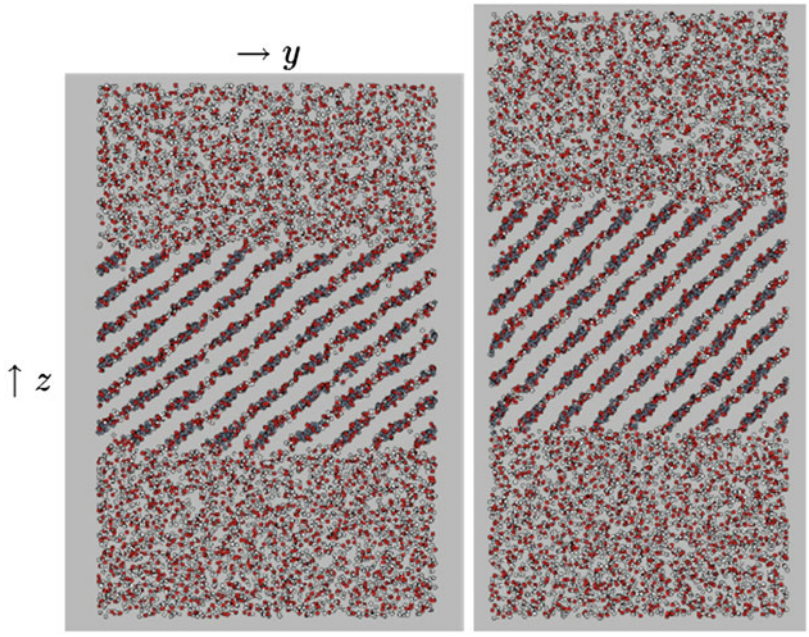

Fig. 4 Pictures of surface-water simulations after equilibration of about 400 ps. Left: 110-cellulose (wide), Right: 1–10-cellulose (narrow). The cellulose chains run into the drawing plane (x-direction)

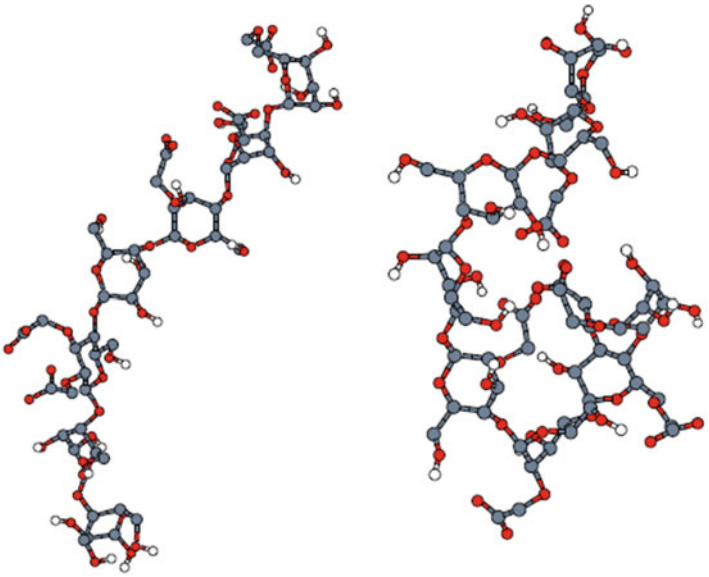

Fig. 5 Snapshots of CMC I (left at 2:0 ns simulation time) and CMC IIa (right at 3 ns)

3.3 Computational Details: Cellulose Surfaces

We examined two different cellulose-water systems: The first one with an interface between the monoclinic surface and water and the second one with the monoclinic surface exposed to water. The simulation setup is almost identical with that used by Heiner. A slab of six cellulose layers has two interfaces toward water. The z-axis of the periodic box is parallel to the normal of the respective surface. The cellulose crystal's c-axis (chain direction) runs along the Cartesian x-axis. Eight cellulose chains of each three cellobiose units are staggered with a shift of c = along the periodic box's y-axis. However, the simulation of the monoclinic cellulose surface employing an orthorhombic simulation box leads to some distortions of the molecular coordinates. The deviations from the native monoclinic structure are minor and were neglected. The exact procedure, to change the unit cell's geometry, is described. In the angle, from a small change of the monoclinic cell, we arrive at a unit cell which packs into an orthorhombic lattice.

3.4 Computational Details: Aqueous Polyelectrolyte-Cellulose Systems

The third kind of systems examined was the combination of the two systems above: A cellulose-water interface simulation with CMC or polypeptide oligomers dissolved in the aqueous phase. As the oligomers of CMC and polypeptide described

above are too large to fit into a reasonable sized cellulose-water simulation box, we used smaller oligomers: For CMC the first molecules, CMC I was cut into two pieces, a trimer and a tetramer with molecular weights.

With two polymers and two different surfaces, we have four possible solute-surface combinations. The polymers are irregularly placed into the dense water system, by shifting water molecules away from the solute atoms radically as described on page 14. By this procedure, we obtain suitable starting coordinates without overlapping atoms. The cellulose sites are fixed in space using position restraints, and the system is quenched into a low energy stat, and equilibration is started afterward without position restraints. All simulation parameters (temperature, time step, weak coupling, etc.) are as for the cellulose-water system. Cellulose and water coordinates are taken from the respective cellulose-water simulations. an overview over all four solute-surface simulations.

The carboxymethyl side groups are strong H acceptors, because of their flexibility from the carbohydrate backbone and because of their negative charge. The globular CMC conformation is both stable through a multinanosecond simulation and builds dynamically from a stretched starting geometry. On a local scale, the globular conformation undergoes less hydrogen bonding with the solvent, as more intramolecular H-bonds are present and some H-donor and acceptor sites are buried inside the globule and are not accessible to water. This is also visible in the CMC-water radial distribution functions, where the globule state has a more distorted and irregular hydration shell. The polypeptide oligomer in aqueous solution is stretched and is readily solvated by water molecules. Because polypeptide has a high charge density on COOH groups, the mass of salvation water exceeds the polymer's own mass by a factor. The hydrogen bonding for CMC is more complex. There is inter- and intramolecular hydrogen bonding, latter one can be subdivided into inter- and intraglucose-ring bonding. For the collapsed, globule CMC molecules, all kinds of H-bonds are found in a significantly amount. Most remarkable are H-bonds spanning six or seven glucose rings, thus closing the CMC chain to a ring [24].

There are only few counterions close to the CMC strand (about Na^+-ions/AGU). The PP sodium radial distribution function is better defended due to the higher number of counterions. There are about sodium ions under the first peak of the PP-Na^+-rdf. The difference between CMC and polypeptide is understood, as the main interaction of sodium takes place with the carboxylic side groups of the polymers, which favors PP [23]. Counterions play a role during the (dynamic) collapse of the second CMC molecule. Simultaneous with the collapse, the number of sodium ions close to the backbone raises. The increased concentration of positive charges screens the repulsion of COOH groups and initiates the collapse. Two crystal planes of the monoclinic cellulose crystal were simulated for several nanoseconds with an interface to water. Both surfaces are representative for other surfaces like the triclinic ones. The surface has a wider interchain spacing than the surface. Both surfaces are stable against water and they are not penetrated by the solvent. This is due to the mainly hydrophobic and lipophilic character of both surfaces. This property has been accessed either through water densities on the surface [25].

4 Conclusion

Even though poly(acrylate) and (carboxymethyl) cellulose both are water-soluble polyelectrolytes, their behavior in water and toward water differs markedly. This is due to the different charge densities as well as to the different types and qualities of hydrogen bonds that either form with water. In PP, there is one strong hydrogen bond with the deprotonated carboxylate acting as an acceptor. In CMC, the smaller density of carboxylates is only partly offset by the possibility of alcoholic OH groups participating both as donors and as acceptors in hydrogen bonds. Hydrogen bonds to the ether oxygens are irrelevant. Taken per molecular weight of the polymer, it seems safe to say that polypeptide forms at least twice as many hydrogen bonds to water as CMC and that they are of larger binding energy (charge-dipole, rather than dipole-dipole). Based on this argument, the salvation of polypeptide in water should be more exothermic than that of CMC. Unfortunately, no measurements appear to be available for comparison. The comparison of the two CMC oligomers shows that the particular carboxymethylation pattern has an immense influence on the local structure in solution. The two assume entirely different conformations: CMC I is stretched and flexible, whereas CMC II favors a rigid cyclic conformation. We are therefore left to conclude that industrial CMC with its statistical substitution of OH groups behaves locally very diversely. As a consequence of its globular structure, CMC II shows more intramolecular hydrogen bonds than CMC I, fewer hydrogen bonds to water, slower hydrogen bond dynamics, and more contacts with the counterions. Aqueous polyelectrolyte solutions of carboxymethyl cellulose (CMC) and poly(acrylate) (PP) have been investigated. With respect to the size and CH-COOH distribution pattern, two aqueous solutions of different CMC oligomers (one heptamer and octamer) result in two chain structures: We observe one stretched structure, which is for a polyanion is rationalized by repulsion of negative charges, and a globule-like, collapsed structure. The compact structure is held together by intramolecular hydrogen bonds, which bridge multiple anhydroglucose units and often involve COOH groups.

1 Introduction

Hydrogels are three-dimensional hydrophilic polymeric networks and are typically soft and elastic, owing to their compatibility with water. Cross-links and interconnections, which make polymer chains get together, can be formed by physical entanglements or chemical bonds, leading to physical and chemical hydrogels. Chemical hydrogels can be formed by chemical reactions such as radical polymerization [1], photopolymerization [2], high-energy radiation [3], and covalent conjugation [4]. These hydrogels generally show good physical stability and mechanical strength. Physical hydrogels are composed of polymer self-aggregation via non-covalent interactions such as hydrogen bonds [5], hydrophobic interactions [6], electrostatic interactions [7], inclusion complex [8], π–π stack [9], ionic interactions [10], crystallinity [11], and other affinity interactions [12]. These hydrogels exhibit excellent swelling and absorption capacities. Based on the raw materials and synthetic methods, the hydrogels can be classified to be petroleum-based hydrogels or bio-based hydrogels, covalent or physical hydrogels, copolymer networks or interpenetrating networks, degradable or nondegradable hydrogels, and so on. Due to their unique characteristics, hydrogels have been extensively studied in bioscience and material science and widely applied as functional materials, for example, contact lenses [13], disposable diapers [14], wastewater treatments [15], and moist pads for healing wounds [16] or burns [17]. In this chapter, we would like to introduce the advanced research and applications as follows: (1) adsorption hydrogels, (2) stimuli-responsive hydrogels, and (3) self-healing hydrogels.

2 Adsorption Hydrogels

Attributed to the network structure, hydrogels have excellent adsorption capacity to absorb large quantity of water and keep stability. Through designing functional molecular or modifying natural products, the hydrogels can provide complexing sites for the templates as adsorption materials. Recently, lots of researches are dealing with the use of hydrogels for adsorption materials, and also many researchers are investigating the hydrogels for wastewater treatments.

2.1 Wastewater Treatments

With the development of industry, environmental pollution has received great attention and became the focus of research. Water pollution, especially heavy metal ions and organic dye, is a menace to health. Many methods are used to purify water, such as chemical separation, electrochemical separation, adsorption, and cation exchange. Among these methods, adsorption is the most high-efficient method with high adsorption capacity, selectivity, and reusability. In recent years, many researchers pay attention to natural materials and polymer composites for the removal of pollutants from water, which have received excellent achievements.

2.1.1 Broad Adsorption of Heavy Metal Ions

Biomaterials, such as cellulose, chitosan, and their composites, are fitful to be the matrix to prepare adsorption materials for heavy ions [18–22]. A typical composite is cellulose–polyetherimide (PEI) composite hydrogel [23]. It was prepared in alkali/urea solution system with PEI as functional group and cellulose as skeleton in Fig. 1. The composite hydrogel showed good adsorption capacity of heavy metal ions such as Cu(II) 253.8 mg/g, Ni(II) 112.2 mg/g, Zn(II) 148.4 mg/g, Cr(III) 30.4 mg/g, and Pb(II) 248.2 mg/g as shown in Fig. 2. The thermodynamics and kinetics of the system were also studied. The adsorption process followed pseudo-second-order kinetics equation, and the adsorption capacities of cellulose/PEI composite hydrogel were much higher than activated carbon-based adsorption materials. Hence, cellulose/PEI composites could be potential materials for wastewater treatments and the recycling applications of heavy metal ions.

(**b**) The adsorption capacity of cellulose/PEI composite on Zn(II), Ni(II), Cr(III), Pb(II), and Cu(II). Conditions: cellulose/PEI composite (CP-2); initial concentration, 1000 mg/L; adsorption contact time, 80 h; room temperature

Because of efficient separation, magnetic technology has become an attractive method to solve the recycling problems of adsorption material. In recent studies, carboxylated cellulose nanofibrils(CCNFs)-filled magnetic chitosan hydrogel beads [24] (m-chitosan/poly(vinyl alcohol)/CCNFs) were prepared by an instantaneous gelation method as shown in Fig. 3. The magnetic hydrogel was used as adsorbents for Pb(II) ions (171.0 mg/g). The adsorption isotherm was fitted by the Langmuir model and the adsorption kinetics closed to pseudo-second-order model. Moreover, the hydrogel could be easily separated by magnetic field and regenerates in weak acid solution. It showed good reusable ability after four cycles keeping 90% adsorption capacity. M-chitosan/poly(vinyl alcohol)/CCNFs hydrogel could be considered as a promising adsorbent for the removal of Pb(II) ions for the high adsorption capacity, fine biodegradability, and the ability to be rapidly separated from aqueous solution (Fig. 4).

2.1.2 Selective Adsorption of Metal Ions

Sometimes, we need to recycle some certain metal ions, for example, lithium ion. Due to the large solubility product constant of lithium carbonate, the lithium ion is very difficult to be completely retrieved. Many methods have been developed to retrieve lithium ion, such as biological recovery, precipitation recovery, and adsorption recovery. Among them, adsorption is a cost-effective and environmental friendly method for recovering lithium from aqueous solution. However, most adsorbents are nonspecific, showing low selectivity toward a specific metal. Therefore, a novel magnetic ion-imprinted polymer (IIP) with a core–shell structure (Fe_3O_4@SiO_2@IIP) [25] was synthesized by a surface imprinting technique using 2-(allyloxy)methyl-12-crown-4 as the functional monomer, lithium ion as the template, and ethylene glycol dimethacrylate as the cross-linker (as shown in Fig. 5). Fe_3O_4@SiO_2@IIP showed fast adsorption kinetics for lithium ion (10 min to reach complete equilibrium), and the adsorption process obeyed an external mass transfer model. Homogeneous binding sites were proved by the Langmuir isotherm, and the maximum adsorption capacity was 0.586 mmol/g. Fe_3O_4@SiO_2@IIP showed excellent selectivity for Li(I), and the selectivity separation factors of Li(I) with respect to Na(I), K(I), Cu(II), and Zn(II) were 50.88, 42.38, 22.5, and 22.2, respectively, as shown in Fig. 6. The adsorption capacity of the adsorbent remained above 92% after five cycles. This study offered a good method for Li's recovery.

2.1.3 Adsorption of Organic Dyes

A novel environmental friendly composited hydrogels of hydroxypropyl cellulose (HPC) and molybdenum disulfide (MoS_2) were prepared [26]. The obtained

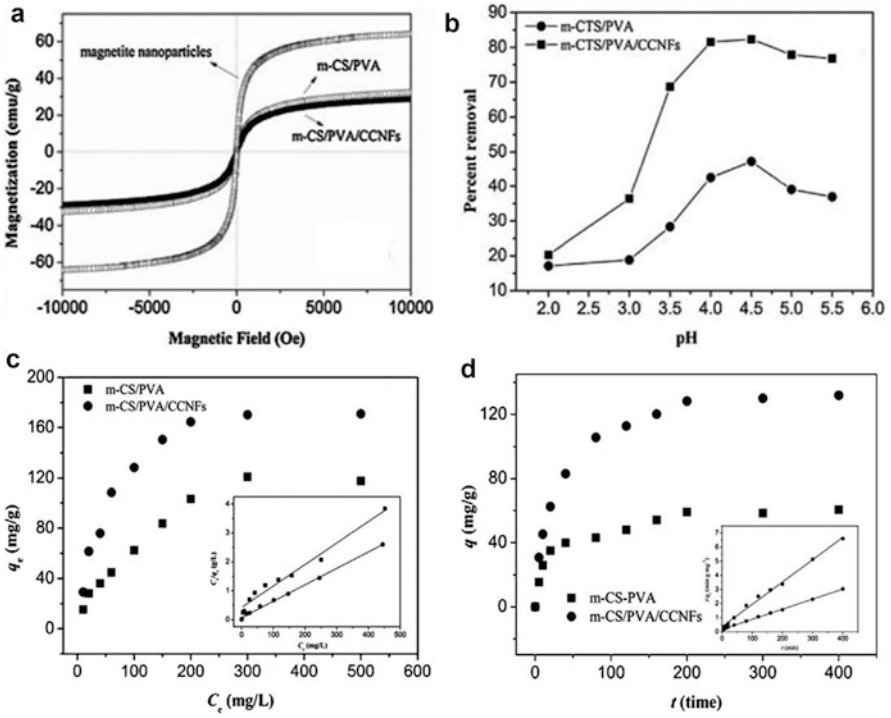

Fig. 4 (**a**) Magnetization curves of magnetite nanoparticles and hydrogels at room temperature. (**b**) Effect of pH on the Pb(II) ion uptake by m-CS/PVA and m-CS/PVA/CCNFs hydrogels. Adsorption isotherms (**c**) and adsorption kinetics (**d**) of Pb(II) ion uptake on m-CS/PVA and m-CS/PVA/CCNFs hydrogels. The inset shows the fitting results by the Langmuir isothermal model (**c**) and pseudo-second-order model (**d**)

HPC-M_oS_2/HPC hydrogels showed an enhanced adsorption behavior for methylene blue (Fig. 7a). The adsorption kinetics and isotherms were studied with different models. It indicated that the adsorption system followed predominantly the second-order rate model, and the adsorption process was mainly monolayer and took place on a homogeneous surface. More important, it could be reused to catalyze the degradation of methylene blue upon exposure to the sunlight as shown in Fig. 7b. The absorbed dyes in MoS_2-HPC/HPC hydrogels could be degraded upon exposure to sunlight, and then the hydrogels were circularly used to absorb dyes again. Considering the recycling properties of low-cost and biocompatible cellulose, the composite hydrogels will become promising candidates to remove dyes from effluents.

2.2 Drug-Selective Adsorption, Delivery, and Release

Hydrogels are hydrophilic polymer networks that can absorb more than 100 times their dry weight in water, giving the physical characteristics like soft tissue. In

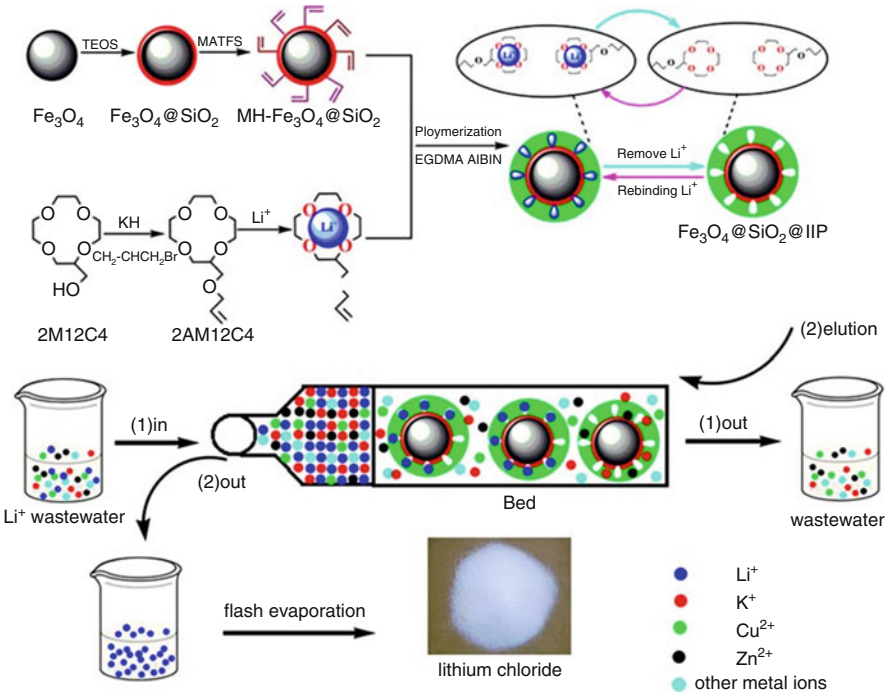

Fig. 5 Synthesis route for Fe_3O_4@SiO_2@ion-imprinted polymer

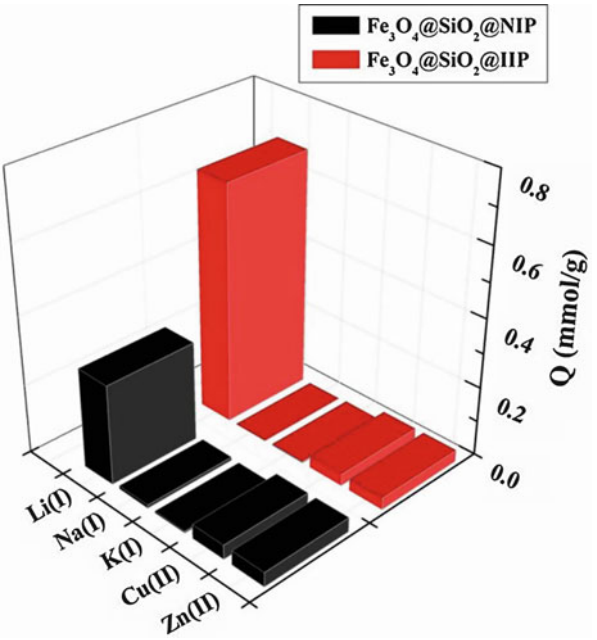

Fig. 6 Selective adsorption of Li(I) by Fe_3O_4@SiO_2@IIP and Fe_3O_4@SiO_2@NIP. Conditions: 50 mg of adsorbent, 50 mL of Li(I) with 10 mmol/L, and temperature of 25 °C

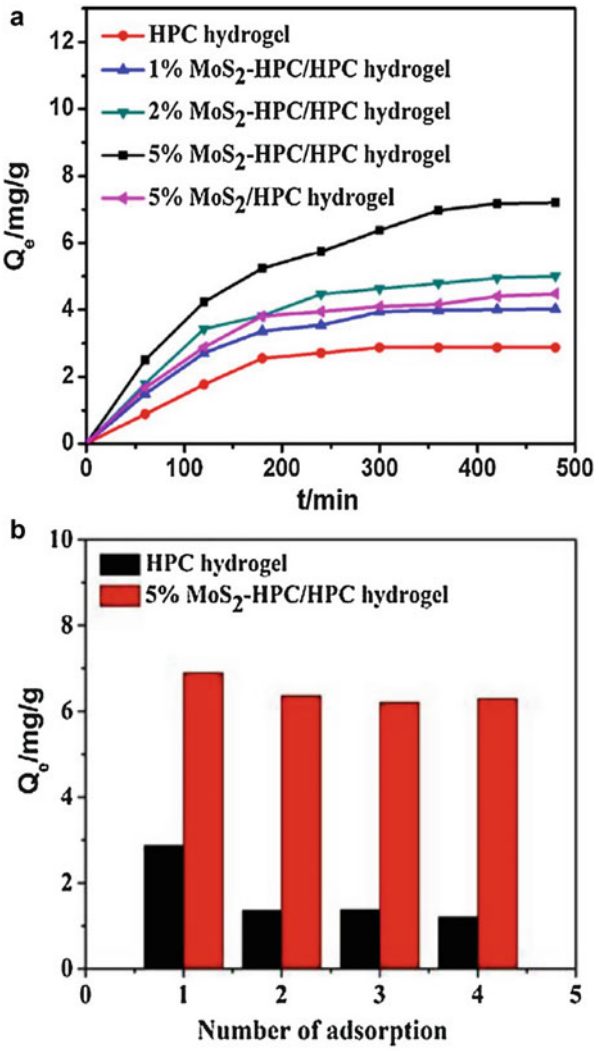

Fig. 7 (**a**) Time profile of methylene blue removal on hydrogel. The hydrogel was 0.19 g and the initial concentration of methylene blue was 50 ppm. (**b**) The photo-induced recycling properties of HPC hydrogel and 5% MoS2-HPC/HPC hydrogel

addition, hydrogels are highly permeable which facilitate exchanges of oxygen, nutrient, and other water-soluble metabolites. Thus, hydrogels are being investigated as drug delivery system due to their potential which can control the transport and release of macromolecular drugs such as pesticides [27–29], proteins [30–32], and nucleotides [33]. The diffusion mechanism of solute molecules within hydrogels is of great interest for a wide variety of industrial applications.

Recently, functional hydrogels are wildly studied in many fields, especially in drug delivery [34–36] and release aspects [37–39]. Molecularly imprinted magnetic cellulose microspheres (MIP-MCM) [40] were developed by a surface functional monomer-directing system. A layer of MIP was coated on the surface of the

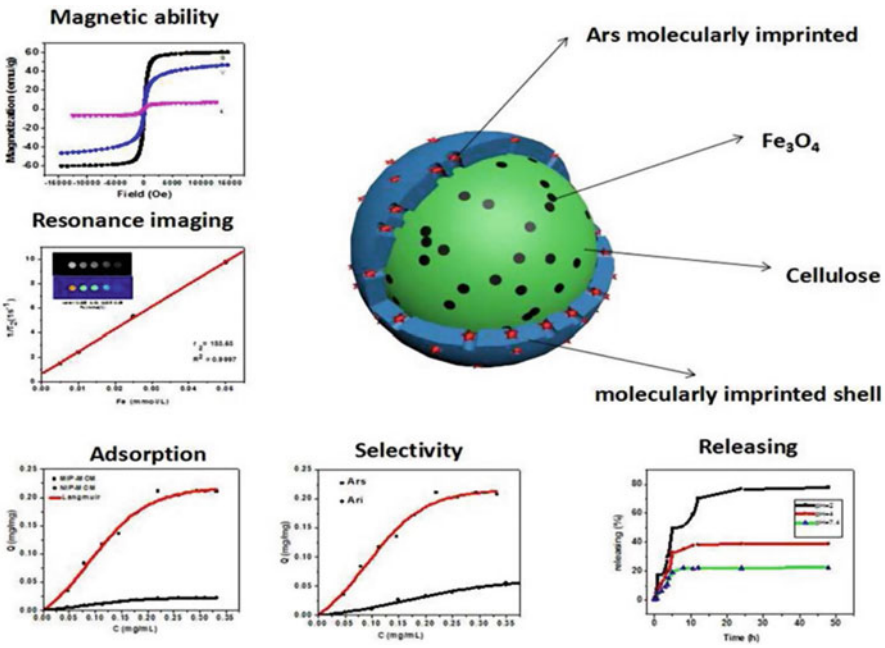

Fig. 8 Schematic procedure for molecularly imprinted magnetic cellulose microsphere preparation

cellulose microspheres in which Fe_3O_4 nanoparticles were embedded before. The process of preparation was shown in Fig. 8. By selecting artesunate (Ars) as template, the product showed high selectivity to Ars. Meanwhile, the MIP-MCM also showed highly regenerate and stable in wide pH and temperature ranges. The adsorption of Ars reached equilibrium within 10 h, and the maximum adsorption quantity was as high as 0.22 mg/mg. Through the Langmuir–Freundlich isotherm and pseudo-second-order kinetic model, the thermodynamic studies suggested that the adsorption of Ars on MIP-MCM was a spontaneous process. MIP-MCM also showed rapid magnetic separation and high reusability (retained 90% adsorption quantity after five cycles). Furthermore, MIP-MCM was good negative MRI contrast agents with good biocompatibility. Due to these properties, this work offered a new potential application for MIP-MCM in aspects of drug delivery, tracking, disease diagnosis, and therapy.

P(2-hydroxyethylmethacrylate/methacralic acid) hydrogels [41] were synthesized by gamma radiation-induced copolymerization of 2-hydroxyethylmethacrylate (HEMA) and methacrylic acid (MAA) in aqueous solution. The hydrogels as carrier for the drug adsorption and controlled release capacities of chlortetracycline HCl were investigated (see Fig. 9). The adsorption and release processes were stable in wide pH and temperature ranges. The influence of MAA content of hydrogels on the adsorption capacities was studied. The adsorption capacity of chlortetracycline HCl increased from 8 to 138 mg per gram dry gel with increasing amount of MAA in the gel system. The release of chlortetracycline HCl from the poly (HEMA/MAA)

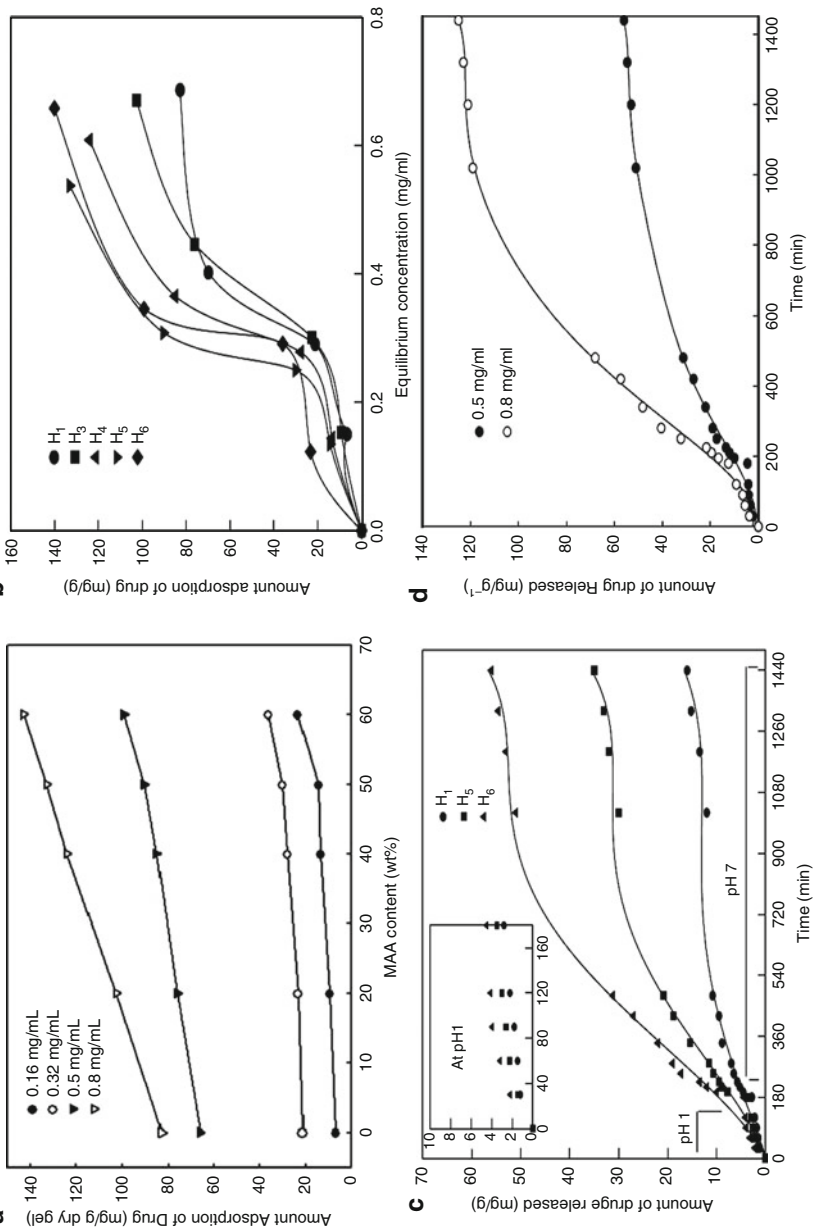

Fig. 9 (**a**) Effect of MAA content on the amount adsorption (mg/g) of (HEMA/MAA) hydrogels, at different drug concentrations. (**b**) Relationship between equilibrium concentration of chlortetracycline HCl and its amount adsorption (mg/g) for different (HEMA/MAA) compositions. (**c**) Chlortetracycline HCl

hydrogels, as studied at the physiological temperature of 37 °C, exhibited a strong pH-dependent release behavior, which offers minimum release at pH 1.0 and maximum release at pH 7–8.

3 Stimuli-Responsive Hydrogels

Stimuli-responsive hydrogels are a broad class of hydrogels whose swelling or deswelling processes, gel-to-solution or gel-to-solid transitions, and shapes can respond to the physical or chemical external stimuli, such as temperature, pH, magnetic, ultrasonic, electrochemistry, or light. Different kinds of stimuli-responsive hydrogels are used in various areas, like sensors [42, 43] and actuators, display and image devices [44–46], conditional controlled drug delivery [27–33], and so on. There are many different synthetic methods and sources to prepare stimuli-responsive hydrogels and exploit different applications.

3.1 pH- and Temperature-Sensitive Hydrogels

Temperature- and pH-sensitive hydrogels are most wildly investigated. Recently, some dual- even multi-stimuli-responsive hydrogels are developed. A novel poly((2-dimethylamino) ethyl methacrylate) PDMAEMA and poly ((2-dimethylamino) ethyl methacrylate-*co*-butyl methacrylate) P(DMAEMA-co-BMA) hydrogels were studied on the mechanical properties and pH- and temperature-sensitive swelling behaviors [47]. Mechanical measurements showed that the addition of hydrophobic comonomer butyl methacrylate (BMA) increased the mechanical strength of the network. Swelling studies showed that these hydrogels were both pH- and temperature-sensitive (see Figs. 10 and 11). It was possible to control the pH- or temperature-sensitive phase transition characteristics of these hydrogels without changing the chemical structure by a change in temperature or pH of the surrounding environments, respectively. Additionally, it also likely to further tailor the phase transition properties of the hydrogels by incorporation of a hydrophobic comonomer butyl methacrylate (BMA). Increasing the BMA content of the hydrogel chemical structure reduced the phase transition points of the temperature and pH.

Fig. 9 (continued) released from different (HEMA/MAA) compositions as a function of time, at two pH values (pH 1 at time up to 180 min and pH 7 at time above 180 min) and at constant concentration of drug 0.5 mg/ml. (**d**) Chlortetracycline HCl released from (HEMA/MAA) (40/60) hydrogels as a function of time for different loaded amounts of drug, at two pH values (pH 1 at time up to 180 min and pH 7 at time above 180 min)

3.2 Light-Sensitive Hydrogels

Due to their remotely triggerable releasing ability and combinational functionalities, light-responsive hydrogel particles are applied in microreactor, drug delivery, and tissue engineering. Light stimuli can be used for remote and noninvasive switching of the therapeutic agents' flux. Near-infrared (NIR) light can penetrate body tissue with limited absorbance. Thus, NIR light-responsive hydrogel particles with desirable compartmental structures were produced using suspended agarose/alginate pre-gel droplets induced by a superhydrophobic surface as templates [48] as shown in Fig. 12. The agarose/alginate double-network hydrogel was synthesized via a two-step sequential gelation process. The synthesized hydrogel particles, when loaded with polypyrrole (PPy) nanoparticles that act as photothermal nanotransducers, were demonstrated to function as near-infrared (NIR) light triggerable and deformation-free hydrogel materials. Compared with the massive release of tetramethyl rhodamine isothiocyanate (TRITC)-dextran (≈45%) from the single-compartmental particles induced by laser irradiation for 10 min, the release process was controlled and regulated to deliver 25% of the TRITC-dextran from the core-

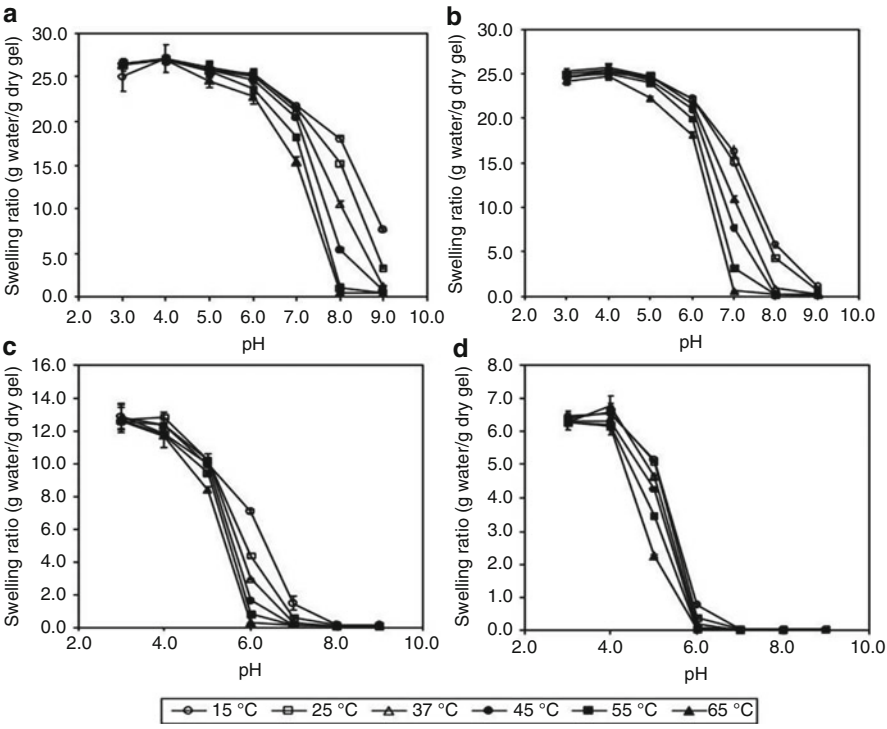

Fig. 11 Swelling ratio of the poly((2-dimethylamino) ethyl methacrylate-*co*-butyl methacrylate) hydrogels as a function of pH at different temperatures. (**a**) 0% butyl methacrylate; (**b**) 20% butyl methacrylate; (**c**) 40% butyl methacrylate; (**d**) 60% butyl methacrylate

shell structured particles. These multi-compartmental hydrogel particles exhibited tailored properties such as tunable particle size, tunable layer thickness, tunable layer number, and selective light sensitivity, which provided a wide range of options for drug encapsulation and remotely controlled release.

3.3 Electric-Sensitive Hydrogels

In recent years, capacitors have been extensively explored as an electrochemical device. The electrode materials are usually coated on the surfaces of current-collecting electrodes. The traditional current-collecting electrodes such as platinum, gold, or titanium are very expensive. The double-layer charges in thick electrode materials cannot be conveniently transferred to current-collecting electrodes (CCEs) and decrease the rate capability of electrochemical capacitors (ECs) with thick electrodes. A graphene hydrogel/nickel foam (G-Gel/NF) composite electrode was prepared by depositing reduced graphene oxide in the micropores of

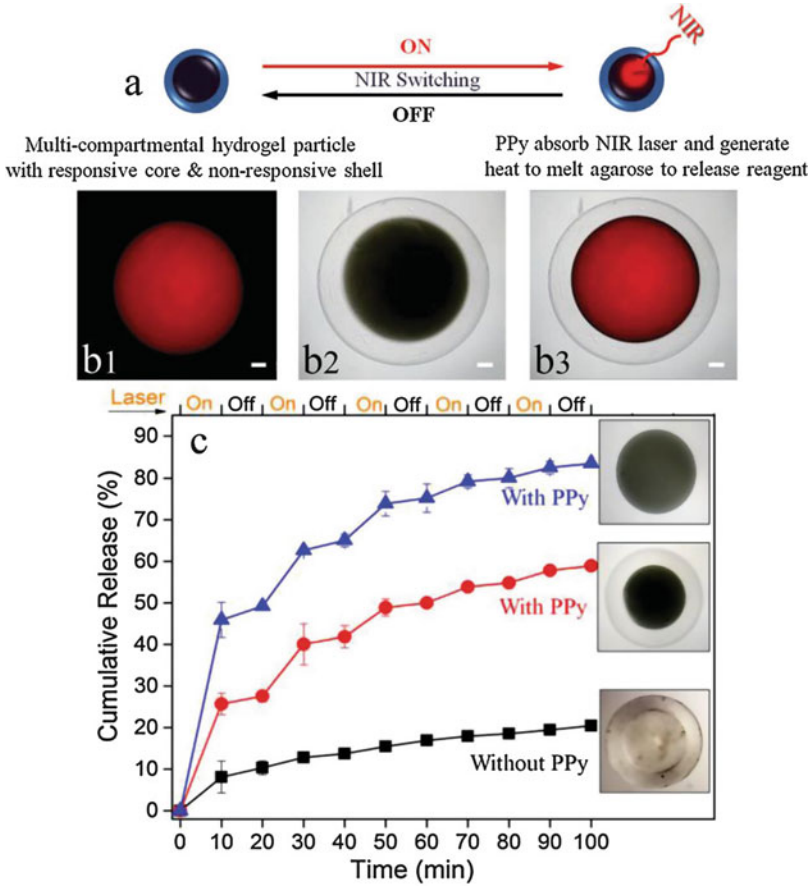

Fig. 12 (**a**) Schematic illustrations showing NIR laser-induced TRITC-dextran released from the multi-compartmental hydrogel particles with a core-shell structure, in which the PPy nanoparticles and the TRITC-dextran-loaded core exhibited NIR laser sensitivity, whereas the non-loaded shell was not responsive to NIR stimulation. (**b1**–**b3**) Microscope observation showing the multi-compartmental hydrogel particles with a core-shell structure, in which (**b1**) was a fluorescent microscope picture indicating the loading of TRITC-dextran in the hydrogel core, (**b2**) was a bright-field microscope picture indicating the loading of PPy nanoparticles in the hydrogel core, and (**b3**) was the overlay of (**b1**, **b2**) to indicate the multi-compartmental hydrogel particle with a loaded core and non-loaded shell. (**c**) NIR laser-induced release of TRITC-dextran from the hydrogel particles; the scale bar was 200 μm

nickel foam [49]. In this case, a thick (1.0 mm) G-Gel was separated into small pieces on the micrometer scale, and each of them was surrounded by Ni framework. Thus, the distances of ion/electron transportation in the electrodes were shortened. Consequently, the ECs based on thick G-Gel/NF electrodes (G-Gel/NF ECs) exhibited high specific capacitances (in terms of area), long durability, and high rate capability as shown in Fig. 13. Therefore, the G-Gel/NF electrodes not only

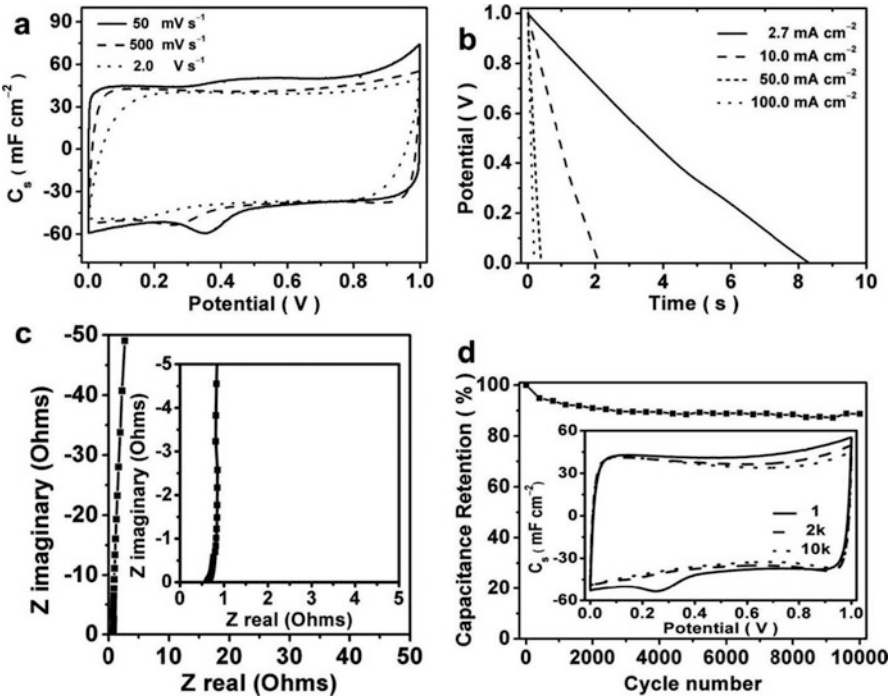

Fig. 13 (**a**) CV curves of G-Gel/NF EC in 5 M KOH at different scan rates. (**b**) Discharge curves of G-Gel/NF EC at different current densities. (**c**) Nyquist plot of G-Gel/NF EC. Inset: Plot on an enlarged scale. (**d**) Cycling stability of G-Gel/NF EC upon charging/discharging at a current density of 10 mA cm^{-2}. Inset: CV curves recorded before and after charging/discharging for 2000 or 10,000 cycles; scan rate = 500 mV s^{-1}

exhibited large specific capacitance and long cycling life but also showed high rate performance. By this way, the graphene material and current-collecting electrode were built in one piece without occupying additional volume. Furthermore, the micropores of G-Gel were exposed to the electrolyte for the access of ions to form electrochemical double layers, and the nickel framework shortened the distances of charge transfer.

An interpenetrating polymer networks (IPNs) composed of hyaluronic acid (HA) and poly(vinyl alcohol) (PVA) hydrogels [50] were prepared, and the effects of various pH conditions and electric field on swelling ability were investigated. The IPN hydrogels exhibited pH-sensitive and electro-responsive properties (see Fig. 14). The IPN hydrogels exhibited a relatively high swelling ratio as HA content is increasing. The HA–PVA (3:1, wt%) sample containing the highest HA content among samples showed the highest swelling ratio of pH-dependent swelling behaviors. IPN hydrogels showed electro-responsiveness as shrinking and expanding reversibly with the on–off switching of the electric field. HA–PVA IPN hydrogel showed the greatest electro-responsiveness volume change with the composition of HA–PVA (1:1, wt%).

3.4 Dissolving Hydrogels

The controllable dissolving hydrogel is another trigger. By external stimuli, the hydrogel can undergo gel-to-solution or reversible phase transitions. On-demand dissolution biocompatible hydrogels [51] were synthesized by thiol−thioester exchanging reactive groups as functional units for aqueous dissolution. When hydrogels was stimulated in water, the thiol−thioester could hydrolyze. The rates of exchange and hydrolysis depended on the temperature and pH of the solvent. The dissolution of thiol−thioester hydrogels was shown in Fig. 15. These hydrogels could be applied as wound dressings which would provide service as a protective barrier against bacterial infection. The management and closure of wounds after traumatic injury or surgical intervention are of significant clinical importance.

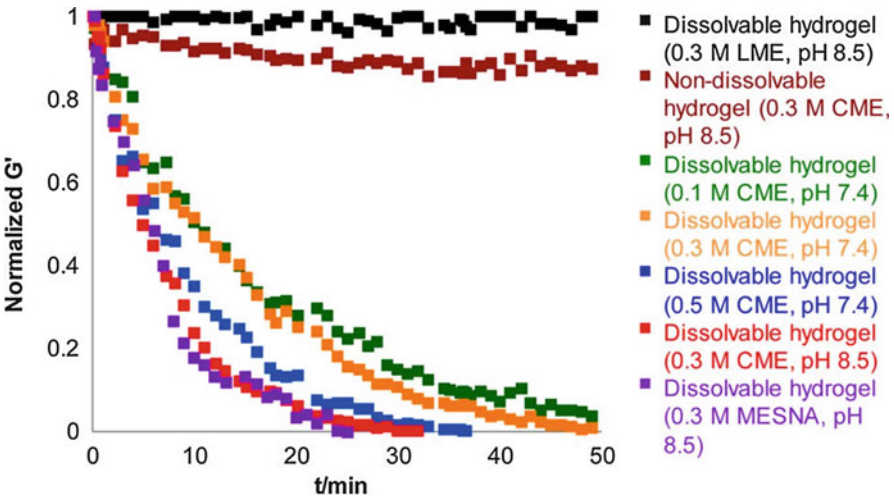

Fig. 15 Hydrogel dissolution as monitored by rheometry

Stimuli-responsive hydrogels that function as sealants, adhesives, or dressings are emerging as vital alternatives to current standards of care that rely upon conventional sutures, staples, or dressings.

3.5 Shape Memory Hydrogels

The "shape memory" effect is defined as an elastic deformation (programming) of a sample into a temporary shape stabilized by reversible covalent or physical cross-links. Shape memory hydrogels can form into a temporary shape and recover the original shape by external stimuli such as temperature, light, pH, or electricity. Based on the biocompatibility, the hydrogels have many biomedical or sensory applications, such as smart medical devices, implants for minimally invasive surgery, and heat-shrinkable tubing or films. The new shape memory hydrogels [52] sensitive to Fe^{3+}, pH, and temperature with tunable mechanical properties were presented in Fig. 16. Three programmable reversible systems including PBA-diol ester bonds (the reversible PBA-diol ester bonds formed by phenylboronic acid groups (PBA) and adjacent hydroxyl groups of glucosamine), AAc–Fe^{3+} (the coordination interactions between acrylic acid (AAc) and Fe^{3+} ions), and coil−helix transition of agar were applied to memorize temporary shapes and endowed the hydrogels with outstanding multishape memory functionalities.

3.6 DNA Hydrogels

Except normal materials, DNA, RNA, or nucleic acids also can be introduced into composite hydrogels as functional components. DNA can be precisely designed with

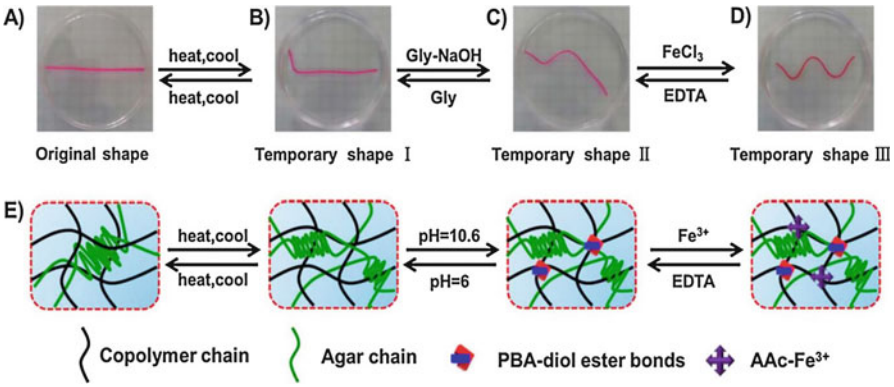

Fig. 16 Fe^{3+}, pH, and thermo-induced multishape memory effect. (**a**, **b**) Temporary shape I was fixed by coil–helix transition of agar upon changing the temperature. (**b**, **c**) Cross-links of dynamic PBA-diol ester bonds can be applied for memorizing temporary shape II. (**c**, **d**) Through the chelation between Fe^{3+} and carboxylic groups, temporary shape III can be fixed. (**e**) Mechanism of programmed multishape memory process

specific sequences and self-assemble into two- or three-dimensional structure to assemble nanoparticles. Through the cross-linked networks of DNA assembly, DNA hydrogels have great potential applications in biomaterials, such as drug and gene delivery, biosensing, and tissue engineering. In the past few years, many DNA hydrogels have been reported. The driving forces of the DNA hydrogels are physical interaction and chemical interaction. For physical interaction, DNA directly extracted from the nucleus in nature, like a long linear polymer, and formed a hydrogel via physical entanglement or by chemical cross-linking of small molecules. For chemical modification, DNA could be covalently grafted onto synthetic polymers and served as a cross-linker. The recognition of complementary DNA strands led to cross-linking of polymer chains and caused hydrogel formation.

A new and general platform created pure DNA hydrogels [53] through self-assembly as shown in Fig. 17. Two building blocks, a Y-scaffold and a linker, led to hydrogel formation. Moreover, by tailoring the DNA building blocks, the DNA hydrogels formed rapidly without any chemical treatment. The formation mechanism and properties of the DNA hydrogels were systematically studied. The DNA hydrogels reversibly responded to thermal stimulus, by switching between the gel and sol state across a transition temperature, as well as respond to enzymes when restriction sites are inserted into one of the building blocks. Therefore, it provided a new class of intelligent materials for a diverse range of biological and biomedical applications.

3.7 RNA Hydrogels

According to the self-assembled three-dimensional structures of oligonucleotides, it has showed promising applicability for imaging and gene delivery mainly using siRNAs. A novel RNA-triple-helix hydrogels [54] was prepared through programmable self-assembly of the two miR sequences to provide a stable and efficient nanovehicle for

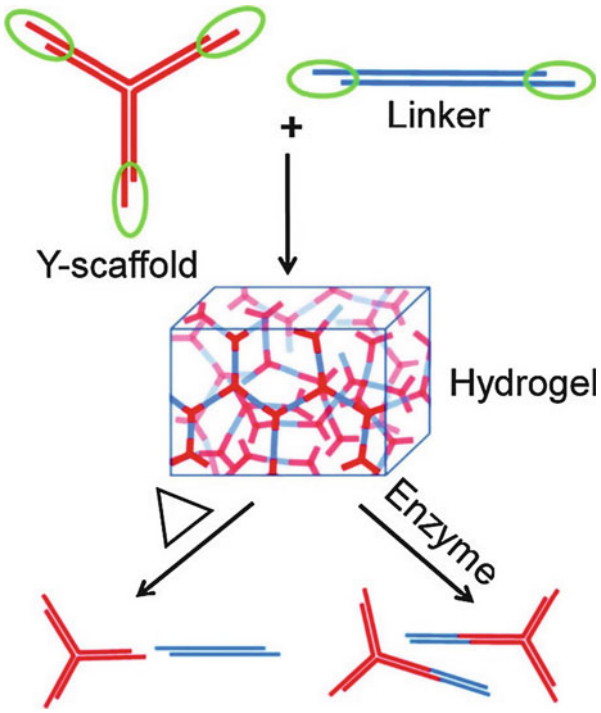

Fig. 17 Schematic representation of DNA hydrogel formation. The Y-scaffold and linker are designed to cross-link by hybridization of their "sticky ends" (emphasized by green circles). By tailoring these "sticky ends" and inserting restriction sites in the linker sequences, the DNA hydrogels show thermal and enzymatic responsive properties

in vivo miR local delivery (see Fig. 18). Conjugating the RNA triple helix to dendrimer (triplex nanoparticles) formed an adhesive hydrogel upon mixing with dextran aldehyde controlled release of the two miRs. The RNA-triple-helix hydrogels was consisted of stable two-pair FRET donor/quencher RNA oligonucleotides.

Self-assembled RNA-triple-helix conjugates remained functional in vitro with high selective uptake and controlled over miRNA expression compared with their respective single-stranded or double-stranded forms (Fig. 19). This method provided a novel strategy for concomitant on miRNA inhibition and tumor suppressor miRNA replacement therapy using a RNA-triple-helix hydrogel scaffold that afforded highly efficacious local anticancer therapy. Hence, cancer gene delivery systems should provide potent, selective, and specific treatment to tumor cells only, unlike the standard delivery of most conventional chemotherapeutic drugs. This approach can be implemented to design self-assembled triplex structures from any other miR combination, or from other genetic materials, including antisense DNA or siRNA, to treat a range of diseases.

4 Self-Healing Hydrogels

Self-healing is one of the most remarkable properties of biological materials. The special ability of natural materials to heal cracks often involves an energy dissipation mechanism due to the so-called sacrificial bonds that break and reform dynamically

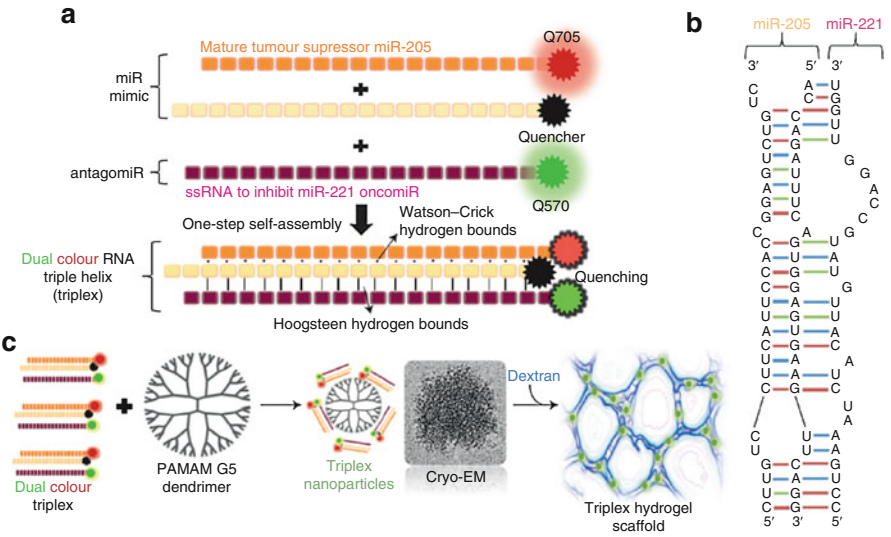

Fig. 18 Self-assembled RNA-triple-helix hydrogel nanoconjugates and scaffold for microRNA delivery. (**a**) Schematic showing the self-assembly process of three RNA strands to form a dual-color RNA triple helix. The RNA triplex nanoparticles consist of stable two-pair FRET donor/quencher RNA oligonucleotides used for in vivo miRNA inhibition (miR-221 antagomiR) strategy and miRNA replacement therapy (miR-205 mimic). (**b**) Secondary structure of an RNA triple helix bearing both miR-205 mimic and miR-221 antagomiR (structure produced/adapted using M-fold software). (**c**) Formation of the RNA-triple-helix hydrogel scaffolds by conjugation of the RNA-triple-helix structure to PAMAM G5 (Cryo-EM image showing the branched spongelike nanoscopic structure) followed by reaction with oxidized dextran to form the adhesive hydrogel

before the fracture of the molecular backbone. Numerous studies have been conducted in recent years to improve the mechanical performance of hydrogels. The self-healing materials which are capable of recovering their original mechanical performance after fracture require intermolecular non-covalent interactions. Although synthetic hydrogels are very similar to biological tissues, they are normally very brittle and lack the ability to self-heal, which hinders their use in any stress-bearing applications.

As new functional materials, self-healing hydrogels are under vast research nowadays for drug delivery, 3D cell proliferation, and tissue engineering. The broken self-healing hydrogels after damaged can regenerate the integral network and stay at the target position, enhancing the medicine delivery efficiency. This property can be introduced into macromolecules by the hydrogen bond driven through the creation of specific non-covalent intermolecular interactions. Moreover, self-healing systems can repair themselves autonomously, restoring the initial structures and functions without external stimulus after the interior or exterior cracks, which is similar to the ability of some living organisms (e.g., human skin). Constructing a non-covalently bonded system is an efficient approach to preparing self-healable polymeric hydrogels. Thus, introducing the self-healing feature to the

(**g**) Kaplan–Meier curves for mice treated with hydrogel scaffolds loaded with triple-helix and control triple-helix nanoparticles, as

hydrogel can improve the functionality and extend the application range of the hydrogel.

4.1 Self-Healing Hydrogels (Imine Bonds)

A straightforward method was used to prepare magnetic self-healing hydrogels by facilely mixing carboxyl-modified Fe_3O_4 nanoparticles in the self-healing hydrogels [55]. Due to the interaction between -NH_2 on chitosan and carboxyl groups on the Fe_3O_4 surface, the Fe_3O_4 nanoparticles could be dispersed well in chitosan solution to form a stable ferrofluid. This chitosan–Fe_3O_4 ferrofluid was subsequently mixed with difunctional poly(ethylene glycol) DF-PEG aqueous solution to quickly generate the target magnetic hydrogel. The chitosan–PEG hydrogels could form quickly through dynamic Schiff-base cross-linkage between amine groups of chitosan and benzaldehyde groups on DF-PEG termini. It was noticeable that the hydrogels healed itself automatically without any external stimuli. Figure 20 demonstrated the excellent self-healing capacity. This novel magnetic seal-healing hydrogel might have potential to be used in biological, medical, and environmental fields.

4.2 Self-Healing Hydrogels (Host–Guest)

Cyclodextrins (CDs) are water-soluble cyclic oligomers of D-(+)-glucose units bound to each other through α-1,4-glucose bonding. CDs of 6, 7, and 8 glucose units are called α-, β-, and γ-CDs, respectively. CDs can interact selectively with hydrophobic compounds of a size and shape matching their cavities to form inclusion complexes. Thus, many supramolecular hydrogels based on CDs inclusion complex with guest-containing polymers have been prepared. Self-healing properties of those based on host–guest interactions have been addressed. This work provided a novel supramolecular hydrogels [56] made of copolymers of *N*,*N*′-dimethylacrylamide (DMA) modified with cholic acid (CA, the most abundant bile acid in humans and many other species) and β-CD, respectively (Fig. 21). The dynamically reversible host−guest complexation built reasonably good mechanical properties of the cross-linked polymer network. The natural origin of the constituents made the hydrogels suitable candidates for biomedical applications.

Fig. 19 (continued) well as for the drugs (DOX, PTX, and Avastin). Statistical analysis (*n*D5) was performed with a Log-Rank Mantel–Cox test (*P*D0.006). Survival cutoff criteria included tumor ulceration or compassionate euthanasia, when the aggregate tumor burden >1 cm in diameter or if tumor impedes eating, urination, defecation, or ambulation. 4.3 Self-Healing Hydrogels (Hydrogen Bonds)

A series of novel self-healing pH-sensitive biodegradable hydrogels [57] based on cytosine- (C) and guanosine (G)-modified hyaluronic acid (HA) were prepared via hydrogen bonding under physiological conditions, with 1,6-hexamethylenediamine

(HMDA) as a bridging unit between nucleobase and HA. The lowest gel concentration, gelling time, pH-sensitivity, self-healing behavior, rheological properties, morphology, swelling ratio, degradation kinetics, and drug delivery behavior of HA-HMDA-C, HA-HMDA-G, and HA-HMDA-C/G hydrogels were investigated. As shown in Fig. 22, the series of pH-responsive self-healing hydrogels exhibited suitable gelling time, good rheology properties, high swelling ratio, biodegradability, effective drug loading capacity, and sustained drug release ability under physiological conditions. More important, these hydrogels could be attractive candidates for short- and medium-term injectable drug delivery systems, tissue engineering, cell scaffold materials, and regenerative medicine.

4.4 Self-Healing Hydrogels (Hydrophobic–Hydrophilic)

Hydrophobic interactions play a dominant role in the formation of large biological systems. These interactions can be generated in synthetic hydrogels by incorporation of hydrophobic sequences within the hydrophilic polymer network chains. The hydrogels [58] without a chemical cross-linker exhibited unique properties due to the strong hydrophobic interactions. They could only be dissolved in SDS solutions demonstrating the physical nature of cross-links. Results of dynamic light scattering and rheological and mechanical measurements showed that the hydrophobic associations between the blocks of stearyl methacrylate (C18) or dococyl acrylate (C22) units prevented water solubility and flow, while the dynamic nature of the junction zones provided homogeneity and self-healing properties together with a high degree of toughness. When fractured, the hydrogels formed using C18 associations could be repaired by bringing together fractured surfaces to self-heal at room temperature as shown in Fig. 23. The hydrogels without a chemical cross-linker exhibited unique properties. Strong hydrophobic associations between the blocks of C18 or C22 prevented dissolution in water and flow.

5 Conclusion

This chapter delivers a brief overview at functional hydrogels, especially adsorption hydrogels, stimuli-responsive hydrogels, and self-healing hydrogels. Due to the unique structure and properties, hydrogels can be used as adsorption materials for water treatment, drug separation and condition-controlled delivery system, sensors and actuators, and many other smart materials.

6 Future Scope

After decades of investigation, significant accomplishments in the development and characterization of hydrogels have been achieved, and the application of hydrogels has been spread to many aspects, such as green materials, new energy,

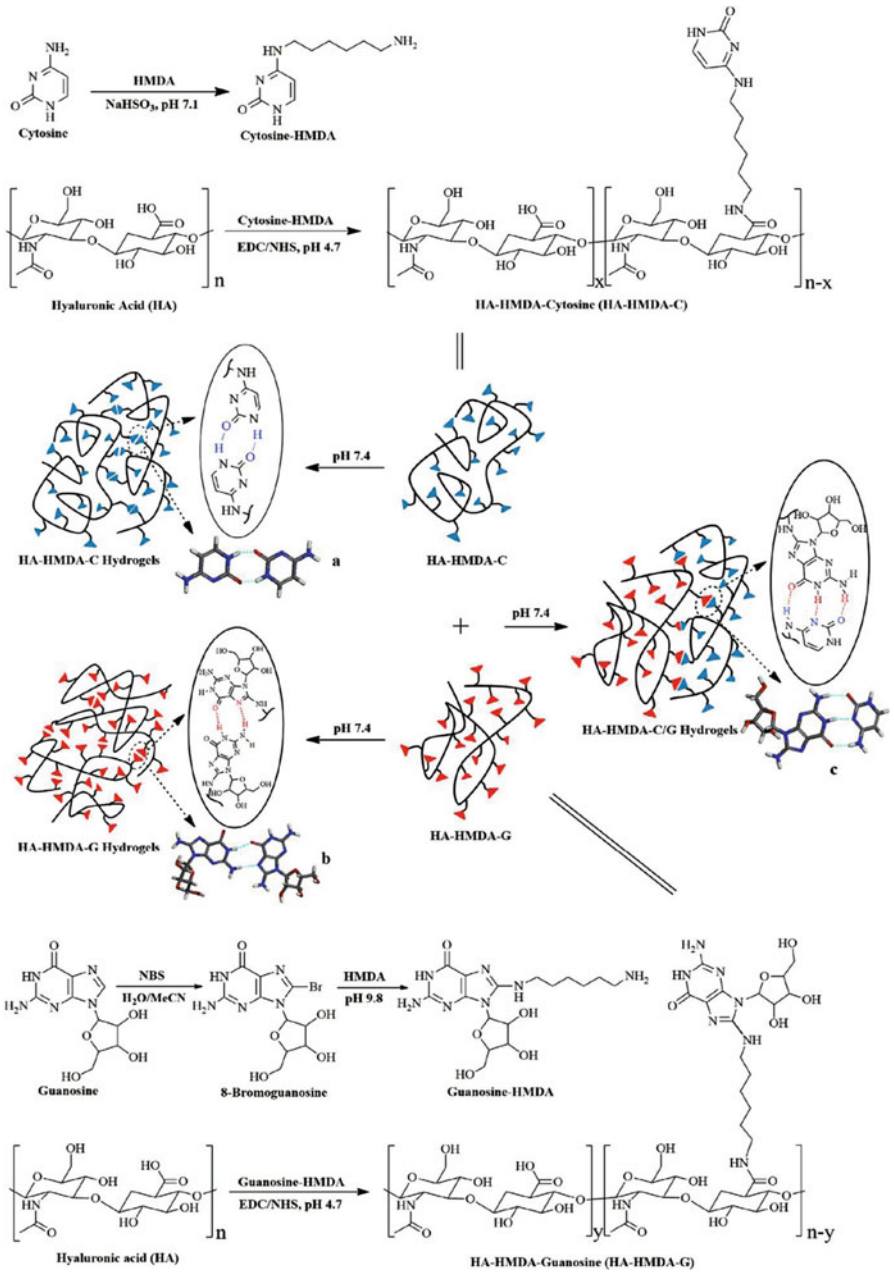

Fig. 22 Schematic illustration of synthesis routes of HA-HMDA-C and HA-HMDA-G and the formation of modified HA hydrogels via hydrogen bonding. The sketches of hydrogen bonds between cytosine and guanosine themselves or each other were carried out by computer simulations using Materials Studio 5.0 (Accelrys, San Diego, USA): (*a*) cytosines, (*b*) guanosines, and (*c*) cytosine and guanosine

biomedicine, etc. The future hydrogels must be more and more smart. The trends of the hydrogel application would be on-demand deformation, artificial organs, wearable devices, etc. Meanwhile, more fundamental researches are necessary to make clear the mechanism of the unique properties of hydrogels.

tensile characteristic of the polymer. To increase its features and/or add a new property to cellulose, preparation and modification methods have been deeply investigated and reported. This chapter is classified into four different sections: preparation, formation, mixture, and modifications of cellulose. The preparation method of cellulose (including bacterial cellulose) is important, because it directly effects to fibril formation and structure. In addition to this, depending on usage area, cellulose is necessary to prepare as whisker, fibril, and nano-formations to sustain desired polymer structure. To increase the targeted property of cellulose hydrogel, different kinds of polymers such as polyvinyl alcohol and polyethylene glycol are mixed with cellulose during the preparation of hydrogel. However, cellulose hydrogels still need to improve its physical abilities. Therefore, various modifications have been developed for cellulose and its hydrogel. The most fundamental derivatives are methyl cellulose, hydroxypropyl cellulose, and carboxymethyl cellulose. In addition to this, in recent years, stimuli-responsive and superabsorbent polymers have become more popular. Swelling behavior of hydrogels can be changed by pH, temperature, composition of solvent, and electric field in stimuli-responsive polymers that are available to use in pharmaceutical, bioengineering, and tissue engineering areas. Superabsorbent hydrogels have the ability to absorb water up to several hundred times of their dried weight that can be used in bioengineering, agricultural, tissue engineering areas, and sanitary products. The reaction mechanisms and configurations of mixtures were clearly illustrated in this chapter. Groundbreaking and latest studies were discussed via the hydrogel properties based on analysis of X-ray diffraction (XRD), thermal gravimetric analysis (TGA), differential scanning calorimetry (DSC), Fourier transformation infrared spectroscopy (FTIR), tensile at break, tensile stress, and Young's modulus.

Cellulose · Hydrogel · Cellulose nanocrystal · Cellulose nanofiber · Cellulose derivatives

1 Introduction

Cellulose is the most abundant biopolymer on Earth. The chemical structure of cellulose is based on repeating unit of glucopyranose sugar with β-(1–4) bindings (Fig. 1). Cellulose is one of the polymers that can be used in different areas because of its properties such as availability, crystallinity, molecular weight, and purity. The obtaining and production methods of cellulose are directly affecting stability and physical properties of it.

Cellulose is found with hemicellulose and lignin in plant. In addition to them, wax, pectin, and residual starch can be present in plant depending on plant type. The most common method for obtaining cellulose follows removal of these impurities using mechanical treatment and chemical treatments with sodium hydroxide [1] which is the most common chemical for cellulose purification. Reaction conditions

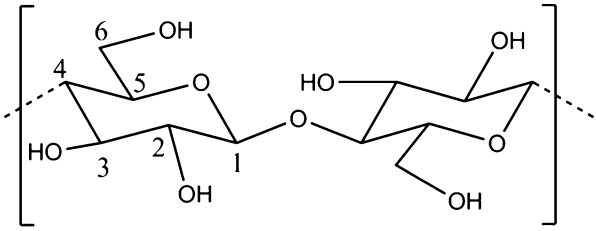

Fig. 1 Molecular structure of cellulose

are generally performed at mild conditions; however, the adjustment of reaction temperature and NaOH concentration is important to obtain highly pure and high degree of polymerization value [2]. Recently, new approaches such as pretreatment with ammonia, ultrasonication, and microwave treatments were proposed by researchers [3–5]. However, ultrasonication and microwave treatments are not suitable for large-scale processes especially for cellulose purification, because of their cost and productivity.

2 Preparation and Formation of Cellulose and Its Hydrogel

Cellulose is a linear-chain carbohydrate; it can be found as structural component of plants which is responsible for their mechanical strength or can be produced from fungi, algae, and bacteria.

Some specific features such as hydrophilicity, biodegradability, chirality, chain stiffness, chemical-modifying capacity due to extended hydroxyl groups, hydrolysis, and oxidation of chain-forming acetal groups and semicrystalline fiber structure make cellulose distinct and favorable among other polymers [6, 7]. Intermolecular reactions, crosslinking reactions, chain lengths and chain length distribution, and distribution of functional groups on repeating units are responsible factors from abovementioned characteristics of cellulose [6, 8].

The essential building blocks of cellulose are D-glucopyranose (glucose) units which are linked together with β-1,4-glycosidic bonds unlike the α-(1,4) glycosidic bonds which exist in other polysaccharide chains. After being linked, an anhydroglucose unit is formed, and two anhydroglucose units build up anhydrocellobiose (β-D-glucopyranose) which is the repeating unit of cellulose. Each anhydroglucose unit consists of six carbon atoms and three hydroxyl groups at C2, C3, and C6 atoms. These repeating β-D-glucopyranose molecules linked covalently together through acetal functions between the equatorial OH groups of C4 and the C1 carbon atoms. On cellulose chain, every second an anhydroglucose unit is rotated 180° in plane to adjust the acetal oxygen bridges angles [6, 8]. A D-glucose unit of cellulose chain includes the reducing end at C1 atom with free hemiacetal or aldehyde group and nonreducing end at C4 atom with free alcohol group [6, 8].

The chain length of cellulose polymer, degree of polymerization (DP), is defined as the number of anhydroglucose units in the polymer chain. Degree of

polymerization is dependent on source of cellulose and treatment of raw material [8] and is responsible for most properties of cellulose [9]. Although the degree of polymerization is different for each cellulose source, 20–30 repeating β (1,4)-linked glucan units exhibit all properties of cellulose [6].

Cellulose structure is semicrystalline that is composed of both crystalline (high-order) and amorphous (low-order) regions. The crystalline form of cellulose is attributed to extensive hydrogen bonds [6, 9]. Although crystallinity of the cellulose is affected by the source of the cellulose and isolation methods, generally degree of crystallinity is in the range of 40–70% [8]. Cellulose can present different types of crystalline structures due to location of hydrogen bonds between and within strands. Native cellulose includes cellulose I with structures Iα and Iβ, which exists dominantly in cellulose-produced bacteria, algae, and higher plants, respectively, and cellulose II exists mostly in structure of regenerated cellulose. Also, cellulose III and IV can be produced chemically. The conversion of cellulose I (metastable) to cellulose II (stable) is irreversible [9].

The morphological structure of cellulose consists of a system of fibrils which are elementary fibrils in 1.5- and 3.5-nm dimensions; microfibrils are built up by elementary fibrils with 10- and 30-nm dimensions, and microfibrillar bands are about 100 nm [6–8].

2.1 Nanocellulose

Different terminations might be used to define nanocellulose such as “cellulose that made up from nano sized fiber network with properties and functionalities determined nanofiber structure” [7] or “cellulose that has at least one dimension in nanoscale (1–100 nm)” [8] (Table 1).

Recently nanocellulose has attracted attention due to its specific chemical and physical features such as nanoporosity and transparency in their dispersion and composite forms [7], large surface area, capacity of surface chemical modifications [8], high surface area-to-volume ratio, high aspect ratio [10], and solubility in water [9] besides other important cellulosic properties.

Mainly classification of nanocelluloses is done according the cellulose source and preparation method. Nanocellulose particles can be produced by bacteria under controlled cultivation conditions, bacterial cellulose, or from plant or other sources of cellulose by disintegration methods either using mechanical forces, cellulose nanofibrils (CNF), or chemical substances and cellulose nanocrystals. While, production of nanocellulose via bio-formation is called bottom-up process, from disintegration methods it is called top-down process [8].

Nanocellulose-based hydrogel studies have been focused on the efficient separation of desired parts from whole cellulose with suitable pretreatments; sometimes modification of the surface of nanocellulose with various chemical reagents depends on target usage, finding appropriate and efficient hydrogel formation methods for incorporation of nanocellulose to polymer matrix with acting reinforcer.

Table 1 Different size values of cellulose formations

Cellulose formation	Source	Method	Length (nm)	Diameter (nm)	Reference
CNW	Cotton	Sulfuric acid hydrolysis	80–220	10–25	[11]
	Cellulose pulp	Sulfuric acid hydrolysis	258.5	35.2	[12]
	Microcrystalline cellulose (VIVAPUR 105)		210	5	[13]
	Wood		100–300	5–10	[14]
			158	45	[15]
CNC	Wood		100–300	3–10	[13]
			100–300	3–5	[16]
CNF			1000	3–10	[16]
			200–2200	3.5–20	[17]
			>1000	4	[18]
			500–2000	4–20	[19]
BC			1000–10,000	10–90	[20]

2.1.1 Cellulose Nanocrystals

Cellulose nanocrystals (CNC) or nanocrystalline cellulose (NCC) also described as crystal nanowhiskers are generally produced via acid hydrolysis treatment such as sulfuric acid or hydrochloric acid. The aim of acid hydrolysis during CNC production is the degradation of amorphous regions and keeping intact crystalline regions. During hydrolysis firstly, polysaccharide bounds on surface of fibrils are eliminated, and then amorphous regions are disintegrated to release crystalline rodlike cellulose [21]. After glucose-chain depolymerization reaches an optimum level, residual of acid and impurities are removed by centrifugation and dialysis processes, and then additional mechanical process is done to obtain uniform nanocrystals [21]. At the end of acid hydrolysis, rodlike rigid CNCs are produced in 3–35-nm diameter dimensions and in 200–500 nm length dimensions [8]. Although, length dimension of CNC can reach micrometers, it remains shorter than CNF [9]. Dimensions of crystals are affected degree of crystallinity of cellulose sources [9, 21]. Apart from degree of crystallinity, reaction conditions as duration, temperature, and concentration of acid influence dimensions of crystals. According the type of acid, it is possible to obtain different surface functionalities. For instance, while HCl causes weakly negatively charges, H_2SO_4 leaves more negatively charges on surface of produced CNC [21].

Although in literature "nanocrystal" and "nanowhisker" cellulose terms could define the same thing, some researches prefer to use nanowhisker terminology in their studies. Therefore, it was aimed to give some examples of hydrogel studies based on specifically nanowhisker cellulose.

Like nanofibril and nanocrytal celluloses, nanowhisker cellulose has been used as a reinforcer agent in polymer-based hydrogel network to enhance mechanical properties of hydrogel. For example, the researches were aimed to enhance mechanical properties of polyvinyl alcohol (PVA)-based hydrogel by surface oxidized microcrystalline cellulose whiskers [22]. Incorporation of MCC whisker into PVA matrix was enabled by direct chemical crosslinking, and they proposed that PVA/MCC whisker hydrogel might be a suitable application for soft tissues in the biomedical field. Also, another group used direct chemical crosslinking method [13]. They crosslinked the cellulose nanowhiskers with poly(methyl vinyl ether-co-maleic acid) (PMVEMA) and poly (ethylene glycol) (PEG). They aimed to find the effect of various concentrations of CNW on polymer matrix. The expected crosslinking mechanism was esterification reaction between hydroxyl groups on the cellulose, terminal hydroxyl groups of PEG, and carboxylic acid groups on the PMVEMA. When they compared water absorption of pure CNW film, CNW incorporated PEG-PMVEMA film, and without CNW PEG-PMVEMA film, results indicated that only CNW/PEG-PMVEMA film showed good swelling and retained integrity performance. They suggested that this is an indication of crosslinking between CNW and polymers. Also, they found that gel content of the films were directly proportional with CNW content.

2.1.2 Cellulose Nanofibrils

It is possible to find nomenclature of this type of cellulose in literature as cellulose nanofibrils (CNF) or nanofibrillated cellulose (NFC).

Cellulose nanofibrils generally are produced by using mechanical forces such as high-pressure homogenizer. Unlike CNC structure, CNF consists of both amorphous and crystalline regions and is more flexible [10]. However, CNF has lower degree of crystallinity than CNC. CNF has on average a 5–50-nm diameter dimension and few micrometer length dimensions [8]. Besides mechanical disintegration, TEMPO oxidation [10] and enzymatic hydrolysis are used to decrease energy demand. CNF has the ability in forming physically entangled networks at low concentrations [10].

To obtain high-quality cellulose fibrils, the combinations of methods are being developed. Some of conventional and nonconventional examples were shown in Fig. 2. The need of desired characteristics of cellulose fibrils sustains to improve processes about production of cellulose fibrils. Around 12 companies are commercially/pre-commercially producing cellulose nanofibrils in global scales. The cost of the method directly affects the commercialization of cellulose nanofibrils. There are still no optimal methods and/or conditions to obtain high-quality and low-cost cellulose nanofibrils.

2.2 Bacterial Cellulose

Bacterial nanocellulose (BNC) is formed by bacteria as pure nm-sized cellulose fibers, and it has no functional groups except hydroxyl groups [7, 21]. Large fiber surface that gives opportunity of strong interactions with surroundings, ability of

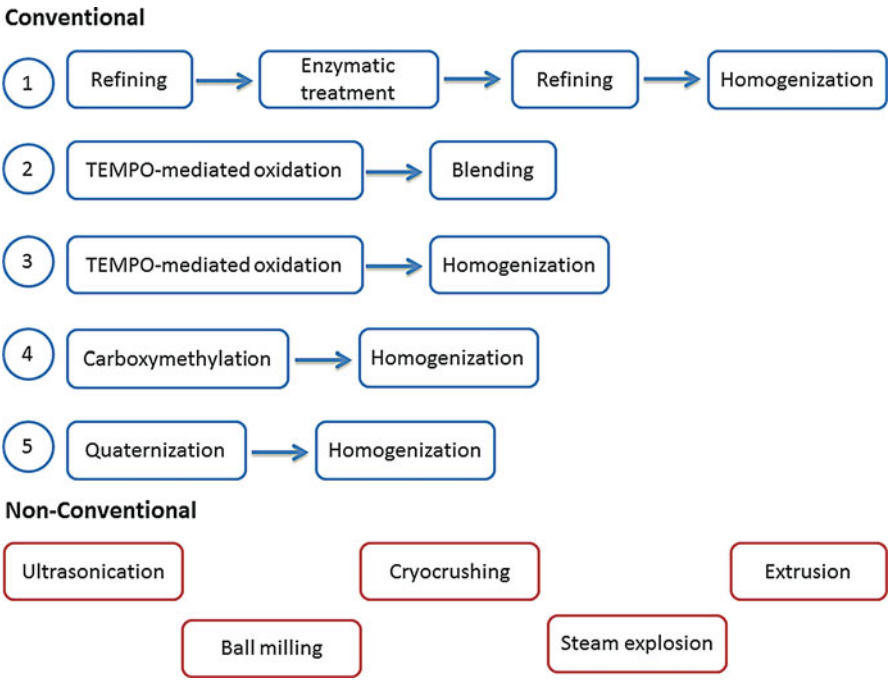

Fig. 2 Conventional and nonconventional methods of cellulose nanofibril methods

incorporation of high amounts of water, well-defined cellulose network structure, high crystallinity, DP, and mechanical strength values can be counted among remarkable features of BNC, in contrast to other nanocelluloses. Also, production of BNC from low molecular weight substrates and control change of cellulose synthesis are other differences from plant-based nanocelluloses [21].

The cellulose fibers produced by bacteria forms ribbons and then specific 3D nanofiber network. This specific 3D structure gives it facility used as template for tissue growth [7, 21].

Unlike shaping from solution which is a single method for cellulose materials from other sources, bacterial cellulose can be shaped in situ during fermentation process with desired shapes [7], such as flat materials which can be produced during static or and BCN in spheres and fibrils shaped under agitated cultivation. Also, thickness and size of bacterial cellulose products can be controlled during cultivation process.

3 Hydrogel

Hydrogel is a three-dimensional hydrophilic network of polymers that can swell with the absorption of water. It has various application fields such as in agriculture industry, biotechnology area, food industry, pharmaceutical area, etc. Hydrogels

can be made from synthetic or natural polymers. The increasing demand for biocompatible, biodegradable, environmentally friendly, and low-cost products led to the replacement of synthetic polymers with natural ones. Among the natural polymers, cellulose is the most attractive one because of its unique properties such as abundance in nature, nontoxicity, and hydroxyl groups on its backbone that give it the opportunity of chemical modifications with different functional materials. Cellulose in the form of native, modified, nanoscale, or even in gel form (e.g., bacterial cellulose) can be used to form hydrogels with numerous aims.

Recent advances in hydrogel-based researches have been depended on reducing limitations and problems caused by less solubility, high crystallinity, non-biodegradability, unfavorable mechanical and thermal properties, unreacted monomers, and toxicity of crosslinking agents [23]. For this reason, most researches have redirected their studies based on biodegradable and renewable sources to produce biocompatible and high-mechanical strength hydrogels. Therefore, cellulose, which is the most abundant polysaccharide polymer in nature, is a favorable polymer due to its unique linear structure, functional groups, and biocompatibility to form hydrogel. In this chapter, the aim is giving brief information about hydrogel formation techniques mostly used for cellulose-based hydrogels, including cellulose structure, properties, cellulose derivatives, nanocrystal cellulose, nanofibril cellulose, nanowhisker cellulose, and bacterial cellulose. Then, hydrogel formation techniques are explained in detail with cellulose-based hydrogel studies.

3.1 Hydrogel Formation

The importance of crosslinks in a hydrogel system is prevention of its dissolution in an aqueous system [24]. Mainly, hydrogels can be separated in two categories based on their owing crosslinking types. The first one is “physical” hydrogels that are commonly in “reversible” formation, and the second type is “chemical” hydrogels that are in “permanent” formation. Due to their covalent bonds to enhance the three-dimensional network, hydrogel formation is not changing in chemical hydrogels. Physical interactions such as ionic, H- bonding, hydrophobic forces, and molecular entanglements between different polymer chains [24] are active in physical hydrogels that result in changing structure. While chemically crosslinked hydrogels can exhibit changes in swelling property due to external conditions such as pH and ion charge of the external medium, physically crosslinked hydrogels can give response to environmental changes by dissolving or swelling [25].

3.1.1 Chemically Crosslinked Hydrogels

Although there can be found several chemical approaches in literature for hydrogel production, basically, preparation of chemically crosslinked hydrogels can be classified in two ways. First one is that polymerization of hydrophilic monomer is achieved with crosslinking agent and second one is crosslinking water-soluble polymers directly [25]. The authors briefly showed (Fig. 3) main differences between abovementioned chemical crosslinking approaches in their studies [25].

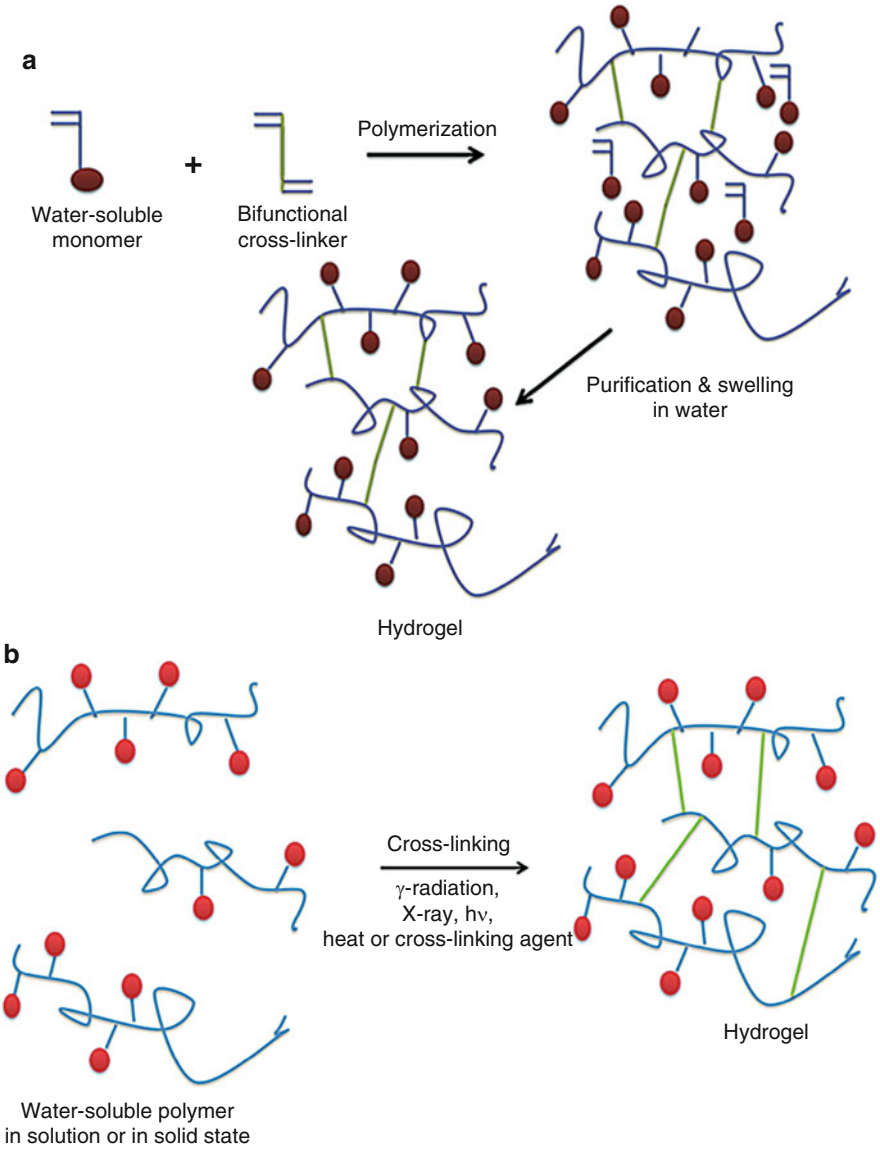

Fig. 3 Basic hydrogel formation mechanisms as (**a**) chemical and (**b**) physical. (Reprinted with permission from [25]. Copyright © 2015, Elsevier)

Poly(acrylic acid), poly(vinyl alcohol), poly(vinyl-pyrrolidone), poly(ethylene glycol), polyacrylamides, and some polysaccharides can be listed in mostly used and nontoxic water-soluble polymers that are used in hydrogel forming [25]. Water solubility of these polymers comes from their functional groups such as OH, COOH, and NH_2 which have an important role in hydrogel formation [24]. Therefore,

functional crosslinking agents react with these chemical reactive groups of water-soluble polymers to form hydrogel [24] via various chemical reactions that will be mentioned below sections. Crosslinking agents can be separated in two classes based on owing reactive groups, esterifying agents consisting of carboxylic acids and carboxylic anhydrides, and etherifying agents consisting of organochlorine, epoxide, and vinyl compounds [26]. In three-dimensional polymerization method, using toxic crosslinking agent causes extra purification steps to remove the residue of these compounds. However, it is possible to produce hydrogels directly by using water-soluble polymers without any purification steps.

Free-radical polymerization is mostly the preferred method for hydrogel preparation due to its high polymerization rate and application capability in aqueous mediums. The main mechanism in this method is polymerization of monomers by the initiators. In cellulose-based applications, cellulose produces free radicals because of initiators, and then interactions between monomers and cellulose occur to produce graft polymers to produce hydrogel [27]. Polymerization can be induced chemically either by free-radical-generating compounds also named "initiator" such as benzoyl peroxide, 2,2-azo-isobutyronitrile (AIBN), ammonium peroxodisulphate (APS) [25], potassium persulfate (KPS), *N*, *N*, *N*′*N*′-tetramethylene-diamine (TEMED) [24], or by physically using UV-, gamma- or electron beam radiation. By radical polymerization method, hydrogel features such as swelling can be adjusted by the amount of crosslinking agents [24].

It is possible to obtain hydrogels by radiation-induced crosslinking in water without using any toxic crosslinking agent under mild conditions. Although radical formed during irradiation might be a limiting factor for biologically active substances [24], this method is favorable in many fields such as pharmaceutical, food, and drug because it is not including toxicity unlike crosslinking agents [26, 28].

During irradiation of aqueous solutions of polymers process, radicals can occur on the polymer chain by homolytic scission of C–H bonds, and due to radiolysis of water molecules, hydroxyl radicals occur. These radicals cause the formation of macroradicals, and macroradicals which exist on different chains lead to formation of covalent bonds, and at the end, crosslinked network structure is formed. Properties of hydrogels that are made by this way can be controlled by adjusting radiation dose and polymer concentration [24].

Strong intermolecular hydrogen bonds of cellulose restrict its solubility in normal aqueous solitons, so development of a hydrogel from only cellulose solution is difficult. Therefore, alkaline or alkaline/urea aqueous solutions are used to form hydrogel from cellulose by using crosslinking agents.

3.1.2 Physically Crosslinked Hydrogels

For production of physically crosslinked hydrogels, instead of crosslinking agents, ionic, H- bonding, hydrophobic connections between different polymer chains develop hydrogel network. These connections can be formed by different mechanisms. For instance, freeze-thawing procedure can be used repetitively to produce microcrystals that cause hydrogel formation. Also, hydrogels can be formed as result of ionic interaction between polyelectrolyte and oppositely charged multivalent ions.

Freeze-thaw method is a hydrogel formation method in which freeze-thawing cycling is repeated more times to cause ice crystals formation due to phase separation of polymer solution, and at the end of the procedure, insoluble gel is obtained. Freeze-thaw or crystallization method is a favorable method due to some of its advantages such as being an energy saver and environmentally friendly because it does not require additional crosslinking agent. Also, it is possible to control the hydrogel mechanical properties by changing parameters of freeze-thaw method such as cycle number, temperature, and time. However, being time-consuming might restrict its usage.

Commonly, cellulose derivatives such as methyl cellulose, carboxymethyl cellulose, hydroxypropyl cellulose, and hydroxypropylmethyl cellulose are preferable in physical crosslinking of cellulose. Because they contain hydrophobic groups, and they have repelling effect to hydroxyl groups of close cellulose chain that prevent intermolecular hydrogen bonding.

Interpenetrating polymer networks (IPNs) are designed to increase mechanical strength and swelling/deswelling response of hydrogels. IPNs are combination of two crosslinked polymers, where one is crosslinked and/or synthesized within other or both are crosslinked at the same time. There is no any covalent bond between two networks. When the two networks are formed at the same time by independent, noninterfering ways, this is called "simultaneous IPN"; if previously formed single network swells in a solution including mixture of monomer, initiator, and activator with or without crosslinker, it is called "sequential IPN." Sequential IPN is separated into two subclasses according to the presence of crosslinker. If crosslinker is present, it is named "fully IPN"; if there is no crosslinker, it is "semi-IPN" [29].

3.2 Production of Cellulose Hydrogels

3.2.1 Solution-Based Prepared Cellulose Hydrogels

The presence of abundant hydroxyl groups of cellulose cause inter- and intramolecular hydrogen bonding networks that give hydrophobicity and restricted dissolution of cellulose in common solvents such as ethanol, methanol, and acetone [30]. Therefore, to produce cellulose hydrogel from native cellulose, dissolution of it must be achieved. The common solvents of cellulose are lithium chloride/dimethylacetamide (LiCl/DMAc), *N*-methylmorpholine-*N*-oxide (NMMO), alkali/urea (or thiourea), and ionic liquids (ILs) [26, 28, 30]. After the dissolution, crosslinking of cellulose chains is accomplished to form a hydrogel [26] physically via ionic interactions, hydrogen bonding, and physical entanglements instead of covalent bonds.

There are various solvent systems that can be used for preparation of cellulose hydrogel. The most common solvent systems are LiCl/dimethylacetamide (DMAc), *N*-methylmorpholine-*N*-oxide (NMMO), and alkali/urea.

LiCl/DMAc solvent system is based on breaking of intermolecular hydrogen bonding from hydroxyl groups of cellulose at C6 position. Li^+ cations have ionic interaction with free DMAc molecules, while Cl^- anions make hydrogen bonding with hydroxyl groups. Hence, cellulose polymers are homogenously dispersed in

LiCl/DMAc solvent system [31] NMMO solvent system is still used in commercial production of regenerated cellulose. The amount of water is important in this solution system. NMMO molecules move freely at 100 °C that result in replacement of water molecules closed by cellulose. At elevated temperatures, around 150 °C, crystal structure is completely destroyed, and transparent cellulose solution is obtained [32]. Isourea or thiourea with sodium hydroxide is commonly used for alkali/urea solution to dissolve cellulose. Different amount ratios of NaOH and urea complexes showed different characteristics of cellulose hydrogel. In addition to that, temperature also effect the gelation result mainly elongation and toughness.

3.2.2 Bacterial Cellulose-Based Hydrogels

Bacterial cellulose (BC) is synthesized by some nonpathogenic bacterial strains as *Acetobacter*, *Komagataeibacter*, and *Gluconacetobacter* in the gel form. High tensile strength, high modulus, high water absorption capacity, highly biocompatibility, high crystallinity, and high purity are promising properties of bacterial cellulose for hydrogel applications [28].

The advantage of bacterial cellulose does not require additional purification procedure unlike cellulose obtained from nature including lignin and hemicellulose and does not require crosslinking agent [26].

Besides plant-based cellulose nanofibrils, the researches [20] produced cellulose nanofibers from bacterial cellulose in the 10- to 90-nm width and 1–10-μ length by acid hydrolysis treatment. Then they produced a hydrogel network composed of polyvinyl alcohol and bacterial cellulose-based CNF with the crosslinking of glutaraldehyde. Obtained hydrogel showed three-dimensional interpenetrating polymer network with the well-dispersed bacterial cellulose nanofibers and pores with the size in several to dozen microns. CNF including hydrogel showed improved mechanical characteristics with the rise of tensile strength and improved thermal stability by shifting decomposition temperature to higher temperature.

3.3 Cellulose Derivative-Based Hydrogels

As mentioned above, cellulose is non-soluble in water due to extended hydrogen bonds on its structure. On the other hand, hydroxyl groups of cellulose make it suitable for chemical modifications with methyl and ethyl units to obtain water-soluble cellulose derivatives such as methyl cellulose (MC), carboxymethyl cellulose (CMC), ethyl cellulose (EC), hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), and hydroxypropylmethyl cellulose (HPMC) (Fig. 4). Modified cellulose-based hydrogels can be formed either by chemical crosslinking or physical crosslinking.

3.3.1 Chemical Crosslinking

Hydrogels formed by covalent bonds in the presence of crosslink agents are irreversible and have more stable structure than physically formed one. The disadvantage of chemically formed hydrogels might be the effect of unbounded groups of

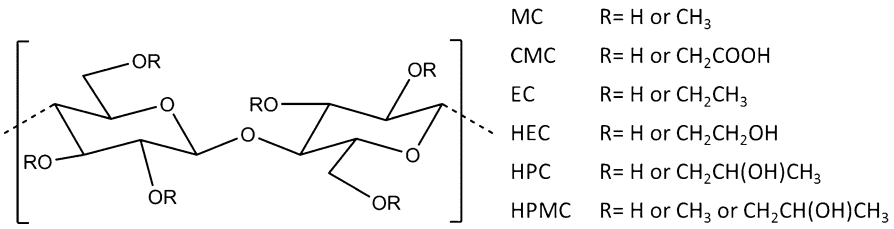

Fig. 4 The chemical structures of cellulose derivatives

crosslink agents that might cause undesirable binding in biological systems. They can be classified based on the chemical reaction involved in crosslinking.

Esterification occurs in hydroxyl and carboxyl groups of cellulose (or its derivatives) and other polymers such as polysaccharides or synthetic polymers, respectively. Requirements of esterification are high temperature and a crosslinker agent. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), citric acid, and fumaric acid are commonly used in an esterification reaction to form a hydrogel. EDC promotes crosslinking between carboxyl groups and hydroxyl or amine groups with the formation of nontoxic, water-soluble urea derivative [26, 28]. EDC is preferable for crosslinking reaction because of high conversion efficiency, mild reaction conditions, nontoxicity, and easiy separation by products and compatibility with materials. Also, during the esterification of cellulose and citric acid, anhydride intermediate is formed [28].

Michael-type addition reaction occurs between hydroxyl groups of cellulose and carbon-carbon bonds. Divinylsulfone (DVS) is used as crosslink agents, but its toxicity restricts its usage [28].

Epoxide crosslinking occurs between epoxy groups of compound and hydroxyl groups of cellulose. Diepoxy compounds such as ethylene glycol diglycidyether (EGDE) which is less toxic and poly ethylene glycol diglycidyl ether (PEGDE) are some examples of epoxide crosslinkers. Epoxide reaction requires strong basic conditions at around pH 11 and high temperature as 60 °C. Alkyl halide reaction happens between halide functional groups and hydroxyl groups of cellulose in strong alkaline conditions. Also, epichlorohydrin is a crosslinker with both halide and epoxide functional groups [30].

Free-radical copolymerization can be achieved with gamma irradiation initiation which is a clean method because there is no need for initiator agent, but its applicability is narrow due to sources [30]. UV initiation, electron beam (EB) [28], or chemical initiation using potassium persulfate (KPS) or ammonium persulfate (APS) by free-radical compounds can be used as an alternative to gamma radiation. *N*, *N*-methylene bisacrylamide (MBA), diallytartardiamide (DATDA), DVS, and PEGDE are some crosslinkers used in free-radical copolymerization [30].

3.3.2 Physical Crosslinking

Physical crosslinking can be achieved via hydrogen bonding, hydrophobic interactions, ionic interactions, and chain entanglements to form cellulose hydrogels.

Unlike chemically formed hydrogels, physically formed hydrogels do not require a chemical agent that can result in toxic by-products to crosslink polymer chains, and this gives the opportunity for application in food and pharmaceutical areas. However, the reversible structure of hydrogels made by physical interactions limits its utilization.

3.4 Cellulose Nanofibril (CNF) Hydrogel

Introducing micro-sized or nano-sized particles in three-dimensional network of hydrogel is a new application area to produce hydrogels with enhanced existing properties such as mechanical strength, swelling, and absorption. It is difficult to exhibit high swelling ability and high mechanical properties at the same time in conventional hydrogel networks [33, 34]. Besides low mechanical strength, conventional hydrogels exhibit lack of low-breaking strain and sensitivity toward fracture when handled at swollen state [16].

For this purpose, nanoparticles with hydrophilic properties have been tried to introduce the hydrogel structure and enhance its properties. Among these materials, synthetic nanoparticles such as clays of montmorillonite, bentonite, kaolinite, and sepiolite can be listed [34]. However, dispersion problems of inorganic clays might be a limited factor for use in hydrogel systems [16, 34] because there might be need of an extra processing step such as modification or special mixing of clays [16].

Some characteristics of nanocellulose make it advantageous and differ it from synthetic nanoparticles such as being renewable and lightweight with a density 1.5 g cm^{-3}, low-cost, safe processing conditions [35], strong reinforcing effect, high-aspect ratio, biodegradability, sustainability [16] and, self-assembly behavior [36].

Cellulose nanofibrils (CNFs) which are flexible elongated nanoparticles possesses large surface-to-volume ratio due to their nanometer diameter that facilitates dissipation of energy into the composites including CNFs by interfacial interactions. Dispersed CNFs can readily form networks in aqueous media, and they are better than nanocrystals to increase viscosity of a hydrogel because of entanglement provided by fibers [36]. Dispersion mechanism of CNF differs based on the presence of any chemical pretreatment before disintegration to nanofibrils. Without the chemical pretreatment, dispersion is achieved by entanglement in water. On the other hand, chemically treated CNF aligned spontaneously, and dispersion is performed by the repulsive forces as in the case of carboxylate CNF [18]. There is capability of CNFs to form hydrogel at even low concentrations, and stability of these hydrogels is provided by transient interactions such as entanglement of fibrils, nonspecific ionic interactions, and hydrogen bonds which are sensitive to environmental changes such as chemical or physical [17]. High stiffness and modulus properties of nanocellulose fibrils make them promising reinforcing fillers to improve existing hydrogel properties. Apart from high stiffness and modulus properties, ability of formation continues; network makes both cellulose nanocrsytals and nanofibrils a reinforcer agent in a polymer matrix [16]. Reinforcement of

nanofibers is achieved with complete dispersion of particles in hydrogel matrix due to increased contact surface area between hydrogel chains and fiber structures [33].

The scientists in their research pointed out reinforcing ability of cellulose nanofibrils produced from softwood kraft pulp in composite hydrogel which was produced by free-radical polymerization of monomer of acrylamide (AAm) at the presence of 10 wt.% CNF, potassium persulfate as initiator, and *N*, *N*′-methylenebis (acrylamide) (MBA) as crosslinker [37]. In this composite hydrogel, while the covalent bonds were produced in PAAm matrix, dynamic hydrogen bonds were produced between CNF and matrix. During hydrogel formation interaction between hydroxyl groups of CNF and PAAm matrix with hydrogen bonds caused adsorption of polymer chains onto CNF surface to show reinforcing capability at the interface. According the research results [37], dynamic hydrogen bonds between the matrix and CNF improve the mechanical properties via enhancing fracture resistance, self-recovery, and energy dissipation.

In another study [16], CNF was introduced to the poly(acrylic acid-co-acrylamide) matrix which was produced by free-radical polymerization in the presence of bisacrylamide as crosslinking agent (Fig. 5). Grafting of polymers chains onto the CNF was achieved by transfer reaction between sulfate anion radicals and hydroxyl groups of CNF. In this study, the effect of CNF on the swelling and mechanical performance of the hydrogel was examined. Results showed that increasing CNF content led to reduction of swelling ability of hydrogel, and they ascribed this situation to entangled cellulose fibrils and chemical grafting of polymer chains that increased crosslinking density of the hydrogel. Unlike swelling behavior, CNF caused the improvement of modulus and compression strength, and this attributed to good dispersion of CNF and grafting polymer chains onto CNF.

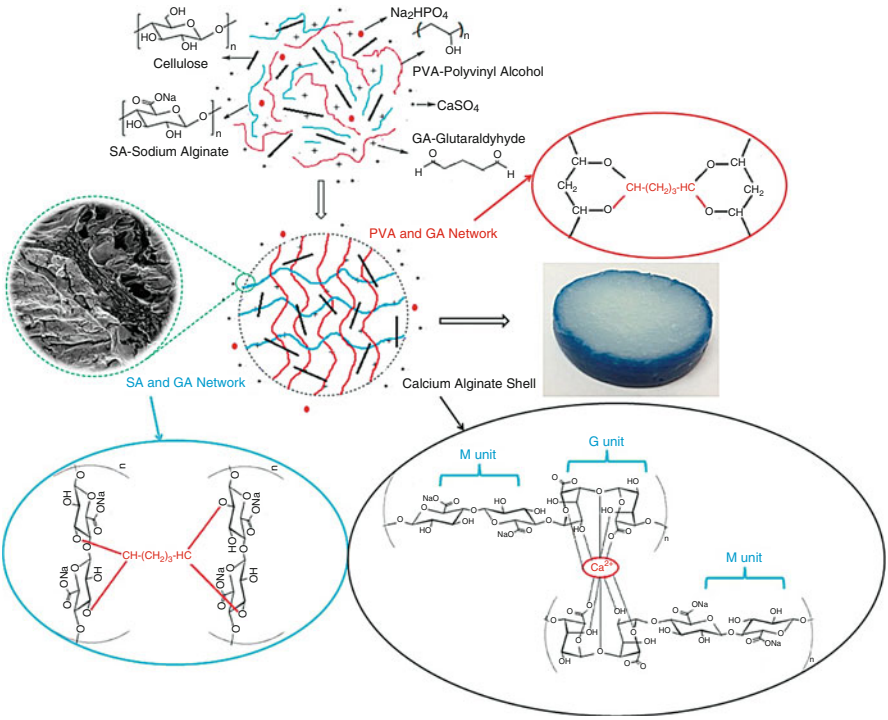

Fig. 6 Schematic representation of core shell structure. (Reprinted with permission from [38]. Copyright © 2016, Elsevier)

Also, a polyacrylamide-methylcellulose (PAAm-MC) hydrogel by free-radical polymerization technique was performed and then incorporated cellulose micro- and nanofibers into hydrogel matrix to test reinforcement effect of cellulose particles [33]. The results exhibited that while the mechanical properties of hydrogel increased with the addition of micro- or nanofiber cellulose, they caused small pore-sized hydrogel structure.

Differently from above studies, a research group introduced CNF in a hydrogel system which was produced by two distinct methods for adsorption and desorption dye studies [38]. This hydrogel system consisted of two parts as core and shell which were produced by IPN and semi-IPN networks systems, respectively (Fig. 6). Polymer matrix was produced from sodium alginate (SA), polyvinyl alcohol (PVA) with Ca^{+2}, and glutaraldehyde, and then CNF was incorporated the hydrogel.

Besides the native cellulose nanofibers, nanofibers of cellulose derivatives or modifications can be utilized in the formation of cellulose nanofiber-based hydrogel. TEMPO oxidation is the most preferred method to obtain cellulose with carboxyl groups. The study showed cellulose anionic hydrogel preparation from TEMPO-oxidized cellulose nanofibers [39]. For this study, TEMPO-oxidized CNF was dissolved in NaOH/urea aqueous solution, and then the three-dimensional structure

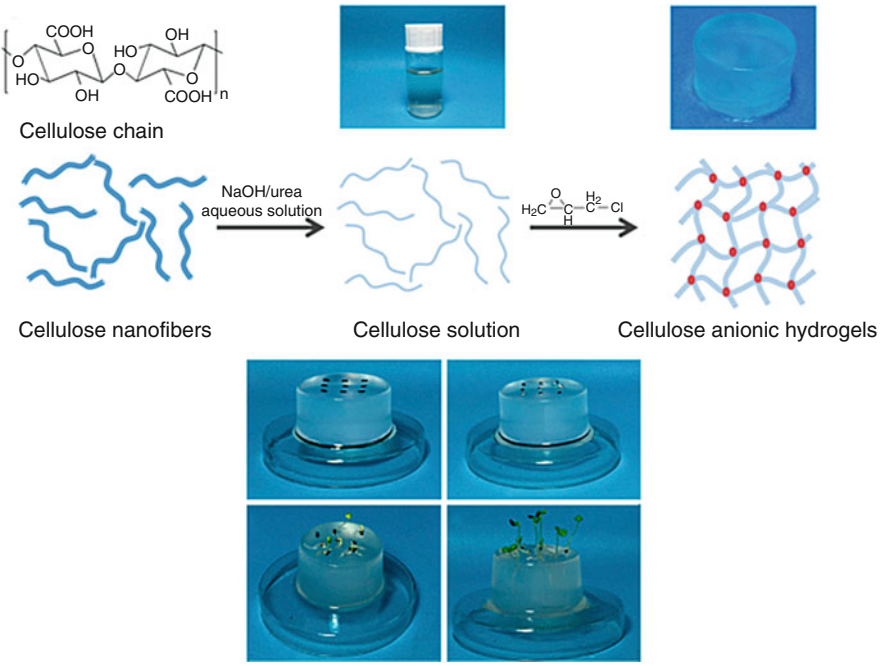

Fig. 7 Preparation of TEMPO-oxidized cellulose hydrogel and growing of sesame seeds by days. (Reprinted with permission from [39]. Copyright © 2017, ACS Publications)

of the hydrogel was maintained by using epichlorohydrin (ECH) as a crosslinker. Unlike the utilization of CNF for improvement of mechanical properties of hydrogel, the researches aimed to make a hydrogel with a carboxylate content to test for seed germination and growth [39]. Therefore, the main reason was the test of the water absorption of the hydrogel. The results showed that water absorption was directly proportional to carboxylate content of the hydrogel, because as the carboxylate content increases, the hydrophilicity increases and causes more water absorption and enlargement of the pore sizes (Fig. 7).

Another study benefited from surface carboxylation of CNF by TEMPO oxidation [18]. However, in this study and unlike other studies, a crosslinker agent was not used, hydrogel formation was provided by partially assemble of carboxylate CNF, and there was a dilute acid addition (pH 2) under the pKa (3–4) of the carboxyl groups. Also, some researchers examined reinforcement ability of carboxylated CNF in gelatin hydrogel network, and they suggested that the reinforcing ability of CNF was due to its intrinsic stiff characteristic [19]. In other study, hydrogel was produced from refined bleached beech pulp (RBP) by UV polymerization of *N*-vinyl-2-pyrrolidone with Tween 20 trimethacrylate as crosslinker and reinforced this hydrogel with carboxymethylated, nanofibrillated cellulose (c-NFC) [40]. According the results, it was suggested that hydrogel properties such as swelling behavior and compression moduli might be controlled with the amount of c-NFC and its degree of

substitution. Because the results revealed that higher amount of c-NFC caused decrease in swelling ratio but increase in compressive moduli. Additionally, high DS of c-NFC increased the swelling ratio of hydrogel.

Apart from carboxyl groups, also aldehyde groups can be introduced onto surface of CNF. A hydrogel network was produced from CNF which was modified with TEMPO-mediated oxidation procedure to introduce aldehyde groups on CNF surface [17]. Crosslinking was performed by amine-aldehyde reaction and ionic interactions. To achieve crosslinking by amine-aldehyde reaction, diamines which were ethylenediamine (EDH) and hexamethylene diamine (HMDA) were used as crosslinkers. It tried to show the effect of crosslinker molecule and concentration on elastic modulus of CNF based hydrogel. Results showed that without crosslinker water absorption increased, but with the highest degree of Young's modulus (highest degree of crosslinking), water absorption reduced. It might be said that these results are similar with result of [16] where crosslinking density caused reduction in swelling behavior.

Until here we mentioned from reinforcement studies of CNF, but some studies benefited hydrogel formation capability of CNF to produce stimuli-responsive hydrogels. For instance, smart hydrogels were produced from carboxylated CNF to sense, AgNPs, laccase enzyme and, 2,4,5-trichlorophenol TCP, respectively [41–43].

3.5 Cellulose Nanocrystal (CNC) Hydrogel

Biomedical and tissue engineering fields frequently benefited from different hydrogel applications to improve biodegradable, nontoxic, environmentally friendly hydrogel networks. Injectable hydrogel is one of the new hydrogel applications, and there is no need for gelation initiators such as heat, UV, and chemical agents to make it favorable for biomedicine applications. Injectable hydrogels can be prepared in situ and applied by extruding hydrogel components from a syringe to the target location in vivo. Besides these advantages of injectable hydrogel, its low mechanical strength is one limited factor for its usage. Therefore, reinforcement of this hydrogel type by biodegradable, nontoxic agents is an important point for in vivo applications. Some scientists have been using cellulose nanocrystals (CNC) in their injectable hydrogel studies to enhance mechanical properties of hydrogels [44, 45]. Carboxymethyl cellulose and dextran-based hydrogel were prepared and reinforced with CNCs and aldehyde-functionalized CNCs (CHO-CNCs) [44]. Aldehyde-functionalized CNC and aldehyde-functionalized dextran were mixed, and mixture was coextruded with hydrazide modified CMC. It was suggested that unmodified CNC acted as filler and modified CNC as chemical crosslinker. CNC-reinforced hydrogels were formed by hydrazone crosslinks. Both CNC and CHO-CNC showed well dispersion in hydrogel, and injectable hydrogel reinforced with CNC showed more elastic but less swelling behavior compared to unfilled gels. Additionally, CNC reinforced poly(oligoethylene glycol methacrylate) (POEGMA) injectable hydrogel was obtained by the same way [45]. In here, covalent hydrazone crosslinks between POEGMA precursors and physical crosslinks between CNC and POEGMA were

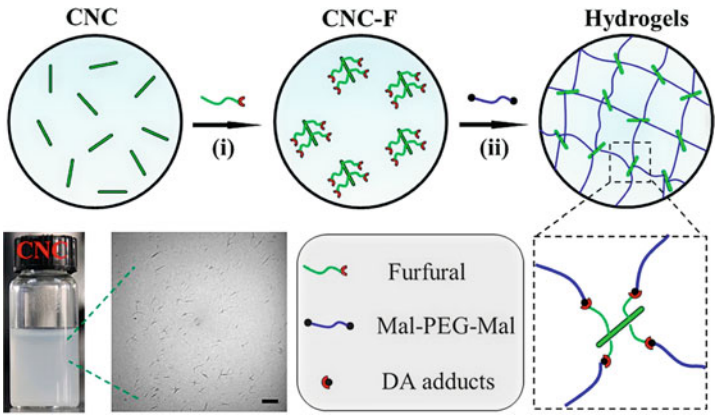

Fig. 8 Preparation of self-healing CNC hydrogel. (Reprinted with permission from [46]. Copyright © 2017, ACS Publications)

formed to maintain the hydrogel structure. The researchers suggested that the incorporation of well-dispersed CNC decreased gelation time and swelling and increased the degradation time and enhanced the mechanical performance.

Also, the Diels-Alder (DA) click reaction was performed to produce a self-healing hydrogel from the furfural modified CNC (CNC-F) and poly(ethylene glycol) with maleimide terminal groups (MAL-PEG-MAL) [46]. While PEG served as backbone, CNC acted as both reinforcer and chemical crosslinker (Fig. 8). It was explained that the reasons of choosing DA reaction in this study were high efficiency, high selectivity, and high yields without by-products and no need for extra chemical reagents. During the thermally induced DA reaction, covalent crosslinks were established between furyl groups and maleimide groups. It was obtained that self-healing hydrogels had excellent recovery ability and good mechanical characteristics which were adjustable by substitution degree of furyl functional groups and the mole ratio furyl to maleimide.

Apart from using CNC as reinforcer agent to strengthen mechanical performance of hydrogel, there are some studies which benefited CNC in various fields such as drug release studies, stimuli-responsive hydrogel, or absorption studies. A hydrogel system was produced from cationic cellulose nanocrystals (CNC) and anionic alginate for drug delivery [47]. Surface cationization of CNCs was achieved by chemical modification with 2,3, epoxypropyl trimethylammonium chloride and physical adsorption of polyethylenimine (Fig. 9). Hydrogel formation was performed by a double-membrane hydrogel system in which combination of anionic alginate and cationic CNC was provided by electrostatic interactions and ionic crosslinking. While the inner part of hydrogel system composed of cationic CNC and anionic alginate, the outer part composed of alginate. Syringe-like device can be used to adjust the shape and size of inner hydrogel part; the duration time can regulate outer part thickness. The results revealed that doubl-membrane hydrogel structure and drug release behavior are suitable for biomedicine applications.

4 Special Cellulose Hydrogel

4.1 Stimuli-Responsive Hydrogels

Stimuli-responsive or smart hydrogels are designed to change their characteristics such as network structure, mechanical strength, and permeability according the environmental alterations. These environmental stimuli might be chemical such as pH, ion charge, chemical compounds, or physical stimuli including temperature, light, electric field, magnetic field, or pressure. The two conditions, temperature and pH, have physiological significance; hence, their responsive hydrogels have been widely studied.

Thermo-sensitive hydrogels are classified into two sections as positive and negative thermo-reversible systems. Polymer solutions have two distinct temperature values which are upper critical solution temperature (UCST) and lower critical solution temperature (LCST) in which polymer solution shrink or contract by below UCST or above LCST, respectively, in positive thermo-responsive systems. The negative thermo-responsive hydrogels are generally be liquid at room temperatures and become gel above 30 °C.

The most used materials for gel preparation are acrylic acid copolymers and *N*-isopropylacrylamide derivatives where they swell below LCST and shrink above LCST in water.

Cellulose derivatives are preferable in preparation of stimuli-responsive hydrogel. Cellulose derivatives are generally water soluble, and hence, it can be gelation with monomers that polymerized during hydrogel preparation. Carboxymethyl cellulose (CMC) is one of the cellulose derivatives [48] and is a fundamental

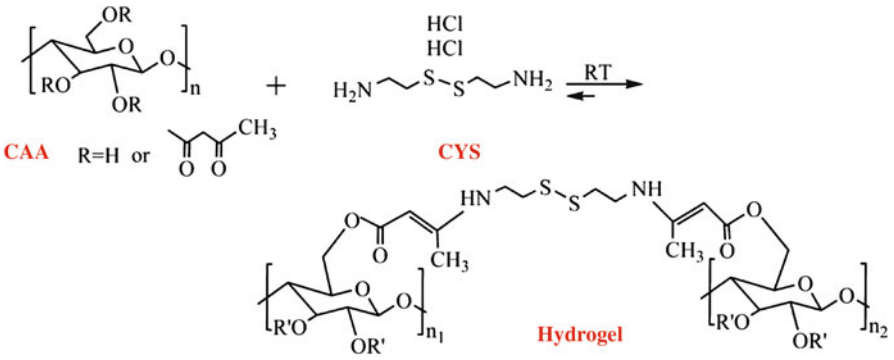

Fig. 10 Redox/pH dual-stimuli-responsive hydrogel by cellulose acetoacetate (CAA) and cystamine dihydrochloride (CYS). (Reprinted with permission from [50]. Copyright © 2017, Elsevier)

material for hydrogel preparation. In addition to this, oxidized CMC was also used in hydrogel with 3,3′-dithiobis propionohydrazide [49]. In addition to this, preparation of hydrogel with cellulose acetoacetate and cystamine dihydrochloride showed redox/pH dual-stimuli responsive (Fig. 10). Enamine and disulfide groups are stimulated by pH and redox, respectively.

Responsive photonic cellulose hydrogels are recently popular in sensor technologies. Photonic hydrogel was prepared by using cellulose nanocrystal, acrylamide, and 2,2-diethoxyacetophenone [51]; a hydrogel was prepared for separation industry [52]. Cellulose nanocrystal, poly(oligoethylene glycol) methacrylate, and poly (methacrylic acid) were used for destabilizing of Pickering emulsions [52]. Bacterial cellulose is also used in pH-responsive hydrogels. The scientists prepared bacterial cellulose-g-poly(acrylic acid-co-acrylamide) hydrogels using potassium persulfate in NaOH/urea solution via bulk polymerization [53]. At neutral pH, swelling ratio increased 30-fold higher than acidic pH [53]. In another study with bacterial cellulose, it mixed with sodium alginate to prepare pH and electric field stimuli-responsive hydrogel [54]. A thermo-responsive hydrogel formation was studied by TEMPO-oxidized bacterial cellulose and elastin-like poly-peptide (ELP). In this hydrogel system, positively charged ELP behaved like a crosslinker for negatively charged nanofibril of bacterial cellulose and formation induced with the temperature rise.

Besides producing directly mechanically reinforced hydrogel, a group [11] benefited from reinforcer properties of cellulose nanowhiskers to produce a smart hydrogel which was thermally responsive. For this purpose, a semi-interpenetrating network of cellulose nanowhisker obtained after sulfuric acid hydrolysis treatment by cotton and *N*-isopropylacyrlamide (NIPAm) was formed by free-radical polymerization in the presence of metyhlenebis acrylamide (MBA) as crosslinker and potassium persulfate (KPS) as iniator. In this study PNIPAm was used as smart material with thermo-responsive feature and CNW as reinforcement material. According their results, a homogenous hydrogel with well-proportioned network structure, dense architecture, and with evenly distributed pores was obtained. Also,

equilibrium swelling ratio (ESR) was enhanced with the incorporation of CNW into the PNIPAm structure. Additionally, other group [14] tried to enhance thermal properties of CNW-reinforced gelatin hydrogel besides mechanical properties. Chemical crosslinking was formed between aldehyde groups of periodate oxidized CNW and free ε- amino groups of the lysine hydroxylysine residues of gelatin. Periodate oxidation causes cleavage at the C2–C3 glycol bond which results to dialdehyde groups at the respective carbon atoms. Therefore, these aldehyde groups act as crosslinker by reacting free amine groups of gelatin. Because as commonly known, gelation is not usable at the higher temperatures (above 35 °C), so they aimed to improve thermal properties of gelatin. Results pointed out that as aldehyde groups increased, degree of crosslinking increased. With the rise of the degree of crosslinking mechanical and thermal properties of gelatin, hydrogel improved but caused the reduction in water uptake ability.

Because of their changing formation by thermal and ionic strength, stimuli-responsive hydrogels are generally preferred in drug delivery and process-based systems.

4.2 Superabsorbent Hydrogels

Superabsorbent hydrogels have the ability retain huge amounts of water or aqueous solutions compared with general absorbing materials [11, 55]. Existent superabsorbent products are usually based on petroleum polymers so production of superabsorbent from natural, biodegradable polymers attracts attention.

Superabsorbent hydrogels have the capability to absorb, swell, and retain aqueous solutions up to hundreds of times their own weight [27]. The unique properties that differ superabsorbent hydrogels from common hydrogels are fast-swelling rate and absorption of extraordinary amounts of water than common ones. It is possible to prepare several hundred microns diameter pore sizes in hydrogel matrix to enhance water movement in the matrix [56]. Most superabsorbents are produced from synthetic polymers such as acrylic acid, sodium, potassium salts of acrylic acid, and acrylamide due to their low cost and high efficiency. Although it is possible to produce economical superabsorbent hydrogels from these synthetic materials, biodegradability and biocompatibility problems of these synthetic materials lead to the looking new materials [27].

As in the conventional hydrogels, using renewable, nontoxic, biodegradable, biocompatible, low cost materials in superabsorbent hydrogels is an emerging application to replace synthetic polymers and reduce negative effects coming from synthetic polymers. Abundance of cellulose and its intrinsic degradability make cellulose a promising material for superabsorbent hydrogel applications. Also, high absorbency, high strength, and good salt resistance features of cellulose-based superabsorbent hydrogels give various applications opportunity. There are several application fields of cellulose-based superabsorbent hydrogels such as in agriculture, personal health care, water treatment, and biomedical field. Some researchers have been tried to produce cellulose-based superabsorbent hydrogel with various properties such as high water absorption performance or stimuli responsive with the alteration in environmental conditions such as pH, salt, or temperature to import

obtained hydrogel systems abovementioned or distinct fields [27]. For instance, it was aimed to produce superabsorbent hydrogel from starch-g-poly (sodium acrylate) matrix with cellulose nanowhisker with pH and salt-responsive behavior [56]. Additionally, a superabsorbent hydrogel based on acrylic acid, acrylamide and 2-acrylamido-2-methyl-propanosulfonic acid, and sodium carboxymethyl cellulose was prepared to test the water absorption ability in aqueous mediums with different salt and pH conditions [57]. Also, a carboxymethyl cellulose and clay-based superabsorbent hydrogel were produced with the purpose of elimination of toxic dyes from water [58]. It was tested cellulose clay-based superabsorbent hydrogel by using methylene blue dye, and results demonstrated that formed hydrogel is suitable for dye decontamination treatments. Additionally, a superabsorbent hydrogel from quaternized cellulose (QC) and native cellulose was produced to improve the biocompatibility, mechanical strength, and antimicrobial activity of disposable diapers [59]. A cellulose and carboxymethyl cellulose-based superabsorbent hydrogel was produced to test its swelling; salt sensitivity and protein release studies were conducted to show it as a candidate hydrogel system in biomedical field [55].

5 Characterization Methods of Cellulose Hydrogels

Characterization assays should be performed efficiently, because the properties of cellulose (and its derivatives) and hydrogels have to be well understood. Depending on their properties, they can be used in usage area effectively. Different kinds of characterization assays for understanding the structure of cellulose hydrogels are summarized in Table 2.

Table 2 Characterization methods and their aims for cellulose hydrogels

Investigation site	Assays	Advantages/disadvantages
Chemical composition	Fourier transformation infrared spectroscopy (FTIR)	+ Easy perform + Trusted result − Sample should be well-dried − Difficult to understand the result
Fibril structure	X-ray diffraction (XRD)	+ Trusted result for fibers − Sample should be well-dried
Fibril strength	Tensile assays	+ Trusted result + Suitable for dry and wet state of hydrogel
General property of hydrogel	Thermal gravimetric analysis (TGA) Differential scanning calorimetry (DSC)	+ Suitable for thermal decomposition and water-retention analyses
Surface property	Scanning electron microscopy (SEM)	− Sample should be well-dried
Fiber size/ property	Transmission electron microscopy (TEM)	− Sample should be well-dried +/− TEM should be performed in low voltage

After preparation of different type of celluloses, they can be easily characterized. Because cellulose can be prepared in dry state that is needed in all characterization assays. However, after it is formed as hydrogel, it should be dried for characterization assays. During the drying process, cellulose fibers are composted, and surface characteristic as ionic strength are changing. Therefore, even some of the characterization assays are not suitable for hydrogel analysis; there are no alternative assays up to now. In this perspective, tensile assays are only assays for analyzing hydrogel correctly.

5.1 Keynotes of Experiments

Fourier transform infrared (FTIR) spectroscopy: FTIR spectrum of the hydrogel should be recorded by Fourier transform infrared spectrophotometer in the range from 400 to 4000 cm^{-1}. If cellulose material is not derived, there is no need to use potassium bromide disk; otherwise the transparent disk should prepared by grinding around 2 mg of the samples 45 mg of KBr and pressing it at high pressure.

Scanning electron microscopy (SEM): After the cellulose hydrogel is completely dried, film is placed on glass plate. If it is possible, surface and cross-section images should be taken. The magnitude can be arranged around 10–100 KX.

Transmission electron microscopy (TEM): Cellulose hydrogel should be dried at ambient temperature. The voltage of electron microscopy is essential that should be around 3–30 kV. Cellulose may be burned at elevated voltages.

X-ray diffraction (XRD): Crystallinity value is important for preparation of cellulose derivatives and hydrogels. Because calculation of crystallinity is based on the pattern of X-ray diffraction, sample surface has to be prepared in smooth.

Thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC): Both systems use elevated temperatures. The change of weight and heat generation are followed in TGA and DSC assays, respectively. Before analysis, samples should be dried at ambient temperature. Heating rate can be adjusted to 10–20 °C/min for both assays under nitrogen atmosphere.

Tensile sssays: Sample is both prepared in dry and wet states. The difference between dry and wet hydrogel is important which directly affect the usage areas. To increase the reliability of the data, sample should be cut and measured precisely. The calculation of tensile properties such as tensile at break, elongation, and Young's modulus depends on the sizes of hydrogel.

6 Conclusion

Cellulose is the most abundant biopolymer, and because of its binding system, it has found the chance to be used in various areas. However, to increase the quality of material, cellulose is to be prepared in different forms and derivatives. The most used formations and derivatives of cellulose are cellulose nanocrystal and nanofiber and carboxymethyl, methyl, hydroxypropyl celluloses, respectively. Even though there are various studies about preparation of cellulose hydrogels, there is still no

optimized preparation and hydrogel for usage areas. Researchers have continuously found novel hydrogels, but almost each hydrogel has one or more disadvantages such as cost, difficulty of preparation, and restricted usage conditions. With the increasing interest on biomedical area and its products, hydrogels are promising materials for industrial areas.

desired properties of cellulose, it's necessary to manipulate the cellulose structure. Therefore, the modification of cellulose becomes important. The modification of cellulose is introducing organic and inorganic compounds on the polymer. A significant variation in the cellulose properties can be observed with the binding of polymers. Also, mineralization of cellulose has attracted a great deal of attention in recent years. This chapter investigated all of these modifications on cellulose.

1 Modification of Cellulose with Organic and Inorganic Materials

Cellulose is a carbohydrate polymer constructed from the repeating of ß-D-glucopyranose units. The polymer is in nature in different forms and has always been a part of nature and human life, such as wood, paper, or cotton fabrics. Cellulose has a high degree of functionality because of the presence of many hydroxyl groups in this molecule. This most abundant natural biopolymer has characteristic properties such as hydrophilicity, chirality, biodegradability, and high functionality. It has applications in composite materials, textiles, drug delivery systems, and personal care products. In recent years, much attention has been paid to cellulose and its derivatives due to their biological, chemical, as well as mechanical properties. Cellulose and its derivatives can be used as supports due to their renewable, biodegradable, and nontoxic properties. One of the drawbacks of this compound is related to its polar and hydrophilic nature. Surface modification has been used for fixing this problem. The surface structure of cellulose contains highly active and attractive hydroxyl groups toward various chemical modifications with the polymers and inorganic or hybrid organic/inorganic compounds.

1.1 Cellulose Esters

Esterifications with inorganic and organic acids are interesting reactions of cellulose with broad applications in the industry. Cellulose acetate, cellulose nitrate, and cellulose xanthogenate are known as the important esters of cellulose. The cellulose esters were investigated in two main categories including organic and inorganic esters of cellulose.

1.1.1 Organic Esters of Cellulose

The reaction of cellulose with carboxylic acids gives cellulose organic esters with removal of a H_2O molecule. Cellulose acetate is the most important ester of cellulose with industrial applications such as in the sunglasses, linings, blouses, dresses, wedding and party attire, home furnishings, draperies, upholstery, and slip covers.

Cellulose Acetate

The first organic ester of cellulose was synthesized from the reaction of cotton cellulose with acetic anhydride in a sealed tube at 180 °C by Schutzenberger (1865 and 1869) [1, 2]. Franchimont (1879) performed the reaction with H_2SO_4 and $HClO_4$ catalysts as the industrial approach for the production of cellulose acetate [3]. Commercial cellulose acetates have high strength and high melting point and exhibit a high UV stability and film transparency, combined with low inflammability. Acetic anhydride is predominantly implied as the esterification reagent of cellulose, mostly as a liquid, in special cases, also in the vapor phase. High degree of acetylation was reported for bacterial cellulose in 1-*N*-butyl-3-methylimidazolium chloride as an ionic liquid [4]. Acetyl chloride represents a still more reactive agent of esterification. Acetylation of cellulose can be performed in dimethylformamide (DMF)/pyridine using an alkali or alkaline earth salt of acetic acid in the presence of *p*-toluenesulfonyl chloride [5]. Synthesis of cellulose acetate was also performed by the transesterification with ethylene diacetate via dissolving of cellulose in the *p*-formaldehyde/dimethyl sulfoxide (DMSO) at high temperatures [6]. Acid-catalyzed esterification reactions can promote the reaction yield by shifting the equilibrium reaction to the products. This phenomenon is attributed to the assisting of acids to the formation of acetyl cation CH_3CO^+ as the reactive intermediate. The esterification reaction with acetyl chloride showed high yields with tertiary amines such as triethylamine (TEA) or pyridine due to forming of acylium complex. 4-Dimethylaminopyridine (DMAP) is an efficient catalyst for the esterification reaction, especially in a homogeneous system with a nonpolar reaction medium [7]. For the acetylation of fibers, the preactivated cellulose is reacted with a large excess of acetic anhydride (Ac_2O) in the presence of acetic acid (HAc), usually with $HClO_4$ as the catalyst.

Also, Ac_2O vapor can be employed for the fiber acetylation, by adding some propionic or butyric anhydride to the vapor phase, obtaining the appropriately mixed ester, i.e., cellulose acetopropionate or acetobutyrate. Among the numerous nonderivatized solvent systems for cellulose, two systems including the solution in *N*,*N*-dimethylacetamide (DMA)/LiCl and a melt solution in *N*-ethylpyridinium chloride have been successfully employed for the acetylation of this polymer [8], indicating a preferential substitution at the C-6 position. Ac_2O/pyridine in the paraformaldehyde/DMSO solvent is the effective system for the acetylation of all the hydroxy end groups of the methylol side chains. The system afforded a high degree of substitution (DS) of the acetyl groups by transesterification of ethylene diacetate in the presence of natrium acetate at 90 °C [9]. Acetylation of cellulose in the chloral/DMF/pyridine system leads to the complete substitution of the hydroxyl groups by the acetal groups with a DS of 2.5 by Ac_2O or acetyl chloride [10]. Production of cellulose acetate from tosylcellulose (DS = 0.9–2.3) has been reported by the reaction with 3 mol of Ac_2O per mol of hydroxy groups in the presence of sodium acetate in pyridine at 60 °C [11]. This reaction can be performed with trimethylsilyl (TMS) cellulose (DS = 2) with an excess of Ac_2O [12]. Acetylation of the free hydroxyl groups was performed in a benzyl ether of cellulose with DS = 2; in benzene using Ac_2O catalyzed with TEA [13], an addition of

4-dimethylaminopyridine to the system promoted the DS of acetyl groups from 0.1 to 0.35. The reaction was also reported for nanocellulose [14].

Cellulose Formate

Formylation of cellulose for the first time was performed with DS values of about 2.5 using 98–100% formic acid at room temperature after a reaction time of about 2 weeks [15]. The rate of reaction was increased with the addition of H_2SO_4, HCl, or $ZnCl_2$. Phosphoric acid also can catalyze the reaction in water with a DS of about 0.6 [16]. A special approach was described by Vigo et al. for the synthesis of cellulose formate via reacting of cellulose with thionyl chloride in DMF [17].

Other Cellulose Alkylates

Cellulose esters of higher aliphatic acids were synthesized along the same methods as described for cellulose acetate such as employing the acid anhydride in the presence of the suitable catalyst or the acid chloride with a tertiary base. The propionylation of cellulose can be performed with the corresponding anhydride and an acid catalyst. For obtaining high DS, a cellulose suspension in dioxane/pyridine can be employed with propionic acid chloride for propionylation. The heterogeneous propionylation of cellulose was investigated with Farvardin and Howard using propionic acid, propionic anhydride, and a metal chloride as the catalyst in an aprotic solvent [18]. Acylation of cellulose with an aliphatic chain length of between three and eight carbon atoms can be carried out using a 2% cellulose solution in DMA/LiCl with 9% LiCl, and a mixture of the appropriate acid with its anhydride in the presence of *N*,*N*′-dimethylcyclohexylcarbodiimide (DCC) or pyrrolidinopyridine as the catalyst [19]. The propionylation of partially substituted methyl and ethyl celluloses to give stable ether esters has been performed by Guo and Gray [20].

The esterification with higher aliphatic acids is challenging and must be taken in the dry solvent. For such esterification, a preactivation of the polymer with an aliphatic amine is a good strategy for increasing DS. Esterification of microcrystalline cellulose with pelargonic acid chloride, up to a DS of 3, has been reported by Battista et al. [21]. A mixture of *p*-toluenesulfonyl chloride and the sodium carboxylate in a medium of DMF and pyridine was found to be effective in the preparation of higher cellulose esters [22]. Homogeneous transesterification of cellulose trinitrite by lauroyl chloride in a N_2O_4/DMF solution of cellulose was reported by Shimizu et al. [23].

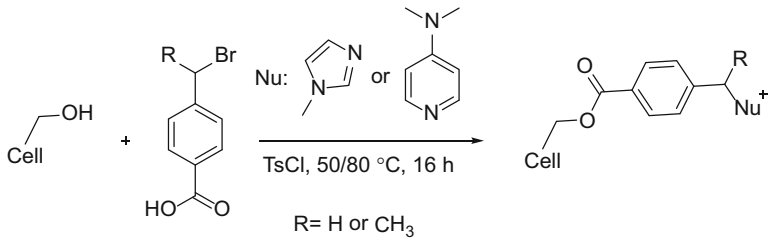
Palmitoyl ester of cellulose was prepared by the reaction of cellulose with the appropriate acid chloride without the presence of a solvent at a sufficiently high temperature [24]. In this "vacuum acid chloride technique," the HCl formed is eliminated from the system continuously by vacuum. The effects of fatty acid chain lengths and solvent on the esterification of cellulose with fatty acids are described [25]. The esterification of bacterial (and vegetable) cellulose fibers with a wide variety of anhydrides (acetic, butyric, hexanoic, and alkenyl succinic anhydrides) and hexanoyl chloride suspended in an ionic liquid, tetradecyltrihexylphosphonium bis(trifluoromethylsulfonyl)imide, [TDTHP][NTf_2], can be performed [26]. The esterification of cellulose can be performed in the gas phase. In a report, the reaction

of palmitoyl chloride vapors with aerogels of cellulose nanocrystals gave palmitate ester of the polymer [27]. Heterogeneous esterification of softwood cellulose nanofibers (CNF) using pyridine/tosyl chloride gives cellulose oleate [28].

Cellulose Aromatic Esters

Cellulose benzoate and phthalate are cellulose aromatic esters. Cellulose tribenzoate with a DS between 2.8 and 2.9 is obtained in a one-step reaction of the polymer with benzoyl chloride in the presence of pyridine [29]. Nitrobenzene as a solvent and pyridine as the catalyst were used for this reaction at 130–140 °C. In this approach, a monobenzoate could be conveniently prepared by reacting alkali cellulose with an appropriate amount of benzoyl chloride [30]. An unconventional route of synthesis has been reported by Isogai et al. who used ozonization of cellulose tribenzyl ether with DP of 1200 to produce a cellulose benzoate with DS of 2.5 and a DP of about 800 [31]. Derivatization of cellulose benzoates was performed with high DS using the appropriate free acids containing $–NO_2$, –Cl, or $–OCH_3$ in the presence of pyridine and *p*-toluenesulfonyl chloride [23]. Cellulose cinnamates with a DS of up to 3 have been synthesized by the reaction of cellulose dissolved in DMA/LiCl with cinnamoyl chloride in the presence of pyridine at 30–60 °C [32]. The esterification of cellulose with carboxylic acid can help to introduce ionic compounds on cellulose. As an example, the reaction of nanocellulose with benzoic acid which contains a leaving group such as bromide gave an intermediate for the reaction with 1-methylimidazole and 4-dimethylaminopyridine according to Scheme 1 [33].

Phthalic anhydride is generally employed for the esterification of cellulose in the presence of a basic catalyst for the phthaloylation of cellulose. The esterification of cellulose with the anhydrides of phthalic acid, nitrophthalic acid, and trimellitic acid in the presence of TEA and DMAP in DMSO was reported [34]. Cellulose acetophthalates are important commercial products, which are generally obtained by the reaction of cellulose acetate in the DS range between 1.7 and 2.5 with phthalic anhydride in the presence of a basic catalyst such as pyridine or TEA, in a dipolar aprotic or rather a nonpolar medium (DMSO, DMF, dioxane, acetone, benzene). Also, tetrahydro- and hexahydrophthalic acid anhydride have been introduced as esterifying agents in the presence of a catalyst such as TEA, pyridine, picoline, lutidine, DMAP, and 1,4-diazabicyclo-2,2,2-octane (DABCO).



Scheme 1 The loading of 1-methylimidazole and 4-dimethylaminopyridine on nanocellulose

Cellulose Esters with Amino Acids

The esterification reaction susceptibility of cellulose makes it possible to bind the polymer with the most of the carboxylic acids. The modifications of cellulose were reported with various hydrophilic (Gly, Ser), aliphatic (Ala, Val, Leu, Ile), and aromatic amino acids (Phe, Tyr, Trp). The carboxylic acid group of amino acids can be reacted with cellulose hydroxyl groups by the esterification reaction while this group is a neighbor of an amine group. It is shown that the aromatic amino acids, particularly Trp, enhanced cell spreading [35]. Modification of cellulose whiskers was reported with l-leucine amino acid via esterification reaction [36].

Cellulose Esters with Sulfonic Acid

Esters of cellulose can be formed also with sulfonic or phosphonic acid groups. Two important sulfonic acids are methylsulfonic acid, so-called mesylcellulose, and the esters of cellulose with *p*-toluenesulfonic acid, so-called tosylcellulose. The reaction of cellulose with a large excess of *p*-toluenesulfonyl chloride in pyridine at room temperature up to 80 °C led to the formation of tosylcellulose [37]. In a homogeneous system, tosyl chloride was employed in the presence of TEA as the base, for the tosylation of cellulose with a degree of polymerization (DP) between 280 and 5100, arriving at tosylcelluloses of DS values between 0.4 and 2.3 during 24 h at 8 °C [38].

Phenyl Carbamate of Cellulose

The reaction of cellulose with an excess amount of phenyl isocyanate in a dipolar aprotic medium in the presence of pyridine at 70–100 °C yields a cellulose tricarbanilate. The reaction system changes gradually from a heterogeneous one to a homogeneous one, and only negligible chain degradation has occurred in this process [39]. A homogeneous route to the preparation of cellulose tricarbanilate was reported by dissolving the sample in DMA/LiCl and its reaction with an adequate amount of phenyl isocyanate in the presence of pyridine as the catalyst [40]. Some derivatives of cellulose carbamate such as 3,5-dimethylphenyl carbamate residue in the C-2/C-3 positions and a 3,5-dichlorophenyl carbamate residue in the C-6 position were synthesized by Kaida and Okamoto [41].

Other Organic Esters of Cellulose

Cellulose, extracted from sugarcane bagasse, was successfully succinylated using DMAP as a catalyst in ionic liquid of 1-butyl-3-methylimidazolium [42]. The esterification of cellulose can be assisted to the immobilization of ligands capable of complexation with metal cations on the polymer. The esterification reaction of cellulose with citric acid gives cellulose citrate as a ligand for removal of copper pollutions [43].

1.1.2 Inorganic Esters of Cellulose

Some of the cellulose esters with inorganic compounds containing S, N, P, and B are introduced. The chemistry of these compounds is challenging due to the impossibility of isolation the products.

Cellulose Sulfuric Acid

The reaction of SO_3 or XSO_3H with the hydroxyl group of cellulose can lead to the formation of cellulose sulfuric acid (CSA). CSA can be converted to a neutral sodium salt soluble in water above a DS of 0.2–0.3. The synthesis of medium to high DS cellulose sulfates was performed with the SO_3/DMSO or the SO_3/DMF complex [44]. Most frequently H_2SO_4, SO_3, and $ClHSO_3$ were applied as the sulfonating agents of cellulose, which in some cases alcohols, amines, or inert media such as chlorinated hydrocarbons used for improving the yield.

After the first report about the reaction between cellulose and sulfuric acid, the reaction was improved in the presence of some reagents such as SO_3 and $ClSO_3H$, also SO_2Cl_2, FSO_3H, $ClSO_2–OC_2H_5$, $CH_3–CO–SO_4H$, and $NO–SO_4H$. Among these reagents, SO_3 and $ClSO_3H$ showed high activities. Sulfation of cellulose with SO_3/DMF in several solvent media was investigated in the presence of TEA, indicating a positive effect of the presence of TEA.

Cellulose Inorganic Ester Containing Nitrogen

Cellulose Nitrate

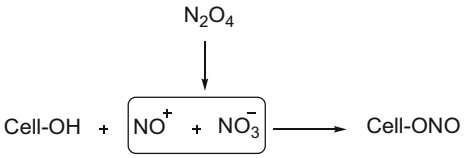
Cellulose nitrate had been prepared already in 1847 by reaction of the polymer with HNO_3 in the presence of H_2SO_4/H_2O [45]. This route is still of interest for the industrial production of cellulose nitrate. Nitration of cellulose was reported under different conditions [46]. The nitration systems of this report include $HNO_3/H_2SO_4/H_2O$, HNO_3/inorganic nitrate, HNO_3 vapor, HNO_3 vapor + NO_x, $HNO_3/H_3PO_4/P_2O_5$, N_2O_5, N_2O_5/CCl_4, HNO_3/CH_2Cl_2, $HNO_3/CH_3–NO_2$, $HNO_3/CH_3COOH/Ac_2O$, and HNO_3/propionic acid/butyric acid. High nitrogen contents, >14%, can be obtained without significant chain degradation by the systems HNO_3/CH_2Cl_2 at 0 to −30 °C, $HNO_3/H_3PO_4/P_2O_5$, and HNO_3/acetic acid/acetic anhydride. Also, nitronium salts like $[NO_2]^+[BF_4]^-$ and KNO_3 in 98% H_2SO_4 can make a little nitration of cellulose [47]. Formation of cellulose nitrate was also claimed to occur on heating a solution of cellulose in N_2O_4/DMF [48]. Cellulose mixture with 0.5 M $[NO_2]^+[BF_4]^-$ in sulfolan, as well as with KNO_3 in 98% H_2SO_4, gives cellulose nitrate [47].

Cellulose Nitrite

The nitrite of cellulose cannot be synthesized by esterification with HNO_2 due to the low acidity and the low stability of nitrous acid. However, a highly substituted nitrite of cellulose can be prepared by the reaction of cellulose with N_2O_4, NOCl, or several salts like nitrosylic compounds under anhydrous conditions in a suitable dipolar aprotic solvent like DMF. The general reaction for the preparation of cellulose nitrite from N_2O_4 is according to Scheme 2.

The O-6 position is preferred for the modification to nitrite formation. Some of the important reagents for the esterification of cellulose with nitrite are N_2O_4, NOCl, $NOSO_4H$, $NOBF_4$, and $NOSbCl_6$ [49].

Scheme 2 Synthesis of cellulose nitrite from N_2O_4



Cellulose Inorganic Esters Containing P

The covalent binding of phosphorus to the cellulose gives one of cellulose phosphate Cell-O-P(O)$(OH)_2$, cellulose phosphite Cell-O-P$(OH)_2$, and cellulose phosphonic acid groups Cell-P(O)$(OH)_2$.

Cellulose Phosphate

Pentavalent phosphorus compounds such as H_3PO_4, P_2O_5, and $POCl_3$ are the most frequently used reagents for phosphorylation of cellulose. Compared to the corresponding compounds of hexavalent sulfur, these phosphorylating agents which usually give anionic cellulose phosphates show a lower reactivity in the esterification and lead to much less chain degradation during this process. Concentrated orthophosphoric acid has been widely used as an effective phosphating agent, and various procedures have been reported for the synthesis of cellulose phosphates with phosphorus contents of about 10% [50]. Water-soluble cellulose phosphates of rather high DP can be obtained with water-free H_3PO_4, in which P_2O_5 was employed for increasing phosphorylation yield [51]. A system including H_3PO_4/P_2O_5/DMSO, and also with ternary systems of H_3PO_4/P_2O_5/aliphatic alcohols with 4 to 8 C atoms, produced water-soluble cellulose phosphates [51]. The reaction of cellulose with a melt solution of H_3PO_4 and urea gives a soluble, but strongly degraded, cellulose monophosphate monoammonium salt [52]. Phosphorus oxychloride ($POCl_3$), as an effective phosphating agent for cellulose, in the reaction with a cellulose suspension in DMF or pyridine gives cellulose phosphate with some by-product such as chlorinated cellulose. Phosphorylation of cellulose hydrogels was reported with a mixture of phosphorus pentoxide, triethyl phosphate, and phosphoric acid [53].

Cellulose Phosphite

Cellulose phosphite can be prepared by the reaction of cellulose with a trivalent phosphorus such as PCl_3 [54] or by transesterification with dimethyl phosphite, arriving at hydrolysis-susceptible phosphite esters of cellulose [55]. Cellulose phosphites have also been synthesized, employing mixed anhydrides of hydrophosphoric and acetic acid and arriving at phosphorus contents of up to 8% [56].

Cellulose Phosphonic Acid

Preparation of cellulose phosphonates, the phosphorus directly bound to a C atom of the cellulose, is either an esterification with methyl or phenylphosphonic anhydride [57] or a two-step reaction consisting of the chlorination of cellulose

with $SOCl_2$ to give chlorodesoxycellulose with a high Cl content (up to 16%) and the subsequent reaction of this compound with triethylphosphite to the cellulose phosphonate via an Arbuzov rearrangement. 3-(Hydroxyphenylphosphinyl)-propanoic acid (3-HPP) esters of cellulose were synthesized in DMA/LiCl homogeneously by the method of in situ activation with *p*-toluenesulfonyl chloride [58].

Cellulose Borates

Boron-containing cellulose derivatives are interesting due to unique properties such as flame retardancy or heat stability. The synthesis of cellulose borates was reported by two approaches including (i) the direct esterification of cellulosic hydroxy groups with orthoboric or metaboric acid and (ii) a transesterification of cellulose with boronic acid esters of lower aliphatic alcohols (boron alkoxides). A direct borylation of cellulosic hydroxy groups can be performed with ortho- or metaboric acid in a melt of urea at 150–200 °C [59]. The preparation of a mixed borate/phosphate cellulose has been described by subsequent reaction of the cellulose borate with H_3PO_3/urea and with $H_4P_2O_7$ or HPO_3/urea in the temperature range 100–200 °C [60].

1.2 Desoxycelluloses

Desoxycelluloses are cellulose derivatives obtained from the substitution of a hydroxy group by halogen, sulfur, nitrogen, or even carbon. Cellulose esters, tosylcellulose or mesylcellulose, are efficient intermediates for the synthesis of desoxycelluloses. The desoxycelluloses are produced from the reaction of these intermediates with inorganic salts containing the group to be introduced as the nucleophilic reagent in this displacement reaction. The use of tetraalkylammonium fluorides proved to be successful for reaching a high degree of substitution [61]. Chlorodesoxycellulose is most conveniently synthesized from the reaction of cellulose with $SOCl_2$ in pyridine [62], DMF [63], CCl_4 [64], or $CHCl_3$. Carre and Manclere [62] reported the synthesis of cyclic sulfide-modified cellulose. Also, SO_2Cl_2 can be applied to prepare chlorodesoxycelluloses with DS values of 0.4–0.8 [65]. A homogeneous approach to the preparation of chlorodesoxycellulose was reported by Furuhata et al. [66], starting from a solution of the polymer in DMA/LiCl and reacting with *N*-chlorosuccinimide and triphenylphosphine. A homogeneous chlorination of cellulose can also be performed with methylsulfuryl chloride after dissolving the polymer in the chloral/DMF system. Fluorodesoxycellulose was prepared via a treatment of mesylcellulose with an aqueous NaF solution [67]. Bromodesoxycellulose can be prepared by *N*-bromosuccinimide and triphenylphosphine [68]. Some of the routes for the synthesis of desoxycelluloses from tosyl- to mesylcellulose were described in Table 1.

Tosylcellulose is also applied as the starting material for the preparation of aminodesoxycellulose by reacting with NH_3, aliphatic amines, or hydrazine [69].

Table 1 Preparation of desoxycelluloses via tosyl- or mesylcellulose

Entry	Desoxy group	Tosyl- or mesylcellulose	Reagents and conditions
1	Fluoro-	mesylcellulose	NaF in H_2O
2	Chloro-	tosylcellulose	Tosyl chloride and pyridine at high temperature
	Chloro-	tosylcellulose	LiCl in acetylacetone (2 h at 130 °C)
3	Bromo-	mesylcellulose	NaBr in H_2O
	Bromo-	tosylcellulose	NaBr in acetylacetone (2 h at 130 °C)
4	Iodo-	tosylcellulose and mesylcellulose	NaI in acetylacetone (2 h at 130 °C)
5	Mercapto-	tosylcellulose	H_2S in pyridine (8 h at 40 °C, then 70 h at room temperature)
	Mercapto-	tosylcellulose	$Na_2S_2O_3$ in DMSO
6	Cyano-	tosylcellulose	KCN in DMF or methanol (100–150 °C)
7	Thiocyanato-	tosylcellulose	NaSCN in acetonylacetone (11 h at 110 °C)
8	Azido-	tosylcellulose	NaN_3 in DMSO (110–130 °C)

1.3 Cellulose Ethers

Cellulose ether was prepared for the first time in 1905 by Suida, who reacted the cellulose with dimethyl sulfate to give a methylcellulose. Later, some other important classes of cellulose ethers such as carboxymethyl cellulose, benzyl cellulose, or hydroxyethyl cellulose had been introduced. In the early 1920s, industrial production of carboxymethyl cellulose (CMC) started in Germany. Two important routes are introduced for the production of cellulose ethers on the large scale:

(i) The reaction of hydroxy groups of cellulose with an alkyl chloride in the presence of strong alkali metal hydroxides, according to the Williamson ether synthesis
(ii) The ring-opening reaction of an alkylene oxide with the hydroxy groups of cellulose, which is catalyzed by alkali metal hydroxides

Also various silyl ethers have been synthesized by the reaction of cellulose especially with trialkylchlorosilanes.

1.3.1 Aliphatic Ethers of Cellulose

Most important aliphatic ethers of cellulose are methylcellulose, CMC, and hydroxyethyl cellulose (HEC).

Alkyl Ethers of Cellulose

As the most important compound from alkyl ether category, methylcellulose is commercially produced by a Williamson reaction of alkali cellulose with gaseous or liquid CH_3Cl. The etherification of cellulose in the presence of alkali hydroxide is accompanied by the hydrolysis of methyl chloride with the water. Methylation of

cellulose by the Williamson reaction is generally carried out at elevated temperature with cellulose in the solid state. Some of the systems employed in laboratory methylation of cellulose include DMSO/NaOH/CH_3I [70], DMSO/LiH/CH_3I [71], DMF, THF/NaH/CH_3I [72], CH_2Cl_2/2,6-di-i-butylpyridine $(CH_3)_3O^+[BF4]^-$ [73], and $(CH_3)_3PO_4$/2,6-di-*t*-butylpyridine/$CF_3SO_3CH_3$ (methyl triflate) [73]. Instead of methyl chloride, also methyl iodide, dimethyl sulfate, diazomethane, or special agents such as trimethyloxonium tetrafluoroborate, or methyl triflate can be used. NaH or LiH, metallic Na dispersed in an ammonia, and di-*t*-butylpyridine are bases applicable in this reaction. Methylcellulose has also been synthesized in aqueous solutions of tetraalkylammonium hydroxides [74]. Some of the methylation systems of cellulose are CH_3I/NaH in THF and CH_3I/powdered NaOH in DMSO [75].

Ethylation of cellulose has been performed by reacting alkali cellulose with ethyl chloride, arriving at a substitution pattern with about equal partial DS at C-2 and C-6 and again a low degree of etherification at C-3 [76]. Propylation of cellulose required either a previous partial methylation for "widening" the cellulose structure or employing a tetraalkylammonium hydroxide of high swelling power in aqueous solution as the base and reaction medium [77].

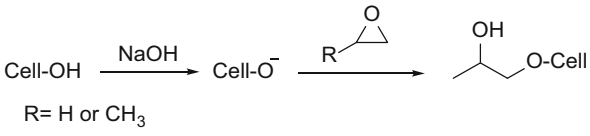
The preparation of long-chain cellulose alkyl ethers was reported in nonaqueous system by reaction of cellulose acetate with the appropriate alkyl bromide in the presence of NaOH in DMSO [78]. Blasutto (1995) reported the preparation of long-chain alkyl ethers from the reaction of cellulose with appropriate alkyl bromide in isopropanol or in DMSO in the presence of NaOH or NaH [79]. Recently, etherification of cellulose with chloroacetic acid has attracted attentions, since cellulose acetic acid as the product has the ability of more modification. Modification of cellulose acetic acid with *D*-penicillamine gave a good cellulose-based ligand for grafting of Co(II) [80]. Cellulose acetic acid was also modified with ethylenediamine for preparation of a Pd ligand [81].

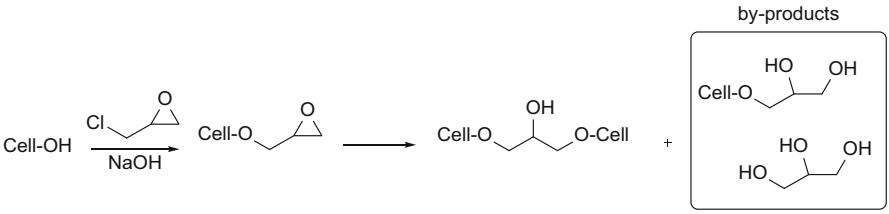
Hydroxyalkyl Ethers of Cellulose

Two commercially relevant derivatives of cellulose are hydroxyethyl cellulose (HEC) and hydroxypropyl cellulose (HPC), which are prepared by the reaction of cellulose with ethylene oxide and propylene oxide, respectively (Scheme 3).

The acid-catalyzed cleavage of the epoxy ring for alkylation of cellulose leads to the homopolymerization of epoxy instead of the intended etherification. Hydroxyalkylation of cellulose using basic catalyst is generally performed with the weight ratio of NaOH/cellulose varying within the wide limits of between

Scheme 3 Preparation of HEC and HPC





Scheme 4 The reaction of cellulose with epichlorohydrin

Scheme 5 The reaction of cellulose with formaldehyde

0.3:1 and 1:1 and that of H_2O/cellulose between 1.2:1 and 3.5:1. In this route, an excess of a fairly inert diluent like *i*-propanol, *t*-butanol, or acetone is employed in hydroxyethylation [82].

Etherification with Epichlorohydrin

Epichlorohyrin having two electrophilic sites acts as a cross-linking agent of cellulose in an aqueous alkaline medium with some by-products. This process is described in Scheme 4.

For this reaction catalytic amounts of NaOH required for epoxy ring cleavage and the stoichiometric amount of 1 mol/mol of epichlorohydrin are necessary for the epoxide formation [83]. Etherification with epichlorohydrin has also been performed with cellulose dissolved in DMA/LiCl and powdered NaOH or with LiOH as the base [84].

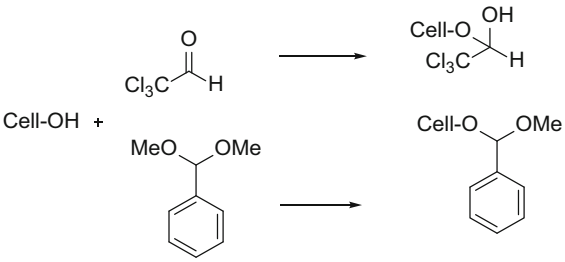
Hydroxymethyl Cellulose

Hydroxymethyl ("methylol") cellulose can be produced from the reaction of cellulose with a large excess of formaldehyde above 80 °C or, more comfortably, with paraformaldehyde in DMSO at 135–140 °C (Scheme 5). A methylolated cellulose preparation was examined in various solvents at elevated temperature with gaseous CH_2O, as well as with paraformaldehyde [85]. DMSO, DMA/LiCl, and DMF/LiCl are good solvents for the preparation of methylol cellulose.

The synthesis of a methylol cellulose octadecylcarbamate was reported by the reaction of cellulose with octadecyl isocyanate in the presence of stannic octoate at 50 °C in DMF/LiCl as the solvent [86].

Some of the interesting derivatives of methylol celluloses were reported using reagents with similar behavior with formaldehyde such as trichloroacetaldehyde (chloral) and hemiacetals (Scheme 6) [87].

Scheme 6 The reaction of cellulose with chloral and hemiacetal



Cyanoethyl Cellulose

Cyanoethylation of cellulose proceeds via a Michael addition of partially anionized cellulose hydroxyl group to an activated C=C bond of acrylonitrile. Bikales reported a procedure for the preparation of a fibrous cyanoethyl cellulose with DS = 2.75 (12.6% N) from regenerated cellulose with acrylonitrile and aqueous NaOH at 50 °C [88]. Wide studies were performed on the cyanoethylation of cellulose. Cyanoethylation of cellulose has been reported as an equilibrium reaction with the cellulose either by simultaneous (one-step process) or by subsequent (two-step process) addition of the components aqueous NaOH and acrylonitrile at a temperature between 30 °C and 50 °C, within some hours. The reaction rate of cyanoethylation can be improved significantly by a preactivation of the cellulose sample by 18% NaOH or by pretreatment with liquid NH_3 and could also be enhanced by the addition of DMSO to the system for increasing the solubility of acrylonitrile [89]. *N*-Methylmorpholine also can play a base role for the cyanoethylation of cellulose [90]. The nitrile group of cyanoethyl cellulose can be reduced to an aminopropyl substituent with diborane [91]. An amidoxime can be prepared from the reaction of hydroxylamine with carbamoylethyl cellulose in a neutral aqueous system at 70 °C [92].

Aminoalkylcellulose

The reaction of cellulose with aziridine gives the aminoethylcellulose in an aqueous alkaline medium. The route is preceded by employing cellulose suspension in toluene and reacting it with aziridine in the presence of benzyl chloride in an autoclave at 70 °C for 10 h. Aminoethylation of cellulose and cellulose derivatives was reported with ethylenimine, 2-methylethylenimine, 2,2-dimethylethylenimine, trimethylethylenimine, 2-phenylethylenimine, 2-(*p*-tolyl) ethylenirnine, Z-biphenylethylenimine, 2-(*p*-aminophenyl)ethylenimine, and 2-(2,4-dinitrophenyl)ethylenimine [93]. Figure 1 shows some of the starting materials for the reaction with cellulose to produce aminoalkylcellulose.

Sheets of bacterial cellulose were chemically modified with glycidyltrimethylammonium chloride in the presence of sodium hydroxide to introduce a positively charged amine to cellulose [94]. DABCO-cellulose nanofibers can be prepared via the activation of cellulose with tosyl group and subsequent reaction of cellulose tosylate with DABCO [95]. Immobilizing of amine groups on cellulose can be

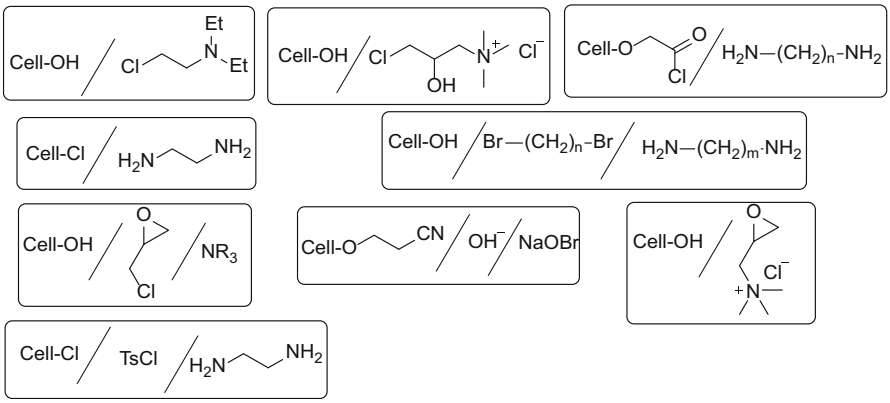


Fig. 1 Some of the starting materials for the reaction with cellulose to produce aminoalkylcellulose

improved metal complex with the modified cellulose. Modification of cellulose can be performed with glycidyl methacrylate (GMA) and diethylenetriamine to deposition of amine groups on cellulose for the preparation of Cu(II) and Hg(II) absorbent [96]. Keshipour et al. modified cellulose with ethylenediamine to improve cellulose activity in Pd or Co complexation for the synthesis of efficient catalyst for coupling [97], cycloaddition [98], and oxidation reactions [99, 100].

Sulfoalkyl and Thioalkyl Ethers of Cellulose

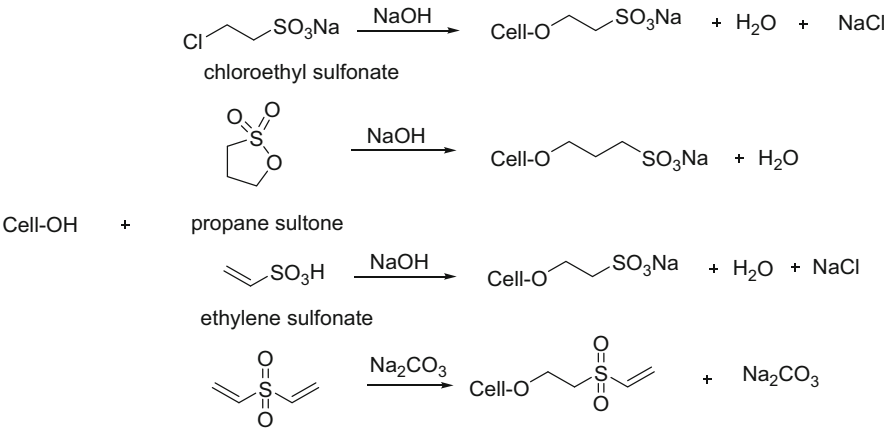
This category of cellulose derivatives is synthesized from the reaction of alkali cellulose with chloroalkane sulfonate, propane sultone, or ethylene sulfonate (Scheme 7) [101].

The order of reactivity of the agents for this reaction is propane sulfone < chloroalkyl sulfonate < vinyl sulfonate. Other reagents for the sulfoalkylation are $Cl–CH_2SO_3Na$, $HSO_3–O–CH_2–CH_2SO_3H$, and $CH_2=CH–SO_2–CH=CH_2$.

Thioalkyl cellulose synthesis can be performed via thiol-ene click reaction in two steps including the reaction of cellulose with allyl chloride to give allyl cellulose and then the reaction of allyl cellulose with a sulfide [102]. The thiol-ene reaction also was reported with vinyltrimethoxysilane and 3-mercaptopropyltrimethoxysilane [103].

Arylalkyl Ethers of Cellulose

Benzyl cellulose as the most important ether of this type was first synthesized by Leuchs in 1917. The chemical library of arylmethyl ethers was developed by the introduction of substitute that contained different types of alkyl residues [104], halogen substituents [105], and functional groups like methoxy, nitro, and amino groups mainly in para position of the benzyl units or in some cases aryl groups other than phenyl [106]. The synthesis pathway consists in the reaction of cellulose with



Scheme 7 The procedures for the preparation of sulfoalkyl ethers of cellulose

the corresponding arylmethyl halogenides in presence of a base [107]. The reaction proceeds in water using sodium hydroxide [108].

Triphenylmethyl ("trityl") cellulose as the most important ether of a class of organosoluble aryl cellulose ethers was formed by the reaction of phenylmethyl halides with cellulose in the presence of an organic base [109]. Some similar compounds such as benzhydryl (diphenylmethyl)cellulose, benzyl(phenylmethyl)cellulose, and phenylcellulose were generally prepared via this route. Heterogeneous tritylation of decrystallized cellulose was reported using pyridine by treatment with 15% aqueous ammonia and yields colorless products with DS values from 0.81 to 1.21 [110].

1.3.2 Aryl Ethers of Cellulose

The introduction of an aromatic group via an ether bond leads to cellulose aryl ethers, especially to phenyl and substituted phenylcelluloses. The reaction can be performed via the etherification of cellulose with activated aryl halogenides or the displacement reaction of cellulose tosylate with corresponding phenolates. Various phenyl derivatives were employed for this reaction such as phenyl containing nitro, carboxylic acid, amine, bromide, chloride, etc. [60].

1.3.3 Silyl Ethers of Cellulose

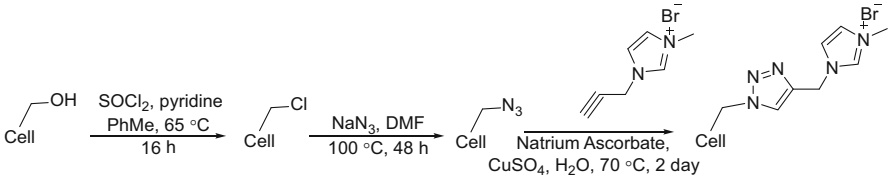
The reaction of cellulose with TMS-Cl in the presence of pyridine has been reported for the first time by Schuyten et al. [111]. Silylation of cellulose with TMS-Cl and pyridine gave TMS cellulose with DS values of 2.4 to 3.0. The reaction was investigated in some solvents such as xylene, toluene, and petroleum ether, in which short reaction times in toluene and mild reaction conditions in petroleum ether were obtained. In addition, NH_3 instead of pyridine improved the reaction conditions [112]. Klebe and Finkbeiner have synthesized cyanopropyldimethyl-, phenyldimethyl-, and diphenylmethylsilylcelluloses. Hexamethyldisilazane is a convenient reagent for the trimethylsilylation of cellulose [113]. The reaction proceeded

in polar solvents in the presence of catalyzers such as NH_4Cl or TMS-Cl/pyridine. Cellulose activated with ammonia at 80 °C has been reacted with the thexyldimethylsilylamine, prepared from the reaction of thexyldimethylchlorosilane (TDMSCl) and *N*-methylpyrrolidone (NMP) to give corresponding silylated cellulose. The chemical modification of cellulose with silanes contains another functional group which assisted the loading of the desired functionality on cellulose. For example, the modification of cellulose paper with 3-aminopropyltrimethoxysilane leads to the deposition of an amine group on cellulose [114].

1.4 Heterocycles Grafted on Cellulose

Heterocyclic-nanocellulosic derivatives were prepared by surface modification of cellulose nanocrystals with 4-chloro-2,2′:6′,2″-terpyridine and subsequent coupling with other terpyridine-functionalized derivatives via Ru^{III}/Ru^{II} reduction [115]. Alkynylated cellulose nanocrystals were modified with a series of reactive GAP (glycidyl azide polymer)/PTPB (propargyl-terminated polybutadiene) nanocomposites by the Huisgen click chemistry [116]. In this reaction, cellulose contains alkyne group which reacted with the polymers containing azide groups to give triazide cycles. Coumarine, as one of the important pharmaceutical scaffolds, was introduced to the cellulose structure via chemical bonding to the hydroxyl group of cellulose. For performing the reaction, at first the acyl chloride group was created on coumarine, and then the new group reacted with the hydroxyl group of cellulose [117]. For loading of the imidazolium group on cellulose nanocrystals, the procedure described in Scheme 8 was performed [118].

A similar strategy using introducing of azide group to cellulose and subsequent reaction of azido cellulose with an alkyne was described [119]. The synthesis of triazide heterocycle on cellulose can be performed by introducing an alkyne group on cellulose and cyclization of the alkyne with an alkyl azide [120]. Chemical modification of cellulose with triazine derivative, 2,4,6-tri-[(2-hydroxy-3-trimethyl-ammonium) propyl]-1,3,5-triazine chloride (Tri-HTAC), was also reported. Tri-HTAC under reaction with NaOH produces a terminal epoxide, in which ring opening occurred under nucleophilic attack of cellulose [121]. Binding of a macrocyclic compound was also investigated, which phthalocyanine-Co(II) [122] and *N*-doped graphene quantum dots [123] were chemically attached to cellulose surface.



Scheme 8 Loading of imidazolium on cellulose nanocrystals

2 Polymers Grafted on Cellulose

The modification of cellulose can be performed with absorbent polymers. Modification of microfibrillated cellulose (MFC) by hydroxycarbonate apatite (HAP) or epoxy gives nanostructured adsorbents for the removal of hydrogen sulfide (H_2S) from the aqueous solutions [124].

2.1 Atom Transfer Radical Polymerization (ATRP) of Cellulose

ATRP, as one of the most popular living/controlled polymerizations [125], is an important approach for the modification of cellulose. In ATRP, the radicals or the active species are generated through a reversible redox process undergo one electron oxidation give an active intermediate for the polymerization. The applications of ATRP for surface graft modification of cellulosic materials were first reported by Carlmark and Malmstom [126]. The general ATRP reaction on the cellulosic material was shown in Scheme 9.

Various functional groups were immobilized on cellulose and cellulose derivatives to perform an ATRP. Vinyl groups are one of the interesting functionalities to initiate an ATRP, which is widely studied. Table 2 gives a summary of the vinyl group as the cellulose ATRP initiator. These ATRPs were initiated by cellulose-X initiators and catalyzed with copper salts in the presence of various amine-type ligands. Table 2 shows the ATRP methods reported for the polymer loading on cellulosic materials.

The ATRP can be performed in both heterogeneous and homogeneous reactions, and the homopolymerization is effectively avoided since the anchored haloacyl groups are the only initiating sites in the system.

2.2 Reversible Addition-Fragmentation Chain Transfer (RAFT) of Cellulose

RAFT polymerization was first reported by Chiefari et al. [172] and developed as MADIX polymerization by Charmot et al. [173]. In both cases, a small amount of dithioester was introduced as chain transfer agent (CTA) in the classic free radical

system. RAFT agents are thiocarbonylthio moieties which are susceptible to undergo radical addition. Two important groups in the RAFT polymerization are R and Z, in which the R group initiates the growth of polymeric chains and the Z group activates the thiocarbonyl bond toward radical addition and then stabilizes the resultant adduct radical. The propagating radical is added to the C=S moiety of the RAFT agent to form an intermediate radical that will fragment back either to the original propagating radical or to a new carbon-centered radical. In the RAFT polymerization of cellulose at first, CTA is attached to cellulose. Then, the reaction completes with the binding of monomer assisted with an initiator such as AIBN. Table 3 shows some RAFT for cellulosic materials.

2.3 Nitroxide-Mediated Radical Polymerization (NMP) of Cellulose

NMP is based on the use of a stable nitroxide radical, such as (2,2,6,6-tetramethylpiperidin-1-yl)oxyl (TEMPO), which is the more commonly used nitroxides. In NMP approach, the propagating species (P_n°) can propagate by reacting with a monomer (M), or it can terminate with other radicals [198]. NMP is usually undertaken at high temperatures.

Nitroxide-mediated grafting of cellulose under homogeneous conditions was first reported by Daly et al. [199]. In their approach, carbonates of *N*-hydroxypyridine-2-thione have first immobilized onto hydroxypropyl cellulose (HPC) backbones and subsequently irradiated the cellulose derivatives in the presence of an excess of TEMPO and styrene (St) to form St-TEMPO adducts promoting the preparation of HPC-g-PS graft copolymers. Nitroxide-mediated polymerization was reported for the synthesis of cellulose-grafted polystyrene (PSt) and poly(methyl methacrylate) (PMMA) as the branches. For this purpose, cellulose was acetylated by 2-bromoisobutyryl bromide, and then the bromine group was converted to 4-oxy-2,2,6,6-tetramethylpiperidin-1-oxyl group by a substitution nucleophilic reaction. The produced intermediate was subsequently used in controlled graft and block copolymerizations of St and MMA monomers to yield cellulose-grafted (g)-PSt and cellulose-g-(PMMA-b-PSt) [200]. Poly(lactic acid)/cellulose nanofiber (PLA/CNF) composites were prepared by TEMPO-mediated oxidation of CNF. MCNF was synthesized by the controlled amidation of CNF with *cis*-9-octadecenylamine (OA) that resulted in PLA/MCNF composites with improved mechanical properties and tunable elongation compared to PLA/CNF [201]. The CNC surface was also functionalized with the nitroxide SG1 (4-(diethoxyphosphinyl)-2,2,5,5-tetramethyl-3-azahexane-*N*-oxyl), yielding a CNC-macroalkoxyamine. Poly(methyl acrylate) and poly(methyl methacrylate) chains were then grafted from the CNC-macroalkoxyamine surface to give polymer-modified CNC [202].

2.4 Single-Electron Transfer Living Radical Polymerization (SET-LRP) of Cellulose

The last controlled polymerization method based on radical mechanism is SET-LRP in which dormant chains (or initiator) are activated via the outer-sphere electron transfer [203]. SET-LRP needs an initiating system that contains halide-type initiator (sulfonyl halides, haloacid esters, etc.), similar to those for ATRP, zero-valent copper, and appropriate ligand, like pentamethyldiethylenetriamine (PMDETA) or tris(2-dimethylaminoethyl)amine (Me_6TREN), in various solvents [198]. SET-LRP differs from ATRP regarding the low activation energy in an outer-sphere electron transfer mechanism for SET-LRP and also the rapid disproportionation of Cu^I with *N*-containing ligands in polar solvents [204]. Since CuX can disproportionate into Cu^0 and CuX_2 species in polar solvents in the presence of *N*-containing ligands [198], rapid living radical polymerization was observed in SET-LRP via the outer-sphere single-electron transfer mechanism. Therefore, Cu^I-mediated ATRP of *N*-isopropylacrylamide in polar solvent proceeded via Cu^0-mediated SET-LRP, and the reaction is not an ATRP [205]. The solvent effect is crucial because deactivating complex salt of Cu^{II} originates from the disproportionation of the Cu^I salt. The rate of which substantially depends on the solvent used [206]. Hence, polar solvents such as DMF, DMSO, and methanol are generally used in SET-LRP. The modifications of cellulose using SET-LRP are listed in Table 4.

2.5 Other Modification Methods of Cellulose with Polymers

While most of the cellulose-grafted polymers take place with one of the radical mechanism mentioned in previous sections, some of the modifications were reported in an unradical mechanism or a radical mechanism with unusual routes. Table 5 describes some of these reports regarding used methods and materials and obtained products.

Table 4 Polymer-grafted cellulosic materials prepared via SET-LRP method

3 Cellulose Modification by Different Nanoparticles and Other Minerals

3.1 Nanoparticles

Metal nanoparticles have attracted more attention due to their various applications such as water purification, catalysis of chemical reactions, and hydrogen storage. Nanoparticles such as different metals, magnetic nanoparticle (iron oxides, cobalt-iron oxide, nickel, etc.), silica, and metal oxide tend to agglomerate to form stable and larger-size particles due to their high active surface area. In recent years, in order to prevent the agglomeration and to stabilize the nanoparticle structures, immobilization of metal nanoparticles on different kinds of substrates such as dendrimers, synthetic polymers, natural polymers, surfactants, and carbon nanotube-grafted polymers has received considerable interest. These synthesized nanocomposites have important applications in optics, electronic devices, catalysis, sensors, medical applications, etc. [223].

3.2 Modification of Cellulose Surface with Different Nanoparticles

Surface modification of cellulose with different nanoparticles led to producing of the modified nanocomposite with a wide range of applications. Here we will introduce and investigate the properties of these modified nanocomposites.

3.2.1 Palladium Nanoparticle

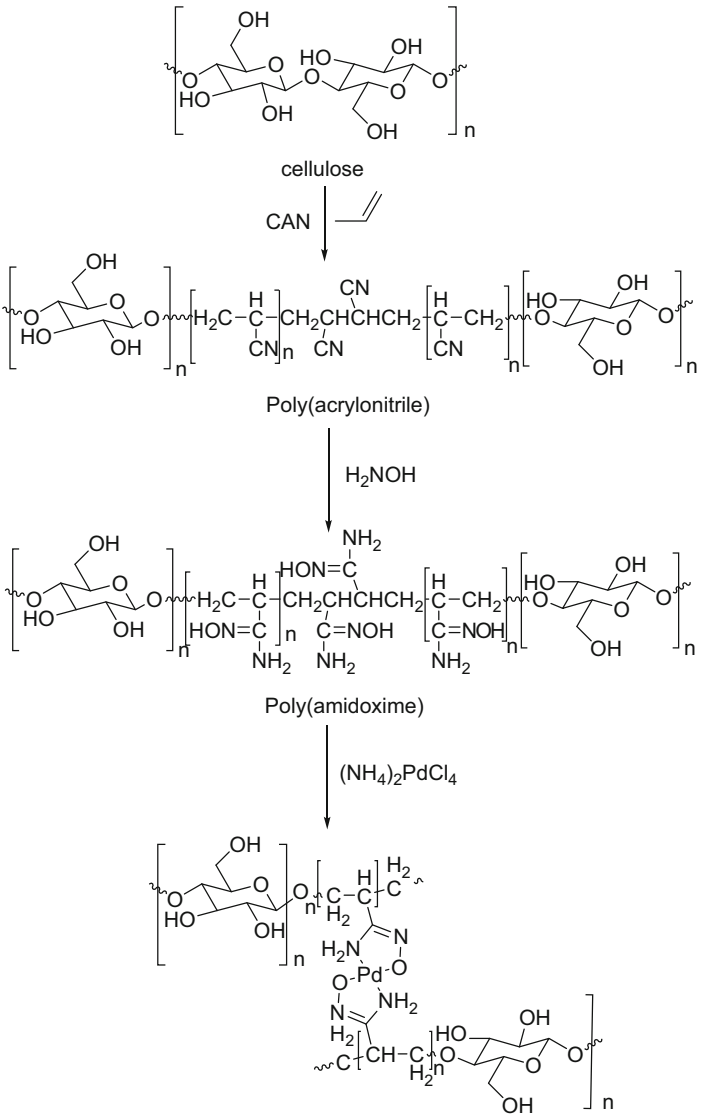
Palladium is one of the most efficient transition metals in catalysis field [224]. Recently, much attention has been paid to the palladium-based materials. Palladium nanoparticles have been investigated in a wide range of catalytic applications such as hydrogenations, oxidations, carbon-carbon bond formation, and electrochemical reactions in fuel cells [225]. However, these materials have different applications. For example, due to the tendency of palladium for adsorbing hydrogen, palladium nanoparticles are applied in hydrogen storage and sensing applications [226]. Due to the aggregation and precipitation of palladium metal in homogeneous palladium catalysts, they lose their catalytic activity. However, tedious workup procedures, loss of catalyst, and contamination of residual metals in the final product are the major drawbacks of these methods. Using heterogeneous palladium catalysts is the best choice to resolve these problems. Thus, it is possible by immobilizing palladium on suitable supports, which can be easily separated from the product without losing catalytic activity. Notably, chemical modification of the cellulose can be occurred by immobilization of transition metal onto the cellulose surface. In order to immobilize more metal on the cellulose surface, various polymers and linkers modify the cellulose surface.

Catalytic Activity

Transition metal catalysis can be catalyzed by 1,3-dipolar cycloaddition reaction, oxidation, direct arylation, and cross-coupling reactions. Palladium-catalyzed

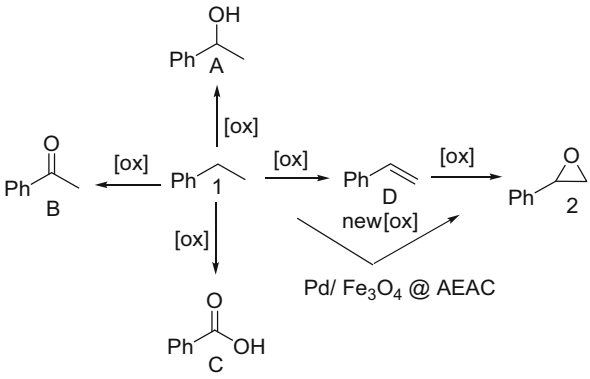
Suzuki, Sonogashira, and Heck couplings are all very important and powerful strategies for the formation of carbon-carbon bonds. There are many examples in this area; some of them will be presented below.

In 2017, a bio-waste corncob cellulose-supported poly(amidoxime) Pd(II) complex was synthesized by S.M. Sarkar and coworkers for the catalytic application in Mizoroki-Heck reaction (Scheme 10). The Pd(II) complex showed an excellent



Scheme 10 Synthesis of cellulose-supported poly(amidoxime) Pd(II) complex

Scheme 11 Oxidation reactions of ethylbenzene



catalytic activity toward the Mizoroki-Heck reaction of aryl halides and aryl diazonium tetrauoroborate salts with a variety of olefins under ambient reaction conditions with regeneration of the Pd(II) complex [227].

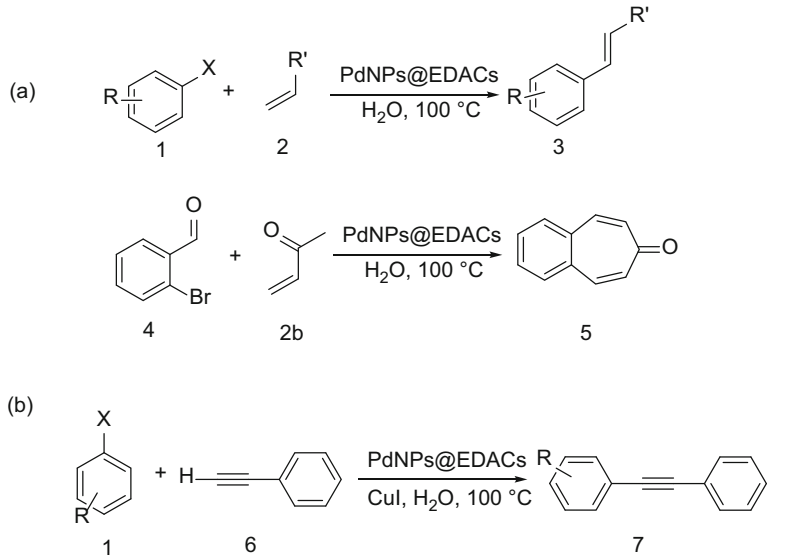
As can be seen in Scheme 11, Keshipour et al. have reported the oxidation of ethylbenzene to styrene oxide in the presence of cellulose-supported Pd magnetic nanoparticles. In this work, a new and efficient catalytic system involving Pd(0)/Fe_3O_4 nanoparticles (NPs) supported on *N*-(2-aminoethyl)acetamide-functionalized cellulose (AEAC) was synthesized and applied as a heterogeneous recoverable catalyst (Pd/Fe_3O_4NP@AEAC) with H_2O_2 as a green oxidant in the oxidation of ethylbenzene to styrene oxide [81].

As shown in Scheme 12, palladium nanoparticles supported on ethylenediamine-functionalized cellulose was synthesized in 2013 by Keshipour et al. and applied as a novel and efficient catalyst for the Heck and Sonogashira couplings in H_2O as a green solvent at 100 °C in a very low loading of Pd. After completion of the reaction, the catalyst could be easily recovered by simple filtration and reused for at least four cycles without significant loss of catalytic activity [97].

Also, this catalyst was used as an electrocatalyst for oxidation of hydrazine. In this work, cellulose was functionalized with ethylenediamine and then used as a support for the preparation of PdNPs immobilized on ethylenediamine cellulose (PdNPs-EDAC) which consisted of uniformly distributed palladium nanoparticles with the main average size of 4.7–6.9 nm. Finally, electrocatalytic activity of a PdNPs-EDAC has been investigated for the oxidation of hydrazine as an important model compound [100].

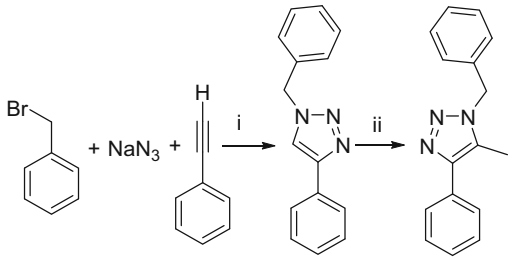
In 2013, Keshipour and coworkers have presented copper(I) and palladium nanoparticles supported on ethylenediamine-functionalized cellulose and suggested for it to be catalytically applicable to both 1,3-dipolar cycloaddition and direct arylation reactions (Scheme 13) [98].

Recently, this group has shown a new efficient catalyst for the green reduction of nitroaromatics (Scheme 14). The catalyst was obtained via modification of cellulose with N-doped graphene quantum dots and Pd nanoparticles. The new cellulose nanocomposite after characterization was applied as the catalyst in the reduction



Scheme 12 (**a**) Heck coupling reaction of styrene and methyl vinyl ketone with halobenzenes and (**b**) Sonogashira coupling of halobenzenes and phenylacetylene

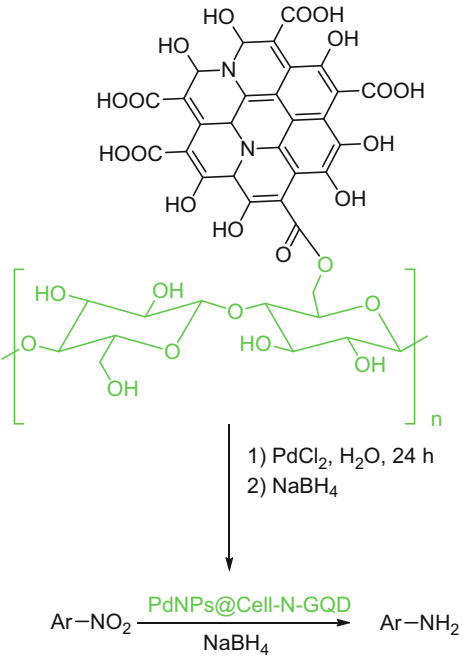
Scheme 13 Cu(I)/PdNPs@EDAC-catalyzed one-pot synthesis of triazoles



reaction of nitroaromatics using $NaBH_4$ at room temperature. Aromatic amines were obtained as the product of the reduction reaction over 2 h. This reaction has green reaction conditions such as mild reaction conditions, high yield, green solvent, and recyclable catalyst. In addition, the recovered catalyst is applicable in the reduction reaction six times without significant decrease in activity [123].

In 2017, a novel ferrocene tethered *N*-heterocyclic carbene-Pd complex anchored on cellulose has been synthesized in several steps by Salunkhe and coworkers. Then it is used as an efficient heterogeneous catalyst for synthesis of biaryls in Suzuki-Miyaura cross-coupling reaction. Some of the notable features of this procedure are good catalytic efficiency, high yields of products, easy separation, large-scale synthesis, and facile recyclability [228].

Scheme 14 Reduction of nitroaromatics with PdNPs@Cell-*N*-GQD



3.2.2 Silver Nanoparticle

Much attention has been paid to silver nanoparticles (AgNPs) due to their unique properties at the nanoscale size. These nanoparticles have several applications in optical, catalytic, magnetic, electrical, and antimicrobial devices. Immobilization of Ag onto polymer and biopolymer surfaces led to improve the properties and applicability of such polymers and biopolymers. As a result, bionanocomposites will be obtained [229]. Some of these applications will be presented as below.

Electrical Activity

Liu et al. in 2017 have developed an in situ polymerization of aniline monomer onto the porous-structured cellulose scaffolds, and then electrodeposition of Ag nanoparticles carried out on the obtained conductive composites. In this study, Ag nanoparticles were deposited homogeneously on the matrix of polyaniline (PANI)/cellulose gels which will increase the conductivity of composites. The conductivity of Ag containing PANI/cellulose nanocomposite gels was increased to 0.94 S C m^{-1}, which was higher than that of pure PANI/cellulose composites (3.45×10^{-2} S C m^{-1}). Thus, this synthesized conductive composite could be used as an electrode for the supercapacitors [230].

Sun and coworkers have presented a self-reporting aerogel toward stress-sensitive electricity (SSE) via combined routes of silver mirror reaction and ultrasonication. Sphere-like Ag nanoparticles (AgNPs) with a mean diameter of 74 nm were tightly immobilized in the cellulose nanofiber. The resulted Ag/CNF as a self-reporting

material for SSE not only possessed quick response and sensitivity but also easily recovered after 100th compressive cycles without plastic deformation or degradation in compressive strength. Consequently, Ag/CNF could play a viable role in self-reporting materials as a quick electric stress-responsive sensor [231].

Antibacterial Activity

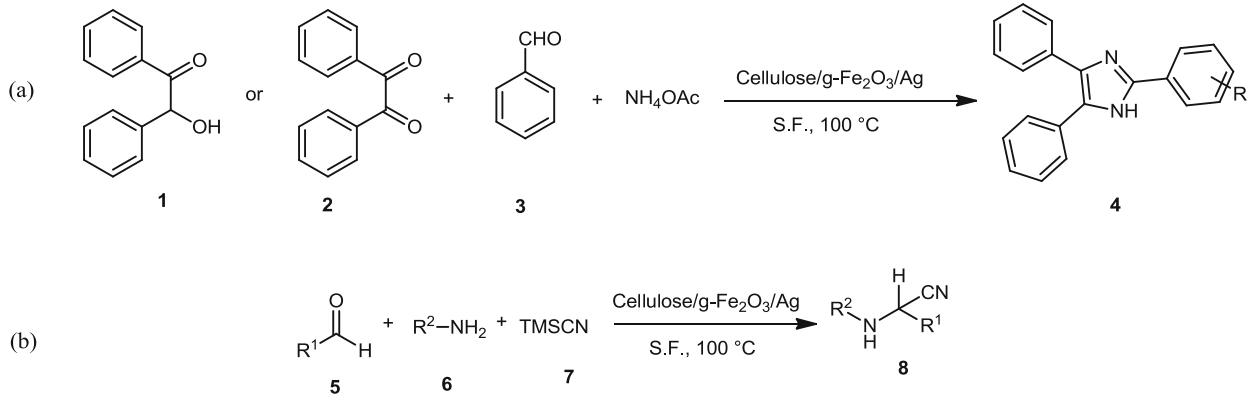
A porous hydrophobic Ag/Ag_2O@cellulose hybrid membrane was prepared by Zhang et al. in 2015. Cellulose is much more flexible, lighter, biodegradable, and ventilated in comparison with most of the existing water-strider-mimicking boats which are built from metals. In addition, the synthesized membrane has shown a water contact angle of 140°. Also, this hybrid membrane exhibited oil/water separation capacity, and it has strong antibacterial activity against *Escherichia coli* [232].

Huang and coworkers have synthesized an antibacterial cellulose/titania/chitosan hybrid material. Firstly, these hybrid materials were prepared by continuously depositing titania gel layer and chitosan layer on the cellulose microfibril bundles of filter paper. After that, silver ions adsorbed with the titania/chitosan composite film, followed by in situ reductions of the immobilized silver ions under UV irradiation. The finalized antibacterial cellulose/titania/chitosan/AgNP hybrid materials were obtained having the fibrous structure of the initial cellulose substance. These hybrid composites showed splendid antibacterial activities due to the intrinsic biocidal effect of titania composition, positively charged chitosan component, and high loading content of AgNPs with small size. Therefore, these AgNP-containing cellulose materials have antibacterial applications such as antibacterial wound dressing, antibacterial packaging, antibacterial adhesion, air/water purification, and so on [233].

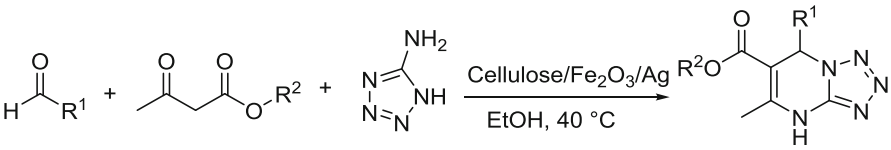
Vosmansk and coworkers have presented the three-step modification of the standard cellulose wound dressing. This method is cost-effective and environmentally benign and does not require the large and complicated device. The best outcome has been shown in the three-step modification of wound dressing including argon plasma treatment, chitosan impregnation, and AgCl precipitation. It also has antibacterial activity against *E. coli* and *S. epidermidis*. The surface of cellulose wound dressing was hydrophilic with the highest amounts of chitosan and AgCl in it. Chitosan was used here due to the antibacterial and healing promoting activity. The amount of adsorbed chitosan has positively affected on the amount of the AgCl in the surface, and as a result, AgCl and chitosan were responsible for the antibacterial effect of the wound dressing. It was found that the combination of chitosan and AgCl precipitation showed better antibacterial effect than each of them alone [234].

Catalytic Activity

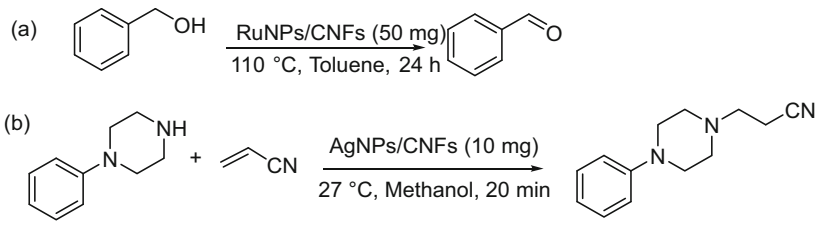
In 2016, Maleki and coworkers have synthesized a cellulose/γ-Fe_2O_3/Ag nanocomposite and applied as a catalyst for the synthesis of trisubstituted imidazoles and α-aminonitriles (Scheme 15). This method is simple and the yields of the products are very high in very short reaction time. The catalyst can be easily separated from the reaction mixture due to its remarkable magnetic properties, and it can be used for several times without considerable loss of catalytic activity. Meantime,



Scheme 15 (**a**) Synthesis of 2,4,5-trisubstituted-1*H*-imidazoles **4** and (**b**) synthesis of α-aminonitriles **8** using cellulose/γ-Fe_2O_3/Ag nanocatalyst under solvent-free conditions



Scheme 16 Synthesis of 5-methyl-7-aryl-4,7-dihydrotetrazolo[1,5-a]pyrimidine-6-carboxylic esters in the presence of magnetic cellulose/Ag bionanocomposite



Scheme 17 (**a**) RuNP/CNF-catalyzed oxidation of benzyl alcohol to benzaldehyde and (**b**) Ag/CNF-catalyzed *aza*-Michael reaction of 1-phenylpiperazine with acrylonitrile

antibacterial properties of the nanocomposite are investigated in this paper. For this purpose, *S. aureus* as the representative of gram-positive bacteria and *E. coli* as the representative of gram-negative bacteria are evaluated. As a result, it has antibacterial activity as well as catalytic application [235].

Also in 2017, for another time, this bionanocomposite catalyst was used by Maleki's group for green synthesis of tetrazolo[1,5-a]pyrimidines. This method has shown various advantages such as easy catalyst recycling, inexpensive catalyst, environmentally benign procedure, short reaction time, and high product yield (Scheme 16) [228].

Hussain et al. in 2014 have represented various methods to immobilize gold and silver nanoparticles on the surface of cellulose fibers. It this work, formation and immobilization of gold and silver nanoparticles occurred through boiling of the cellulose fibers in an alkaline solution of gold and silver salts. The synthesized thiol-modified cellulose fibers loaded with gold and silver nanoparticles were investigated for the catalytic reduction of 4-nitrophenol into 4-aminophenol [236].

Chung et al. have reported noble metal/functionalized cellulose nanofiber composites and investigated their catalytic activities in the aerobic oxidation of benzyl alcohol to benzaldehyde. These heterogeneous nanocomposites are highly efficient, stable, and reusable. In this work, simple reduction method has been used to synthesize MNPs supported on CNFs (RuNPs/CNFs and AgNPs/CNFs). As can be seen in Scheme 17, after characterization of the RuNPs/CNFs and AgNPs/CNFs, their catalytic activities were investigated for the oxidation of benzyl alcohol and *aza*-Michael reaction, respectively [237].

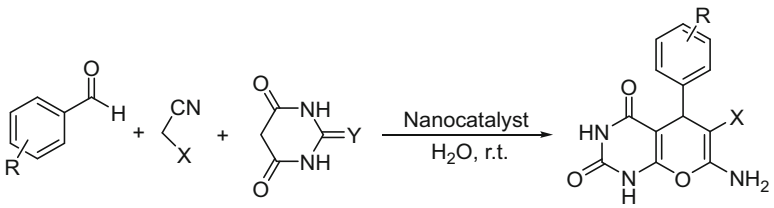
3.2.3 Iron Nanoparticle

Among all transition metals, iron is the most important one and the fourth most plentiful element in the Earth's crust. Iron nanoparticles can be prepared via several methods. Much attention has been paid to this nanoparticle due to their important applications such as treatment to many types of contamination; magnetic data storage and resonance imaging (MRI); medical and laboratory applications, using memory tape due to their magnetic properties; and catalyst applications.

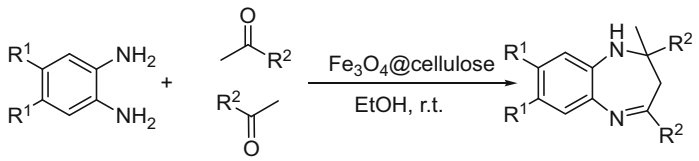
Catalytic Activity

A cellulose-based nanobiocomposite decorated with Fe_3O_4 nanoparticles has been reported by Maleki et al. in 2017 and used as an easily recoverable and reusable green nanocatalyst in the synthesis of pyrano[2,3-*d*]pyrimidine derivatives in water at room temperature (Scheme 18). In this study, two series of pyranopyrimidine and pyrazolopyranopyrimidine derivatives were synthesized by using the present cellulose-based nanocomposite. There were several advantages in these methods including reusability, high yield of the products, short reaction times, mild reaction conditions, and easy workup procedure [238].

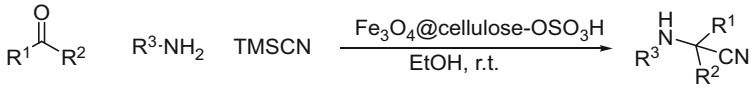
As can be seen in Scheme 19, in 2014, Maleki et al. presented a new cellulose-based nanocomposite with highly loaded Fe_3O_4 nanoparticles. Then, its catalytic activity was investigated in the condensation reaction between *o*-phenylenediamines and ketones to provide benzodiazepine derivatives in good to excellent yields under mild reaction conditions. A good correlation between the amounts of surface acid sites and the morphology of the catalyst and its catalytic activity was found. The nanocatalyst could be recycled and reused without significant loss of its catalytic activity [239].



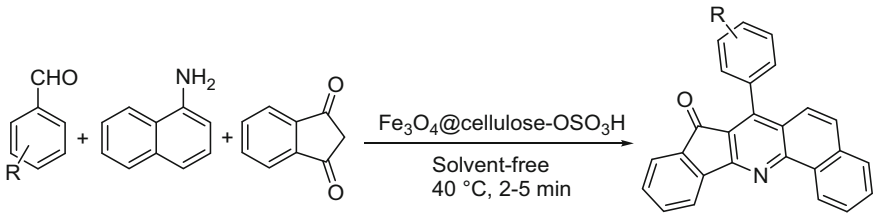
Scheme 18 Synthesis of pyrano[2,3-*d*]pyrimidine derivatives in the presence of the nanocatalyst



Scheme 19 Synthesis of 1,5-benzodiazepines in the presence of Fe_3O_4@cellulose nanocomposite



Scheme 20 MCSA-catalyzed Strecker reaction



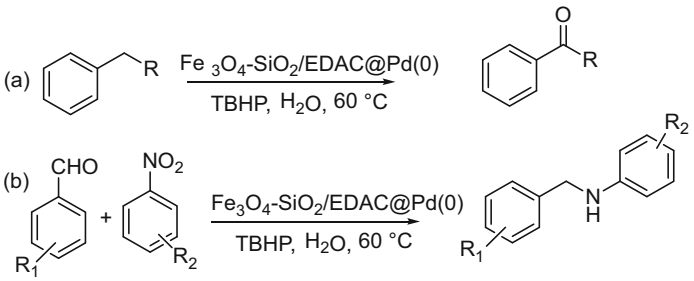
Scheme 21 MCSA-catalyzed synthesis of 7-aryl-8*H*-benzo[*h*]indeno[1,2-*b*]quinoline-8-ones

In 2014 Lu et al. reported a facile synthetic method for in situ immobilization of Au nanoparticles (NPs) on magnetic γ-Fe_2O_3@carboxylated cellulose nanospheres. Firstly, the γ-Fe_2O_3@cellulose NPs were synthesized via an ionic liquid-assisted coprecipitation process. After that, oxidation of cellulose occurred in the presence of TEMPO to produce carboxyl groups on the surface of magnetic nanoparticles (MNPs). Finally, by reducing of Au^{3+} by cellulose, AuNPs were dispersed onto the surface of magnetic γ-Fe_2O_3@carboxylated cellulose. The synthesized magnetic biopolymer-metal nanohybrids are used as a magnetic catalyst in the reduction reaction of 4-nitrophenol to 4-aminophenol [240].

In 2016, Maleki and coworkers have introduced a sulfonated magnetic cellulose-based nanocomposite [Fe_3O_4@cellulose-OSO_3H (MCSA)] and investigated its catalytic activity for the synthesis of α-aminonitriles via a one-pot three-component reaction of aldehydes or ketones, amines, and trimethylsilyl cyanide (TMSCN) in EtOH at room temperature (Scheme 20) [241].

In 2017, Maleki and coworkers in another study have applied above sulfonated magnetic cellulose-based nanocomposite as an efficient, inexpensive, and green catalyst for the one-pot three-component synthesis of 7-aryl-8*H*-benzo[*h*]indeno [1,2-*b*]quinoline-8-ones starting from 1,3-indanedione, aromatic aldehydes, and 1-naphthylamine under solvent-free conditions in high yields within short reaction times. The advantages of this nanobiostructure catalyst are easy separation by using an external magnet and reusability for several times (Scheme 21) [242].

Cellulose-magnetite nanocomposites were synthesized via the adsorption of magnetite onto the surfaces of functionalized nanocellulose, using different organic and inorganic acids such as acetic anhydride, succinic acid anhydride, chlorosulfonic acid, and $POCl_3$ by El-Nahas and coworkers in 2017. The properties of these functionalized nanocellulose derivatives and cellulose-magnetite nanocomposites were evaluated, and then the catalytic activity of the functionalized nanocellulose and cellulose-magnetite nanocomposites was investigated for the esterification



Scheme 22 (**a**) C–H bond oxidation and (**b**) reductive amination of aldehydes with nitroarenes in the presence of Fe_3O_4@SiO_2/EDAC-Pd(0)

of oleic acid with methanol for the production of methyl oleate (biodiesel). In this study, the sulfonated cellulose-magnetite nanocomposite (MSNC) showed the highest catalytic activity toward the esterification reaction (96%) due to the high dispersion of the Lewis acid sites which resulted from the impregnation of magnetite (0.98 wt%) in addition to the already presented Brönsted acid sites on the surface of the nanocellulose [243].

In 2013, a facile and novel methodology for the synthesis of palladium nanoparticles onto amine-functionalized inorganic/organic magnetic composite [Fe_3O_4@SiO_2/EDAC-Pd(0)] was reported (Scheme 22). The catalytic activity of the novel Fe_3O_4@SiO_2/EDAC-Pd(0) was investigated in the oxidation of benzylic C–H bond using TBHP and for the one-pot reductive amination of aldehydes with nitroarenes in the presence of molecular hydrogen. As a result, the catalyst has an excellent catalytic activity in both reactions and could be reused efficiently several times with high efficiency [244].

Antibacterial Activity

Glucose-reinforced Fe_3O_4@cellulose-mediated amino acid was developed by Rezayan et al., and this is the first report of applying magnetic cellulose nanocomposite as a support for bacteria capturing. In this study, two kinds of amino acid were applied as a linker to immobilize glucose on the surface of magnetic cellulose. It was found that using amino acids as a linker for glucose anchoring led to increase capturing efficiency for gram-positive bacteria as a sample pathogen. Also, this synthesized system was evaluated as a green biocompatible nanostructure for water treatment [245].

Wastewater Treatment

Liu and coworkers have reported ferric hydroxide-coated cellulose nanofibers ($Fe(OH)_3$@CNFs) and applied for the removal of phosphate from wastewater. This modified nanofiber has maximum sorption capacity of 142.86 mg/g which has higher adsorption capacity than many adsorbents reported in the literature. It was found that an increased solution ionic strength would increase the adsorption

capacity. Furthermore, the effect of PH conditions was investigated for determining a favorable adsorption performance of these nanofibers. The maximum adsorption capacity of $Fe(OH)_3$@CNFs was achieved at pH of 4.5. This study showed that ferric hydroxide-modified CNFs had a unique ability to remove phosphate from aqueous medium [246].

3.2.4 Zinc Oxide Nanoparticle

Due to nutritional properties, effective antimicrobial properties at low concentrations, high stability against high temperatures, nontoxicity, and good UV absorbance properties, zinc oxide has attracted much attention in food and pharmacy fields. Thus, the addition of ZnO NPs to the film packaging and its probable diffusion of the food products are not harmful to human health because these nanoparticles are used as nutrient agent [247]. Recently, the effective antimicrobial properties of ZnO NPs in active films have been reported for starch films against *Staphylococcus aureus* [248], polylactic acid-ZnO NP nanocomposite films against *Escherichia coli* and *Staphylococcus aureus* [249], chitosan-neem oil-based film against *E. coli* [250], and sodium alginate-gum acacia hydrogels versus *Pseudomonas aeruginosa* and *Bacillus cereus* [251]. Due to the high surface area of metal nanoparticles, they have superior antimicrobial properties [252].

Antimicrobial Activity

Ghanbarzadeh and coworkers have represented an active nanocomposite based on carboxymethyl cellulose-chitosan-oleic acid (CMC-CH-OL) incorporated with different concentrations (0.5–2 wt%) of zinc oxide nanoparticles (ZnO NPs) toward casting method. Then effects of ZnO NPs on the morphological, mechanical, thermal, physical, and antifungal properties of the films were investigated. Antifungal properties of these active nanocomposite films by disc diffusion test confirmed considerable antifungal rule against *Aspergillus niger*, especially in 2 wt% of CMC–CH–OL–ZnO which illustrated more than 40% fungal growth inhibition [253].

Rujiravanit and coworkers have reported that bacterial cellulose (BC) is a remarkable natural polymeric template to support the ZnO synthesized via solution plasma process (SPP). In addition, in SPP method, there was no need for a reducing agent. The ZnO/BC composites obtained via SPP had strong antibacterial activity against *E. coli* and *S. aureus*. Meantime, by increasing the ZnO content in the ZnO/BC composites, the antibacterial activity of the ZnO/BC composites will be increased. Notably, these composites might be applied in wastewater treatment but also in biomedical applications [254].

3.2.5 Cobalt Nanoparticle

Cobalt nanoparticles are a gray or black powder with spherical morphology. These nanoparticles have attracted much attention due to their magnetic properties. Due to these properties, they have been shown in imaging, sensors, catalyst, and many other areas.

Catalytic Activity

Ethylenediamine-functionalized nanocellulose complexed with cobalt(II) was reported by Shaabani and coworker in 2014 as a highly efficient heterogeneous catalyst for the room temperature aerobic oxidation of various types of primary and secondary benzylic alcohols into their corresponding aldehydes and ketones, respectively. Noteworthy, this catalyst was recovered and reused for five times with no significant loss of efficiency [122].

Magnetic *D*-penicillamine-functionalized cellulose as a new heterogeneous support for cobalt(II) was presented by Keshipour and coworker and applied in the green oxidation of ethylbenzene to acetophenone. The catalyst was obtained in three steps: first of all functionalization of cellulose with D-penicillamine occurred, after that deposition of Fe_3O_4 nanoparticles on cellulose-D-penicillamine, and finally, anchoring of Co(II) to the magnetic cellulose-D-penicillamine. The catalytic activity of composite was investigated for the oxidation of ethylbenzene to acetophenone in ethanol under reflux conditions using H_2O as a green oxidant. Also, the recovered catalyst could be used several times without significant loss of activity [80].

3.2.6 Titanium Dioxide Nanoparticle

Titanium dioxide (TiO_2) has attracted considerable attention as a semiconductor for photocatalysis activity because of its high stability, low cost, and safety toward both humans and the environment. TiO_2 nanoparticles have been used for resolving the drawbacks of traditional epoxy fillers such as rubber beads and glass and can be overcome by increasing the stiffness, strength, and toughness [255].

Gas Separation

Surface modification of TiO_2 nanoparticles with biodegradable nanocellulose and synthesis of novel polyimide/cellulose/TiO_2 membrane has been developed by Ahmadizadegan in 2017. In this paper, novel polyimide/cellulose/TiO_2 bionanocomposites (PI/BNCs) were synthesized by a simple and inexpensive ultrasonic irradiation method. In this study, PI was synthesized toward direct polycondensation reaction of novel monomer dianhydride with 4-(2-(4-aminophenyl)-1,1,1,3,3,3-hexafluoropropan-2-yl)benzenemine. The gas separation properties of PI membrane with three cellulose/TiO_2 concentrations (5, 10, and 15 wt%) are investigated for gas permeation. The titania weight percentage of the PI/BNC membranes was evaluated for the permeability of this membrane, and the results showed that increasing TiO_2 concentration increased the permeabilities of CO_2, H_2, CH_4, and N_2 [256].

Drug Delivery

Kessler and coworkers have investigated the potential drug delivery systems for dermal applications of cellulose nanofiber-titania nanocomposites. In this work, a new type of cellulose nanofiber-titania nanocomposites grafted with three different types of model drugs such as diclofenac sodium, D-penicillamine, and phosphomycin was successfully synthesized. One of the most important advantages of this work is the use of titania as a binding linker between cellulose nanofibers and a drug molecule, which provides a slow and controlled release. The drug release was

investigated in the presence of three drug molecules. It was shown that the quickest release was observed for the more soluble painkiller, slower one for the anti-inflammatory agent, and the longest release took place for the strongly chemisorbed antibiotic agent [257].

3.2.7 Silica (SiO_2) Nanoparticle

Silica particles have wide applications in industries related to the production of pigments, pharmaceuticals, ceramics, and catalysts [258]. Furthermore, silica-based adsorbent materials have industrial applications for the removal of heavy metals and lanthanides [259, 260]. Also, in the recent years, much attention has been paid to improve the adsorptive properties a variety of functional groups grafted on the surface of mesoporous silica.

Removal of Lanthanides from Aqueous Medium

Iftekhar and coworkers have successfully synthesized cellulose-based silica (CLx/SiO_2) nanocomposite and investigated for the removal of Eu(III), La(III), and Sc(III). In this paper, two different cellulose-based silica (CLx/SiO_2) nanocomposites were synthesized and characterized by several techniques. XRD and FTIR analyses have confirmed the presence of mixed phases of cellulose and SiO_2. In this study, CLN/SiO_2 nanocomposite could be explored as an appropriate adsorbent for Eu(III), La(III), and Sc(III) and can be exploited for the preconcentration of REEs from the diluted aqueous medium [261].

Nasir et al. have synthesized SiO_2-cellulose acetate nanofiber via electrospinning process and investigated the characteristic of nanofiber composites such as nanostructure, morphology, and surface property. SiO_2 in nanofiber is a key factor for controlling the spreading time of water droplet on the surface of nanofiber. It was found that the spreading time of water droplet on the surface of cellulose acetate nanofiber is much faster than SiO_2-cellulose acetate nanofiber surface. SiO_2-cellulose acetate might be used as lithium ion battery separator and water purificator [262].

3.2.8 Gold Nanoparticle

Gold nanoparticles (AuNPs) have been utilized for the several applications such as optoelectronics [263], sensing [264], biomedicine [265], bioimaging [266], and gene delivery [267]. In addition, the catalytic activity of AuNPs is investigated for various chemical reactions such as the CO oxidation, C–C coupling reaction, aerobic oxidation of alcohols, and reduction reaction via transfer hydrogenation [268–270]. However, due to the large active surface areas, AuNPs are unstable and tend to irreversibly aggregate in solution. Therefore, catalytic activity will be reduced. The most effective way to resolve this drawback is immobilization of AuNPs on polymeric supports or inorganic material.

Catalytic Activity

TEMPO-oxidized bacterial cellulose nanofiber-supported gold nanoparticles have been reported by Chen and coworkers in 2016. In this work, the nanohybrid was successfully prepared by deposition of gold nanoparticles (AuNPs) onto the

surface of TEMPO-oxidized bacterial cellulose nanofibers (TOBCNs). The prepared AuNP/TOBCN nanohybrids were characterized by UV-vis spectral analysis, XRD, TEM, and HRTEM, and their catalytic activity for the reduction of 4-nitrophenol (4-NP) to 4-aminophenol (4-AP) was estimated by UV-vis spectrometry [271].

Huang and coworkers have shown the deposition of gold nanoparticles on titania gel film pre-coated cellulose nanofibers of filter paper. In this work, the catalytic activities of finalized bulk cellulose-based membranes were investigated for the reduction of 4-nitrophenol to 4-aminophenol through a facile filtration process [272].

3.2.9 Metal-Organic Frameworks

Metal-organic frameworks (MOFs) have been widely utilized for gas adsorption and separation [273], catalysis [274], sensors [275], drug delivery [276], humidity measurement [277], and nonlinear optics [278] due to their high porosity, high surface areas, versatile synthesis conditions, and unique properties [279]. These crystalline porous materials consist of metal ions or clusters and metal-ligand coordination bonds.

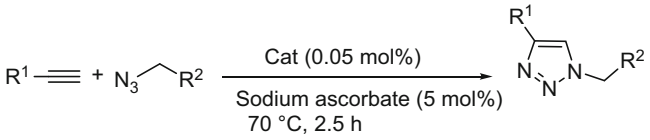
Gas Adsorption Activity

Shunxi Song and coworkers have prepared cellulose paper@MOF-5 composites with gas adsorption capacity. The synthesized cellulose paper@MOF composites were characterized by XRD, ATR-FTIR, SEM, and nitrogen adsorption analysis. In this study, cellulose paper@MOF-5 composite materials were prepared via in situ deposition of MOF-5 onto precipitated calcium carbonate (PCC)-filled cellulose paper. Hydrogen bonding between cellulose fibers decreased due to the presence of PCC fillers in the cellulose paper. Therefore, hydroxyl groups on the cellulose surface will be available for reacting with the organic ligand, i.e., 1,4-benzenedicarboxylic acid (BDC) in the MOF-5 formation process. The synthesized cellulose paper@MOF-5 composite materials had zeolite-like frameworks with high specific surface areas. Gas adsorption activity of this composite was investigated, and it was found that prepared paper@MOF-5 composites showed a high nitrogen gas adsorption capacity and could have great potential to adsorb or store gaseous products such as H_2, CO_2, CH_4, etc. [280].

3.2.10 Copper Nanoparticle

Copper is one of the most widely used materials in the world. The applications of copper (Cu) and Cu-based nanoparticles have attracted a great deal of interest in recent years, especially in the field of catalysis.

Sarkar and coworkers have reported a waste corncob cellulose-supported poly (hydroxamic acid) Cu(II) complex and applied their catalytic activity in the Huisgen 1,3-dipolar cycloaddition reaction using sodium ascorbate under mild reaction conditions (Scheme 23). In this study, waste materials have been used as a source of catalytic support. This resulted catalyst is recyclable, environment-friendly, and cost-effective bio-heterogeneous catalyst in chemical synthesis. Therefore, waste materials like corncob can be utilized as a heterogeneous solid support for metal-catalyzed chemical transformation reactions to ensure maximum use of our limited wealth [281].



Scheme 23 Huisgen cycloaddition reaction of azides and alkynes

4 Conclusion

Cellulose was found as a susceptible material for various modification reactions. Loading of various organic materials such as esters, ethers, silanes, halogens, amines, carbomates, polymers, and heterocycles on cellulose was reported. High activity of hydroxyl groups of cellulose makes the polymer as an active compound in the modification reactions. Also, cellulose can be modified with inorganic materials for the preparation of special compound with unique properties. While the cellulose reactions were investigated widely, the publications about cellulose modification are increasing that shows the high importance of cellulose-based materials in modern chemistry.

use of cellulose in preparation of various hydrogels. Cellulose-based hydrogels are generally synthesized by two steps, (i) solubilization of cellulose fibers or powder and (ii) physical and/or chemical cross-linking, in order to obtain a three-dimensional network of hydrophilic polymer chains. The physical synthesizing method includes ionic interaction, hydrophobic interaction, and hydrogen bond formation, whereas the chemically cross-linked hydrogel preparation involves different polymerization techniques such as chain-growth polymerization, irradiation polymerization, and step-growth polymerization. Further, another technique such as bulk polymerization is also used to form gels mainly using lactic acid as monomer. Indeed, the high density of free hydroxyl groups present in the cellulose structure permits them to undergo functionalization/chemical modification, which allows producing cellulose derivatives. The properties of cellulosic hydrogels change based on the different environmental stimuli. The external stimulus includes pH, temperature, light, electric or magnetic field, mechanical stress, etc. The responses of the hydrogel based on the exposure to different stimuli are discussed in this chapter. However, the cellulose hydrogels basically have good biocompatibility and non-toxicity combined with relevant mechanical properties. They showed highest absorption capacity, the swelling/deswelling behavior, and its rate depends on various factors such as particle size, porosity, solvent concentration, cross-linking density, etc. The swell behavior is addressed using various kinetic models such as Fickian, non-Fickian, and Flory. Further, biodegradation, mechanical, and rheological properties variation with respect to cross-linking density and other parameters (shape, pore size, reinforcement, etc.) and stimuli are considered and discussed.

Polymerization · Hydrogel · Cross-linking · Properties

1 Introduction

Hydrogels are polymer networks that take in and keep huge quantities of water [1]. The characterizations of many kinds of hydrogels are prepared from different types of cellulose, alone or mixed with its derivatives, such as lignin, chitin, or polyvinyl alcohol [2, 3]. The cellulose-based hydrogel is generally prepared by two steps, (i) solubilization of cellulose fibers or powder and (ii) physical and/or chemical cross-linking, in order to obtain a three-dimensional network of hydrophilic polymer chains [4].

Hydrogels are held together by either physical interactions (chain entanglements, van der Waals forces, hydrogen bonds, crystallite associations, and/or ionic interactions) or chemical cross-links (covalent bonding) [5]. In case of physical cross-linking, the hydroxyl groups in cellulose can easily form hydrogen bonding network. Generally, it is very difficult to dissolve the cellulose in common solvents due to its highly extended hydrogen-bonded structure [6]. However, solvents such as *N*-methylmorpholine-*N*-oxide (NMMO), ionic liquids (ILs), and alkali/urea (or thiourea) are used to dissolve cellulose for the preparation of hydrogels. In

case of chemical cross-linking, the covalent bond formation takes place, depending on the cellulose derivatives, and a number of cross-linking agents and catalysts are used to form hydrogels. Epichlorohydrin, aldehydes, aldehyde-based reagents, anhydrides, urea derivatives, carbodiimides, multifunctional carboxylic acids, difunctional molecules [7], and cellulose/PVA are the most widely used cross-linkers for the preparation of cellulose hydrogels [8].

Several hydrogels are prepared by various researchers, and those cellulose-based hydrogels are commonly prepared using physical and cross-linking methods. The cellulose hydrogels based on its derivatives include methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropylmethyl cellulose (HPMC), carboxymethylcellulose (CMC), ferrocene-cellulose (FC), and cyclodextrin-cellulose (CC), which are obtained by both physical and chemical cross-linking approaches [5].

The cross-linked hydrogels possess tridimensional and flexible structure, able to swell when they are immersed in aqueous solutions. Indeed, chemical or physical cross-linking avoids their solubilization, since water can penetrate through the network without breaking the strong interactions that bind the polymer chains together. Some hydrogels can also change their own volume in response to external stimuli such as solvents, temperature, pH, ionic force, electric field, light irradiation, and salt concentration. Because of these peculiar features, most of hydrogels are used in many applications such as tissue engineering, wound healing, drug delivery, hygiene, superabsorbent, biosensors, agriculture, etc. Furthermore, hydrogel properties such as swelling/deswelling, mechanical, rheological, biocompatibility, cytotoxicity, and biodegradability are tuned based on the requirement and particular application. Thus, this chapter focused on detail discussion on the preparation of cellulose and its derivation-based hydrogels (i.e., different physical and chemical cross-linking techniques). Further, the properties of the hydrogels and its response to environmental stimuli are discussed.

2 Preparation Methods of Cellulose-Based Hydrogels

Hydrogels can be prepared by different methods depending on the designed structure and the preferred application. General method of hydrogel formation is depicted in schematic representation, Fig. 1.

2.1 Physical Cross-Linking

Physically cross-linking is of great interest in the current era due to the absence of cross-linking agents and relative ease of production. The physical hydrogels (also called self-assembling hydrogels) are formed when macromolecules self-assemble through non-covalent, secondary molecular interactions such as hydrophobic, electrostatic, and H-bonding. In physically cross-linked gels, dissolution is prevented by physical interactions, which exist between different polymer chains (Fig. 2) [9]. All of these interactions are reversible and can be disrupted by changes in physical conditions or application of stress [10].

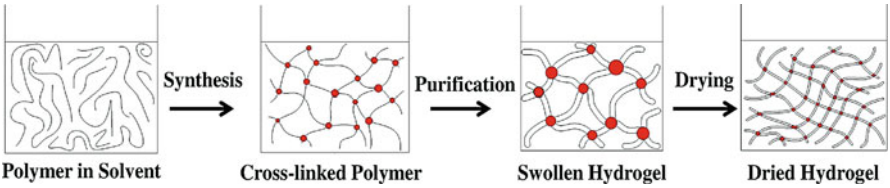

Fig. 1 Schematic representation of the steps involved in preparation of a hydrogel

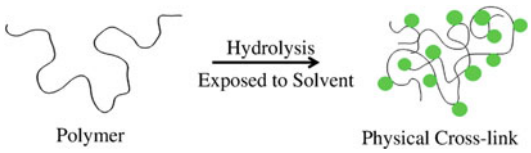
Fig. 2 Representation of physical cross-linking of hydrogel



2.1.1 Cross-Linking by Hydrophobic Interaction

Hydrogels formed via hydrophobic interactions are mainly prepared by copolymerization of a hydrophilic monomer with a small amount of a hydrophobic comonomer, most typically by a free-radical mechanism [11]. Hydrophobic interactions are relatively stronger than other weak intermolecular forces (i.e., van der Waals interactions or hydrogen bonds). The strength of hydrophobic interactions depends on several factors which include temperature, number of carbon atoms on the hydrophobes, and shape of the hydrophobes. To create strong hydrophobic interactions between the hydrophilic polymer chains, a higher number of carbon-based hydrophobic polymer are utilized. In particular, the temperature has a remarkable effect on the hydrophobic interactions between hydrophobic polymer segments and the hydrophilic interactions between hydrophilic polymer segments and water molecules. The most abundant alkylated cellulose derivatives are methyl, ethyl, hydroxyethyl, and hydroxypropyl methyl cellulose. When solutions of these polymers are heated above certain temperatures, depending on the level of cellulose alkylation, hydrogels are obtained. The hydrophobic interaction occurs between the alkylated hydroxyl groups, and at low temperature, cellulose chains are hydrated, whereas at high temperature, water is repelled from the chains, and the alkylated hydroxyl groups interact with one another to form hydrogel [12].

2.1.2 Cross-Linking by Ionic Interactions

Ionic polymers can be cross-linked by the addition of di- or trivalent counterions. This method underlies the principle of gelling a polyelectrolyte solution (e.g., Na + alginate-) with a multivalent ion of opposite charges (e.g., Ca_{2+} + $2Cl^{-}$) [11]; i.e., simple ion exchange mechanism occurs to form hydrogels. Alginate is a well-known example of a polymer that can be cross-linked by ionic interactions. It is a polysaccharide with mannuronic and glucuronic acid residues and can be cross-linked by calcium ions [13]. Martínez-Ruvalcaba et al. developed ionically cross-linked two natural polyelectrolytes, chitosan and xanthan; since chitosan is a cationic

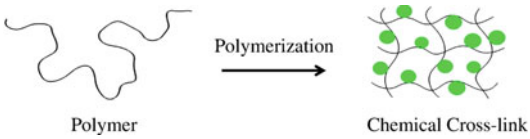


Fig. 3 Representation of chemical cross-linking of hydrogel

polyelectrolyte polymer with ionizable amine group anions, xanthan was employed as ionic cross-linkers to form hydrogel. The cross-linking are usually performed at room temperature and physiological pH; thus, they are particularly attractive in wound healing, drug delivery, and tissue engineering applications [14].

2.1.3 Cross-Linking by Hydrogen Bonds

Cellulose contains many hydroxyl groups which can form hydrogen bonding network. Hydrogen bonding interaction occurs between a pair of other atoms having a high electron affinity. Several gels were prepared through strong H-bonding interactions between highly hydroxyl functionalized chains. The presence of two functional groups produces hydrogen bonding with water to form gel structure. Hydrogels extended by this technique are influenced by various factors like polymer concentration, molar ratio of each polymer, type of solvent, solution temperature, and the degree of association of polymer functionalities [13, 15]. When polymer concentration is higher, gels become more and more organized and stable due to the higher degree of entanglements and hydrogen bonding interactions [16]. The hydrogen bond formation happens only when the carboxylic acid groups are protonated. However, hydrogen-bonded networks would be diluted and dispersed over a few hours owing to the influx of water [17].

2.2 Chemical Cross-Linking

In chemically cross-linked gels, covalent bonds are present between different polymer chains. Usually chemical modifications are performed to produce cellulose derivatives either by esterification or etherification [18]. Chemical cross-linking is a highly versatile method to create hydrogels with good mechanical stability. However, the cross-linking agents used are often toxic compounds, which will be extracted from the gels before they are utilized (Fig. 3) [9].

2.2.1 Chain-Growth Polymerization

Chemically cross-linked hydrogels are produced by chain-growth polymerization which includes free-radical polymerization; the process includes three steps, viz., initiation, propagation, and termination. Most commonly the hydrogels are synthesized by free-radical chain polymerizations of hydrophilic monomers containing a carbon double bond. The free-radical polymerization begins with initiator species, which produces active radical centers. The free radicals are produced by homolytic dissociation of weak bonds or by redox reactions. Once the active sites are produced, they rapidly propagate through the carbon double bonds of monomer, to form

polymer chains. The generation of active sites depends on the type of monomer and solvent and the reaction condition employed. In addition they are also based on the initiator heat (thermal initiators), light (photoinitiators), γ radiation, or electron beam. Chain termination occurs when the propagating radicals react by combination, disproportionation, and transfer [19, 20]. When hydrogels are synthesized using chain-growth polymerization, they create more heterogeneous network structure. The formation of hydrogel occurs by rapid propagation of active sites through monomers that contain multiple carbon-carbon double bonds [21]. These hydrogels would have high-molecular-weight kinetic chain, and they serve as cross-linking points. Due to the random nature of radical propagation and termination in chain-growth polymerization, cross-link functionality or the number of arms per cross-linking point is not static. The hydrogel formation occurs, once the network reaches the critical gelation point. This method of hydrogel preparation can be expressed in solution, suspension, and photopolymerization. The process is versatile and much employed to produce hydrogels in a variety of structures.

Solution Polymerization

In solution polymerization, the monomer, the initiator, and the resulting polymer are all soluble in the solvent or solvent blend. The solution polymerization usually starts with high concentration of monomer and minimum proportion of catalyst, initiator, and solvent. As the reaction proceeds, more solvent is added to regulate the viscosity, and additional catalyst/initiator is added to adjust the reaction rate. Among the homogeneous polymerizations, the solution polymerization is preferred due to better control of the heat of polymerization, lower cost, and ease of synthesis. Most of the cellulose-based superabsorbent hydrogels are produced in this way; Sannino et al. developed hydroxyethylcellulose (HEC) and carboxymethylcellulose sodium salt hydrogels using solution polymerization technique [22–25]. Author utilized different cross-linking agents and catalyst with a common solvent (water). Suo et al. developed cellulose-based superabsorbent polymer, i.e., carboxymethylcellulose-graft-poly(acrylic acid-co-acrylamide); their study adapted free-radical grafting solution polymerization of acrylic acid (AA) and acrylamide (AM) monomers onto carboxymethylcellulose (CMC) in the presence of *N,N′*-methylenebisacrylamide as a cross-linker and potassium persulfate/sodium metabisulfite as an initiator [26]. Researchers developed hydroxypropyl cellulose (HPC) hydrogels by free-radical polymerization in water; in their process the reaction was initiated by oxidant, and polyacids were grafted and interpenetrated with HPC [27–30]; and their report revealed that the prepared hydrogels were temperature responsive and pH responsive. This type of polymerization was used extensively because of high polymerization rate; in addition the reaction occurs in an aqueous medium, which is safe and harmless. Further, this process adds up an advantage over other cross-linking methods since it is performed at room temperature.

Suspension Polymerization

Suspension polymerization (wherein monomer-forming droplets, with the initiator in them, are completely insoluble and suspended in a solution) is the most common technique for the production of a variety of hydrogel networks by reacting

hydrophilic monomers with multifunctional cross-linkers and initiators. In the case of suspension polymerization, monomers and initiator are dispersed in the organic phase. In other words, the reaction mass is dispersed as minute droplets in a continuous aqueous phase; each droplet acts as tiny bulk reactors. Heat transfer occurs from the droplets to the water having large heat capacity and low viscosity. Thereby the cooling jackets are used to facilitate heat removal, and agitators are used along with suspending agents in the aqueous phase in order to maintain a specific droplet size and dispersion. The hydrogel properties developed through suspension polymerization depend on the viscosity of the monomer solution, agitation speed, rotor design, and dispersant type [31, 32]. The suspension gelation method (microcapsule templating method) is described to prepare macroporous polymeric hydrogels [33]. An aqueous suspension is formed by dispersing the microcapsules as a pore template (porogen) into a pre-gel aqueous solution containing monomers and cross-linking monomers. Then, the composite hydrogel containing distributed microcapsules are prepared by copolymerizing the pre-gel aqueous solution [34].

Photopolymerization

Photopolymerization is one of the important processes that enable in situ formation of cross-linked networks. Photopolymerizations are initiated by light and both the initiating species, usually induced by ultraviolet (100–400 nm), visible (400–700 nm), or infrared (780–20,000 nm) radiation. This process converts a liquid monomer or macromer to a hydrogel by free-radical polymerization [35]. Visible or UV light interacts with light-sensitive compounds, creates free radicals, and initiates polymerization to form cross-linked hydrogels [36]. Three major classes of photo-initiation depend on the mechanism involved in photolysis, which include radical photopolymerization through photo-cleavage, hydrogen abstraction, and cationic photopolymerization [36–38]. Many researchers have shown interest in utilizing the photo-initiated polymerization; for example, Reeves et al. developed carboxymethylcellulose (CMC) hydrogels using ultraviolet light as initiator [39], and Mann et al. developed a tissue-engineered hydrogel scaffold through photopolymerization of PEG derivatives with proteolytically degradable peptides [40]. The photopolymerized hydrogel systems can afford better temporal control over the gelation process. The alginate-based hydrogels were cross-linked by photo-irradiation; the rate of cross-linking was controlled by the exposure to ultraviolet (UV) light and physiological conditions [41]. Many researchers are interested in utilizing the photo-initiated polymerization of PEG-based macromolecular monomers to produce hydrogels as cell delivery vehicles for tissue regeneration. A comprehensively studied PEG hydrogel system occupied ultraviolet irradiation to generate radicals from specific photoinitiators, which will further react with the active end group on tailored PEG to form a covalent cross-linked bond. In addition to PEG, alginate, chitosan, hyaluronic acid, and chondroitin sulfate were also methacrylated, and the hydrogels were synthesized by photopolymerization [13].

2.2.2 Irradiation Polymerization

Radiation polymerization technique is an emerging technique to synthesize cellulose-based hydrogels. High energy radiations such as gamma rays and

electron beam are used to polymerize unsaturated substances [42, 43]. Water-soluble polymers could be transformed into hydrogels using high energy radiation. Ionizing radiations, such as electron beam and γ-rays, have high energy as much as necessary to ionize simple molecules either in air or water. During irradiation of a polymer solution, many reactive sites are generated alongside the polymer strands. After that, the combination of these radicals leads to formation of a large number of cross-links [13]. Electron-beam radiation (ionizing radiation) initiates the cross-linking and produces pure, sterile, and residue-free hydrogels. Unlike conventional chemical cross-linking methods, this method does not require the addition of catalysts or any other additives to modify the material [9]. Using this method, the degree of cross-linking and the pore size of hydrogels, which strongly determine the extent of swelling, can be easily controlled by varying the irradiation dose [44, 45]. Further, the use of toxic chemicals is completely eliminated in this method; hence, the poly-gels produced are free of toxic elements.

Frediani et al. adapted the microwave radiation to induce cross-linking; his study reported that the synthesized product possessed faster swelling and shrinking kinetics in comparison to the hydrogels prepared by conventional methods [46]. Fei et al. developed radiation cross-linked poly (ε-caprolactone) in supercooled state, and the product has shown high heat stability at a low dose of irradiation (30 kGy) [47–49]. Reeves et al. prepared CMC-methacrylate gels and CMC-methacrylate/PEG-DM copolymer gels using photoinduced free-radical cross-linking [39]. Liu et al. have also reported the preparation methodology of carboxymethylcellulose (CMC) hydrogels under γ-irradiation [50]. The concentration of free radicals in the system, determined by the dose rate, is an important factor for influencing the gel formation [51]. Considerably higher gel fraction occurs with the radiation dose. However, the product attained through radiation mechanism undergoes faster rate of degradation than the radiation of cross-linking.

2.2.3 Step-Growth Polymerization

Step-growth polymerization involves a reaction between dissimilar chemical groups which are part of the monomer molecules and forms a new bond (covalent bond) between the two functional groups. In this technique, the molecular weight of the polymer chain builds up slowly to form the polymer, i.e., only one reaction mechanism occurs in this method. The distinct initiation, propagation, and termination steps of chain-growth polymerization are meaningless in step-growth polymerization [52]. And more, the homogenous hydrogels are usually prepared via step-growth polymerization as they are formed by reacting at least two multifunctional monomers with mutually reactive groups; each monomer with defined functionality serves as a cross-linking point. Two cross-linking mechanisms form different hydrogel network structures; the variation on monomer molecular weight or concentration may have differential effect on hydrogel formation. Four-arm PEG functionalized with cycloctyne was reacted with azide difunctionalized polypeptides via strain-promoted alkyne-azide cycloaddition (SPAAC) reaction to form a hydrogel network via step-growth mechanism [53].

3 Environmental Stimuli

Macromolecular networks present in hydrogels absorb and release water solutions in a reversible manner; the response depends on specific environmental stimuli [54]. External stimuli include pH, temperature, light, magnetic field, and mechanical force [55–59]. The potential response to these stimuli also involves changes in shape, volume, phase, and optical properties. The stimuli-responsive volume change of the gels is a result of many factors such as the type of monomers, hydrophilic-hydrophobic balance, cross-link density, osmotic pressure, conformation of chemical groups, etc. (Fig. 4).

3.1 pH Responsive

pH-sensitive hydrogels consist of gel structure which varies with a change in pH values. The pH-sensitive hydrogels expand or contract depending upon the pH of the solutions. The cellulose-based gels are responsive to pH changes of the external solution. Appropriate pH and ionic strength generates electrostatic repulsive force results in swelling or deswelling of the hydrogel [60]. pH-responsive hydrogels could offer desirable physical and chemical properties at specific pH ranges. The acidic groups deprotonate at high pH, while the basic groups protonate at low pH. The association, dissociation, and binding of various ions to polymer chains cause hydrogel swelling in an aqueous solution [12]. The swelling capacity is directly related to both osmotic pressure and electrostatic repulsion according to the level of dissociation [61].

Polysaccharides usually respond to pH stimuli, which make them attractive for sustained drug release application [62]. In general, the size of the gel will respond to environment pH as well as salt concentration. Thus, an equilibrium model was established by Moore's group to predict the swelling/deswelling behavior of hydrogels in different pH solutions [63]. The effects of different hydrogels and solution conditions on the degree and rate of swelling/deswelling were investigated by many authors; they found that the higher the concentration and buffer diffusivity, the faster the kinetic [12].

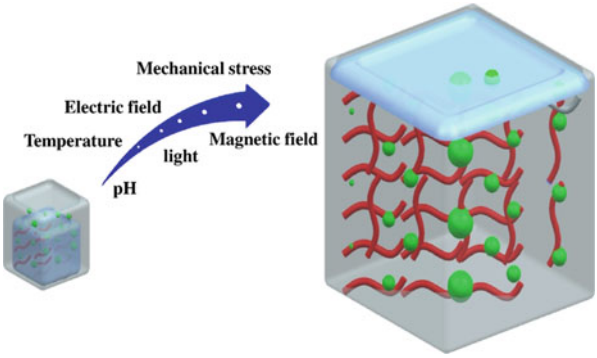

Fig. 4 Stimuli-responsive swelling of hydrogels

3.2 Temperature Responsive

The temperature is one of the important reaction parameters determining the grafting kinetics [64]. Temperature-sensitive hydrogels are also called as thermo-gels [65, 66]. These stimuli-sensitive hydrogels show changes in their swelling behavior of the network structure according to the external environments. The thermally induced abrupt change in the solubility is controlled by the Gibbs free energy of mixing [67].As most widely reported, thermally induced gelation is based on the equilibrium between hydrophobic and hydrophilic interactions [12]. There are many polymers belonging to the family of thermo-responsive polymer, systems mainly characterized by the presence of hydrophobic groups, such as methyl, ethyl, and propyl groups, which are used in the synthesis of hydrogels. These hydrogels are classified into positive thermosensitive, negative thermosensitive, and thermally irreversible hydrogels.

When the cellulose derivative polymer has positive thermo-sensitivity of swelling, they will be miscible at upper critical solution temperature (UCST), below which the polymer will be immiscible [45]. In case of negative thermo-sensitivity, the solubility of the hydrogels decreases at a temperature above lower critical solution temperature (LCST). In other words, the hydrogel starts to shrink when the temperature rises beyond the LCST because of the interpolymer chain association through hydrophobic interactions [68].

The other category is irreversible hydrogels; the non-covalent cross-linking in the hydrogels has the tendency to undergo sol-gel phase transition instead of swelling and shrinking transitions. Such hydrogels exhibit inverse temperature-dependent sol-gel behavior; they become sol as the temperature increases [64].

3.3 Light Responsive

Light-responsive materials have the ability to respond to stimuli triggered by the exposition to light sources such as UV, Vis, or infrared [69]. Light is a particularly interesting stimulus to manipulate the properties of a hydrogel, as it is a remote stimulus that is easily controlled. Common light-responsive materials are synthesized by the addition of photosensitive groups. Those gels undergo reversible photomechanical changes upon exposure to UV, visible, or IR light. Upon irradiation to ultraviolet light, the gels tend to deswell, while the reversal process occurs when exposed to visible/IR light [70]. Photoinduced self-healing polymers can mimic the biological systems in which damage triggers a self-healing response. These materials are used to repair fiber fracture, delamination, or propagation of micro-cracks of polymeric components used in a variety of applications, extending the functional life and safety of the polymeric components. The light-responsive hydrogels render higher advantages over others, as they could be instantly and accurately imposed. Also, the capacity for instantaneous delivery of the sol-gel stimulus renders light-responsive polymers potentially applicable for the development of optical switches, display units, and ophthalmic drug delivery systems [58, 71]. Further, various light-

sensitive drug delivery systems are used in photoresponsive prodrugs and photoresponsive drug carriers in diverse form including vesicles [70].

3.4 Electro-Responsive

Electric field-responsive hydrogels are polymers that swell, shrink, or bend in response to an applied electric field. They are usually made of polyanions, polycations, or amphoteric polyelectrolytes [72]. Under the influence of an electric field, electric-sensitive hydrogels deswell or bend, depending on their shape and their position relative to the electrodes. The extent of deswelling depends on the amount of charge transported through the gel, rather than on the applied voltage. When the electric field is removed, the hydrogel absorbs the solution and swells [73, 74]. The electrical response of polyelectrolyte hydrogels is influenced by many parameters, such as the shape and the orientation of the gel, its composition (charge density, nature, and hydrophobicity of cross-links, monomers, and pendant groups), the nature of the aqueous conducting medium, and the eventual presence of electrolytes in the medium [75]. These hydrogels play a vital role in electronic applications; CMC/chitosan and cellulose/alginate hybrid hydrogels are used as electroactive sensors or actuators in electronic devices because they swell or shrink differentially on two electrode sides (anode and cathode) as a consequence of mobile ion transport in an electric field, causing bending toward one electrode [75, 76].

3.5 Magnetic Field Responsive

Magnetic field is another stimulus for hydrogels; the application of magnetic field causes a change in pores of the gel and thereby influences the swelling. The high-strength magnetic field can also induce anisotropy in the supramolecular materials, and the relative orientations occur in the structures [77].

Several forms of magnetic targeting gels have been synthesized; those magnetic gels are also called as ferrogels, which consist of polymer networks, into which magnetic nanoparticles are embedded. The gels are sensitive to magnetic fields and undergo volume change after the application of external magnetic field. Different cellulose derivative-based hydrogels were modified and used as magnetic field-responsive hydrogel such as polysaccharide hydrogels with the combination of Fe_3O_4 nanoparticles [78]. The compounds are generally obtained by incorporating colloidal magnetic solution, named "complex fluid" into the polymer network: through this combination solid-like and fluid-like behavior is induced, the influence of external field on the hydrogels the responsiveness is enhanced. CMC hybrid hydrogels containing $CoFe_2O_4$ nanoparticles, chitosan- and CMC-coated Fe_3O_4 nanoparticles, etc. are used as magnetic field-responsive hydrogels. The Fe_3O_4 magnetic nanoparticles were used to generate heat through the application of an alternating magnetic field; the phenomena adapted were based on the use of magnetic particles in hyperthermia treatment. The application of the magnetic field causes a strong volume change in the hydrogel systems through the thermal

response. These hydrogels have found their applicability in biomedical sectors, such as cell separation [79–81], gene and drug delivery, and magnetic intracellular hyperthermia treatment of cancer [82, 83].

3.6 Mechanical Stress Response

Another stimulus of hydrogel is mechanical force; when the gels are subjected to mechanical stress, the level of energy sources and the molecular interactions are affected. In general two different conditions persist when stress is applied to the hydrogels; one is under the mechanical stresses which the hydrogel's mechanical integrity gets improved which directly relates to the diffusion of macromolecules through the hydrogel network [19], and the other is gel relaxation as the cross-links dissociate and reform elsewhere, and water is lost from the gel, leading to plastic deformation [84]. However, the mechanical stability of the hydrogels is the prime importance for a number of applications [85]. The polymeric network, in the gels, absorbs and retains a large quantity of solvent by increasing their volume but still maintaining the shape and poses some mechanical resistance [51]. The resistance depends on their composition and structure. Irregular cross-linking points and broad distributions of chain length will result in higher swelling; thus, the gels lead to have poor mechanical stability [86], whereas the higher and regular cross-linked gels behave vice versa.

4 Properties of Hydrogels

Hydrogels have a variety of properties including swelling/deswelling behavior, permeability, absorption capacity, mechanical properties, biodegradability, biocompatibility, cytotoxicity, etc., which make them promising materials for a wide variety of applications. The features of the polymer chains and the cross-linking structures in these aqueous solutions play an important role in deciding the properties of the hydrogels. The variations in the properties with respect to various factors are discussed as below.

4.1 Swelling and Deswelling Behavior

Hydrogels have hydrophilic networks with a high capacity of water uptake which can absorb, swell, and retain aqueous solutions up to hundreds of times their own weight, i.e., dry sample.

The swelling behavior of the hydrogels is accessed by immersing the sample into distilled water at room temperature. The swelling process was controlled by frequent weighting. Before weighing, the swollen polymer is removed from water, and the surface moisture was wiped with tissue paper, and its ability of swelling was expressed as the swelling ratio (SR), via Eq. (1) [54, 87].

$$SR = (W_t - W_d)/W_d \tag{1}$$

where W_d is the weight of the dried hydrogel sample (g) and W_t is the weight of the swollen hydrogel sample at time t (g).

Many researchers have investigated the swelling/deswelling behavior of chemically and physically cross-linked hydrogels. Cellulose-based hydrogels have shown various swelling degrees; most important factors that trigger a hydrogel response are pH, temperature, and swelling medium [88]. Apart from the external stimuli, the chemical and structural integrities such as size, shape, porosity, and its distribution may affect the water absorption capabilities.

Water-absorbing ability of cross-linked hydrogel depends on the amount of carboxylic groups of polymer because they remain free after the cross-linking, as they are responsible for swelling [89]. Xiao et al. study reported that the higher cross-linking density had reduced the degree of swelling, due to the inhibition of network expansion [90]. The same effect was also observed by author Suo et al. [26], their study has shown reduced water absorbency with considerable increase in the cross-linking concentration, and similarly irreversible changes occurred during drying. Generally, the swollen hydrogel releases water through a diffusion-driven mechanism, if a gradient of humidity between the inside and the outside of the material exists [91].

The swelling characteristics are determined from hydrogel densities; the densities of the hydrogels are evaluated through simple pycnometric experiments by using nonpolar solvent (n-hexane) for dry hydrogels and water for swollen hydrogels.

The dry hydrogel density (ρ_P) and the swollen hydrogel density (ρ_S) were calculated using the following Eq. (2) [92, 93]:

$$\rho_p(\rho_s) = \frac{m_s}{m_1 - m_2 + m_s} \cdot \rho_L \tag{2}$$

where ρ_L is the liquid solvent density; m_s is the weight of dried hydrogel (for dry hydrogel density), respectively, or the weight of swollen hydrogel (for swollen hydrogel density); m_1 is the weight of the pycnometer filled with solvent; and m_2 is the weight of the pycnometer with sample and solvent.

Hydrogels are also characterized by determining polymer volume fraction in the swollen state and the Flory-Huggins polymer-water interaction parameter (χ) is used to evaluate swelling rate. The polymer volume fraction in the swollen state ($\nu_{2,\ s}$) shows the amount of liquid that can be imbibed in hydrogels, and it is calculated using Eqs. (3 and 4).

$$\nu_{2,S} = Q^{-1} = \frac{\frac{1}{\rho_p}}{\frac{Q_m}{\rho_L} + \frac{1}{\rho_P}} \tag{3}$$

$$\chi = \frac{1}{2} + \frac{\nu_{2,s}}{3} \tag{4}$$

where Q is the volumetric swollen ratio and Q_m is the mass swollen ratio.

The swelling behavior varies based on the temperature; at low temperatures, polymer chains in solution are hydrated and simply entangled with one another. As temperature increases, macromolecules gradually lose their water of hydration, until polymer-polymer hydrophobic associations take place, thus forming the hydrogel network.

The hydrophilic characteristics of cellulose and its derivative-based hydrogels make them appropriate in wide applications such as disposable diapers, hygienic napkins, soil for agriculture and horticulture, gel actuators, water-blocking tapes, drug delivery systems, absorbent pads, etc.

4.2 Water Retention Capacity

Water holding capacity of hydrogel is a significant property to use as absorbent. Particularly when it is used in agricultural application, i.e., during irrigation or rain, the hydrogel absorbs and retains the water; when the soil dries, the hydrogel releases the stored water in a sustained manner through a diffusion mechanism and thereby helps to keep the soil or substrate humid over quite long periods of time [94]. Water held in the expanded hydrogel is intended as a soil reservoir for maximizing the efficiency of plant water uptake. However, due to their extremely high water retention capacity, overdosage of cellulose-based derivatives may have dangerous effects to cultivations. A few research studies have been carried out to determine appropriate hydrogel amounts and application rates for different environmental conditions [54].

In general, the water retention capacity of the hydrogels is characterized using simple experiments; hydrogel samples would be well mixed with 200 g of dry sandy soil and placed in separate containers. Then a quantified amount of tap water will be added to those containers and weighed as (W_1). The containers will be maintained at 25 °C (relative air humidity = 28%) and are weighed at a certain interval (W_i). The water retention ratio [*W(%)*] of sandy soil is calculated using Eq. (5).

$$W(\%) = \frac{W_1 - W_i}{100} \tag{5}$$

The retention capacities of cellulose are generally affected by various factors such as crystallinity, amorphous regions, total surface area, and pore volume. In addition, the cross-linking density also plays a major role in water retention capacity; when there is no enough cross-linking density, loose network formation occurs; thereby gels do not tend to have enough strength to hold water inside the molecular structure [95]; and the effect was also conformed with the study of Nada et al., and their report revealed that the increase in soil water retention are attributed to the hydrophilic polymer network [96]. Besides, the holding capacity of water decreases with increasing temperature. At higher temperature, water holding capacity decreases due to rupture of hydrogen bonds [97, 98]. Moreover, cellulose water retention capacity can be affected by the differences in microstructure of cellulose fibers obtained from different methods of extraction [99]. By introducing microporous structures into the hydrogel, by means of a phase inversion desiccation technique,

the improvement in the water retention capacity is achieved due to capillarity effects. The higher purity and water retention capacity make them suitable for wound healing application; the bacterial cellulose and the series of bacterial cellulose hydrogels wound dressings are currently marketed [54].

4.3 Biodegradation Properties

Biodegradation is the ability of the material to degrade by microorganisms, i.e., material has to be digested or metabolized when implanted in vivo. The labile bonds that are present either in the polymer backbone or in the cross-links tend to break under physiological conditions either enzymatically or chemically [9, 100], in most of the cases wherein hydrolysis occurs.

In general two different methods are carried out to evaluate the rate of biodegradation of hydrogels, namely, enzymatic degradation and microbial degradation:

Method 1: The enzymatic degradation is usually carried out using cellulase C-0901 enzyme, obtained from *Penicillium funiculosum* which is dissolved in an acetic acid – NaOH buffer of pH 5.0 at 37 °C with shaking. About 10 mg of extracted soluble part of the gel is then incubated in enzyme solution at different times. Concentration of the enzyme in buffer is maintained as 0.1 mg ml/1. Then the sample is washed continuously with distilled water and dried in vacuum at 35 °C to a constant weight followed by the incubation.

The result of degradation is expressed as a percentage of the weight loss, and it is evaluated using Eq. (6).

$$\text{Weight loss}\% = (W_0 - W_i)/W_0 \times 100 \tag{6}$$

where W_0 and W_i are the weights of gel before and after enzymatic treatment, respectively.

Method 2: The microbial degradation process utilizes a specially designed microbial oxidative degradation (MOD) analyzer, which consists of four independent columns in which 10 g of the sample along with rinsed sea sand – 450 g – and compost, 130 g, after mixing, are placed. The system is kept under a controlled temperature of 35 °C, and as a result, CO_2 dissipates out of column as the polymer decays. The dissipated CO_2 is collected through a series of columns filled in turn with silica gel, calcium chloride, soda lime, and calcium chloride, respectively. Ammonia formed from the sample was trapped in sulfuric acid solution, and water vapor was absorbed into first two columns (silica gel and calcium chloride). Then the CO_2 was collected quantitatively by soda lime, and water produced during the reaction was caught in the last calcium chloride column. Thus, the mass of produced carbon dioxide was calculated as a difference in the weight of two last columns (containing soda lime and calcium chloride) at the beginning and the end of the test.

The pure compost mixed with sea sand was used as a blank and cellulose as a reference sample [51].

The biodegradation of cellulose-based hydrogels has been widely investigated by many of the researchers [7, 54, 101]. In general, the rate of biodegradation of cellulose depends on degrees of crystallinity. The cellulose-based gels are composed of (1 → 4) glucopyranose repeating units and form fibrous structures with high crystallinity, which is a starting material for biodegradation [102]. The chemical structure (responsible for functional group stability, reactivity, hydrophylicity and swelling behavior, cross-linking network) affects the rate of biodegradation [103].

Most of the cellulose-based hydrogels used in the biomedical application are cross-linked using hyaluronic acid (HA); the presence of HA in the cellulose network provides enzyme-sensitive degradation sites. Various hydrogels from natural polymers have been fabricated by using hyaluronate [104], alginate [105], starch [106, 107], gelatin [108], cellulose [109], chitosan, and their derivatives [110–112]. These sensitive sites are produced due the hyaluronate which could be controlled to a certain extent during synthesis. The degradation rate is dependent on the amount of degradable sites as well as the degree of cross-linking of the network, which affects enzyme diffusivity through the mesh size. The cellulose-based hydrogels leave no residual monomers after cross-linking, which help to rapidly biodegrade in environment [113]. This biodegradation of gels undergoes a significant change in their mechanics, their physical properties, and their chemical structure under specific environmental conditions, and the degradation does not produce any adverse or reproductive effects when utilized in biomedical applications.

The biodegradable materials are those that undergo a significant enough change in their mechanics, their physical properties, and their chemical structure under specific environmental conditions. For many of the biomedical applications such as controlled drug release devices, wound healing dressings, and bioactive scaffolds, the biodegradation of the hydrogel is highly preferred.

4.4 Mechanical Properties

Several researches studied the mechanical properties of the hydrogel including Young's modulus, yield strength, and ultimate tensile strength. Generally the hydrogels are soft and rubbery in nature [114]; their mechanical stiffness depends on the degree of cross-linking [57]. If a gel consists of higher cross-linking density, then the distance between the cross-linked segments remains to be shorter. When a load is applied, these shorter segments require a greater force to deflect. Thus, the higher cross-linked gel structure will have better strength, hardness, or stiffness. For example, when a gel is formed using HA as a cross-linking agent, a low cross-linking density network will be formed which results in softer gels. In order to improve the mechanical properties of such gel, different strategies such as cross-linking or conjugation are used to stabilize HA and obtain a more stable material [115]. The mechanical strength of the gels was improved by increasing the cross-

linking degree [116]. Double network hydrogels with bacterial cellulose and gelatin resulted in higher mechanical strength including low frictional coefficient [7].

In case of physical hydrogels, the dissolution method used for the preparation of hydrogels affects the mechanical properties; in other words the mechanical stability depends on the formation of hydrogen bonds. The mechanical strength of the hydrogels is improved by employing pre-gelation process before performing coagulation [5]. For example, hydrogels prepared from chitin/NaOH/urea solution through coagulation in acidic or aqueous salt solutions had smoother surfaces, more homogeneous structure, and relatively smaller pore sizes, which resulted in improved tensile strength and transparency [117]. The inhomogeneities in the hydrogels will have weak portions of macroscopic network integrity, thus lowering the mechanical properties of the hydrogels.

4.5 Rheological Properties

The rheological property includes shear stress, viscosity, and viscoelastic response; these properties of the gels depend on the types of structure (i.e., association, entanglement, cross-links) present in the system. The rheological response is based on the contributions of cross-links such as covalent bonds and physical cross-links such as electrostatic interactions and hydrogen bonds and some chemical interaction (entanglements) between the molecules.

In order to study the viscoelastic response of the hydrogels, shear modulus measurements are performed at room temperature as a function of frequency. The cross-links between the different polymer chains are also responsible for viscoelastic or pure elastic behavior [13]. For example, the polysaccharide hydrogels behave elastically at small strains and become viscoelastic at large strains, which tend to achieve excellent toughness of the gels [118]. The viscoelastic characteristic of several different hydrogels including agarose and alginate was studied by Ahearne et al., and their study represented that the behavior depends on concentration of cellulose, but these concentration dependencies are smaller than those for viscosity [119]. However, the dynamic viscoelasticity changes with respect to the temperature; the temperature dependencies are different from those of the thermo-reversible gels. Further, the change in deformation over time is also used to characterize the viscoelastic creep response of the hydrogels. For polymers to flow, the chains must move past each other, and cross-linking prevents this movement. The result of restriction in flow will result in the improvement of creep behavior [120].

The cross-links in the hydrogels tend to reduce the intrinsic mobility of the polymer chains and are not able to release stress; consequently the material will have predominant elastic behavior ($G' > G''$) and behaves as a three-dimensional network [115].

Generally, the polymer solutions are essentially viscous at low frequencies, which fits to the scaling laws: $G' \sim \omega^2$ and $G'' \sim \omega$. At high frequencies, elasticity dominates ($G' > G''$); the effect corresponds to Maxwell-type behavior, where G' and G'' are the elastic and viscous moduli, respectively, ω is scaling of the viscous modulus, and ω^2 is scaling dependence of the elastic modulus.

Furthermore, higher concentration of cellulose tends to have higher viscosity, hardness, and cohesiveness. The complex changes occur in both the structure and chemistry of cross-linked hydrogels during rheological characterization, Szcześniak developed methyl cellulose-based hydrogels, and their study found that the addition of chitosan gels based on methylcellulose affected the rheological property. The rheological studies showed that the process was nonlinear, and gels have shown thixotropic properties, i.e., increasing the concentration of chitosan has influenced the viscosity and hardness of the gels [121].

4.6 Biocompatibility and Cytotoxicity

Biocompatibility and cytotoxicity are the important characteristics for biomedical application. Biocompatibility consists basically of two elements, namely, biosafety and bio-functionality. In vitro test for biocompatibility are generally performed in two different ways; in the first method, the hydrogels are positioned in direct contact with the host environmental cells and incubated for a specific period of time at 37 °C; and in the other method, the material is positioned in a suitable physiological solution and then incubated for a specified period of time at 37 °C to permit any leaching from the material. The obtained leachates are used to accomplish the biocompatibility tests in the presence of the cells [14]. The cell viability and cell proliferation from the cytotoxicity test are usually performed. The cell proliferation is visualized by microscopy as well as by carrying out MTT (tetrazolium salt, 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazolium bromide) assay, i.e., a colorimetric method which permits quantification of cell growth and proliferation [122].

Hydrogels possess a good biocompatibility since they have hydrophilic surface and low interfacial free energy when in contact with body fluids; thereby, it induces low tendency for proteins and cells to adhere to the surfaces of hydrogels [13]. The excellent biocompatibility and non-toxicity of cellulose and its derivatives have prompted the large use of cellulose-based devices in biomedical areas such as scaffold for cell culture, cartilage model, and implanted in bone defects [123]. A variety of polysaccharides like heparin, chitosan, dextran, and alginate have been explored as hydrogels for tissue engineering owing to their good biocompatibility. The water-soluble cellulose derivatives are mostly biocompatible which can be used as thickener, binding agents, emulsifiers, film formers, suspension aids, surfactants, lubricants, and stabilizers, especially as additives in food, pharmaceutical, and cosmetic industries [7].

5 Conclusion

In this chapter various methods involved in the preparation of cellulose and cellulose derivative-based hydrogels are discussed. In general the gels are synthesized either by physical or chemical cross-linking. The physically cross-linked gels are produced through different mechanisms, i.e., hydrophobic interaction, ionic interaction, or

hydrogen bonding. The chemically cross-linked gels utilize chemicals or radiation to produce 3D network. The chapter discussed different polymerization techniques followed in the preparation of cellulose and cellulose-derived hydrogels, namely, chain-growth polymerization, irradiation polymerization, and step-growth polymerization. The hydrogels have the remarkable ability to respond to different environmental stimuli. The potential response of the cellulose hydrogels w.r.t. external stimuli such as pH, temperature, light, electric field, magnetic field, and mechanical stress is discussed. The chapter addressed the stimuli-responsive materials based on cellulose that have great potential applications in many fields such as drug delivery, electric sensor, water treatment, etc.

Furthermore, various properties of the cellulose-based hydrogels such as swelling/deswelling, water retention capacity, biodegradation, mechanical, rheological, biocompatibility, and cytotoxicity are considered. The property variation with respect to cross-linking density and other parameters such as stimuli, shape, pore size, reinforcement, etc. is discussed.

Abstract

Experimental and theoretical tools to describe and tailor polymer network formation processes are here addressed. Although a special emphasis is given to the synthesis, characterization, and applications of smart and superabsorbent polymers, other networks with higher cross-linker contents are also prospected. Purely synthetic and cellulose-based hydrogels are both considered in this research. The reactor type (e.g., batch or continuous flow micro-reactor), polymerization process (e.g., bulk, inverse suspension, or precipitation polymerization), and polymerization mechanism (e.g., classic free radical polymerization or reversible deactivation radical polymerization RDRP) are highlighted as possible tools to change the morphology and the molecular architecture of polymer networks and hydrogels. The tailoring of cellulose-synthetic hybrid materials is also addressed through the use of RAFT-mediated polymer grafting. Case studies showing the applications of the synthesized materials are presented, namely, molecularly imprinted hydrogel particles for retention of aminopyridines, molecularly imprinted polymers for polyphenols, caffeine or 5-fluorouracil selective uptake/release, as well as modified cellulose adsorbents for polyphenol retention. Cellulose-based hydrogels are also considered as possible vehicles for polyphenol-controlled release. The mechanisms of liberation of polyphenols from these materials are analyzed, namely, when supercritical CO_2 is used in the hydrogel impregnation process.

1 Introduction

Hydrogels are generically defined as low cross-linked hydrophilic polymer networks. Owing to their unique properties, hydrogels present useful applications in medicine and pharmaceutics, hygiene and sanitary industries, agriculture, environment, separation processes, and others [1, 2]. Indeed, due to the swelling capacity of

these kinds of polymer networks, hydrogels are able to absorb a large amount of water without being themselves dissolved. Moreover, some kinds of hydrogels present responsive swelling or shrinking triggered by changes in parameters such as temperature, pH, electric/magnetic fields, ionic strength, etc. These materials, often called "stimuli-responsive" or "smart" hydrogels, exhibit reversible transitions between shrunk and swollen states that are macroscopically apparent. Neutralization of charged groups present in the polymer network due to pH shift and changes in hydrogen-bonding efficiency or in ionic strength are examples of mechanisms inducing such reversible transitions in hydrogels [1].

Polymer networks with the specific ability to absorb huge amounts of water relatively to their dry weight are often called superabsorbent polymers (SAPs). Superabsorbent behavior of such kinds of materials is driven by the water dissolution into the polymer network when it is enhanced by the presence of dissociated ionic pendant functional groups due to a strong solvation process. The difference between a traditional absorbent material (e.g., a polyurethane sponge) and a SAP becomes evident when their absorbencies (mass of absorbed water per mass of dry material) are compared: 10 g/g for polyurethane sponge and up to 1000 g/g for acrylic SAP [2]. It is possible to find polymer gels showing super absorbency features both based on synthetic and natural polymers. Well-known examples of these latter, which generate useful superabsorbent materials, are polysaccharides (such as cellulose), alginates (anionic), chitosan (cationic), and polypeptides (involving physical gelation). On the other hand, polymer networks based upon poly(acrylic acid), polyacrylamide, poly(ethylene oxide), or poly(vinyl alcohol) are commonly used to produce synthetic SAPs. Partially neutralized poly(acrylic acid) networks are especially relevant in SAP industry and present outstanding superabsorbency properties. Hybrid materials containing natural and synthetic polymers, such as starch/polyacrylonitrile or cellulose/poly(acrylic acid), can also be used as superabsorbent materials [2].

Polymers are known to be an important example of "products-by-process" which means that the structure and final properties of the products are mainly defined during the synthesis process [3]. Thus, the molecular architecture of polymer networks, such as smart hydrogels and SAPs, and their end-use properties (e.g., swelling, water absorbency, degree of stimulation, adsorption capabilities, elastic properties) are strongly dependent on the synthesis conditions used in their production. Initial composition, polymerization mechanism (e.g., conventional free radical polymerization or controlled radical polymerization), temperature, and reaction process (e.g., reactor type, solution/bulk/suspension/emulsion polymerization) are examples of key parameters with a crucial effect on the final properties of hydrogels and SAPs. A good knowledge of the mechanisms intervenient in the formation of these kinds of networks is therefore critical in order to make possible a consistent production of advanced materials with tailored properties. Polymer reaction engineering aims at providing the connection between the fundamental kinetic mechanisms occurring during a synthesis process and the microstructure of the resulting polymer and will be here explored in the framework of the production of hydrogel and SAPs. Besides the purely synthetic approach, polymer reaction engineering will be also considered to aid in the production of materials based on synthetic and natural polymers, especially cellulose.

2 Experimental Techniques

2.1 Materials

The following materials were used in the synthesis, purification, and testing of the different kinds of polymers and polymer networks addressed in this research.

Monomers acrylic acid (AA); methacrylic acid (MAA); N-isopropylacrylamide (NIPA); N,N-dimethylacrylamide (DMA); acrylamide (Am); 2-hydroxyethyl methacrylate (HEMA); 2-(dimethylamino)ethyl methacrylate (DMAEMA); and styrene (S) were purchased from Sigma-Aldrich, whereas 4-vinylpyridine (4VP) was provided by Alfa Aesar.

Cross-linkers methylene bisacrylamide (MBAm), trimethylolpropane triacrylate (TMPTA), and ethylene glycol dimethacrylate (EGDMA) were also purchased from Sigma-Aldrich. Polymerization initiators and catalysts 2,2′-azobis(2-methylpropionamidine) dihydrochloride (V50), azobisisobutyronitrile (AIBN), ammonium persulfate (APS), and tetramethylethylenediamine (TEMED) were supplied by Sigma-Aldrich, and 2,2′-azobis[2-(2-imidazolin-2-yl)propane] dihydrochloride (VA-044) was purchased from Wako Chemicals.

RAFT polymerization agents 2-cyano-2-propyl benzodithioate (CYDB), 4-cyano-4-(phenylcarbonothioylthio)pentanoic acid (CPA) and 2-cyano-2-propyl dodecyl trithiocarbonate (CPDT) were purchased from Strem Chemicals. The Sigma-Aldrich commercially available RAFT agents CPA, cyanomethyl dodecyl trithiocarbonate (CDT), S-(thiobenzoyl)thioglycolic acid (TBTGA), and 2-(dodecylthiocarbonothioylthio)-2-methylpropionic acid (DDMAT) were also used in our synthesis tasks. Thioglycolic acid (TA) (Sigma-Aldrich) was used as a chain transfer agent.

Analytical reagent grade acetonitrile (ACN), dimethylformamide (DMF), acetic acid (AcOH), methanol (MeOH), tetrahydrofuran (THF), and acetone were bought from Fisher Chemical (UK). Paraffin oil was received from Vencilab (Portugal). Cyclohexane, n-heptane, dichloromethane, and chloroform were purchased from Sigma-Aldrich. Surfactant sorbitan monooleate (span 80) was purchased from Panreac (Spain). Millipore water (Milli-Q quality) was used in all the experiments unless otherwise mentioned.

Cellulose fibers (medium, cotton linters), microcrystalline cellulose (powder, 20 μm, cotton linters), and Whatman No. 1 cellulose filter paper have been purchased from Sigma-Aldrich and used for the synthesis of cellulose-based hydrogels, the generation of cellulose-based materials with modified physicochemical properties, and also for the production of RAFT-grafted modified cellulose. Sodium hydroxide and urea (Sigma-Aldrich) were used to dissolve cellulose in aqueous solutions. Epichlorohydrin (ECH, Sigma-Aldrich) was used as a cellulose cross-linker. N,N-′-dicyclohexylcarbodiimide (DCC) and 4-(dimethylamino)pyridine (DMAP), both from Sigma-Aldrich, were used as coupling agent and catalyst, respectively, in the Steglich esterification of cellulose with RAFT agents containing carboxylic acid functional groups. Some of the aforementioned monomers were considered in the studies concerning the RAFT-grafting of cellulose, as below discussed in this work.

Different kinds of molecules were considered in retention and release studies involving the polymer networks synthesized as sorbents, namely, 3-aminopyridine (3-APy) and 4-aminopyridine (4-APy) that were obtained from Alfa Aesar. Caffeine (CAF), theophylline (THP), theobromine (THB), ibuprofen (IBU), and isoniazid (INH) were procured from Acros Organics. 5-fluorouracil (5FU), uracil (UR), thymine (THY), and polydatin (POL) were purchased from Sigma-Aldrich.

2.2 Reaction Apparatus and Instruments

Different kinds of reaction apparatus have been used in the synthesis performed in the framework of this research, namely, (i) an atmospheric stirred reactor with maximum capacity of 2.5 L; (ii) a Parr 5100 pressurized glass reactor, mechanically stirred, with 1 L capacity and maximum operation pressure P = 10 bar; and (iii) a supercritical reaction/extraction unit assembled by Paralab SA. This latter unit comprises a Parr 970 mL steel reaction/extraction vessel with mechanical stirring, a pumping system to supply carbon dioxide, control and purge valves, back pressure regulator (BPR), and a trap collector. An automatic control system allows the specification of the set points for the temperature of the coil used to heat the inlet CO_2, temperature of the reactor/extractor, temperature of the BPR, and the temperature of the trap. The amount of CO_2 supplied to the vessel is controlled through a Coriolis flowmeter (mini CORI-FLOW Bronkhorst). The maximum operation temperature and pressure are T = 350 °C and P = 200 bar. (iv) Glass vessels with magnetic stirring were chosen in order to perform batch polymerizations at smaller scales (e.g., 20 mL total volume). (v) A continuous flow micro-reactor including two Knauer HPLC pumps (model Azura P 4. 1S, titanium head) with maximum delivery pressure of 40 MPa and flow rate in the range 0.001 to 10 mL/min is also used in our research. Valco tee devices connect the two lines coming from the pumps with generation of the feed to the micro-reactor. Different tubes with variable internal diameters and lengths (e.g., PTFE tubing with ID ranging from 0.2 to 1.5 mm and L = 20 m) can be used as continuous flow micro-reactors. The micro-reactor tubing is immersed in an oil bath at controlled temperature, and a container at the outlet collects the carrier fluid (e.g., liquid paraffin, cyclohexane) and the polymer particles (e.g., hydrogel particles). A flow of dry argon was used in all the synthesis processes to purge the reactants.

A size exclusion chromatography (SEC) apparatus with refractive index (RI) and multi-angle laser light scattering (MALLS) detection, composed of a Polymer Laboratories PL-GPC-50 integrated SEC system with a differential refractometer with a NIR light source of wavelength 950 ± 30 nm, attached to a Wyatt Technology DAWN8$^+$ HELEOS 658 nm MALLS detector, was used in the characterization of the soluble fraction for the different kinds of polymers synthesized. Information concerning the molecular weight distribution, the average molecular weights, and the *z*-average radius of gyration of the soluble polymer population was thus obtained. Monomer conversion was also estimated through the quantification of the correspondent peaks in the SEC analysis. This SEC system was mostly used to

perform the polymer analysis in organic eluents (e.g., THF and DMF). Through a flow-to-batch conversion kit, the MALLS DAWN8$^+$ HELEOS instrument was also used to perform the *in-line* measurement of the scattered light intensity during hydrogel formation, as below described.

Another SEC apparatus was used for the size fractionation of the soluble polymers considering the direct analysis in aqueous eluents with controlled pH. This system is composed of a Viscotek GPCmax VE 2001 integrated solvent and sample delivery module coupled to a tetra-detector array including refractive index, light scattering, viscosity (IV-DP), and ultraviolet (UV) detection.

An Axiom Analytical Attenuated Total Reflection (ATR) immersion probe, model DRR207, was used to carry out the *in-line* monitoring of the polymerization reactions. A three-arm light guide connected the immersion probe to an ABB Bomem Fourier Transform Infrared (FTIR) spectrophotometer model FTLA2000–104. The spectrophotometer was equipped with an ABB Bomem Mercury-Cadmium Telluride (MCT) detector (model D10B) cooled with liquid nitrogen. The optical system is continuously flushed with argon. This FTIR system was also used to perform the *off-line* analysis of polymer samples.

Other apparatus and techniques used for the polymer network cleaning and characterization include Soxhlet extraction, solid-phase extraction (SPE) in a Visiprep (Supelco, Bellefonte, USA) processing station manifold, and batch and continuous mode adsorption/desorption of selected molecules. In the latter case, networks to be tested were packed in empty GPC columns with bed lengths/internal diameters (mm/mm) ranging from 10/4.6 to 300/4.6, and the uptake/release of the analytes was measured in different solvents. *In-line* and *off-line* measurement of UV absorption was used to quantify these processes. Swelling measurements for the different materials was performed through gravimetric analysis. Standard microscopy (in a Nikon Microscope ECLIPSE 50i) and scanning electronic microscopy (SEM) yielded information concerning the morphology of the different hydrogels and other synthesized polymer networks.

3 Synthetic and Cellulose-Based Hydrogels

A possible division in two main classes of chemically cross-linked hydrogels is based on the provenience of the materials considered in their production: synthetic hydrogels that are obtained through the copolymerization of petrochemical-derived monomers and hydrogels including natural polymers such as polysaccharides or polypeptides. Cellulose-based hydrogels will be here specifically considered in the latter case.

3.1 Overview of Synthesis Routes for Hydrogels

A key tool to design synthetic hydrogels is the selection of the monomers leading to the polymer network. For instance, sensitivity to external stimulation of hydrogels

(a critical feature in many applications) can, in principle, be modulated using different kinds of functional monomers. Indeed, AA and MAA are often used to generate anionic hydrogels with high pH sensitivity, whereas DMAEMA, e.g., is often chosen for obtaining cationic hydrogels with inverse pH stimulation in contrast with the former group. NIPA monomer is often chosen for obtaining hydrogels exhibiting temperature stimulation with a critical transition at around T = 32 °C, which is commonly exploited in biomedical applications. Critical transitions triggered by temperature changes at higher ranges (e.g., around 50 °C) are found with other monomers, namely, with DMA. In certain applications, nontoxic and nonionic hydrogels are sought, and, in this case, HEMA-based polymer networks are good candidates owing to their biocompatibility. When mixed effects are to coexist in the same hydrogel, a polymer network including different functionalities can be used. Amphoteric hydrogels based on AA/DMAEMA and pH/temperature-sensitive AA/NIPA are two examples of such kinds of materials.

Another parameter with a huge impact on synthetic hydrogel properties is the cross-linker content. For instance, commercial superabsorbent polymers (SAPs) are mostly produced through the copolymerization of AA with a very small amount of a cross-linker such as MBAm or TMPTA, e.g. Usually this production process is carried out directly in aqueous phase. Hence, the low water solubility of some cross-linkers is an important issue in this context; organic solvents could also be used, but the process would become less eco-friendly and/or with higher operating costs. Both a very high swelling ratio and a low fraction of soluble polymer must be achieved in SAP synthesis, both implying a mole fraction of cross-linker in the global monomer mixture as low as 0.0025 to 0.5%. The degree of neutralization and initial concentration of AA also plays an important role in SAP performance since polymerizations are often directly performed in alkaline aqueous solutions (e.g., 15 to 40% AA in water with 50 to 70% neutralization using NaOH). Industrially, thermal initiation is preferred, with an operation temperature in the range 40 to 70 °C. The final outcome is a sodium acrylate polymer network. Note that a posttreatment of non-neutralized hydrogels with an alkaline solution is also possible, but a lower efficiency is associated with this alternative.

A higher cross-linker content as compared to the one usually chosen for the soft hydrogels (up to 2%), including the SAPs and other kinds of highly swellable hydrogels, leads to stiffer materials presenting advantageous properties when lower swelling in aqueous media is required. Indeed, in some applications (e.g., biomedical, sensing, etc.) a lower and controlled degree of swelling of the networks is sought, and the cross-linker content used in their synthesis can increase to 5–10%. Moreover, in some other materials such as the molecularly imprinted polymers (MIPs) or other kinds of sorbents, a high geometrical stability of the polymer network must be achieved, and a cross-linker content as high as 80% is practically used.

Changes in the morphology and in the porous structure of polymer network materials (including generic hydrogels and SAPs) can also be used to enhance their performance, namely, the intervenient mass transport mechanisms. Introduction of fillers or porogens in the reaction mixture is usually considered with this goal. Additionally, instead of bulk/solution processes, suspension, inverse suspension, emulsion, precipitation, or dispersion polymerization can be used to produce

hydrogel particles with controlled size and shape. Continuous flow micro-reactors have been chosen in the last few years also aiming at the tailoring of the size and shape of these materials. Figure 1a depicts an image of an acrylic hydrogel powder produced in this research through an inverse suspension process. Figure 1b shows the correspondent water-swollen hydrogel. Note that a fast water absorption process is generally observed with this kind of hydrogels and a huge value for the equilibrium swelling ratio is possible (e.g., SR close to 1000, as described in [4] and references therein).

Owing to the huge abundance of cellulose and its biocompatibility, the development of materials incorporating this natural polymer has been carried out in many recent studies. As far as hydrogels are concerned, several different techniques have been studied in the last few years in order to incorporate cellulose in such materials, as reported in some review papers (see [5, 6] and references therein). Chemically cross-linked cellulose-based hydrogels can be obtained through different synthesis routes, making use of the reaction with the OH groups, namely, through bifunctional molecules such as divinylsulfone, epichlorohydrin, or citric acid. Radical cross-linking processes [5] avoid the toxicity problems associated with some bifunctional cross-linkers and offer some advantages for producing cellulose-based hydrogels.

A major problem to be faced when hydrogels are prepared directly from native cellulose is the very low solubility of this polymer in common solvents due to its extensive hydrogen-bonding interactions. Fortunately, new solvents of cellulose have been lately found such as LiCl/dimethylacetamide (LiCl/DMAc), N-methylmorpholine-N-oxide (NMMO), ionic liquids (ILs), and alkali/urea aqueous mixtures [5]. Hydrogel generation can therefore be easily carried out after cellulose dissolution.

3.2 Case Studies with Acrylic and Cellulose/Epichlorohydrin Hydrogels

In Table 1 are presented some recipes used in our research to generate cellulose-based hydrogels. The alkali/urea method for dissolution of cellulose in aqueous systems was chosen including, as reported in the literature [7–9], cycles of cooling

Fig. 1 (**a**) Dried acrylic hydrogel powder obtained through inverse suspension. (**b**) Water-swollen acrylic hydrogel. (**c**) Water-swollen cellulose/epichlorohydrin hydrogel

(e.g., at T = −30 °C) followed by room temperature thawing. Afterward, epichlorohydrin was used as cross-linker, following also the methods before developed [7–9] (24 h reaction time was used in our synthesis). The image of a typical cellulose-based hydrogel obtained under these conditions is presented in Fig. 1c. These results illustrate the possibility for effective cellulose-based hydrogel preparation, using relatively simple processes, following recent research results on this subject [7–9].

The dynamics of swelling and deswelling is a key aspect in the application of hydrogels as superabsorbents, sensors, controlled release vehicles, chromatographic supports, general adsorbents, or biomedical technologies [5]. Obviously, this dynamics and the equilibrium swelling ratio depend on many factors, such as the chemical composition of the hydrogel, the cross-linking density of the network, the morphology and porosity of the materials, etc. Additionally, the swelling conditions, namely, the composition of the solvent, the pH, temperature, and ionic strength, also play a central role on the hydrogel swelling.

Figure 2 illustrates the dynamics of swelling with different kinds of hydrogels synthesized in our research. In Fig. 2a is presented the behavior of an AA-based acrylic hydrogel, obtained in the powdered form through inverse suspension, when dipped either in deionized water or in a 0.9% NaCl aqueous solution. A very fast swelling process is observed, and very high equilibrium swelling ratios are obtained in both conditions, namely, SR~200 in deionized water and SR~100 in 0.9% NaCl aqueous solution. Note however the large drop of swelling ratio when the ionic strength of the solution is increased. Figure 2b shows the dynamics of swelling for two different cellulose-based hydrogels, generated from the cross-linking of microcrystalline and filter paper cellulose with ECH (samples HCEL-5 and HCEL-8 in Table 1). In both cases, the swelling process starts from the dried hydrogels in the form of a single cylinder piece with typical diameter × thickness = 10 × 3 mm × mm. These results put into evidence that the swelling of cellulose-based hydrogels depends strongly on the synthesis conditions used, namely, the kind of cellulose, the dissolution conditions and, among others, the cross-linking conditions. Obviously, changes of the synthesis conditions can be considered to modulate the

Table 1 Synthesis conditions used for cellulose dissolution in aqueous solutions followed by hydrogel preparation with ECH as cross-linker

Hydrogel alias	Cellulose type	NaOH (wt.%)	Urea (wt. %)	CEL (wt. %)	Solution vol. (mL)	ECH vol. (mL)	Preparation T (°C)
HCEL-1	Microcrystalline	7	12	2	10	1	60
HCEL-2	Fibers	7	12	2	10	1	60
HCEL-3	Filter paper	7	12	2	10	1	60
HCEL-4	Fibers	6	4	2	10	1	60

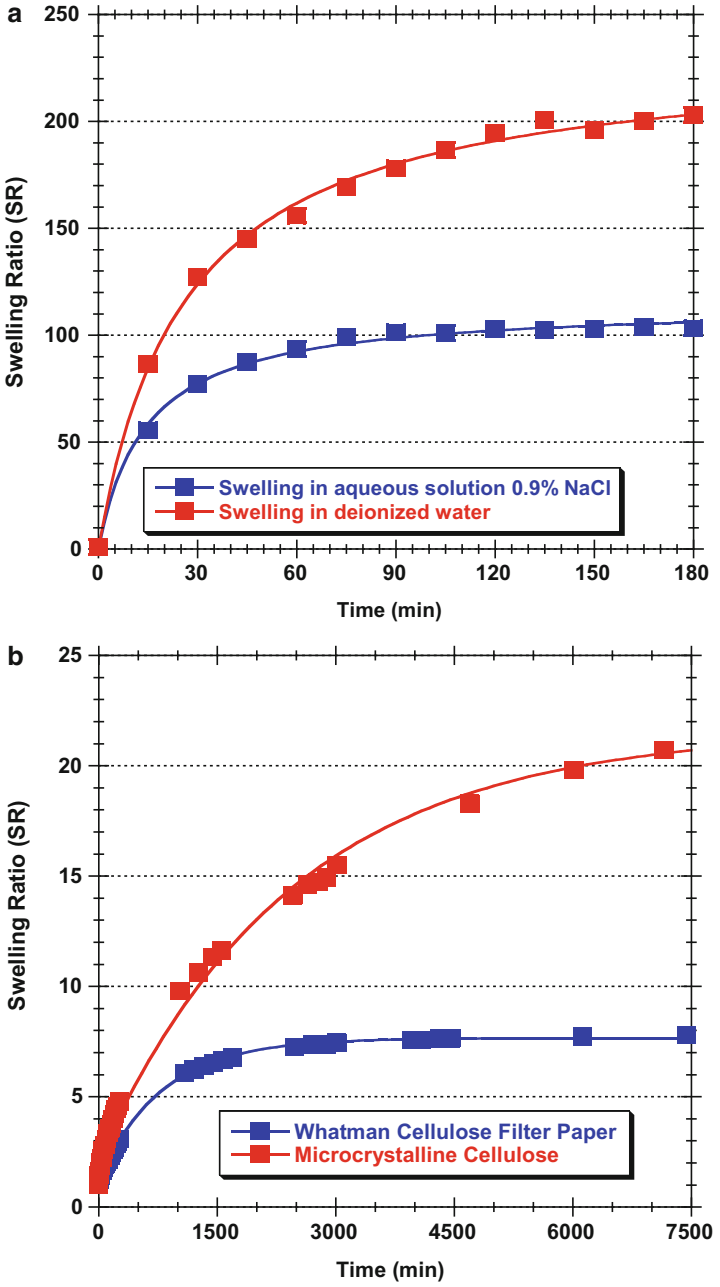

Fig. 2 (**a**) Dynamics of the swelling ratio of an acrylic hydrogel in deionized water and in a 0.9% NaCl aqueous solution. (**b**) Dynamics of the swelling ratio for two different cellulose/epichlorohydrin hydrogels

swelling of the cellulose-based hydrogels in view of the desired application (superabsorbency, controlled release, biomedical, etc.).

The comparison of results presented in Fig. 2a for acrylic hydrogels and in Fig. 2b for cellulose-based hydrogels highlights that considerable differences are observed in the swelling of the two classes of materials. With the selected samples, a much faster swelling dynamics is observed for the acrylic hydrogel comparatively to the cellulose-based networks. Additionally, the equilibrium swelling ratio of the acrylic hydrogels is roughly 10 times higher than that of cellulose materials. Note however that besides the intrinsic chemical differences between the two classes of networks, the morphologies of the products tested are also very distinct (acrylic powder vs. a single piece of cellulose hydrogel). These morphological differences also have a large impact on the dynamics of swelling thus affecting the performance of both kinds of hydrogels. Indeed, several different kinds of parameters are being considered in the scientific community to design these materials. The generation of hybrid hydrogels incorporating both synthetic polymers and cellulose is a promising route in view of the modulation of the properties and the use of sustainable natural resources. The use of synthetic/cellulose interpenetrating polymer networks (IPNs) and grafting of synthetic polymers in cellulose (as below discussed in the present work) are two important approaches to target this issue [5, 6].

The above-presented results illustrate some basic principles involved in the synthesis and application of both synthetic and cellulose-based hydrogels. However, there is plenty of room to improve the structure and properties of these polymer networks concerning the synthetic and the cellulose-based products as well as the hybrid materials. Indeed, a major opportunity to control and design the molecular architecture of polymers was created with the discovery of the reversible deactivation radical polymerization (RDRP) mechanisms. These techniques allow the precise synthesis of many complex structures such as block copolymers, stars, and comb polymers. RDRP mechanisms (e.g., RAFT, ATRP, NMRP) can also be used to achieve improvements of polymer networks, namely, by increasing their structural homogeneity due to the control of the cross-linking process and of the size distribution of the chains between cross-linking points. New grafting processes, functionalization of polymer networks, and creation of complex architectures (e.g., surface brushing) are also possible in the framework of RDRP techniques, especially RAFT polymerization. These new opportunities will be discussed along this work in the context of both the synthetic and the cellulose-based polymer networks.

4 Dynamics of Network Formation and Structural Inhomogeneities

4.1 Light Scattering Measurements and Network Inhomogeneity

The timeline for synthetic network and gel production begins with the vulcanization of natural rubber in the nineteenth century. The synthesis of Bakelite in the beginning of the twentieth century, ion-exchange resins in the 1930s, contact lenses in the

1950s, SAPs and volume phase transition gels in the 1970s, responsive polymers in the 1980s, high strength gels in the beginning of the twenty-first century, and nowadays' synthesis of nearly ideal polymer networks are some important milestones in this context [10]. Different kinds of theories were also developed along the time with the goal of describing the formation, structure, and performance of these materials. Since the 1930s, molecular and phenomenological theories (elasticity, swelling, etc.) were developed by Kuhn, Flory, James, Guth, Treloar, and many others [10]. The entanglement concept in polymer networks was worked out in the 1970s (e.g., Graessley theory), and in a third step, starting in the 1990s until nowadays, the inhomogeneities of polymer networks were addressed using, e.g., Cohen-Colby and Panyukov-Rabin theories [10]. Most of these theories were developed considering the concept of "ideal polymer network" where the sub-chains between cross-links have the same length and defects and entanglements are absent. However, it is known that real polymer networks contain different kinds of irregularities (e.g., distinct kinds of cross-links, through their chemical nature, connectivity, and mobility) due to poor control of the cross-linking process during synthesis, occurrence of side reactions, and inevitable topological complexity of the network structure (such as the presence of short loops). Therefore, the behavior of real polymer networks is far from the expected for a treelike architecture, and an important deleterious effect of the structural inhomogeneities on material performance is often observed.

Thus, the assessment and control of structural inhomogeneities in polymer networks and gels is an important issue that can be addressed considering different approaches. Light scattering studies provide valuable information in this context because an increase in the scattered intensity is commonly observed as a consequence of a cross-linking process. It is accepted that the observed excess scattering is an effect of the polymer structure and shows the degree of heterogeneity of the networks [11]. Often, the practical application of such methods is based upon the evaluation of the difference between the excess scattering of the gel and of the analogous linear polymer solution (formed in the absence of cross-linker), as described in the following equation:

$$R_{ex,q} = R_{gel,q} - R_{sol,q} \tag{1}$$

The Rayleigh ratios for the gel and for the analogous linear polymer solution at the scattering angle θ are obtained through Eq. (2):

$$R_{ex,\theta} = \frac{\left(I_\theta - I_{\theta,solvent}\right) r^2}{I_0 V} \tag{2}$$

Variable I_θ above represents the scattered light intensity at the scattering angle θ, I_0 the intensity of the incident beam, V the volume of the scattering medium, and r the distance between the scattering volume and the detector. Usually, calculations are performed using as independent variable the scattering factor q instead of the scattering angle:

$$q = \frac{4\pi n}{\lambda_0} \sin(\theta/2) \tag{3}$$

With n, λ_0, and θ representing the solvent index of refraction, the wavelength of the incident light, and the scattering angle, respectively.

In practice, it is possible to carry out the *in-line* measurement of the scattered light intensity (I_θ) during the polymer formation [12, 13]. A typical analysis of such kind is presented in Fig. 3 for the polymerization of partially neutralized AA with initiation by APS/TEMED at room temperature. These measurements were performed in a DAWN8+ light scattering instrument and using a flow-to-batch conversion accessory.

From Fig. 3, it can be observed that, after an induction period, the polymerization is accompanied by an increase of the scattered light intensity, eventually reaching a maximum. This maximum corresponds to the critical overlap polymer concentration, and gelation occurs at or slightly beyond this point [12, 13]. Due to the growth of polymer concentration, the scattered light intensity starts to decrease after the critical point. Such kinds of measurements are helpful in the assessment of the spatial heterogeneity of the formed synthetic polymer but can also be used to investigate the formation of gels based on natural polymers, such as cellulose/epichlorohydrin hydrogels (for instance). Additional information concerning the mesh size of the networks and the average molecular weight between cross-linking points ($\bar{M}_c$) can be obtained using dynamic light scattering and mechanical measurements, respectively [12, 13].

4.2 Swelling Analysis

Swelling analysis can also be used to obtain information concerning the average molecular weight between cross-linking points, according the Flory-Rehner theory (see [14, 15] and also Chap. 11 in Ref. [1]):

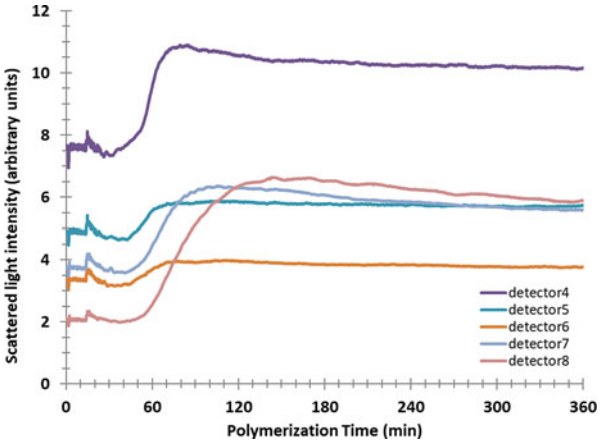

Fig. 3 In-line measurement of the scattered light intensity (I_θ) recorded at different angles (detectors) as a function of the reaction time for the polymerization of partially neutralized AA with initiation by APS/TEMED at room temperature

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} - \frac{\bar{v}\left[\ln(1 - v_N) + v_N + \chi v_N^2\right]}{V_S\left(v_N^{1/3} - v_N/2\right)} \tag{4}$$

In the above equation, V_S stands for the molar volume of the solvent, $\bar{v}$ for the specific volume of the polymer network, v_N for the volume fraction of polymer network in the swollen mass, $\bar{M}_n$ for the molecular weight of the primary polymer chains, and χ for the solvent-polymer interaction parameter (according to Flory-Huggins theory). The volume fraction of polymer network in the swollen mass (v_N) can be experimentally estimated through swelling experiments and is related to the mass swelling ratio by the equation:

$$v_N = \frac{1}{1 + (SR - 1)\dfrac{\rho_N}{\rho_S}} \tag{5}$$

In the above equation ρ_N and ρ_S represent the mass densities of the polymer network and of the solvent, respectively. If the solvent-polymer interaction parameter (χ) is known (estimation methods are also often used [16]), Eq. (4) provides a simple form to measure the $\bar{M}_c$ network parameter. This analysis has been considered in very recent works [17] to assess the homogeneity of polymer networks, namely, through the comparison of gels produced by free radical processes and reversible deactivation radical polymerization (e.g., RAFT polymerization).

4.3 FTIR Analysis of Network Formation

In general, FTIR analysis provides important information concerning polymer formation and final composition of the materials. This technique can also be applied to elucidate the mechanisms of formation of networks and their final chemical functionalities [18–24]. Besides the usual *off-line* analysis of the products [23, 24], *in-line* FTIR monitoring of network development can also be performed [18–22].

In Fig. 4 are presented results concerning the *in-line* FTIR-ATR monitoring of free radical processes involved in typical synthetic hydrogels production, namely, the aqueous polymerization of AA/MBAm (Fig. 4a) and the terpolymerization of MAA/AAm/MBAm (Fig. 4b). These results illustrate the dynamics of change observed in specific peak assignments, showing the polymerization progress.

4.4 Size Exclusion Chromatography

Size exclusion chromatography (SEC) is a powerful technique disclosing important information concerning the soluble polymer species in a specific eluent. In general, for linear polymers, information concerning the entire polymer population is obtained if a proper solvent is available. With nonlinear polymers, although the

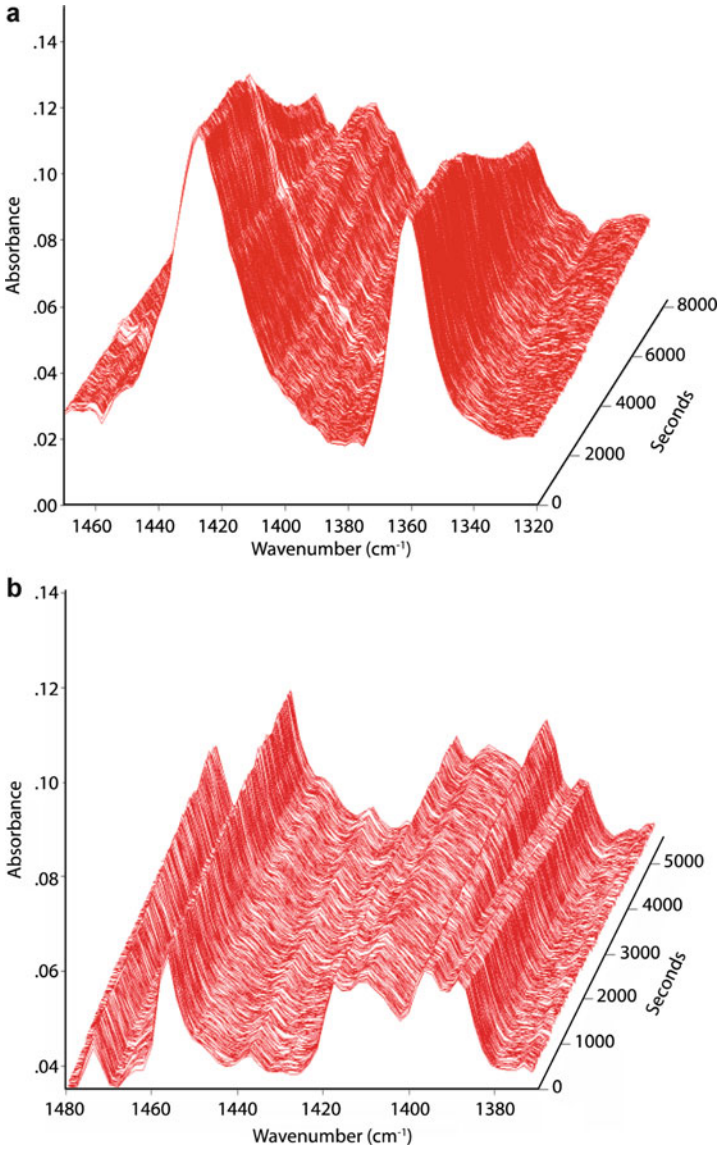

Fig. 4 *In-line* FTIR-ATR monitoring of free radical polymerization processes considered in synthetic hydrogels production: (**a**) aqueous polymerization at room temperature of AA/MBAm (99.5/0.5 mol %), 15% monomer concentration, and 0.1% APS/TEMED. (**b**) Aqueous polymerization at room temperature of MAA/AAm/MBAm initiated by 0.66% APS/TEMED. Initial monomer composition: 13% v/v of MAA in water, 5% w/w of AAm, and 0.5 mol% of MBAm in global monomer composition

soluble phase in the selected solvent can be analyzed by SEC, the superposition of chromatograms of species with different molecular masses or structures but same effective sizes in solution complicates seriously the quantitative analysis. Molecular size distribution and *z*-average radius of gyration are typical structural features that can be investigated through SEC with multiple detection (usually RI and MALLS). Monomer conversion can also be estimated using SEC when the peaks of the involved monomers are detectable in the chromatographic traces.

Some important features provided by SEC analysis in the framework of synthetic hydrogel formation (or their linear counterparts) are presented in Fig. 5. Figure 5a shows the possibility for monomer conversion measurement when the SEC traces of polymer and monomer(s) are identifiable. An inverse suspension RAFT polymerization process, involving the AA and NIPA monomers, is here considered for illustration purposes. Depletion of both monomers in samples collected at different polymerization times is clearly seen. Note that, in the formation of hydrogels, the amount of cross-linker is very small in comparison with the main monomers, and its reliable measurement by SEC is not possible in these conditions.

Figure 5b depicts SEC chromatographic traces for a sample correspondent to the AA/MBAm RAFT polymerization in DMF. The RI and light scattering signals are simultaneously presented in this plot. The existence of soluble polymer is identifiable through the LS and RI signals with the latter also showing the AA monomer peak. Note, however, the huge difference between the RI and LS signals showing the formation of a polymer cluster at a very low concentration (almost nil RI response) but very high molecular size (high LS response). Similar analysis provides useful information concerning the development of the polymer population during the synthesis, namely, an imminent gel formation due to the cross-linking process (predated by the formation of a very large polymer cluster).

In Fig. 5c are compared the LS signals correspondent to samples collected at different polymerization times during inverse suspension DMA RAFT polymerization. The dynamics of the development of a secondary polymer population is here illustrated (see also [21]). Note that these measurements can enlighten key kinetic steps involved in the polymerization mechanisms such as the eventual formation of three-arm adducts during RAFT polymerization due to the termination of intermediate radicals (see [25] and references therein for a detailed discussion on these issues).

Figure 5d compares the SEC analysis correspondent to the FRP of AA in the absence and in the presence of a chain transfer agent (thioglycolic acid was used). The effect of the chain transfer agent on the molecular weight distribution of the polymer is here illustrated, and a possible manipulation of the polymer molecular size through this mechanism is highlighted (a substantial decrease on molecular size is clearly observable). Note that the knowledge on the formation processes and structure of the linear counterparts of the main polymer chains involved in hydrogel formation is critical to understand and tailor the properties of these networks. Indeed, primary chains (those remaining when the cross-links are severed in a network) play a central role in gel formation (as described in Sect. 5) and also in networks properties (elasticity, swelling, and so on). Thus, comparative measurements, such

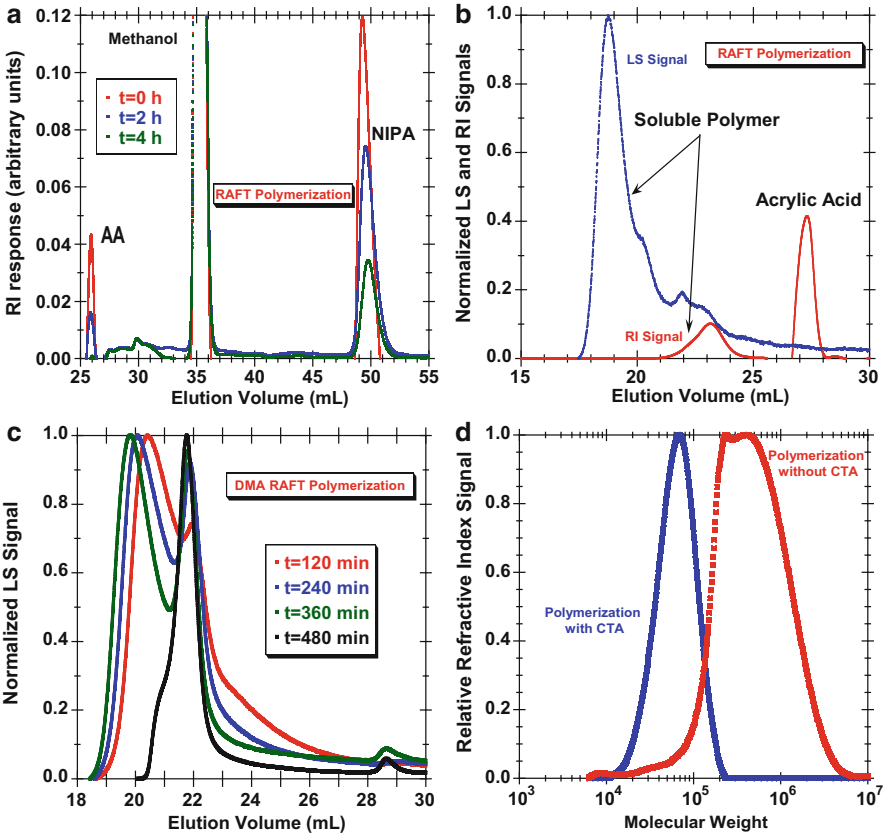

Fig. 5 Results of different SEC analysis carried out for samples of synthetic hydrogels or their linear polymer counterparts. (**a**) Measurement of AA and NIPA concentration in a RAFT copolymerization process involving these two monomers. (**b**) Light scattering and RI signals for an AA-based hydrogel synthesized through RAFT polymerization. (**c**) Light scattering signal for samples correspondent to the DMA RAFT polymerization collected at different polymerization instants. (**d**) Measured effect of the presence of a chain transfer agent (thioglycolic acid) on the molecular weight distribution of an AA polymer

as those provided in Fig. 5a and d for linear polymerization, are helpful to design the hydrogels obtained in similar conditions. In this context, tailoring of the average molecular weight between cross-linking points ($\bar{M}_c$) using RAFT polymerization, as above discussed, is an important opportunity that is being considered in the scientific community.

The knowledge on the kinetics of polymerization plays also an important role on the design and control of hydrogel formation. Some information provided by SEC analysis is illustrated in Fig. 6. The measured dynamics of monomer conversion for AA/MBAm copolymerization with three low contents of MBAm is shown in Fig. 6a. The effect of the degree of neutralization with NaOH in the polymerization

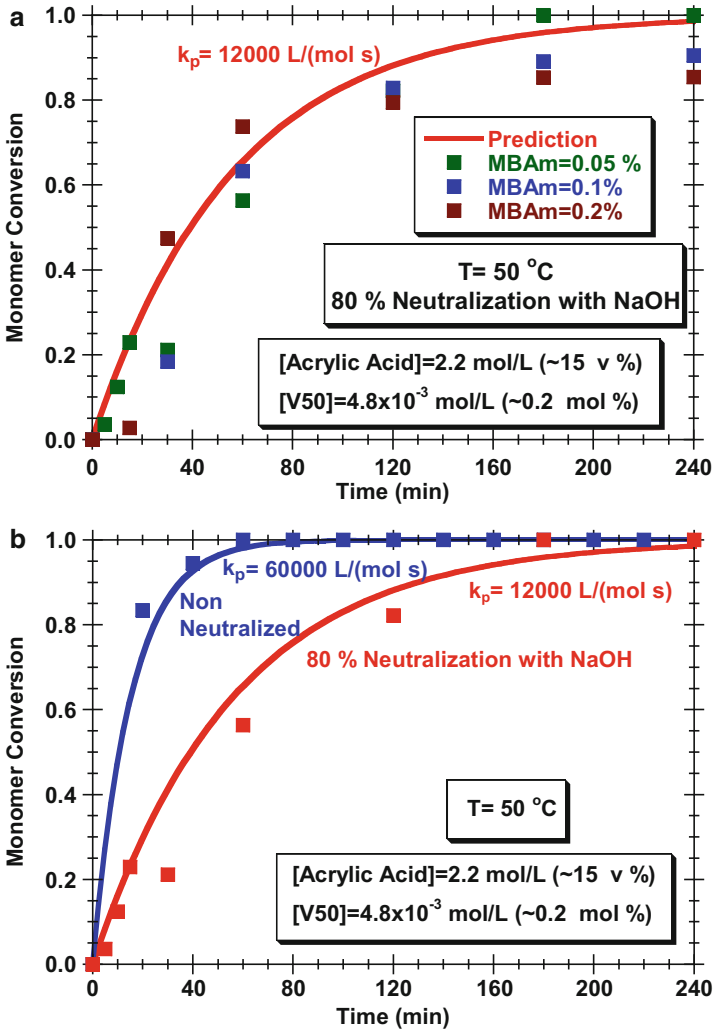

Fig. 6 (**a**) Kinetics of polymerization in an AA/MBAm hydrogel formation obtained by SEC. Cross-linking processes with mole fraction of MBAm ranging from 0.05 to 0.2% were considered. Polymerizations at T = 50 °C with V50 as initiator, concentration of AA ~ 15 v%, and 80% neutralization with NaOH. (**b**) SEC measured effect of the degree of neutralization on the rate of AA polymerization. Non-neutralized and 80% neutralized polymerizations are compared

kinetics is presented in Fig. 6b, evidencing the fall of the polymerization rate when the degree of neutralization is increased. Such kind of experimental data can be used to estimate kinetic parameters (e.g., the propagation rate constants) and to develop models to aid in the design of these polymerization processes, as explored in the next section.

5 Calculation Tools to Describe Network Formation

5.1 Overview

This section presents calculation methods often used to describe the formation of synthetic hydrogels. The modeling of general polymerization process where the branching and cross-linking mechanisms are intervenient is analyzed. The applicability of such tools to design hybrid materials including natural polymers, such as cellulose, is also discussed. Modeling tools for nonlinear RDRP are also briefly addressed.

5.2 Flory-Stockmayer Theory of Gelation

Synthesis of materials presently known to consist of cross-linked synthetic polymers is documented since the first half of the nineteenth century starting with the vulcanization of natural rubber by brothers Charles and Nelson Goodyear.

Along with other important contemporary contributions by W.H. Carothers, W. Kuhn, and G. V. Schulz, it was P.J. Flory [26–30] who laid out the modern foundations of the analysis of polymerization reactions, using either population balances of species [30] or elementary probabilistic deductions [26–29]. The formation of "infinitely" large three-dimensional networks (gels) and the general condition for gelation in condensation polymerization of a symmetrical monomer with f self-reacting groups A_f (such as a silanetriol, with $f = 3$) was established:

$$p_g = \frac{1}{f-1} \tag{6}$$

Here, p is the probability that a chain starting from a branch unit would lead to another branch unit rather than to a terminal group. The derivation of this critical condition is based on a random branching process, as depicted in Fig. 7a for a trifunctional system [26]. Soon afterward, W.H. Stockmayer [31–33] generalized Flory's theory and the whole approach become known as the Flory-Stockmayer (FS) theory of gelation. Using a probabilistic and combinatorial reasoning, W. Stockmayer found in particular an expression for the weight fraction of all isomer species carrying n units for this step-growth polymerization [31]:

$$w(n) = \frac{f(fn-n)!}{(n-1)!(fn-2n+2)!} p^{n-1}(1-p)^{(f-2)n+2} \tag{7}$$

It is worth noting that W. Stockmayer took the trouble to show that Eq. (7) can also be found through the population balance of polymer species, leading him and his contemporaries to believe that both reasonings are always equivalent and lead to the same results, something which would take nearly three decades to be understood as a mistake, as we discuss in the next section. Nevertheless, these results are

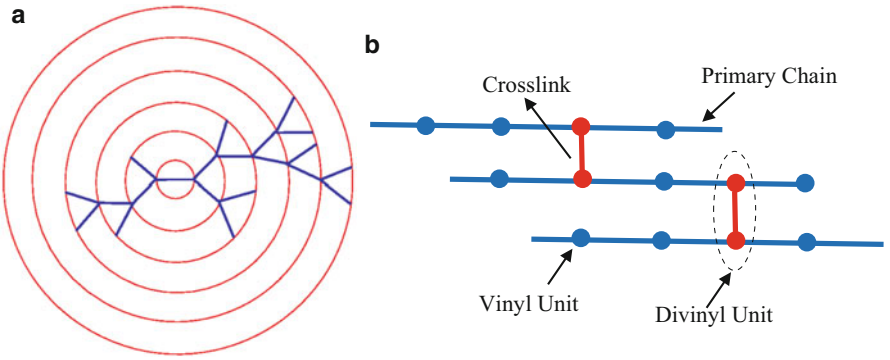

Fig. 7 (**a**) Depiction of the condensation of a trifunctional monomer ($f = 3$) leading to a branched polymer according the Flory's theory: formation of an infinite network is possible if $p > 1/2$ [26]. (**b**) Depiction of the primary chains and cross-links in a network formed through a vinyl/divinyl copolymerization. The same formalism can be used to describe the cross-linking of linear polymer chains (e.g., the cross-linking of cellulose chains)

rigorous for equilibrium step-growth polymerizations and a good approximation even for many chain polymerizations; thence, it is worth pursuing the presentation of these classical findings.

Flory, using the formation of three-dimensional polymers with tetrafunctional branch units as a case study [28], also initiated the extension of the theory of gelation to chain polymerizations. The copolymerization of vinyl and divinyl compounds and the vulcanization of rubber was pointed as two examples involving tetrafunctional branching. Such chemical systems were also later discussed by Stockmayer and co-workers [32, 33], and an expression to predict the critical gelation conversion was derived in the framework of the FS theory:

$$p_g = \frac{1}{y_f\left(\bar{x}_w^* - 1\right)} \tag{8}$$

In Eq. (8), y_f represents the mole fraction of double bonds residing on the divinyl monomer, p_g the conversion of double bonds at the gel point, and $\bar{x}_w^*$ the weight-average chain length of the primary chains. Primary chains are defined as the polymer chains that would remain if every double-reacted divinyl units (cross-links) were severed in the network, as depicted in Fig. 7b (see also the early contribution of Walling for a simplified scheme of vinyl/divinyl copolymerization [34, 35]). Note that the formalism of the FS theory for cross-linking processes can be applied both to the cross-linking of preformed linear polymer chains (e.g., the cross-linking of cellulose that play the role of primary chains) and to the network formation due to vinyl/divinyl copolymerization. In the latter case, the primary chains are considered to be formed during the course of the cross-linking process. Indeed, Flory [28] and Stockmayer [33] derived the expression for the molecular size distribution of the network resulting from the random cross-linking of primary molecules with uniform length:

$$w_P(m) = \frac{m^{m-1}}{\gamma m!}(\gamma e^{-\gamma})^m \tag{9}$$

In Eq. (9), $w_P(m)$ represents the weight fraction of polymer molecules containing m primary chains and γ and the cross-linking index, defined as the number of cross-linked units per primary molecule. On other hand, the cross-linking density of the network (ρ) is defined as the fraction of units that are cross-linked (each cross-linkage bears two cross-linked units, as depicted in Fig. 7b). These two parameters are related through $\gamma = \rho\bar{x}_n^*$, with $\bar{x}_n^*$ representing the number-average chain length of the primary chains.

Note that the critical condition for gelation described by Eq. (8) can be rewritten as $\rho_g\left(\bar{x}_w^* - 1\right) = 1$ with $\rho_g = p_g y_f$ representing the cross-linking density of the network for the vinyl/divinyl system at the gel point (indeed, $p_g y_f$ is the fraction of created cross-linked units at gelation due to the vinyl polymerization process). These equivalences also illustrate the applicability of the FS formalism to the cross-linking of preformed primary chains or the copolymerization of vinyl/divinyl monomers.

For primary polymer chains with uniform length ($\bar{x}_n^* = \bar{x}_w^*$), the critical condition for gelation due to cross-linking is thus $\rho_g\left(\bar{x}_w^* - 1\right) \sim \rho_g\bar{x}_w^* = \rho_g\bar{x}_n^* = 1$, and therefore $\gamma_g = \rho_g\bar{x}_n^* = 1$. For heterogeneous primary chains, the critical cross-linking index is lower than one because $\bar{x}_w^* > \bar{x}_n^*$ (e.g., for primary chains with most probable distribution $\bar{x}_w^* = 2\bar{x}_n^*$, and gelation occurs with cross-linking index $\gamma_g = 1/2$). Note that the theory dealing with the random cross-linking of primary polymer molecules with arbitrary distribution sizes [36] is especially important to describe some processes of gel formation from cellulose chains (e.g., through the cross-linking reactions involving the cellulose hydroxyl groups and epoxides, isocyanates, or carboxylic acids). In particular, it is possible to show that the molecular size distribution for the random cross-linking of a population of primary chains with the most probable distribution is correspondent to the condensation of $A_2 + A_4$ units [36].

FS theory leads to some simple relations valid for the post-gelation period, such as the weight fraction of sol in the random cross-linking of primary chains with uniform length:

$$w_s = e^{-\gamma(1-w_s)} \tag{10}$$

In this equation, w_s represents the weight fraction of sol, while $w_g = 1 - w_s$ stands for the weight fraction of gel. If the size of the primary chains is arbitrarily distributed, the analogue equation for the weight fraction of sol is:

$$w_s = \sum_{n=1}^{\infty} w(n)[1 - \rho(1 - w_s)]^n \tag{11}$$

$w(n)$ in the above equation represents the weight fraction of primary molecules with n units. The applicability of this equation is limited to systems with low cross-linking density ($\rho \ll 1$). Other expressions allow the calculation of the cross-linking density of the sol and the gel as well as the number and weight-average degree of polymerization of the sol before and also after gelation [36]. In Figs. 8, 9, 10, 11, 12, 13,

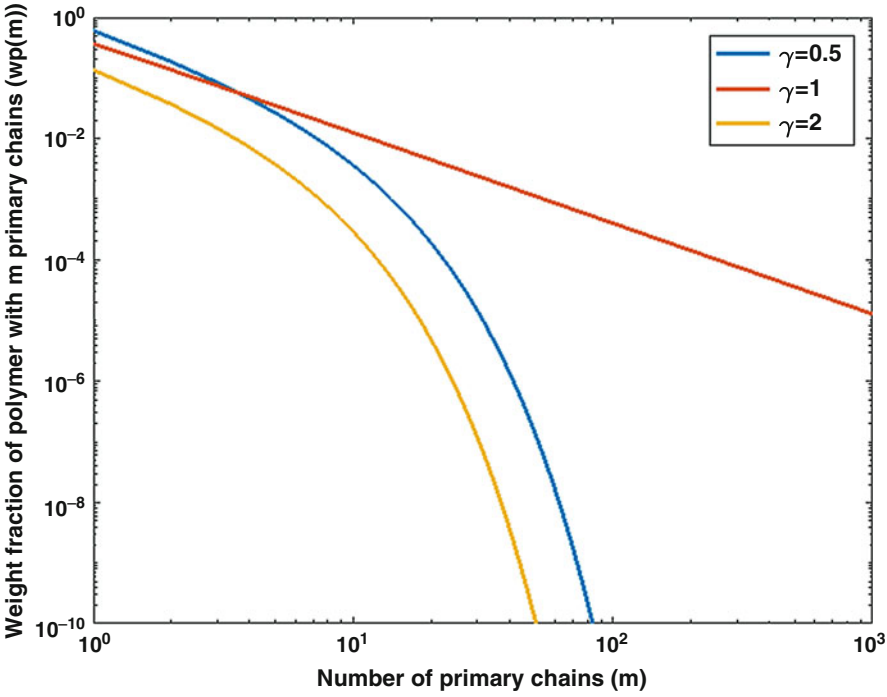

Fig. 8 Weight fraction of polymer with m primary chains, $w_P(m)$, in the random cross-linking of primary molecules with uniform length. Three values for the cross-linking index were selected in order to illustrate the pre-gelation period ($\gamma = 0.5$), gel point ($\gamma = 1$), and the post-gelation ($\gamma = 2$). The overall cross-linking density (ρ) is related with γ through $\gamma = \rho \bar{x}_n^*$ (e.g., with $\bar{x}_n^* = 500$, $\rho = 0.001$, 0.002, and 0.004 for $\gamma = 0.5$, 1, and 2, respectively)

and 14 are illustrated some calculations in the framework of the FS theory, highlighting the possibility to describe relevant variables in cross-linking processes, such as weight fraction of gel, cross-linking density, and molecular weight of the sol and gel.

Note that the above-described calculation methods in the framework of the FS gelation theory can also be applied to the irreversible batch formation of gels such as cellulose-epichlorohydrin polymers. Using a plausible chain length distribution for the primary chains (the cellulose polymer) and taking into account the amount of cross-linker considered in the polymerization (e.g., epichlorohydrin), which defines the number of cross-linkages and therefore the cross-linking density (ρ), the extent of gel formation and the sol/gel properties can be calculated, as above discussed. In practice, the extent of reaction between the OH and epoxy groups and the occurrence of side reactions with epichlorohydrin (e.g., the hydrolysis process in alkaline conditions [7, 8]) are factors with important influence on the real cross-linking density values attained in the gel formation.

The combinatorial reasoning used by Stockmayer is not at all convenient and in 1963 the mathematician I. J. Good and the physical chemist M. Gordon have replaced it with the application of the more powerful *Theory of the Branching*

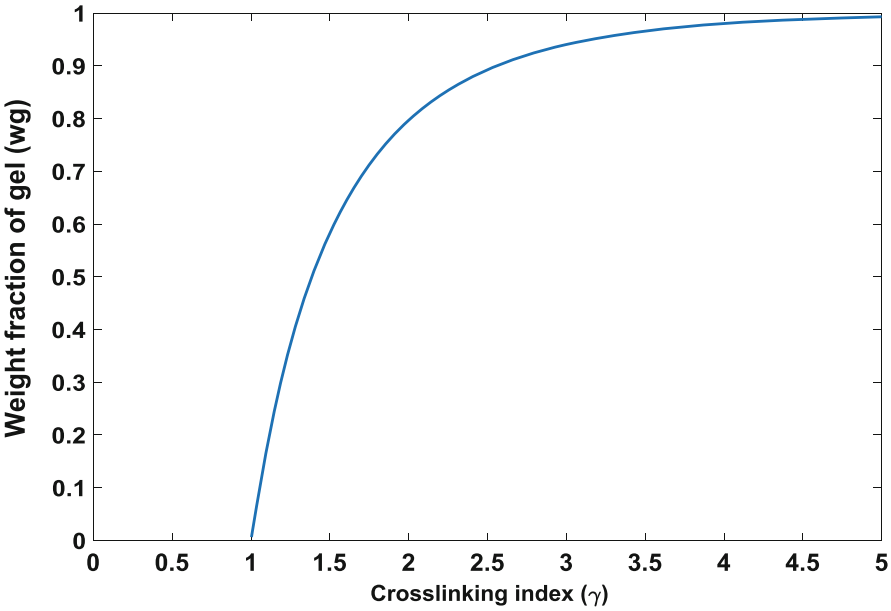

Fig. 9 Weight fraction of gel (w_g) as a function of the cross-linking index (γ) in the random cross-linking of primary molecules with uniform length

Processes (TBP) [37, 38] (with a later impoverished implementation called "recursive approach" by Macosko and Miller [39]). Then, it became possible to tackle chemical systems where different chemical groups and/or substitution effects were present. It then became apparent that some results were not compatible with the analysis by rate equations (see next section).

Another even more important issue is the tackling of intramolecular reactions. Slight disagreements with observed gelation of step-growth polymerizations were long known [27, 28], but the disagreement for chain polymerizations turned out to be very serious [34, 35].

Another issue arises from the stochastic character of real polymerizations leading to fluctuations according to position which diffusion is unable to erase instantaneously. Gelation will not occur for a real network everywhere at the same time even if starting with a perfectly homogeneous mixture. Numerous fundamental studies have used Monte Carlo simulation in a restricted space mesh to gain insight on those phenomena; they have not yet made their way into engineering practice.

5.3 Calculation Methods for Kinetically Controlled Nonrandom Processes

In spite of the appealing simplicity of the FS gelation theory, this approach presents important shortcomings in the description of some cross-linking processes, namely,

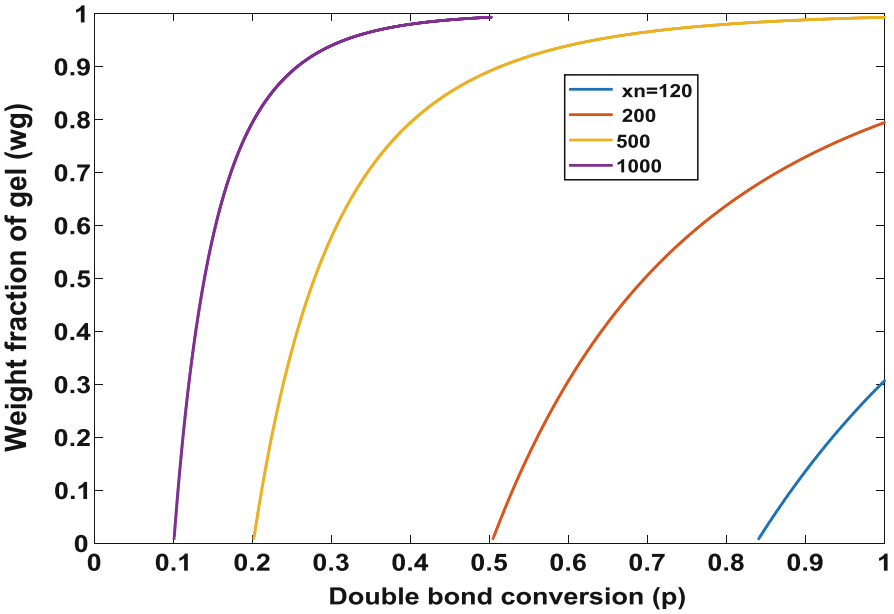

Fig. 10 Weight fraction of gel (w_g) as a function of the double bond conversion (p) in the random cross-linking of vinyl/divinyl monomers. Primary molecules of uniform length but with different values for the number-average chain length ($\bar{x}_n^* = 120$, 200, 500, and 1000) were considered in these simulations. The initial mole fraction of divinyl monomer $y_{DVM} = 0.5\%$ ($y_f \sim 1\%$) is the same in the different systems

when the formation of the primary chains and the network development is simultaneously performed, as in the case of the vinyl/multivinyl copolymerization. Indeed, the free radical copolymerization of multifunctional monomers is a kinetically controlled nonrandom process, and the network properties are critically dependent on the reaction path. It should be stressed that, in a free radical process, polymer molecules present a wide span on birth/death times. Hence, molecules are exposed to very different conditions during the reaction path, and the probability for cross-linking is not homogeneous (e.g., "primary" chains formed at the start and at the end of polymerization have unequal reaction conditions). Moreover, the vinyl groups of the different monomers involved and also the formed pendant double bonds often present distinct reactivities (see Fig. 15a). Cyclization reactions also occur to a great extent after incorporation of a multivinyl monomer (primary cyclization), increasing a lot the complexity of such cross-linking processes. These chemical effects can be magnified due to physical phenomena arising from the reaction of huge molecules with smaller polymer chains. These large molecules (see Fig. 15b) usually bear many pendant double bonds and radical centers, which can become inaccessible to further reaction due to steric hindrance.

Important deviations between predictions and measurements for vinyl/multivinyl radical copolymerizations were observed since the first works on this subject (e.g.,

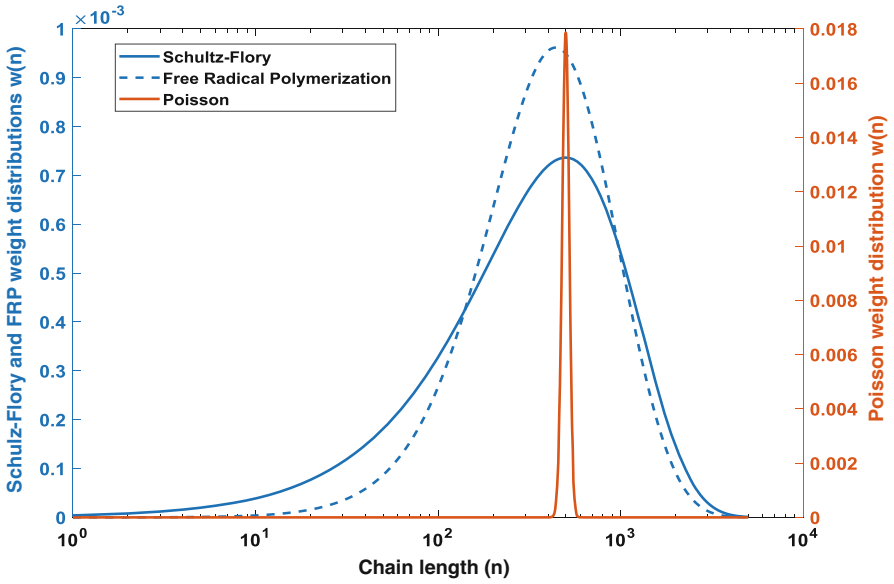

Fig. 11 Different kinds of weight chain length distributions ($w(n)$) considered in the simulations for the random cross-linking of primary chains arbitrarily distributed (see, e.g., Eq. (11)). With all the distributions the value $\bar{x}_n^* = 500$ was considered

much delayed gelation with respect to FS predictions was reported by Walling [34] when studying vinyl/divinyl copolymerization). Limitations of the statistical methods to describe nonlinear free radical polymerization, which is inherently kinetically controlled, stimulated the development of new modeling techniques. The first attempts to tackle branching by transfer to polymer are due to Beasley [40] and Bamford and Tompa [41]. In the latter approach [41], the solution of population balance equations (PBE) for polymer species was obtained through a continuous variable approximation in the Laplace domain. These ideas were at the origin of the nowadays called "method of the moments", allowing the description of kinetically controlled nonlinear polymerization systems when equal reactivity of functional groups holds.

Solution of the conservation laws for polymer species through a continuous variable approximation was considered by Zeman and Amundson [42, 43] along with several approximations to obtain a mathematically tractable problem. It is now deprecated given the use of appropriate numerical methods below described.

Kuchanov and Pis'men introduced important improvements in the kinetic theory of nonlinear polymerization in the early 1970s [44, 45]. Combination of PBE with generating functions and the solution of the resulting partial differential equations through the method of the characteristics allowed avoiding drastic approximation conditions used in precedent approaches. Avoiding the quasi-steady-state assumption for estimating radical concentrations and consideration of multiple active centers in the same molecule are decisive improvements introduced with the

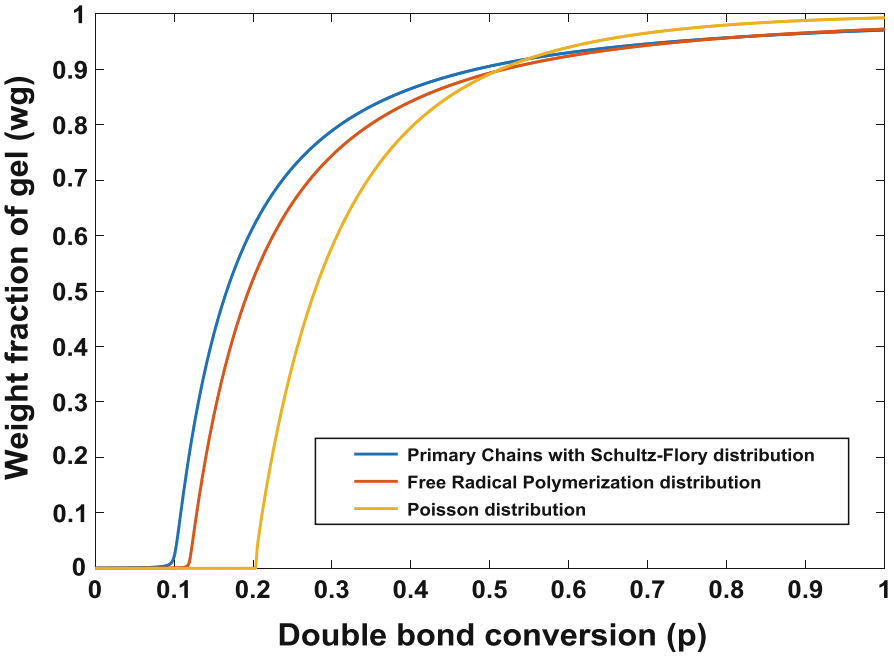

Fig. 12 Weight fraction of gel (w_g) as a function of the double bond conversion (p) in the random cross-linking of vinyl/divinyl monomers. Different kinds of weight chain length distributions for the primary chains ($w(n)$) were considered in these simulations ($\bar{x}_n^* = 500$ for all the distributions). Initial mole fraction of divinyl monomer $y_{DVM} = 0.5\%$ (y_f~1%)

Kuchanov and Pis'men works. Description of the post-gelation period is another important outcome of this kinetic theory.

In late 1980s, Tobita and Hamielec [46] introduced the pseudokinetic rate constant method to describe network formation in free radical polymerization. This method is based upon the use of moment equations, and the post-gelation period is described through the adaptation of Flory's cross-linking theory. The kinetic theory developed by Tobita and Hamielec [46] preserves the history of the generated network structure and allows a heuristic inclusion of primary and secondary cyclization. The simplicity of the numerical calculations involved makes this technique (often known as the Flory/Tobita (FT) model) very appealing for practical applications. The computations involve the instantaneous distribution of primary chains. In the framework of the pseudokinetic rate constant method, that distribution for a free radical process is described [46] by:

$$f_w(n,\theta) = \frac{n\alpha(\theta)}{(1+\alpha(\theta))^{n+1}}\left[\gamma(\theta) + 0.5\alpha(\theta)\beta(\theta)(n-1)\right] \tag{12}$$

With $\alpha(\theta) = \gamma(\theta) + \beta(\theta)$, $\beta(\theta) = k_{tc}R^{\bullet}/(k_pM)$, $\gamma(\theta) = (k_{td}R^{\bullet} + k_{fm}M + k_{fs}S)/(k_pM)$, and θ representing the birth conversion of the chains. In these equations k_p, k_{tc}, k_{td},

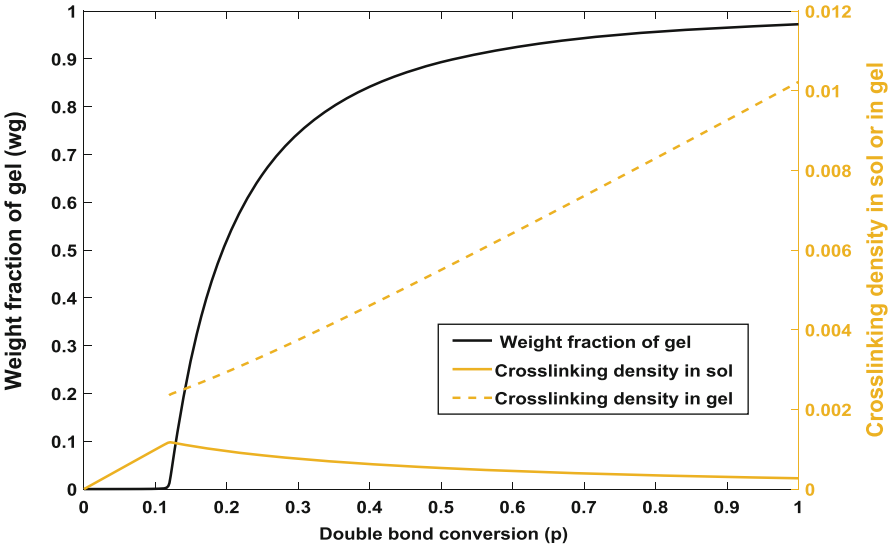

Fig. 13 Weight fraction of gel (w_g), cross-linking density of the sol (ρ'), and cross-linking density of the gel (ρ'') as function of the double bond conversion (p) in the random cross-linking of vinyl/divinyl monomers. The weight chain length distribution for the primary chains ($w(n)$) is correspondent to a polymer resulting from a free radical polymerization with $\bar{x}_n^* = 500$. Initial mole fraction of divinyl monomer $y_{DVM} = 0.5\%$ (y_f~1%)

k_{fm}, and k_{fs} stand for the pseudokinetic rate constants for propagation, termination by combination, termination by disproportionation, chain transfer to monomer, and chain transfer to solvent, respectively. On the other hand, M, $R^{\bullet}$, and S represent the total concentrations for monomer, radicals, and solvent, respectively.

The total cross-linking density at conversion ψ of the chains born at conversion θ in given by:

$$\rho(\theta,\psi) = \rho_i(\theta) + \rho_a(\theta,\psi) \tag{13}$$

The cross-linking densities and weight fraction of sol are calculated through:

$$\rho_i(\theta) = \frac{k_p^{*0}(\theta)[\bar{F}_2(\theta) - \overline{\rho}_a(\theta) - \overline{\rho}_c(\theta)]\theta}{k_p(1-\theta)} \tag{14}$$

$$\frac{\partial \rho_a(\theta,\psi)}{\partial \psi} = \frac{k_p^{*0}(\psi)[F_2(\theta) - \rho_a(\theta,\psi) - \rho_c(\theta,\psi)]}{k_p(1-\psi)} \tag{15}$$

$$w_s(\theta,\psi) = \sum_{n=1}^{\infty} f_w(n,\theta)[1 - \rho(\theta,\psi)(1 - w_s(\theta,\psi))]^n \tag{16}$$

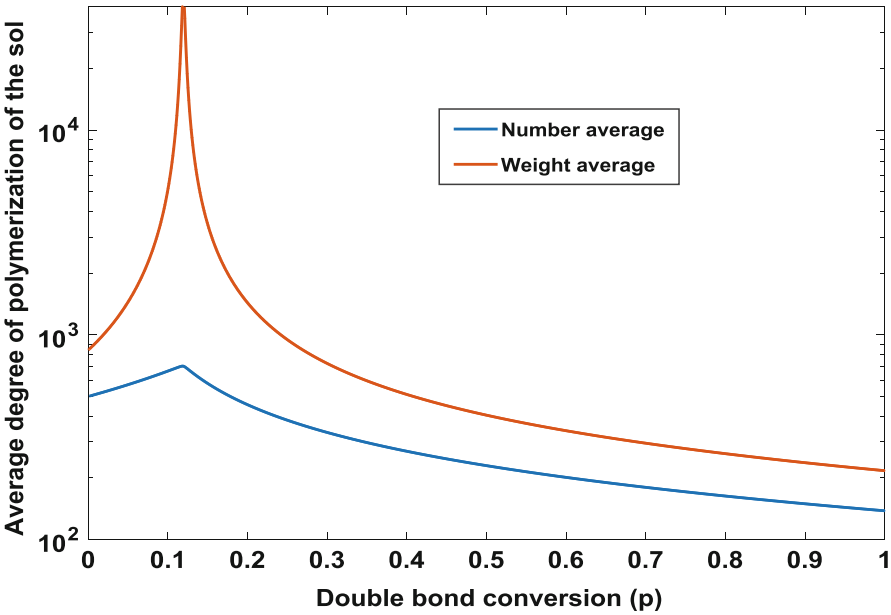

Fig. 14 Number- and weight-average chain lengths of the sol as function of the double bond conversion (p) in the random cross-linking of vinyl/divinyl monomers. The weight chain length distribution for the primary chains ($w(n)$) is correspondent to a polymer resulting from a free radical polymerization with $\bar{x}_n^* = 500$. Initial mole fraction of divinyl monomer $y_{DVM} = 0.5\%$ (y_f~1%)

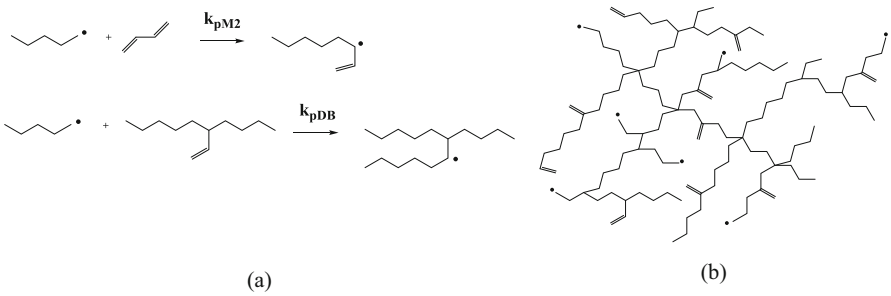

Fig. 15 (**a**) Depiction of divinyl monomer and pendant double propagation during a cross-linking process. (**b**) Large polymer molecule bearing many pendant double bonds and radical centers. Different reactivities of vinyl groups, intramolecular cyclization, and steric hindrance are examples of phenomena hampering the description of vinyl/multivinyl cross-linking systems

Details on the application of these equations and calculation methods with nonlinear free radical polymerization can be found in the original Tobita-Hamielec work [46].

The "numerical fractionation" technique was introduced by Teymour and Campbell in the 1990s [47]. This method splits the polymer population into an arbitrary

number of generations defined by a count of branching events and carries out the calculation of the moments for the polymer PBE in each generation. Transfer rules for transition of species between generations are defined. The average properties of sol and gel, as well as the chain length distribution (CLD) of the sol, can be obtained (note that the calculation of the sol CLD is not possible in the framework of the FT theory). Recently, the numerical fractionation technique was improved in order to take into account the existence in polymer population of multiradical species [48], a flaw in its original formulation. Note that modifications of the method of the moments for nonlinear FRP were also recently published [49].

This technique provides a heuristic approximation of polymer size distribution and its averages, but it is neither consistent nor convergent, in contrast with some well-based approaches, as discussed below.

5.4 Population Balances of Generating Functions

A general kinetic approach to describe different kinds of nonlinear irreversible polymerizations started to be developed in our research group in the 1990s [50]. This method stems from the ideas of Kuchanov and Pis'men [44, 45] and uses multidimensional generating functions to describe polymer populations. Through the use of a numerical approach for the solution of the resulting PBEs, several mathematical approximations inherent to alternative approaches can be avoided, namely, in nonlinear free radical polymerization processes [51]. Distinctive features of this approach comparatively to alternative methods, computation of different polymer molecular architecture parameters (CLD before and after gelation, weight fraction of gel, sequences, average radius of gyration), and its application to different kinds of polymerization systems (condensation, free radical polymerization, coordination polymerization, controlled radical polymerization) can be found elsewhere [50–61]. In a recent paper [62], the performance of four different modeling approaches (kinetic Monte Carlo, statistic/kinetic Flory/Tobita, PBE with generating functions, and PBE with numerical fractionation) was also compared in the framework of the bulk cross-linking copolymerization of vinyl/divinyl monomers.

The next case study highlights the use of population balance equations of generating functions to deal with hydrogels synthesis processes. Indeed, Eqs. (17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, and 29) depict a possible kinetic scheme describing a hydrogel synthesis (e.g., superabsorbent hydrogel) through the free radical copolymerization of an acrylic monomer (e.g., acrylic acid) with a cross-linker such as methylene bisacrylamide (MBAm, functionality $\alpha = 2$) or trimethylolpropane triacrylate (TMPTA, functionality $\alpha = 3$). In these equations, I, R_0, M_1, M_2, S, and Z stand for the initiator, primary radicals, acrylic monomer, cross-linker, solvent, and inhibitor, respectively. Polymer molecules ($P_{n,m}^{x,y}$) are described using a four-dimensional counting of radicals (n), pendant double bonds (m), polymerized acrylic units (x), and polymerized cross-linker units (y). Initiator (e.g., V50) decomposition is described through Eq. (17). Acrylic monomer, cross-

linker, and PDB initiations by primary radicals are depicted in Eqs. (18, 19, and 20). Propagations of acrylic monomer, cross-linker, and PDB with polymer radicals are shown in Eqs. (21, 22, and 23). Equations (24) and (25) represent chain transfer to acrylic monomer and to solvent, respectively. Inhibition is described through Eqs. (26) and (27) and termination by combination and by disproportionation by Eqs. (28) and (29), respectively.

$$I \xrightarrow{k_d} 2fR_0 \tag{17}$$

$$R_0 + M_1 \xrightarrow{k_{i1}} P^{1,0}_{1,0} \tag{18}$$

$$R_0 + M_2 \xrightarrow{k_{i2}} P^{0,1}_{1,\alpha-1} \tag{19}$$

$$R_0 + P^{x,y}_{n,m} \xrightarrow{k_{i3}} P^{x,y}_{n+1,m-1} \tag{20}$$

$$P^{x,y}_{n,m} + M_1 \xrightarrow{k_{p1}} P^{x+1,y}_{n,m} \tag{21}$$

$$P^{x,y}_{n,m} + M_2 \xrightarrow{k_{p2}} P^{x,y+1}_{n,m+\alpha-1} \tag{22}$$

$$P^{x,y}_{n,m} + P^{x\prime,y\prime}_{n\prime,m\prime} \xrightarrow{k_{p3}} P^{x+x\prime,y+y\prime}_{n+n\prime,m+m\prime-1} \tag{23}$$

$$P^{x,y}_{n,m} + M_1 \xrightarrow{k_{fm}} P^{x,y}_{n-1,m} + R_0 \tag{24}$$

$$P^{x,y}_{n,m} + S \xrightarrow{k_s} P^{x,y}_{n-1,m} + R_0 \tag{25}$$

$$R_0 + Z \xrightarrow{k_z} Inactive\ Products \tag{26}$$

$$P^{x,y}_{n,m} + Z \xrightarrow{k_z} P^{x,y}_{n-1,m} \tag{27}$$

$$P^{x,y}_{n,m} + P^{x\prime,y\prime}_{n\prime,m\prime} \xrightarrow{k_{tc}} P^{x+x\prime,y+y\prime}_{n+n\prime-2,m+m\prime} \tag{28}$$

$$P^{x,y}_{n,m} + P^{x\prime,y\prime}_{n\prime,m\prime} \xrightarrow{k_{td}} P^{x,y}_{n-1,m} + P^{x\prime,y\prime}_{n\prime-1,m\prime} \tag{29}$$

The general kinetic approach developed in our research group [50–61] uses generating functions (GF) of distributions instead of the related real domain functions. The GF of the distribution here used, $P^{x,y}_{n,m}$, is described by:

$$G(s_R, s_B, s_X, s_Y, t) = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\sum_{x=0}^{\infty}\sum_{y=0}^{\infty} s_R^n s_B^m s_X^x s_Y^y P^{x,y}_{n,m}(t) \tag{30}$$

The population balance equation (PBE) for the kinetic scheme described by Eqs. (17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, and 29) in the Laplace domain is:

$$\begin{aligned}
\frac{\partial G}{\partial t} &= k_{i1}[R_0][M_1]s_X s_R + k_{i2}[R_0][M_2]s_Y s_R s_B^{\alpha-1} + k_{i3}[R_0]\left(\frac{s_R}{s_B} - 1\right)\frac{\partial G}{\partial \log s_B} \\
&+ k_{p1}[M_1](s_X - 1)\frac{\partial G}{\partial \log s_R} + k_{p2}[M_2]\left(s_Y s_B^{\alpha-1} - 1\right)\frac{\partial G}{\partial \log s_R} \\
&+ k_{p3}\left[\frac{1}{s_B}\frac{\partial G}{\partial \log s_B}\frac{\partial G}{\partial \log s_R} - [R]\frac{\partial G}{\partial \log s_B} - [B]\frac{\partial G}{\partial \log s_R}\right] \\
&+ k_{fm}[M_1]\left(\frac{1}{s_R} - 1\right)\frac{\partial G}{\partial \log s_R} + k_s[S]\left(\frac{1}{s_R} - 1\right)\frac{\partial G}{\partial \log s_R} \\
&+ k_Z[Z]\left(\frac{1}{s_R} - 1\right)\frac{\partial G}{\partial \log s_R} + k_{tc}\left[\frac{1}{s_R^2}\left(\frac{\partial G}{\partial \log s_R}\right)^2 - [R]\frac{\partial G}{\partial \log s_R}\right] \\
&+ k_{td}[R]\left(\frac{1}{s_R} - 1\right)\frac{\partial G}{\partial \log s_R}
\end{aligned} \tag{31}$$

Starting the polymerization from monomers, initiator, and solvent (and/or other non-polymeric species), the initial condition for Eq. (31) is:

$$G_{|t=0} = G_0 = 0 \tag{32}$$

Numerical inversion of the generating function can be carried out in a stable and accurate fashion through contour integration in complex plane.

This general kinetic approach is also able to deal with more complex kinetic schemes and models describing hydrogel formation, namely, intramolecular chain transfer to polymer, backbiting, or propagations with tertiary radicals [20]. These additional kinetic mechanisms should only be important at high polymerization temperature, very low cross-linker content, and high polymer concentration. Polymerization recipes for the formation of hydrogels from two vinyl monomers (e.g., acrylic acid and acrylamide) and a cross-linker can also be handled in the framework of this modeling approach [22].

Figure 16 illustrates the use of such a modeling approach with hydrogel synthesis. In Fig. 16a, it is presented the experimentally measured dynamics of gel formation in different polymerization runs concerning AA-based hydrogel production (inverse suspension processes). In Fig. 16b, it is compared the predicted and experimentally measured final weight fraction of gel for different polymerization runs concerning hydrogel synthesis. The effect of the reactivity of pendant double bonds on the predictions is here explored. In spite of the fair agreement between experimental and theoretical predictions, improvement of this modeling approach has been considered in the last few years, namely, taking into account cyclization effects [24, 63].

The prediction of the average molecular weight between cross-links ($\bar{M}_c$), an important parameter for the characterization of polymer networks, is also possible in the framework of the present modeling approach. Indeed, segments between cross-linking points can be treated as sequences of the main monomer present in the hydrogel. Methods for the calculation of sequence lengths in linear and nonlinear polymerization have been previously developed by our research group [56, 59] (see also [64] for a comprehensive overview on polymerization processes modeling, including the calculation of sequence length distributions).

5.5 Calculations with RDRP Nonlinear Polymerization

Due to the particular kinetic mechanisms involved, calculations with nonlinear RDRP systems have some numerical issues owing to their huge span of reaction times [60] and critical improvements on the above-described method based on

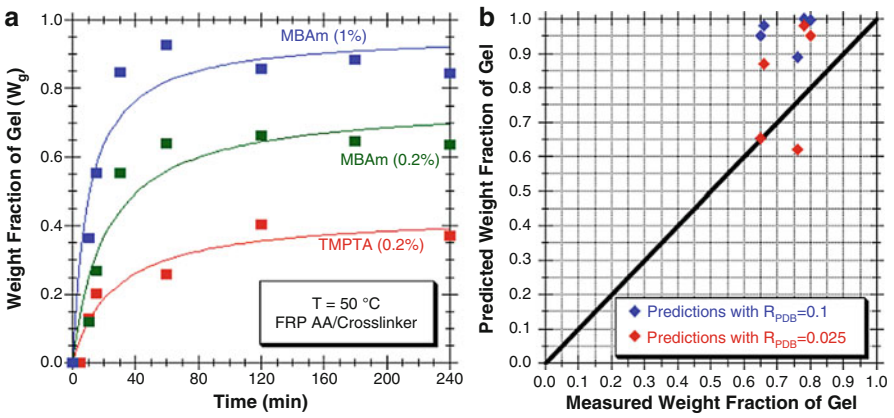

Fig. 16 (**a**) Experimentally measured dynamics of gel formation in AA-based hydrogels production. FRP polymerizations at T = 50 °C with different cross-linkers (MBAm and TMPTA) at different initial contents were considered. (**b**) Comparison of the measured and predicted final weight fraction of gel in different polymerization runs concerning the AA-based hydrogel formation. Predictions with two values for the reactivity of the pendant double bonds are presented

generating functions are being performed at the time this work is being completed. The increase of the efficiency of the numerical methods used with the solution of two-point boundary value problems involved in the calculations after gelation or in inversion of the CLD could overcome most of those issues (indeed, analysis of NMRP and ATRP nonlinear polymerization before gelation was previously performed in the framework of this approach [61, 65, 66]).

Other important tools can be found in the literature to deal with such kinds of problems, mostly based on adaptations of the method of the moments (see, e.g., [67, 68] and references therein). These calculation tools were recently explored for the development of RAFT-surface-grafted molecularly imprinted particles [25], and some useful simulations are illustrated in Fig. 17, namely, the control of the gelation process through the initial amount of RAFT agent (manipulation of the primary chains) and the CLD prediction with linear RAFT polymerization. Note that this kind of analysis is important for polymer networks and hydrogels tailoring, for design of telechelic structures, and also for RAFT-grafting processes, namely, those involving cellulose, as explored in Sect. 6.

6 Tailoring of Branched/Network Polymers and Hydrogels with RDRP Mechanisms

Reversible deactivation radical polymerization (RDRP), formerly named living radical polymerization (LRP) or controlled radical polymerization (CRP), offers the possibility to synthesize polymers with predetermined degree of polymerization and narrow molecular size distribution, tackling a major drawback of classical free radical polymerization (FRP) [69, 70]. Additionally, with RDRP, it is possible to carry out the synthesis of advanced polymer structures with tailored composition (e.g., block, statistical, gradient, or graft copolymers), architecture (e.g., linear, star, comb, network, or branched polymers), and functionality (e.g., telechelic polymers, macromonomers, multi-armed polymers, or multifunctional polymers). RDRP mechanism also provides the efficient production of molecular composites such as hybrids with inorganic and biopolymers, functional colloids, or modified surfaces [69, 70].

In this section are presented results for case studies concerning the tailoring of branched polymers, networks, and hydrogels through RAFT polymerization. The RAFT synthesis of hydrogel particles in continuous flow micro-reactor, the generation of molecularly imprinted particles with surface RAFT-grafted polymer brushes, and the RAFT-grafting of synthetic polymers in cellulose are considered as application examples. Note that, among the main RDRP mechanisms, RAFT polymerization presents some advantages due to the broad range of operation conditions and different classes of monomers that can be used [71]. This technique was also before considered in the cross-linking of different kinds of multi-olefinic monomers to generate polymer networks [72]. However, many similar applications are possible with other RDRP mechanisms, namely, ATRP and NMRP.

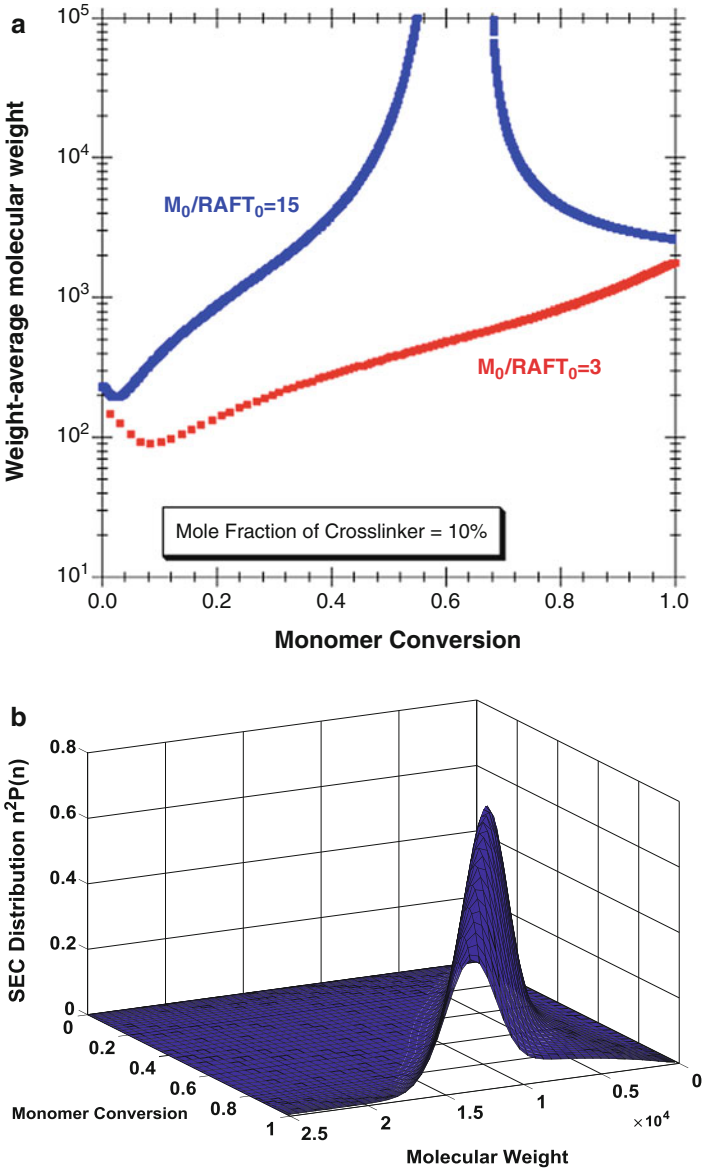

Fig. 17 (**a**) Predicted dynamics of HEMA/EGDMA hydrogel formation for processes with different initial contents of RAFT agent, showing the possibility to avoid gelation even at a high cross-linker content (see [25] for information concerning the relevant kinetic parameters). (**b**) Predicted dynamics of the CLD with the RAFT polymerization of MAA (see [68] for a general discussion concerning the influence of the kinetic mechanisms on the CLD of RAFT linear polymers, namely, the possibility for the development of bimodal distributions)

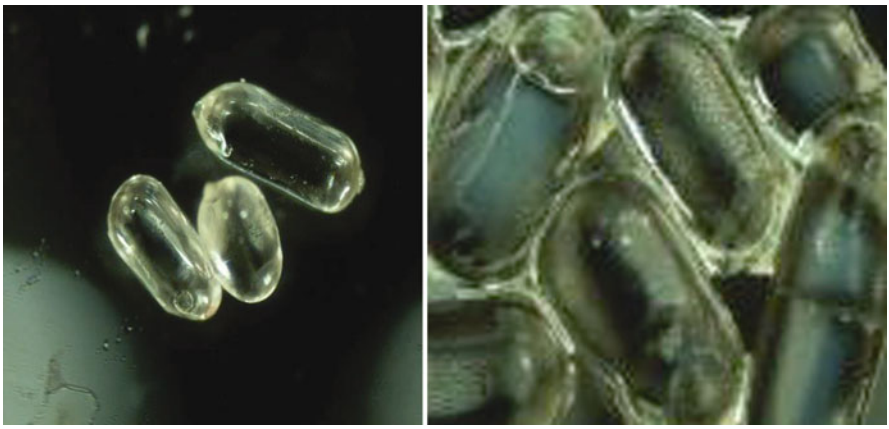

Fig. 18 Images of AA hydrogel particles synthesized in a continuous flow process. RAFT polymerization was considered to control the kinetics of the reaction and the gelation mechanism

6.1 Continuous Flow Synthesis of Hydrogel Particles with RAFT Polymerization

As pointed above, RDRP mechanisms offer the possibility for production of advanced polymer structures with tailored composition. These techniques can also be explored to try the synthesis of more homogeneous polymer networks (e.g., controlling the molecular weight between cross-links), as recently reported with RAFT polymerization [17]. Additionally, the control of the kinetics of polymerization and, eventually, the suppression of gelation (if the primary chains are sufficiently shortened) can also be conceived with these processes, as also recently described [73]. Here, it is illustrated the use of RAFT polymerization in our research to aid in the production of hydrogel particles in a continuous flow micro-reactor [74]. Indeed, it was shown that the inclusion of a RAFT agent in the developed process was important to optimize the experimental conditions in the continuous microfluidic approach. The control of the reaction kinetics, namely, the fast and exothermic reaction involving AA, was thus attained. Moreover, with RAFT polymerization, the gelation time could also be manipulated in this microfluidic approach and molecularly imprinted hydrogel particles were successfully synthesized [74]. In Fig. 18 are presented images of hydrogel particles obtained with such approach. The molecularly imprinted hydrogel particles obtained with this methodology (e.g., using 3-aminopyridine as template) also showed outstanding performance in a selective uptake process guided by the swelling of the networks [74]. These findings illustrate the use of RAFT to help the tailoring of smart hydrogels. Morphological features introduced in the hydrogels by using a microfluidic device will be further discussed in Sect. 7 of this work.

6.2 Network Polymer Particles with Surface RAFT-Grafted Functional Brushes

In the last few years, molecular architectures such as network polymer particles forming a core with surface-grafted functional polymer brushes have been explored to create materials with multiple features. A molecularly imprinted core, able to perform molecular recognition of a target molecule, bearing functional brushes grafted at the particle surface, is an example of such class of materials. The functional polymer brushes are included to provide stimulation features to the final materials and/or to modify their surface properties (e.g., hydrophilic/hydrophobic balance). A possible synthesis route of these kinds of functional materials includes two steps (see [75–80] and references therein): (i) production of network polymer particles using RAFT precipitation polymerization. A high cross-linker content is classically considered in this step if MIPs are intended. (ii) Grafting of functional polymer brushes on the core particles surface through a "grafting from" mechanism. With this goal, the RAFT groups present in the surface of the particles produced at the first stage are reactivated in this second polymerization step.

These ideas were recently explored in our research group to develop MIP particles for 5-FU (used in cancer treatment) with surface-grafted polymer brushes, aiming pH and temperature sensitivity [81]. Imprinted polymer networks based on the functional monomers MAA and HEMA, with EGDMA as cross-linker, were synthesized through RAFT precipitation polymerization in ACN. Functional brushes were afterward grafted on the surface of these MIP particles using alternatively MAA, HEMA, or NIPA as monomers. Improved sensitivity of the particles with PMAA polymer brushes to the pH of the surroundings was also proven, and a boost on drug release at 20 °C as compared to 40 °C was observed for particles with PNIPA grafted brushes [81].

Currently, we are exploring this approach to generate engineered materials for the selective uptake and release of polyphenols. These molecules are present in many vegetable extracts, and, due to their antioxidant activity, many important applications in pharmaceutics and biomedicine are being considered. In Fig. 19 are presented results concerning the batch adsorption of the polyphenol polydatin in MIP particles bearing different kinds of surface-grafted polymer brushes, namely, PMAA, PDMAEMA, and PNIPA polymers. These materials were synthesized considering the above-described RAFT process with 4VP as functional monomer for molecular imprinting and EGDMA as cross-linker. The RAFT-mediated "grafting from" mechanism was afterward considered for brushes formation at particles surface. Results presented in Fig. 19 illustrate the possibility for stimulation of the molecular recognition process through the effect of the grafted polymers (the effect of the temperature is here considered within this purpose). However, other phenomena should be considered in this analysis (e.g., the effect of pH and temperature on drugs solubility) in order to have a clear picture of these stimulated uptake/release mechanisms. Ongoing studies with these classes of materials should help to differentiate the intervenient phenomena.

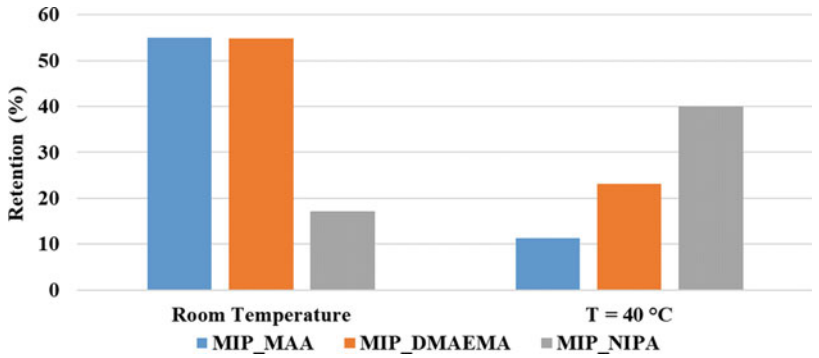

Fig. 19 Batch adsorption of polydatin in MIP particles bearing different kinds of surface-grafted polymer brushes, namely, PMAA, PDMAEMA, and PNIPA chains. Synthesis of these materials was performed through RAFT cross-linking precipitation of 4VP/EGDMA, followed by a RAFT-mediated "grafting from" process

Interestingly, the RAFT "grafting from" processes here briefly discussed have a close connection with the grafting of synthetic polymers on cellulose, as next discussed.

6.3 RAFT-Mediated Grafting of Synthetic Polymers on Cellulose

Grafting is a technique commonly used to modify the surface of many polymers. Grafting of cellulose is usually considered to improve the properties of the native natural polymer, such as water absorption capability, elasticity, hydrophilicity or hydrophobicity, adsorption features, sensitivity to external parameters (e.g., pH and temperature), antibacterial effect, etc. [82, 83]. Three main routes for grafting of cellulose are generally considered [82, 83]: (i) the "grafting from" approach consisting on the polymerization of a vinyl monomer in the presence of cellulose, whose backbone is also properly initiated for polymerization. Different methods can be used to initiate the polymerization in cellulose backbone including, e.g., the use of chemical initiators able to create radicals on cellulose or by the pre-attaching of a RAFT agent on cellulose followed by RAFT polymerization of the vinyl monomer. (ii) The "grafting to" or the "grafting through" approaches consisting on the reaction of a polymer containing reactive end groups with others present in cellulose backbone or the polymerization of a vinyl derivative of cellulose with a vinyl monomer. (iii) The "high-energy irradiation" approach where monomer and cellulose are mutually or separately irradiated.

A major challenge to be faced with cellulose grafting is due to the low solubility of this polymer in common solvents, which can hinder the reaction mechanisms involved in the grafting process. In practice, grafting of cellulose can be performed in homogeneous and heterogeneous conditions. With the homogeneous grafting, native cellulose is dissolved in a proper solvent (e.g., LiCl/DMAc), or a soluble cellulose derivative is used (e.g., hydroxyethyl cellulose or cellulose acetate). In

heterogeneous grafting, native cellulose and common solvents are directly used, and the process takes place only in the accessible regions of the polymer backbone. As a consequence of these effects, a higher grafting efficiency is ascribed to the homogeneous processes [82, 83].

In view of the ecologic/economic importance of cellulose valorization and in result of the challenges briefly described above, there is an intensive research effort on the improvement of the cellulose grafting methods and exploitation of the resulting materials (see [82–88] and references therein).

Here, we present results of our research concerning the grafting of different kinds of synthetic polymers on cellulose, using the "grafting from" approach mediated by RAFT polymerization in heterogeneous conditions. The accomplishment of this task with some of the conditions considered is also shown.

Three different kinds of cellulose were used in the studies performed, namely, cellulose fibers, cellulose microcrystalline, and cellulose filter paper (see Sect. 2). TBTGA and CPA were selected as RAFT agents containing carboxylic acid functional groups. Immobilization of RAFT agents on the cellulose substrates was performed through the esterification reaction of the acidic groups with the hydroxyl groups of cellulose, following the lines of thought reported in the literature (see [83–87] and references therein). DCC and DMAP were used as coupling agent and catalyst, respectively, for the esterification reaction. Note that, RAFT agents can be attached to cellulose via the R-group approach or the Z-group approach [83–87]. Here, the R-group approach was considered, resulting in the formation of a cellulose-supported macrochain transfer agent. Different esterification conditions were tried, namely, by combining the three types of cellulose and the two RAFT agents in three different solvents, specifically, DCM, DMF, and chloroform, following diverse alternatives also reported in the literature [83–87]. All the esterification reactions were performed at 40 °C during 3 days. Afterward, the cellulosic materials were submitted to intensive cleaning procedures [83–87] in order to remove the RAFT molecules without chemical bound to the substrates. Final purified products were dried in a vacuum oven at 40 °C.

The heterogeneous grafting of synthetic polymers on the cellulose was performed using the previously prepared cellulosic materials with attached RAFT agents and DMF as solvent for polymerization reaction. Different monomers were used in the grafting process (e.g., MAA and styrene), AIBN was selected as thermal initiator, and the same RAFT agent attached to the cellulose was considered in the polymer grafting step. All the reactions were performed at 70 °C during 24 h under stirring. The concentration of esterified cellulose in DMF was typically $P = 3$ g/L. Initial concentrations for monomer, initiator, and RAFT agent used in the grafting processes were typically $M_0 = 0.9$, $I_0 = 6 \times 10^{-3}$, and $RAFT_0 = 7.5 \times 10^{-3}$ mol/L, respectively. At the end of the reactions, the solid products and the liquid phase were separated using centrifugation. The presence of soluble polymer in the liquid phase was visually confirmed through the precipitation of a few drops in a large excess of a suitable non-solvent (such as diethyl ether or methanol). The collected liquid phase was stored at low temperature to be later analyzed, namely, using SEC. Solid materials were extensively cleaned considering several extraction processes, and

the final grafted cellulose was obtained through the drying of the products in a vacuum oven at 40 °C.

In Figs. 20 and 21 are presented some results concerning the FTIR analysis of different materials involved in the RAFT-mediated grafting of synthetic polymers on cellulose. For illustration purposes, the TBTGA-mediated grafting of PMAA on microcrystalline cellulose and the CPA-mediated grafting of PS, also on microcrystalline cellulose, are here presented. The comparison of the spectra correspondent to the synthetic polymer (PMAA or PS), the native cellulose, the cellulose substrate with esterified RAFT agent, and the final products of the grafting processes, allows to conclude that the intended cellulose-grafted materials were successfully obtained. Indeed, new FTIR assignments can be clearly identified in the grafted materials in the region 1550 to 1750 cm^{-1}. These new assignments, negligible in the native cellulose or in the correspondent substrate with attached RAFT agent, are compatible with vibrational features associated with the synthetic polymers, namely, the carbonyl C=O stretch (generically in the range 1670 to 1820 cm^{-1}) for PMAA and the aromatic C=C bending (generically in the range 1500 to 1700 cm^{-1}) for PS. In fact, the new assignments observed in the region 1550 to 1750 cm^{-1} for the cellulose-grafted materials can be closely related with vibrational peaks also appearing the spectra collected for the PMAA and PS polymers (see Figs. 20 and 21).

In Fig. 22 are presented results concerning the SEC analysis of the liquid phase correspondent to different grafting processes. These analysis were performed using DMF as eluent in order to have simultaneous solubility of different polymers, namely, PMAA and PS. Note that the same solvent was used in graft polymerization processes in order to keep the formed free polymer soluble during the reaction. These analyses provide an additional evidence for the formation of free polymer (first confirmed through the precipitation in a non-solvent, as above described) and allow to characterize the synthetic polymer population produced. With the two systems selected to illustrate these issues (PMAA and PS RAFT-grafting on cellulose), important differences can be identified with the SEC analysis of the liquid phase. Indeed, for PMAA grafting a unimodal polymer population is observed (with maximum RI intensity at around 8×10^4 molecular weight), while for PS grafting a bimodal distribution is measured (with maximum RI intensities at 4×10^3 and 8×10^4 molecular weight). Moreover, with MAA RAFT polymerization, the monomer peak is not observable in the final liquid phase, while a peak with substantial intensity is measured with S RAFT polymerization at the same conditions. The rates of consumption of the two monomers in these systems are therefore quite different. These issues highlight the important dissimilitudes possibly arising when variable RAFT-grafting systems are considered. In this context, modeling tools for RAFT polymerization, as described in Sect. 5, can provide interesting insights concerning the impact of kinetics, the operation conditions, and some mechanistic effects (e.g., the intermediated radical termination process and bimodality [68]) on the structural features of the formed polymer.

Our current research work in this field aims at the use of cellulose-grafted materials, such as those described above, for the generation of sorbents and controlled release vehicles [88], namely, molecularly imprinted polymers based on

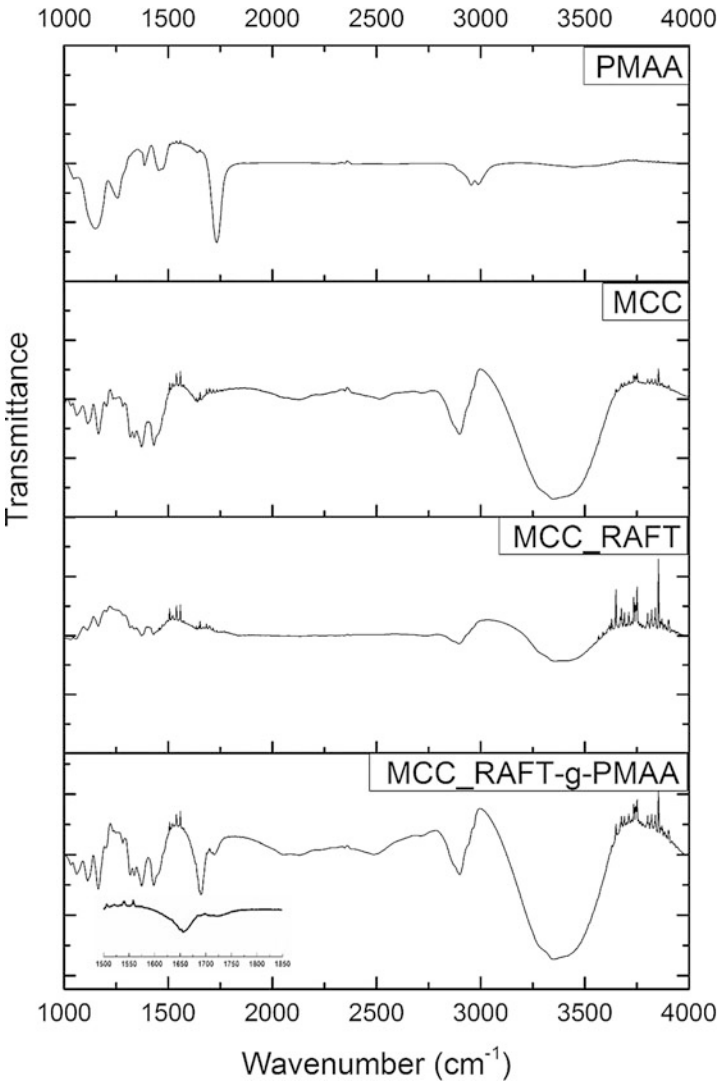

Fig. 20 FTIR spectra of different products involved in the RAFT-mediated grafting of PMAA on microcrystalline cellulose. Spectra collected for the PMAA polymer, microcrystalline cellulose (MCC), product of the esterification of microcrystalline cellulose with TBTGA (MCC_RAFT), and final product for the RAFT-grafting of PMAA on cellulose (MCC_RAFT-g-PMAA) are compared

natural macromolecules. Indeed, through the grafting of functional polymers in cellulose, improved interactions with selected template molecules can be conceived for an efficient molecular imprinting process. The ulterior generation of a polymer network, using a RAFT cross-linking mechanism with a divinyl monomer, e.g., leads (hopefully) to a MIP with molecular recognition capabilities for the template molecule, as generically depicted in Fig. 23.

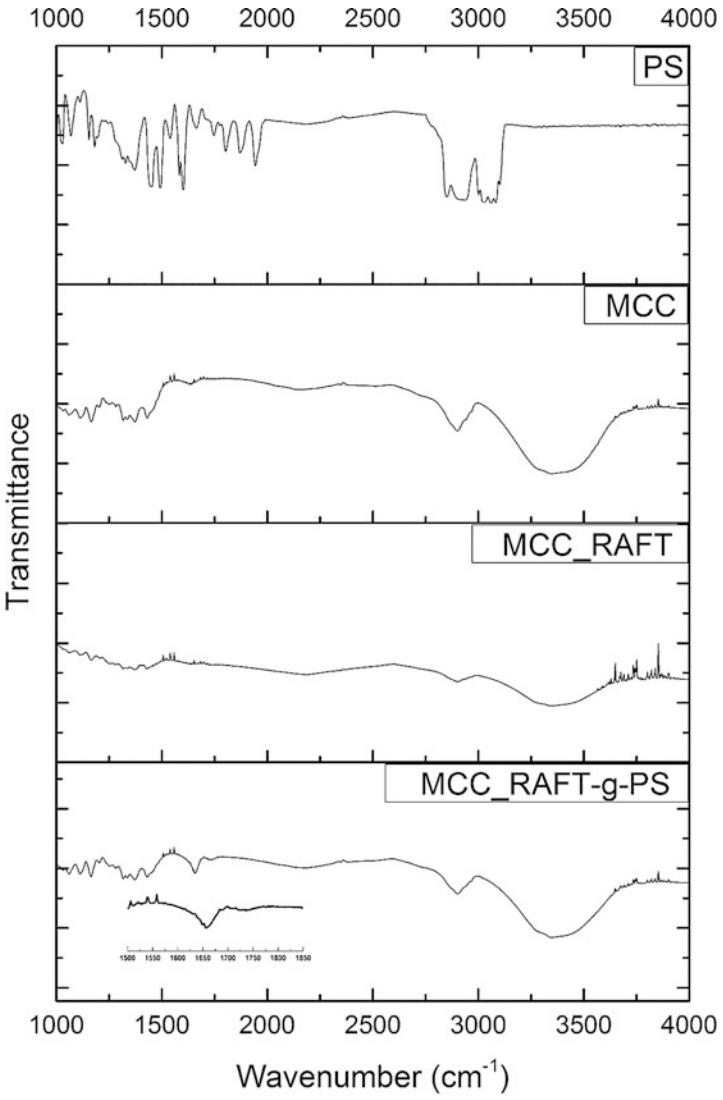

Fig. 21 FTIR spectra of different products involved in the RAFT-mediated grafting of PS on microcrystalline cellulose. Spectra collected for the PS polymer, microcrystalline cellulose (MCC), product of the esterification of microcrystalline cellulose with CPA (MCC_RAFT), and final product for the RAFT-grafting of PS on cellulose (MCC_RAFT-g-PS) are compared

However, some key aspects of the different synthesis steps are being worked out in order to achieve this final goal. Improvement of the RAFT-mediated grafting on cellulose, aiming higher efficiency and upper control on the molecular size of the synthetic functional chains, is an important issue in this context. The homogeneous RAFT-grafting process is a different approach being considered in our research. The

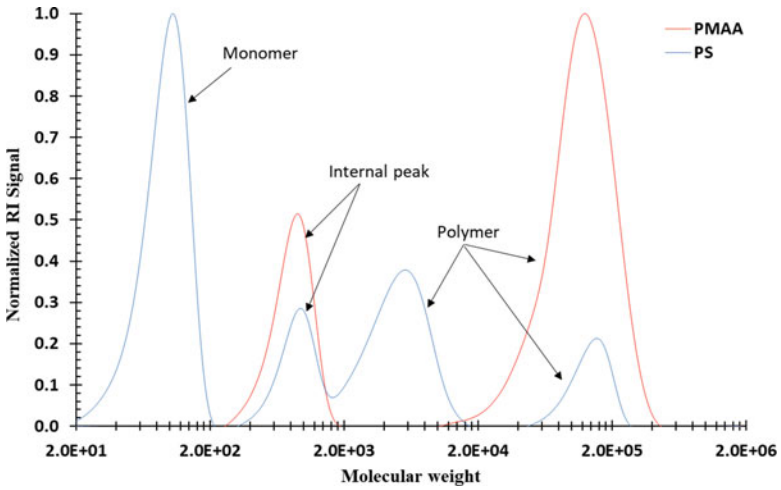

Fig. 22 SEC analysis for the final liquid-phase correspondent to the RAFT-mediated grafting of PMAA and PS on the microcrystalline cellulose. The analyses were performed using DMF as eluent at 0.4 mL/min and T = 35 °C. Polystyrene standards were used to calibrate the relation molecular weight versus elution volume

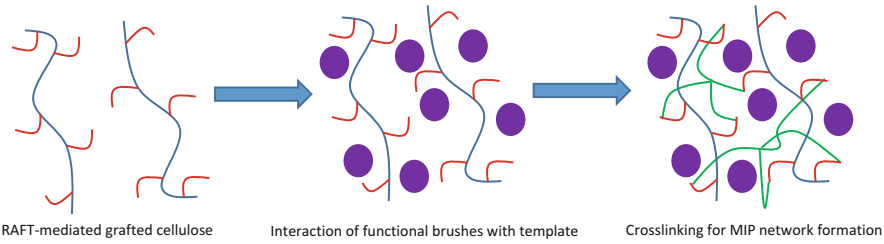

Fig. 23 Depiction of a possible molecular imprinting process based on the use of RAFT-mediated grafted cellulose and a RAFT cross-linking mechanism

favorable conditions for the formation of a polymer network in the final imprinted materials are also being investigated. A RAFT polymerization in the presence of a multifunctional vinyl monomer is being used as starting point.

7 Changing of Materials Morphology and Surface Modification

In many applications, end-use performance of polymer network-based materials and hydrogels strongly depends on mass transfer phenomena. On other hand, these transport mechanisms rely on the morphology, porosity, and surface properties, e.g., of the materials. Swelling ability and sorption/desorption capacity are examples

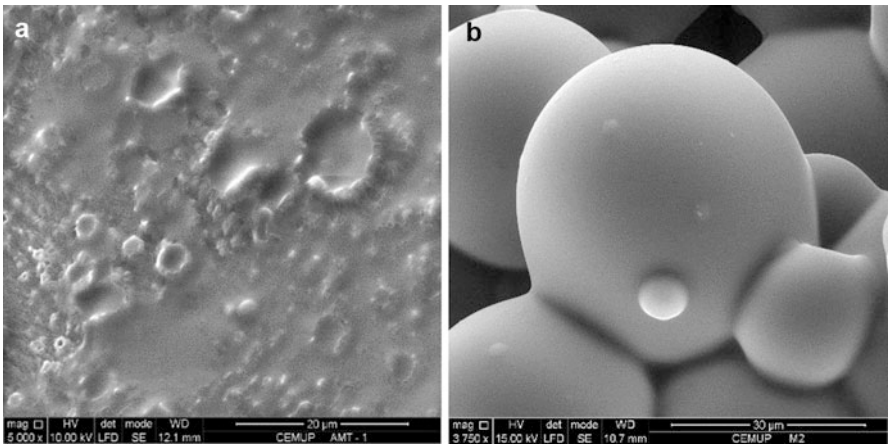

Fig. 24 SEM micrographs of AA/MBAm hydrogels produced through solution free radical polymerization process (**a**) and inverse suspension (**b**)

of important properties of polymer network materials and hydrogels that are changed by their morphology and physicochemical features.

The reaction process used in a polymerization system is an important engineering tool that can be explored to aid in the tailoring of the produced materials. Reactor type (e.g., batch, continuous, etc.) and the alternative use of solution, bulk, suspension, inverse suspension, and emulsion polymerization are examples of process variations with important impact on the morphology and final properties of polymers. Different approaches can also be used to change physicochemical characteristics of the materials, namely, their surface properties. A reaction process making use of functional groups present in the native polymers is a possible route to achieve this goal. In this section we illustrate the use of different reaction processes to change the morphology and the performance of hydrogels and SAPs. The surface modification of the materials, also impacting their applications, is highlighted with the change of the physicochemical properties of cellulose through a cross-linking process.

7.1 Polymerization Processes to Tailor Products Morphology

In Figs. 24, 25, and 26 are presented examples of different morphologies for hydrogels and polymer network products addressed in our research activities. The SEM micrograph for an AA/MBAm hydrogel produced through solution polymerization is presented in Fig. 24a. A continuous material is generally obtained in such conditions. Milling and sieving of the polymer networks is usually performed in order to enhance the mass transport properties and to control particle size. At the expense of a more complex chemistry, possibly introducing undesirable chemicals, hydrogel particles can be obtained using an inverse suspension process (see also [21, 22]). Particles in the range of few micrometers can thus be produced (see Fig. 24b),

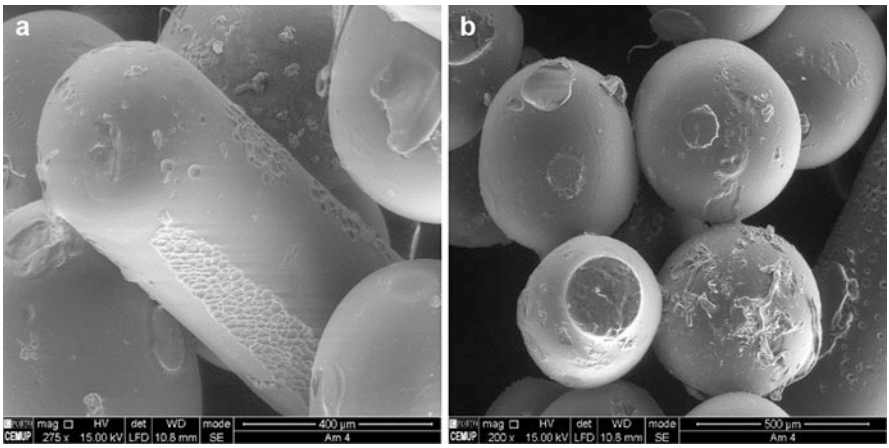

Fig. 25 SEM micrographs of AA hydrogel particles produced in a continuous flow micro-reactor. (**a**) Axial view of the cylindrical hydrogel particles. (**b**) Top view of the hydrogel particles

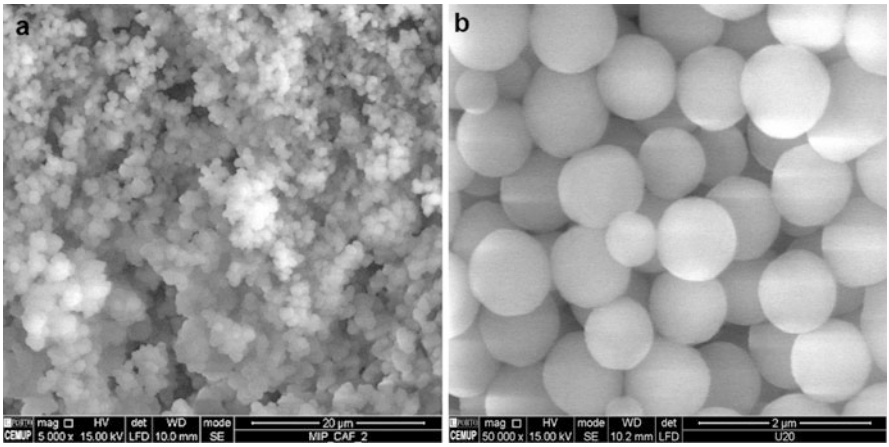

Fig. 26 (**a**) SEM micrograph of caffeine molecularly imprinted particles produced through inverse suspension. (**b**) SEM micrograph of polydatin molecularly imprinted particles produced through precipitation polymerization

and the process conditions (continuous to disperse mass ratios, surfactant concentration, etc.) can be considered in order to manipulate the particle size. Fast swelling of such materials is usually observed, as previously shown in Sect. 3 of this work.

Operation in microfluidic reactors [74] is a possible route to produce hydrogel particles, avoiding the use of some chemicals inherent to inverse suspension (intensive cleaning of the materials is usually needed with this approach) and providing additional possibilities to control the size and the shape of the products. Examples of such kinds of morphologies are presented in Fig. 25. The huge swelling capacity of

these hydrogel particles triggered by a molecular recognition mechanism put into evidence the distinct features that can be obtained with this class of materials [74].

Molecular recognition capabilities and imprinting efficiency of molecularly imprinted polymers (see also Sect. 8 of this work) are strongly dependent on their synthesis process and final product morphology (see also [81, 89] and references therein). In Fig. 26 are presented SEM images correspondent to two different products obtained in this context by using differentiated polymerization approaches. Figure 26a is correspondent to a caffeine MIP produced through inverse suspension [89]. High performance of such particles, namely, as chromatographic packings, was observed [89]. Note that a kind of surface molecular imprinting process, guided by the inverse suspension conditions, should be an important contribution for the molecular recognition capabilities of these particles. SEM images for a polydatin MIP produced through precipitation polymerization are presented in Fig. 26b. Individual particles of very small size (in the microscale or nanoscale if desired) can be produced with this technique, which enhances the mass transfer mechanisms. Moreover, the surface grafting of polymer brushes in these particles can be readily performed (e.g., using a RAFT-mediated process). Introduction of stimuli-responsive features and surface modification are possible advantages of such approach [81].

7.2 Cross-Linking of Cellulose to Modify Physicochemical Properties

Recently, many studies addressed the synthetic modification of cellulose to improve physicochemical properties, namely, the dispersion capacity, hydrophobicity, and biocompatibility (see [90] and references therein). Chemical cross-linking of cellulose is pointed out as a facile route to improve the adsorption capabilities and hydration of the native polymer in consequence of the change of the surface area and related chemical properties [90]. Considering these possibilities, and in view of the development of cellulose-based adsorbents for polyphenols, we illustrate here simple studies concerning the cross-linking of cellulose with epichlorohydrin and the assessment of the resulting materials. The sorption capabilities of the generated cellulose-based materials in comparison with synthetic MIPs specifically designed to target polyphenols are also briefly discussed.

Cross-linking of cellulose with epichlorohydrin was performed following the procedures reported in the literature [90]. In a typical experiment, 2 g of cellulose fibers (medium, cotton linters) was heated under stirring in 16 mL of a 2 M NaOH aqueous solution at 80 °C during 3 h. Argon was used to provide an inert atmosphere in the vessel. Afterward, 1 mL of epichlorohydrin was dropwise added to the mixture, which was kept at 80 °C under stirring during 12 h to promote the cross-linking process. Finally, the products were neutralized with an HCl solution (1 M), and several cleaning steps were performed to isolate the cross-linked cellulose, as described in the literature [90].

A simple evidence for the modification of the physicochemical properties of the cellulose was obtained by submitting the native and cross-linked materials to the alkali/urea method for dissolution in aqueous systems, with cycles of cooling and thawing [7–9], as described in Sect. 3. In Fig. 27 are presented images of the resulting mixtures, showing the total dissolution of the native cellulose and the total insolubility of the modified polymer.

In Fig. 28 are presented results for the SPE retention of polydatin in the native cellulose fibers, in the modified fibers, and in an inverse suspension synthesized polydatin-molecularly imprinted polymer based on 4VP/EGDMA. A 0.02 mM polydatin solution in ACN/MeOH was used to carry out these studies. Measurements here performed put into evidence the superior performance of the specifically designed MIP for the polyphenol uptake comparatively to the cellulose-based

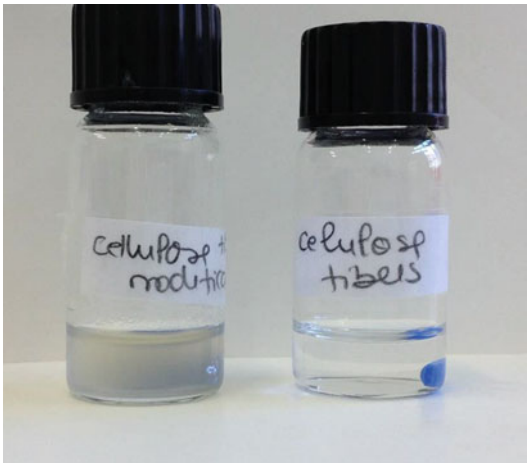

Fig. 27 Images for the mixtures resulting from the dissolution procedures applied to the epichlorohydrin-modified cellulose (left) and the unmodified cellulose (right). Following the alkali/urea method for dissolution of cellulose in aqueous systems with cycles of cooling and thawing, total dissolution was observed for the native cellulose, but the modified polymer remained totally insoluble

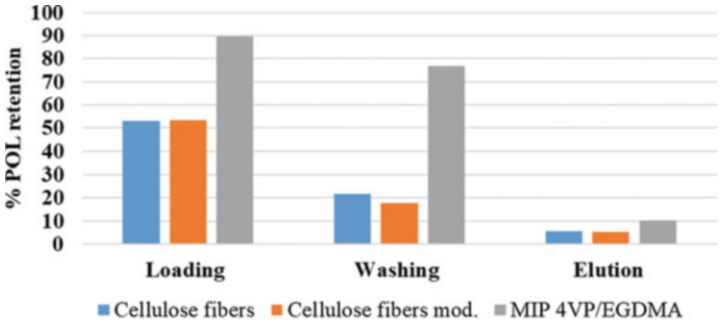

Fig. 28 Results for the SPE retention of polydatin in different sorbents, namely, the native cellulose fibers, the modified fibers, and in an inverse suspension synthesized polydatin-molecularly imprinted polymer based on 4VP/EGDMA. These testing conditions concern the loading of a 0.02 mM polydatin solution in ACN/MeOH (10/1), washing with the same eluent and elution with pure MeOH

sorbents. However, a relatively high retention is observed with both cellulose adsorbents (c.a. 50% retention). These results indicate that the benefits of cellulose modification on the polydatin retention capability are negligible, but some advantages on the use of the cross-linked cellulose can be conceived. Indeed, when the use of these cellulose polymers in continuous adsorption processes is sought, namely, as packing materials, the hardening and insolubility achieved with the cross-linking process are useful (e.g., avoiding the backpressure problem observed with some packing materials). The application of the modified cellulose as packing materials for polyphenol retention is currently being addressed in our research group.

Note that only a simple modification of cellulose for polyphenols adsorption was here discussed but more complex approaches can be considered within this purpose. Indeed, through the grafting of functional brushes on cellulose (e.g., using the RAFT-mediated processes discussed in Sect. 6), more specific interactions between the polyphenols and the adsorbent can in principle be created (e.g., including acidic or amine functional groups in the brushes). Additionally, the formation of a MIP network based on cellulose can also be thought, as depicted in Fig. 23, Sect. 6. In a different perspective, the analysis of the adsorption of polyphenols in cellulose is an important issue nowadays to understand the bioavailability of these antioxidant molecules, their metabolism, and pharmacokinetics [91].

8 Molecularly Imprinted and Non-imprinted Vehicles for Uptake and Controlled Release

Many polymer networks are designed to perform as vehicles for uptake and controlled release of target molecules. Here we illustrate the use of two very different systems within this general purpose. Molecularly imprinted polymers (MIPs), classically synthesized with a very large content of cross-linker to assure geometrical stability of the binding sites, and hydrogels, lightly cross-linked materials designed to allow swelling/shrinking induced mechanisms, are considered to highlight these differences.

8.1 Molecular Recognition with Molecularly Imprinted Polymers

Molecularly imprinted polymers (MIPs) play the role of artificial antibodies and are based on the creation in a polymer network of tailor-made cavities having high specificity and affinity with respect to a specific target molecule [92–94]. Nowadays, an intense research activity on MIPs is observed due to the important applications of these materials in many kinds of separations, solid-phase extraction, sensors, catalysis, and many biological processes (e.g., controlled drug delivery) [94, 95].

Classically, MIPs are produced with a very large content of a cross-linker plus a functional monomer, able to create specific interactions with the target molecule. After network formation, the binding sites formed should preserve the geometrical stability in order to uptake and release the target molecule in several cycles. Thus,

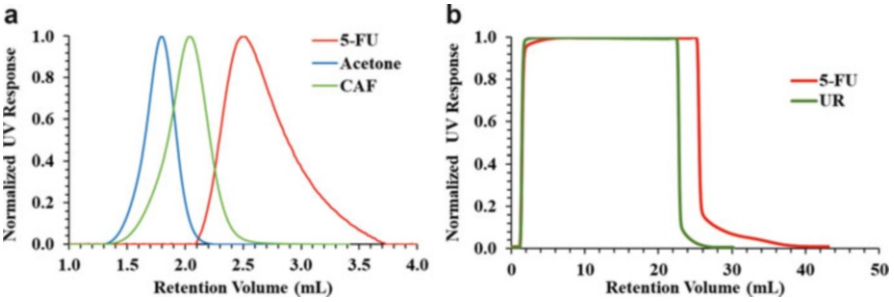

Fig. 29 Application of 5-FU MIP particles based on MAA/EGDMA, obtained by inverse suspension, as column packing for continuous adsorption/desorption processes: (**a**) chromatographic elution of 5-FU, caffeine, and acetone using ACN as eluent. (**b**) Uptake and release of 5-FU and UR in a frontal analysis process. A 50/4.6 length/diameter mm/mm column was used in these experiments

swelling is (in principle) almost unwanted with MIPs. However, performance of MIPs is affected by several factors concerning their preparation (chemical composition, polymerization process, morphology, etc.) and also their application (e.g., hydrophilic/hydrophobic interactions with the solvents considered). Therefore, there is plenty of room to develop new MIPs and improve their performance. MIPs for aminopyridines with swelling-induced molecular recognition [74], molecular imprinting of caffeine, and 5-FU in different kinds of particles (e.g., with inverse suspension or precipitation polymerization) [89] and RAFT-surface grafting of functional brushes in MIP particles to improve stimulation [81] are some recent activities of our research group in this area. Development of MIPs to address the uptake/release of polyphenols is another ongoing task, as before described in Sect. 7 of this work.

In Fig. 29 is illustrated a potential use of MIP particles in molecular recognition processes. 5-FU MIP particles based on MAA/EGDMA were synthesized by an inverse suspension process and packed in a small GPC column for assessment in continuous processes applications. Clear molecular recognition capabilities of the produced materials for 5-FU are evidenced in the chromatographic elution test (acetone and caffeine were considered as alternative molecules) and also in the frontal analysis experiment where the structural analogue uracil was also used. Note that ACN was used as eluent in these experiments and very different results can be obtained if other eluent is considered, such as water, due, e.g., to the role of the hydrophobic interactions [89]. Controlled swelling and morphological features of these particles are also important issues to avoid backpressure problems with continuous operation.

8.2 Swelling-Induced Controlled Release: A Case Study with Cellulose Hydrogels

Hydrogels are appealing controlled release vehicles due to their ability to control the transport of molecules in the network matrix. Additionally, as a consequence of their

high swelling capacity, biocompatibility, biodegradability, and biological functions, hydrogels based on natural polysaccharides, like cellulose, find many interesting applications in biomedicine, pharmacy, cosmetics, or food industry [5–9]. However, in order to design materials for accurate controlled release processes, the specific mechanisms intervenient in the transport of the target molecules inside the hydrogels should be known. Thus, important mathematical tools were developed in this research field in order to understand and develop tailored controlled release vehicles based on hydrogels [96–102].

For non-swellable devices, in the form of a thin polymer film, where the one-dimensional release of a solute from a slab applies, the following solution of the second Fick's law describes the amount $M(t)$ released along at time t:

$$\frac{M(t)}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\left[-\frac{D(2n+1)^2\pi^2}{L^2}t\right] \tag{33}$$

M_∞ in Eq. 33 is the amount of solute released when time approaches infinity and D the diffusion coefficient of the solute in the polymer matrix. A slab of thickness L, initially at uniform constant concentration of solute C_0 and which surfaces are kept along the time at constant concentration C_S, is here considered as model diffusion system [96, 101]. Solutions for analogue problems with cylinders or spheres can be obtained [96, 101]. Note that the solution presented in Eq. (33), as well as the equivalent solutions for cylinders and spheres (see [96, 101] for details on the solutions for these geometries), is independent of C_0 (which defines the initial condition) and C_S (which sets the boundary conditions at the slab surfaces).

In order to simplify the interpretation of experimental data obtained for the drug release in different devices, the empirical equation below was introduced by Ritger and Peppas [96]:

$$\frac{M(t)}{M_\infty} = kt^n \tag{34}$$

The above relation was shown to hold for the initial 60% of the release curve and to be valid for non-swellable vehicles with different geometries. The use of this equation was also extended to swelling-controlled release systems, namely, those prepared by incorporation of a drug in a hydrophilic glassy polymer, as long as a moderate equilibrium swelling ratio is observed (not higher than 1.33) [97].

The picture becomes much more complex with swellable-controlled release devices because the penetrant component (generally water) as soon as it gets into the polymer network also modifies its rate of drug release. Coupling of diffusion with macromolecular relaxation is generally observed and the transport of the drug outward the hydrogels is affected by the magnitude of these two phenomena. Modeling of such processes belongs to the general class of problems known as moving boundary problems or Stefan-Neumann problems (see [97–99] and Chap. 13 in Ref. [101]) and only numerical solutions are usually possible (see also [102] for a comprehensive view of hydrogels modeling). However, a heuristic model

developed by Peppas and collaborators [98] can fit the experimental data and thus allows the estimation of the contribution of the diffusion and relaxation mechanisms for anomalous drug release. It should also be stressed that phase equilibria and convective transport play an important role on drug uptake and release mechanisms in hydrogels, namely, at the boundary layer between the liquid phase and the insoluble polymer phase. Mass balance equations for the two phases should be solved in these circumstances, as depicted below for a hydrogel slab immersed in a liquid:

Hydrogel phase:

$$\frac{\partial C_A^H}{\partial t} = D_A \frac{\partial^2 C_A^H}{\partial x^2} \tag{35}$$

With initial and boundary conditions:

$$t = 0, -L/2 \le x \le L/2, C_A^H = C_{A0}^H$$

$$t > 0, x = \pm L/2, -D_A \left.\frac{\partial C_A^H}{\partial x}\right|_{x=\pm L/2} = k_c\left(C_A^{L*} - C_A^L\right) \tag{36}$$

Liquid phase:

$$\frac{dC_A^L}{dt} = k_c\left(C_A^{L*} - C_A^L\right) a_v \frac{V_H}{V_L}$$

$$t = 0, C_A^L = C_{A0}^L \tag{37}$$

In these equations, C_A^H and C_A^L represent the concentration of the drug in the hydrogel and liquid phase, respectively, L is the thickness of the slab, k_c the convective mass transfer coefficient between the two phases, and a_v is the surface area per unit of volume in the hydrogel. V_H and V_L represent the volumes of hydrogel and liquid in the system, and it is considered that the partition of the drug between the two phases is expressed by the coefficient $K = \frac{C_A^H\big|_{x=\pm L/2}}{C_A^{L*}}$. Thus, C_A^{L*} represents the concentration of the drug in the liquid phase that is in equilibrium with the surfaces of the hydrogel slab.

In Figs. 30 and 31 we present the analysis of experimental data for the uptake and release of the polyphenol polydatin in cellulose-based hydrogels (their synthesis with epichlorohydrin was presented in Sect. 3). Note that the understanding of the positive and negative biomedical interactions of polyphenols with cellulose [91] is being addressed in the scientific community because cellulose-based materials are potential vehicles for their controlled release [9].

The fraction of mass uptake during the impregnation of two different cellulose-based hydrogels with polydatin is presented in Fig. 30. Initially dried hydrogels were swelled in 5% ethanol aqueous solution containing polydatin at the concentration of 2 mM. Ethanol was used in order to provide the total solubility of polydatin in the

liquid phase. Uptake history data for the first stage were fitted to the power law $M(t)/M_\infty = kt^n$. Diffusion exponents close to $n = 0.56$ were obtained for both hydrogels, thus suggesting an anomalous (non-Fickian) transport mechanisms [9, 96–98]. Coupling of diffusion and relaxation phenomena are therefore intervenient in these hydrogel loading processes.

Loaded hydrogels were thereafter dried at 40 °C and submitted to a release process for polydatin in a 5% ethanol aqueous solution. Concentration of polydatin in the liquid phase was measured for different time instants using UV absorption. Figure 31 shows the analysis of experimental data up to 60% release fraction. A diffusion exponent close to $n = 1$ was estimated with HCEL-8, indicating a Case II transport drug release mechanism [9, 96–98] and very close to a zero-order device under these conditions (constant release rate). The diffusion exponent calculated for HCEL-5 was n~0.88; it is also compatible with an anomalous transport mechanism, coupling diffusion and relaxation, but with prevalence of the latter, as further discussed in the next section where the release of polydatin from hydrogels impregnated at supercritical conditions is analyzed.

9 Supercritical Fluid Technology Applications with Polymer Networks and Hydrogels

9.1 Overview

One of the largest potential applications of supercritical fluid technology is the area of polymer synthesis and polymer processing (see [103], Chap. 5, concerning the polymer-supercritical fluid calculations). Indeed, it is well known that supercritical fluids have properties between those of a gas and a liquid, allowing, e.g., to compromise between high diffusion rates and high solubility in many complex mixtures. Based on these and many other advantages (e.g.," green technology," low toxicity in food, pharmaceutical, biomedical applications, etc.), supercritical fluid technology has been used in many different areas, namely, the impregnation of polymers [104, 105], microencapsulation [106], hydrogels tailoring for different applications [107–110], and diverse ranges of polymer synthesis [103, 111–113] including also polymer networks and hydrogels (see [17] and references therein).

In any supercritical fluid technology application, knowledge on the thermodynamic parameters impacting the phase behavior of the mixtures, namely, their solubility levels, is of utmost importance to understand and design the desired extraction, impregnation, separation, or reaction processes. In this context, equations of state (EOS) are especially useful to perform pressure-volume-temperature (PVT) calculations for the pure components and multicomponent mixtures. Peng-Robinson cubic EOS Eq. (38) is often used within this purpose for small molecules:

$$P = \frac{RT}{v-b} - \frac{a(T)}{v(v+b)+b(v-b)} \tag{38}$$

Above, v represents the molar volume of the fluid and a and b model parameters. Combining rules should be used to define these parameters when mixtures are used [103]. However, when huge polymer molecules are involved, these kinds of EOS are no longer valid, and alternative models must be used. The Sanchez-Lacombe EOS is very popular for polymer-supercritical calculations, being represented by:

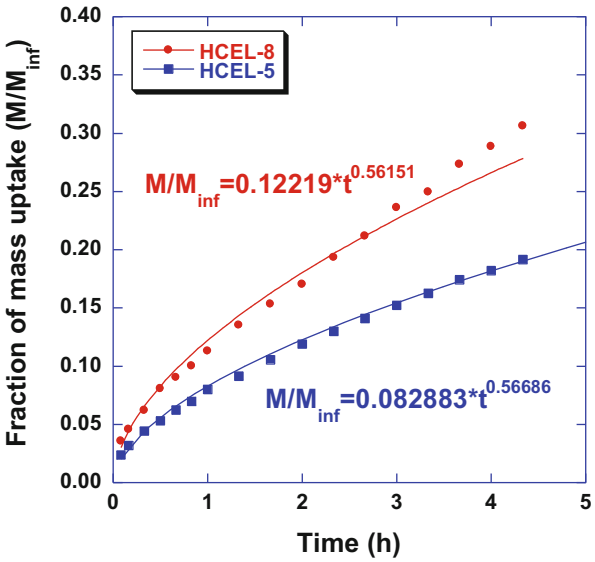

Fig. 30 Initial stage for the fraction of mass uptake, $M(t)/M_\infty$, during the swelling of two initially dried cellulose-based hydrogels in a 5% ethanol aqueous solution containing polydatin at a concentration of 2 mM. Dried hydrogels in the form of single cylinder pieces with typical diameter × thickness = 10 × 3 mm × mm were used. The equilibrium ("infinite") time was 6 days

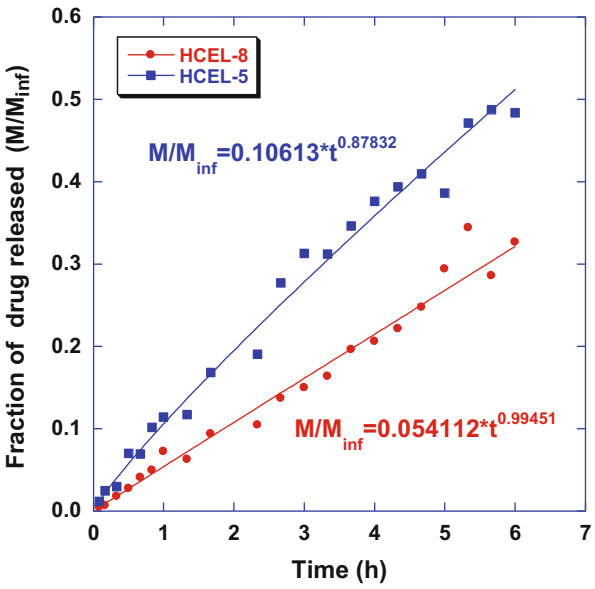

Fig. 31 Initial stage for the fraction of drug (polydatin) release, $M(t)/M_\infty$, from two initially dried cellulose-based hydrogels when poured into a 5% ethanol aqueous solution. The equilibrium ("infinite") release time was 6 days

$$\tilde{\rho}^2 + \tilde{P} + \tilde{T}\left[\ln(1-\tilde{\rho}) - \left(1 - \frac{1}{r}\right)\tilde{\rho}\right] = 0 \tag{39}$$

where $\tilde{P}$,$\tilde{T}$, and $\tilde{\rho} = 1/\tilde{v}$ represent the reduced pressure, temperature, and density, respectively. Definition of model parameters (r and other quantities) as well as combining rules for mixtures can be found elsewhere (see [103] and references therein).

9.2 A Case Study with the Impregnation of Polyphenols in Cellulose-Based Hydrogels

These tools are being used in our research to develop process conditions for different kinds of polymer synthesis and manipulation, namely, networks and hydrogels (e.g., molecular imprinting), cellulose-synthetic hybrids (RAFT-grafting, interpenetrating polymer networks), and materials impregnation for drug delivery. The upload of polydatin in cellulose-based hydrogels using supercritical CO_2 will be here considered to illustrate these kinds of applications.

Figure 32 shows an image of a cellulose hydrogel piece after impregnation with polydatin in supercritical CO_2 at T = 40 °C and P = 170 bar during 1 h. A 5% ethanol aqueous solution containing polydatin at the concentration of 2 mM was also included in the supercritical loading process. The speedup of the impregnation process with sc-CO_2 is one of the advantages introduced due to the higher diffusivity of the molecules in the network matrix, namely, the relatively high size polyphenol template used. Indeed, 1 hour was here used and around 6 days in the swelling process described in Sect. 8.

After impregnation with $ScCO_2$, hydrogels were dried at 40 °C in vacuum oven and submitted to a release process for polydatin in a 5% ethanol aqueous solution, as

Fig. 32 Image of a cellulose hydrogel piece after impregnation with polydatin in supercritical CO_2 at T = 40 °C and P = 170 bar during 1 h. A 5% ethanol aqueous solution containing polydatin at the concentration of 2 mM was also included in the supercritical loading process

before. Results for the dynamics of drug release are presented in Fig. 33, and, in spite of some scattering in the experimental data, steady state seems to be approached at around 60 h of release time.

Analysis of the period up to the first 60% drug release is performed in Fig. 34 where the fitting of the experimental data to the heuristic models $M(t)/M_\infty = kt^n$ and $M(t)/M_\infty = k_1 t^m + k_2 t^{2m}$ is also included. The latter model was developed to quantify

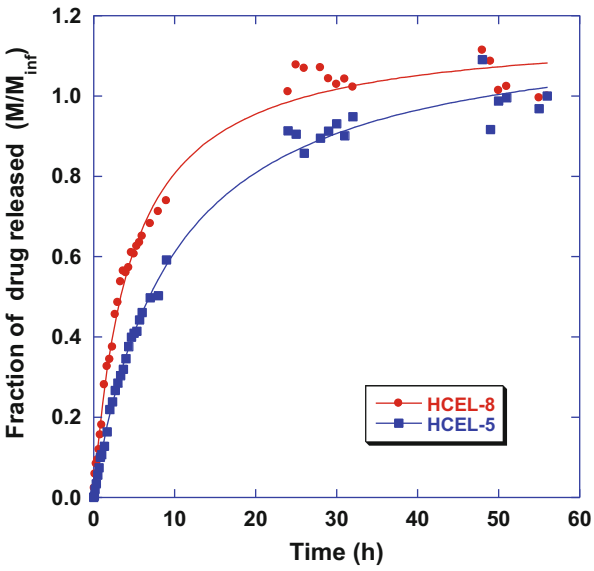

Fig. 33 Fraction of drug (polydatin) release, $M(t)/M_\infty$, from two initially dried cellulose-based hydrogels after pouring into a 5% ethanol aqueous solution. Impregnation of the polydatin in the hydrogels was previously performed in supercritical CO_2 at T = 40 °C and P = 170 bar during 1 h

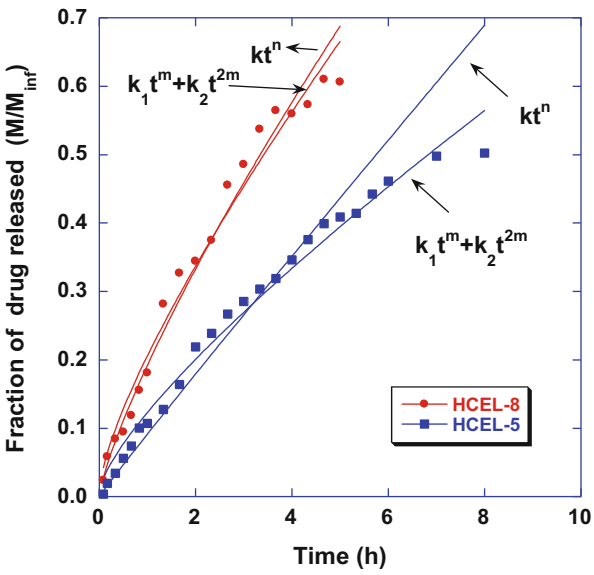

Fig. 34 Fraction of drug (polydatin) release, $M(t)/M_\infty$, from two initially dried cellulose-based hydrogels after pouring into a 5% ethanol aqueous solution. The period up to 60% drug release is here analyzed. Impregnation of the polydatin in the hydrogels was previously performed in supercritical CO_2 at T = 40 °C and P = 170 bar during 1 h

the relative contribution of the coupled diffusion and relaxation mechanisms, knowing the equation exponent (m) through the aspect ratio of the release device [98].

Considering the dimensions of the dried hydrogel pieces, the value $m = 0.43$ was used in our analysis [98]. With the base model, the diffusion exponents calculated for HCEL-8 and HCEL-5 are n~0.79 and n~0.97, respectively, putting into evidence again the anomalous transport mechanism involved. Discrimination of the diffusion and relaxation mechanisms can be estimated through the calculation of the parameters k_1 and k_2 in the second model. The following values were obtained: $k_1 = 0.078$ $h^{-0.43}$ and $k_2 = 0.128$ $h^{-0.86}$ with HCEL-8 and $k_1 = 0.048$ $h^{-0.43}$ and $k_2 = 0.075$ $h^{-0.86}$ with HCEL-5. Using these values, the Fickian release fraction [98] estimated for two cellulose-based hydrogels was obtained, and the results are presented in Fig. 35. After around 30 min release time, the polydatin liberation process starts to be clearly dominated by the relaxation of the polymer network for both hydrogels.

Results just presented show the usefulness of some simple tools to develop cellulose-based hydrogels (eventually including synthetic grafted chains) with tunable relaxation properties for drug release.

10 Conclusions

Polymer networks and hydrogels are "products-by-process" materials, and therefore their structure and final properties are defined during the synthesis process. Calculation tools with different degrees of complexity (and applicability), with the purpose of aiding the design of processes for the production of such materials, were presented

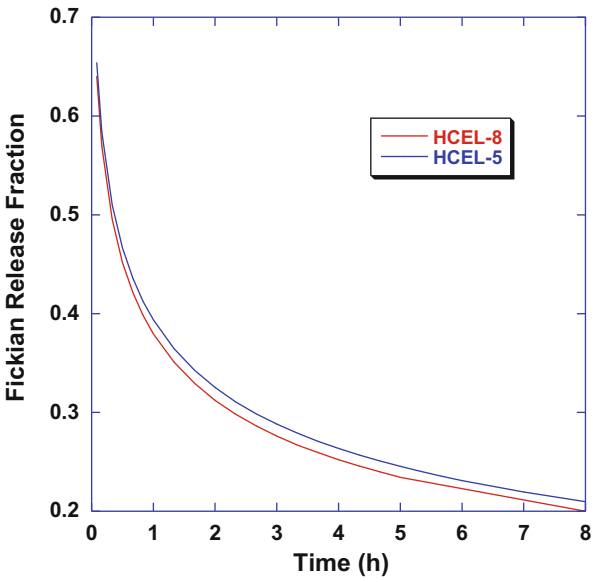

Fig. 35 Fickian release fraction estimated for two cellulose-based hydrogels considering the polydatin liberation in a 5% ethanol aqueous solution

and discussed. Some experimental tools to get information concerning the formation process and structure of polymer networks and hydrogels were also discussed (e.g., light scattering, swelling analysis, FTIR, SEC, etc.). Having in mind the importance of the generation of materials incorporating cellulose, the synthesis of cellulose-based hydrogels, the modification of the physicochemical properties of cellulose through cross-linking, and the RAFT-mediated grafting of synthetic polymers in cellulose were also here described. It was shown that the morphology and the molecular architecture of polymer networks and hydrogels can be changed using tools such as the reactor type (e.g., operation in batch or continuous flow micro-reactor), the polymerization process (e.g., considering bulk, inverse suspension, or precipitation polymerization), and the polymerization mechanism, namely, FRP or RDRP (RAFT polymerization was mainly addressed here). Different case studies were presented to illustrate the practical use of the produced materials in diverse applications, namely, MIP hydrogel particles to target aminopyridines, MIPs for polyphenols, caffeine or 5-fluorouracil, and also cellulose cross-linked with epichlorohydrin for polyphenol retention. The use of cellulose-based hydrogels as controlled release vehicles for polyphenols was also here addressed, and results for the liberation of these kinds of molecules were presented, evidencing the non-Fickian mechanisms involved in such transport systems. The possibility for the use of supercritical CO_2 in the hydrogel impregnation process was also shown.

11 Future Developments

Results here presented show that many different tools can be used to address the tailoring of polymer networks and hydrogels. However, the most promising techniques are based on the use of RDRP mechanisms due to the improved precision achieved in the molecular architecture of such materials. Moreover, with RDRP mechanisms, namely, the RAFT-mediated process, it is possible to improve the control of the grafting of synthetic polymers on the cellulose backbone. Many different engineered products with complex structures can therefore be designed, namely, molecularly imprinted polymers incorporating natural polymers such as cellulose.

Contents

Abstract

Deep eutectic solvents (DESs) are promising green chemicals that can function as solvents, reagents, and catalysts in many applications because of their biodegradability, ready availability, and low toxicity. Here, a DES of choline chloride–urea was used as a non-hydrolytic pretreatment medium to obtain cellulose nanofibril

(CNF) hydrogels from recycled cellulose pulps (boxboard, milk containerboard, and fluting) and virgin birch cellulose pulp using a mechanical Masuko grinder. The mechanical disintegration of DES-pretreated cellulose fibers resulted in highly viscous, gel-like cellulose nanofibril hydrogels with shear thinning behavior. According to transmission electron microscope (TEM) imaging, the nanofibrils had widths from 2 to 80 nm, possessed the initial cellulose I crystalline structure, and had a crystallinity index of 53–56%. The nanofibril hydrogels obtained were further used to produce low-cost, ultralight, highly porous, hydrophobic, and reusable superabsorbing aerogels that were used as efficient sponges to absorb oil and chemicals. The nanofibril sponges prepared by the consequent hydrophobic modification (silylation) of CNF hydrogels and freeze-drying had ultralow density (0.003 g/cm^3) and high porosity (up to 99.8%). The sponges exhibited excellent oil/water absorption selectivity and ultrahigh oil (marine diesel oil, kerosene, gasoline, motor oil, castor oil, or linseed oil) and organic solvent (dimethyl sulfoxide, chloroform, n-hexane, toluene, acetone, or ethanol) absorption capacity. The nanofibril aerogels showed particular selectivity for marine diesel oil absorption from an oil–water mixture and possessed ultrahigh absorption capacities of up to 143 g/g, which were much higher than the commercial absorbent materials (i.e., polypropylenes) (9–27 g/g) used as references. Additionally, the absorbed oil could be recovered by means of simple mechanical squeezing, and the superabsorbent could be reused for at least 30 cycles.

1 Introduction

Cellulose nanofibrils (CNFs) are elemental constituents of plant fibers and possess unique mechanical and chemical properties, including superior strength and low density [1, 2]. Due to their very high water retention capacity [3] which is attributed to their hydrophilic surface hydroxyl groups, CNFs form highly viscous, shear thinning hydrogels with low solid contents. These hydrogels are attractive green alternatives to allow for the development of novel high-end applications. However, the individualization of intact nanofibrils and the production of their hydrogels are complicated and require intensive mechanical treatments because of the strong hydrogen-bonded structures of cellulose materials. Therefore, several different chemical and enzymatic pretreatments have been proposed to loosen the rigid structure of cellulose. Among the most promising new green chemicals to facilitate the production of CNFs and their hydrogels are deep eutectic solvents (DESs), which are readily available green compounds that have low toxicity and, in many cases, are biodegradable [4]. DESs are typically synthesized by complexation of a halide salt of quaternary ammonium or phosphonium cation as the hydrogen bond acceptor (HBA), along with a hydrogen bond donor (HBD) (e.g., urea, glycerol, or ethylene glycol), to form

a mixture that exhibits a notable lower melting point when compared to either HBA or HBD alone. The deep eutectic solvent system used in this research is based on choline chloride–urea as a pretreatment for the nanofibrillation of wood cellulose [5].

The CNF hydrogels can further be processed into various materials. Recently, the novel cellulose aerogels (also designated as cellulosic sponges or foam in the literature) based on CNF hydrogels have attracted considerable research interest due to their renewability, good mechanical properties, low density, high porosity, natural biodegradability, and environmental friendliness. These fascinating properties make it possible to use them as absorbents for oils and chemicals [6–12], for example. The aerogels can be prepared by freeze-drying the CNF hydrogel and removing all moisture while maintaining the porous, entangled 3D network structure of the CNFs. However, due to the presence of abundant hydroxyl groups, native cellulose aerogels display amphiphilicity (i.e., poor selectivity in absorbing hydrophobic compounds, such as oil, and high moisture absorption capacity) [13–15]. The hydrophobicity of the surfaces can be encouraged or created by introducing roughness (i.e., micro- or nanoscale asperities) and low surface energy substances. Typically, hydrophobicity is evaluated in terms of wettability by measuring the water contact angle (WCA) on material surfaces. Depending on their WCA value, materials are classified as hydrophilic, hydrophobic, or superhydrophobic. Materials with a WCA of less than 90° are described as hydrophilic; materials with WCAs of between 90° and 150° are hydrophobic; and those with WCAs of more than 150° are superhydrophobic [16].

High-capacity hydrophobic absorbents based on green materials are strongly desired for removing environmental pollutants, such as oil and chemicals spilled in the aqueous environment. For example, it has been estimated that 224,000 t of oil from oil tanker spills was released into the global marine environment between 2000 and 2011 [17]. In the explosion and sinking of the Deepwater Horizon oil rig in the Gulf of Mexico in 2010, the British Petroleum pipe had been leaking oil and gas on the ocean floor about 42 miles off the coast of Louisiana. By the time the well was capped 87 days later, an estimated 3.19 million barrels of oil had leaked into the Gulf, making the oil spill the largest accidental ocean spill in history. The potential magnitude of the environmental threat of oil pollutants can be gauged by the fact that 1 L of benzene can effectively render several million gallons of water unfit for human consumption [18]. Moreover, oil-contaminated water has a disastrous effect on aquatic and terrestrial life forms and also threatens human health and the economy – particularly tourism – due to its coating properties, unsightliness, and offensive odor [19]. Thus, there is an urgent demand across the world to develop a variety of technologies for the removal of oil and chemical pollutants from contaminated water sources.

Among the different cleanup methods available, such as in situ burning, mechanical methods, chemical treatments, and bioremediation alternatives, absorption through the use of oil and chemical sorbents is generally considered to be the optimal technological approach because of its relatively low cost, high efficiency, and production of less secondary pollution [17]. However, the feasibility of absorbents depends on their characteristics and performance. Hydrophobicity is one of their

most important properties as highly hydrophobic absorbents [20, 21] exhibit more efficient absorption of oil and many chemicals than low-hydrophobic absorbents. The cost of the absorbents must remain low due to the large volumes required for cleaning up such spills. Their environmental impact and costs are also affected by their ability to be reused and recycled. Overall, the capacity of absorbents is associated with their porosity and interaction with the contaminant (e.g., superhydrophobicity). Therefore, sustainable materials with superhydrophobic properties, good absorption selectivity, ability to float (buoyancy), recyclability, and cost efficiency are especially needed [22].

Conventional oil and chemical sorbent materials can be grouped into three major classes: inorganic mineral sorbents, synthetic polymer sorbents, and natural organic sorbents [23]. Inorganic mineral sorbents, also known as sinking sorbents, are highly dense, fine-grained mineral or inorganic materials (natural or processed) used to sink floating oil. Examples include fly ash [24], zeolites [25], exfoliated graphite [26], activated carbon [27], organoclay [28], silica nanoparticles [29], and silica aerogels [30]. Currently, these mineral sorbents are not widely used because of their low oil sorption capacities (typically less than 20 times by weight), poor oil/water selectivity, and low buoyancy, which make them difficult to recycle. Due to their inherent oleophilicity and hydrophobicity, synthetic polymer oil and chemical sorbents, including polypropylene fibers [31], polyurethane foams [32], and polypropylene nonwoven webs [33], are the commercial sorbents most commonly used to clean up spills. Despite their moderate oil sorption capacities, one major drawback of these sorbents is that they degrade or disintegrate very slowly, so their environmental and ecological effects are greater than those of mineral or natural products [34, 35]. In contrast, natural organic sorbents, including kapok [36], sugarcane bagasse [37], cotton [38], rice straw [39], and wood chips [40], are eco-friendly alternatives for removing oil and chemicals from wastewater. They have moderate oil sorption capacities (i.e., 3–50 times their own weight), which is comparable or sometimes lower density than inorganic and synthetic sorbents, and excellent biodegradability [41, 42]. Other advantages include their recyclability, their ability to recover oil and chemicals relatively easily, and the simplicity of their disposal when compared to other types of conventional sorbents. Despite these advantages, the majority of traditional natural sorbents also have many drawbacks, including poor buoyancy/floatability and poor selectivity of oil or chemical sorption, which is due to the relatively high water uptake of these inherently hydrophilic materials.

Here, the fabrication of CNF hydrogels based on a DES pretreatment and the use of hydrogels for the preparation of superabsorbent aerogels for the cleaning of oil and chemical spills is introduced. The CNF hydrogels were obtained from cost-effective recycled cellulose fibers (boxboard, milk containerboard, and fluting) using a simple, environmentally friendly nanofibrillation treatment involving a DES of choline chloride–urea. The CNF sponges were further synthesized from the hydrogels using a straightforward approach based on a reaction caused by a combination of two silylation agents followed by freeze-drying. The CNF aerogels had an ultra-low density (0.0029 g/cm^3) and high porosity (up to 99.81%) and were cost-effective, reusable, and hydrophobic. The increase in paper consumption has yielded a huge

amount of paper waste which contributes to 25–40% of global municipal solid waste [43]. Recycling paper waste will help to preserve forests as well as solve an environmental problem. Recycled cellulose fibers from paper waste are a cheap and abundant resource. Combining an aerogel structure with recycled cellulose fiber will form a new material that is cost-effective and promising in terms of its oil absorption. Prepared CNF sponges exhibited excellent oil/water selectivity and an ultrahigh capacity to absorb oil (marine diesel oil, kerosene, gasoline, motor oil, castor oil, and linseed oil) and organic solvents (dimethyl sulfoxide, chloroform, n-hexane, toluene, acetone, and ethanol). In addition, the absorbed oil was readily recovered by means of simple mechanical squeezing, and the superabsorbent aerogel could be reused for at least 30 cycles.

The chapter describes basic principle of manufacturing CNF hydrogels, which can be further processed into superabsorbent aerogels and how they can be utilized for the cleaning of oil and chemical spills. Utilization of renewable resources, low-cost raw materials, and simple and environmentally friendly manufacturing process makes these superabsorbents possible alternative for cleaning of chemical spills in the near future.

2 Materials and Methods

2.1 Chemicals

Urea (97%) and choline chloride (>98%) for DES were purchased from Borealis (Austria) and Algry Quimica (Spain), respectively. Methyltrimethoxysilane (98%, MTMS) was obtained from Evonik Industries (Germany), and hexadecyltrimethoxysilane (>85%, HDTMS) was purchased from Sigma-Aldrich (Germany). Lightweight marine diesel oil and kerosene were obtained from Neste (Finland), and gasoline (E95) and motor oil (5w40) were purchased from a local gas station. Dimethyl sulfoxide (>99%, DMSO) was obtained from TCI (Germany). Castor oil, linseed oil, chloroform (>99%), n-hexane (>98%), toluene (>99.9%), acetone (>99.8%), and ethanol (>99.9%) were obtained from VWR (Finland). All chemicals were used as received, without further purification. Two different types of commercial oil absorbent booms obtained from local rescue services were used as reference absorbents.

2.2 Raw Materials

Recycled boxboard and milk containerboard were collected directly from board-container collections, and fluting board was supplied by Heinola Fluting (Finland). A dry sheet of industrially bleached birch kraft pulp (*Betula verrucosa*) was used as a reference cellulose raw material. All pulps were first pulped without chemicals using a Kenwood KM020 pulper (UK), which has an operating principle similar to that of the Hobart pulper, at a consistency of 15% at approximately 45 °C using a rotor

speed of 2 for 10 min, and then washed and screened using a Somerville screen (Lorentzen & Wettre, Sweden).

2.2.1 DES Pretreatment and Preparation of CNF Hydrogels

To pretreat the cellulose pulps (boxboard, milk containerboard, fluting, and birch kraft), a DES solution was produced by heating 1620 g of choline chloride and 1223 g of urea in a large beaker (5 dm^3) at 100 °C until the mixture melted, after which it was placed into a water bath at 100 °C under constant stirring for approximately 5 min to obtain a clear, colorless liquid. Then, 25 g (abs) of cellulose material (moisture content of ~30%) was added to the suspension and mixed for 2 h, after which the beaker was removed from the water bath and 1000 cm^3 of deionized water was added while mixing [4]. Then, the treated cellulose was washed with water using a Somerville screen (Lorentzen & Wettre, Sweden) until clear rinse water was obtained.

Next, four batches of each pulp were treated with DES prior to nanofibrillation with a Masuko supermasscolloider grinder MKCA6-2J (Japan) (Fig. 1) to obtain cellulose nanofibril hydrogels. The stones of the grinder were first carefully brought into close contact, as observed by the low friction sound, and then the pretreated pulp slurry was poured into the grinder at a consistency of 1.5%. The pulp was passed through the grinder twice using a zero-grinding stone gap; then, the stones were adjusted to negative gap values to begin the actual nanofibrillation. The pulps were passed through the grinder a total of 10 times, using negative gap values of −20 μm, −40 μm, −50 μm, −70 μm, and −80 μm to obtain viscous CNF hydrogels.

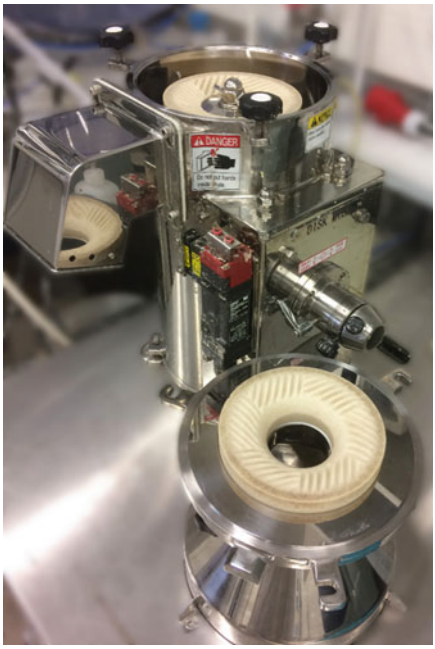

Fig. 1 Masuko supermasscolloider grinder MKCA6-2J and grinding stones

2.2.2 Visualization of Cellulose Nanofibrils

A Tecnai G2 Spirit transmission electron microscope (TEM) (the Netherlands) was used to observe the morphology of the CNFs. Samples were diluted with ultrapure water, and a small drop of the diluted nanofibril suspension was placed on a carbon-coated and polylysine-treated copper grid, and any excess sample was removed from the edge of the grid with filter paper. Negative staining of the samples was performed by placing a droplet of uranyl acetate (2% w/v) on top of each specimen. The excess uranyl acetate was removed with filter paper as described above. The grids were dried at room temperature and analyzed at 100 kV under standard conditions. Images were captured using a Quemesa CCD camera, and iTEM image analysis software (Olympus Soft Imaging Solutions GMBH, Germany) was used to measure the width of the individual cellulose nanofibrils.

2.2.3 Rotational Viscosity

Viscosity measurements of the CNF hydrogels were performed with the Brookfield DV-II+ Pro EXTRA (USA) rotational viscometer. For these measurements, vane-shaped spindles (V-71, V-72, and V-73) were used at rotational speeds of 10, 20, 50, and 100 rpm. The measurements were conducted at a sample consistency of 0.5% and at a constant temperature of 20 °C, using a measurement time of 2–5 min for each rotational speed.

2.2.4 X-Ray Diffractometry

The crystallinity of the cellulose nanofibril was analyzed through wide-angle X-ray diffractometry (WAXD) using a Siemens D5000 diffractometer (USA); Cu Kα radiation ($\lambda = 0.1542$ nm) was used for the measurements. As a pretreatment, the freeze-dried samples were pressed into tablets at a thickness of 1 mm, and the scans were taken over a 2θ (Bragg angle) range from 5° to 50° at a scanning speed of 0.02°/s, using a step time of 1 s. The degree of crystallinity, or the crystallinity index (CrI), was calculated using the peak intensity of the main crystalline plane (200) diffraction (I_{200}) of 2θ at 22.8° and a peak intensity of 2θ at 18.0°, which is associated with the amorphous fraction of cellulose (I_{am}), according to Eq. (1) [44].

$$\mathrm{CrI} = \left(\frac{I_{200} - I_{am}}{I_{200}}\right) \times 100\% \tag{1}$$

2.3 Fabrication of Hydrophobic CNF Sponges

The CNF hydrogels were diluted with deionized water, homogenized using an Ultra-Turrax system set to 8000 rpm for 30 s, and their pH adjusted to 4 using HCl. Various dilutions were used, depending on the sample (Table 1).

The silane solutions (20 wt%) for the hydrophobization of CNFs were prepared by diluting MTMS and HDTMS in ethanol. After dilution, hydrolyzed silane solutions were mixed using a magnetic stirrer for 10 min. Then, 25 wt% of freshly prepared

Table 1 Summary of CNF aerogel samples and references and solid content of CNF hydrogels used for aerogel preparation

silane solutions (MTMS and HDTMS, ratio of 50:50) against CNF amounts were added by micropipette to the CNF suspensions and stirred with a magnetic stirrer at room temperature for 2 h.

Silylated CNF hydrogels (75 cm^3) were introduced into metallic, round molds (77 mm in diameter and 20 mm in height), frozen in liquid nitrogen, and transferred to the vacuum chamber of the freeze-drying device (Scanvac Coolsafe 55-15 Pro, Denmark) for 72 h to obtain hydrophobized CNF sponges. The silylation levels of the prepared sponges were determined by X-ray photoelectron spectroscopy (XPS).

The pH adjusting process is essential to promote the hydrolyzation of the silanes and to form the silanol groups that will later react with the cellulose nanofibers. Xie et al. [45] reported that cellulose is not reactive to many chemicals, and often the OH-groups are not accessible. Generally, the hydrolysis of organosilanes under acidic pH conditions favors the formation of more reactive silanol groups as well as the retardation of their condensation rate, which makes them available to react with the OH-groups of the fibers or to condensate over the fiber surface.

2.3.1 Density and Porosity of CNF Sponges and Reference Polypropylene Absorbents

The apparent volumetric mass density of CNF sponges and reference polypropylene materials was calculated using the following formula (Eq. 2):

$$\rho = \frac{m}{V} \tag{2}$$

where m and V are the mass (g) and volume (cm^3) of the materials, respectively.

Table 2 Density and porosity of CNF aerogels and commercial reference materials

Material	Density (g/cm^3)	Porosity (%)
DES_Cel (1.0)	0.0166	98.91
DES_Cel (0.5)	0.0070	99.54
DES_Cel (0.3)	0.0042	99.72
DES_Cel (0.2)	0.0029	99.81

DES_Flu (0.3)	0.0049	99.68
DES_Flu (0.2)	0.0032	99.79
DES_Boa (0.5)	0.0075	99.51
DES_Boa (0.3)	0.0045	99.71
DES_Boa (0.2)	0.0031	99.79
DES_MCB (0.5)	0.0079	99.48
DES_MCB (0.3)	0.0048	99.69
DES_MCB (0.2)	0.0033	99.78
Ref (strip)	0.0807	91.11
Ref (plug)	0.0521	94.26

The porosity (P, %) of the CNF sponges and polypropylene materials was calculated according to Eq. (3):

$$P = \frac{V - m/\rho_c}{V} \times 100\% \tag{3}$$

where V (cm^3) is the volume of the materials, m (g) is the mass, and ρ_c is the density of bulk cellulose (1.528 g/cm^3) or polypropylene (0.9075 g/cm^3). Density and porosity of CNF sponges and commercial reference materials is presented in Table 2.

2.3.2 X-Ray Photoelectron Spectroscopy

The silylation levels of the prepared sponges were determined by XPS using a Thermo Fisher Scientific ESCALAB 250Xi (UK). A monochromatic Al$K\alpha$ X-ray source operated at 300 W was used with a combination of an electron flood gun and ion bombardment for charge compensation. The takeoff angle was 45° in relation to the sample surface. Low-resolution survey scans were taken using a 1-eV step and a 150-eV analyzer pass energy, and the high-resolution spectra were taken with a 0.1-eV step and a 20-eV analyzer pass energy. The binding energy (BE) scale was referenced to the C 1s line of aliphatic carbon, set at 284.6 eV. All measurements were taken in an ultrahigh vacuum pressure chamber (5×10^{-9} mbar).

Prior to measurement, a dry sample was pressed on the indium film. Three measurements were taken from each of the silane-treated CNF sponges. The first measurement was on top of the aerogel, the second at the bottom, and the third in the center of the aerogel after it had been sliced into two halves. The untreated reference aerogel was measured only once, the center.

2.3.3 Contact Angle Measurement

The surface wettability of the CNF sponges was evaluated using contact angle measurement. The static contact angles of Milli-Q water droplets on the aerogel surfaces were measured at 22 °C and 10% RH using a CAM 2000 (KSV Instruments Ltd., Helsinki, Finland). Measurements were performed by placing a 6.5-μL drop of Milli-Q water on the aerogel surface using a syringe and capturing images at a rate of 1 frame/sec to be sent directly from the CCD camera to the computer for analysis. Determination of the contact angle was based on an analysis of the drop's shape using the full Young-Laplace equation and assuming a spherical drop. The WCAs at 60 s are reported. Five parallel measurements were taken at various positions on each aerogel sample, and the average values and standard deviation were calculated. Typical uncertainties in the experiments were less than 5°.

2.3.4 Field Emission Electron Microscopy (FESEM) Characterization

To visualize the structure of the various CNF sponges, FESEM analysis was performed using a Zeiss Ultra Plus instrument (Zeiss, Germany). The samples were imaged using a low voltage (5 kV) and a working distance of ~5 mm. The CNF sponges were analyzed by simply placing each sample on a sample holder using a carbon pad and coating it with a thin layer of platinum.

2.4 CNF Sponges' Diesel Oil Sorption Selectivity from Oil–Water Mixtures

A fresh sorbent sample (0.05–0.1 g) was placed on the surface of a solution having a 5-mm layer (i.e., 13.00 g) of marine diesel oil floating on an 80-mm layer of water. The sample was left for 15 min, and then the sorbent was removed and left to drip for 30 s before being weighed. The amount of oil left in the oil–water mixture was determined using gravimetric analysis, as accepted by the United States Environmental Protection Agency (US EPA). In this case, diesel oil extracted using a solvent (i.e., n-hexane) from an oil-in-water sample is the EPA-accepted method (EPA 1664) for oil-in-water analysis. After sorption testing, the residual oil–water mixture was acidified to a pH of 2, and the sample was extracted three times using n-hexane. The combined collected extracts were distilled at 85 °C and weighed to determine absorption selectivity in terms of oil absorption capacity (g/g) and water uptake (g/g). At least three measurements were conducted for each sample, and the average value is presented.

2.5 Absorption Capacities for Various Oils and Organic Solvents

In the absorption test, pre-weighed hydrophobic CNF sponges were placed in various oils (marine diesel oil, kerosene, gasoline, motor oil, castor oil, and linseed oil) and organic solvents (dimethyl sulfoxide, chloroform, n-hexane, toluene, acetone, and ethanol) for 2 min to reach absorption equilibrium and then removed and weighed.

The sorption capacity (g/g), defined as the mass of absorbed oil or solvent (g) per unit mass of dry absorbent (g), was used to characterize oil absorption capacity. At least three measurements were conducted for each sample, and the average value is presented as an absorption result.

2.6 Reusability of CNF Sponges

Mechanical compression was used to extract the remaining liquid from the sorbent so that reusability could be tested. The absorbed marine diesel oil was recovered by simple mechanical squeezing. The squeezed CNF sponges absorbed oil again without any posttreatment, and the oil stored in the sponges was measured again. Oil storage capacity, defined as the mass of oil (g) per unit mass of the dry sponge (g), and values presented as capacity left compared to fresh absorbents were used to characterize the reusability of the CNF sponges.

3 Results and Discussion

A deep eutectic solvent based on choline chloride–urea was used as a pretreatment method to nanofibrillate recycled cellulose materials. Mechanical nanofibrillation (with a Masuko grinder) of the pretreated cellulose resulted in individual nanofibrils and an opaque CNF hydrogel. The method uses green bulk chemicals and can be considered a sustainable approach to obtain CNF without the need for toxic or expensive chemicals or other intensive mechanical and/or chemical modifications of the cellulose [46].

A few DESs are reported to dissolve cellulose [47], including a mixture of choline chloride and zinc chloride [48], and choline acetate with quaternary ammonium cation [49], when low-molecular mass microcrystalline cellulose is used. Here, subjecting oven-dried, high-molecular-weight cellulosic pulp to a DES mixture of choline chloride–urea with a molar ratio of 1:2 resulted in the disintegration of the cellulose into a solution without visible solubilization at 100 °C [4].

3.1 Appearance of CNF Hydrogels

During the DES treatment (before mechanical disintegration), the fibers rapidly formed a transparent, nonfibrous gel in the solvent, and after the addition of water, the fibers recovered their initial forms. Therefore, the DES-treated fibers did not show any clearly visible changes in their structures after being washed with water. When exposed to further mechanical disintegration, CNF hydrogels were obtained from the DES-treated fibers.

The visual appearances of these hydrogels after ten passes through the Masuko grinder are shown in Fig. 2. All of the CNF samples had gel-like, highly viscous appearances which indicate that the strong shear forces in the Masuko grinder break

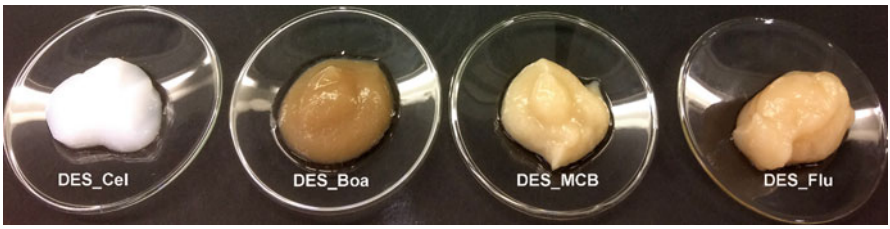

Fig. 2 Visual appearances of the CNF hydrogels (DES_Cel, DES_Boa, DES_MCB, and DES_Flu) after DES treatment and the 10th pass through the Masuko grinder. Solid contents of the hydrogels were between 1.5% and 2.0%

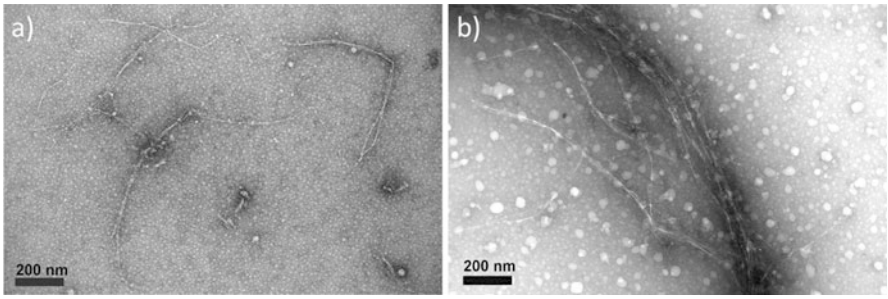

Fig. 3 TEM images of the DES_Flu (**a**) and DES_Boa (**b**). The white dots in the images are from the polylysine in the sample preparation

the hydrogen bonds in the loosened cell walls of the DES-treated cellulose fibers [2]. The choline chloride–urea was observed to promote the nanofibrillation of recycled fibers despite the high moisture content of the original cellulose material (approx. 70%). This result confirms the recent findings of Du et al. [50] who stated that a small amount of water absorbed into the choline chloride–urea solution can even improve the electrolyte system in the DES because water links to urea via strong hydrogen bonds, which in turn promotes ionic dissociation by the generation of more free cationic choline ions [50].

Figure 3 shows examples of TEM images of the CNFs after ten passes through the Masuko grinder. The visual appearances of the CNFs from different cellulose sources differed only slightly, and they all possessed diameters of 2–80 nm. Moreover, some larger aggregates were noted.

3.2 Rotational Viscosity of CNF Hydrogels

Figure 4 shows the rotational viscosities of the CNF hydrogels after their 10th (Fig. 4a) and the 8th passes (Fig. 4b) through the Masuko grinder at a consistency of 0.5%. The low shear rate viscosity of the hydrogel correlates with the morphology

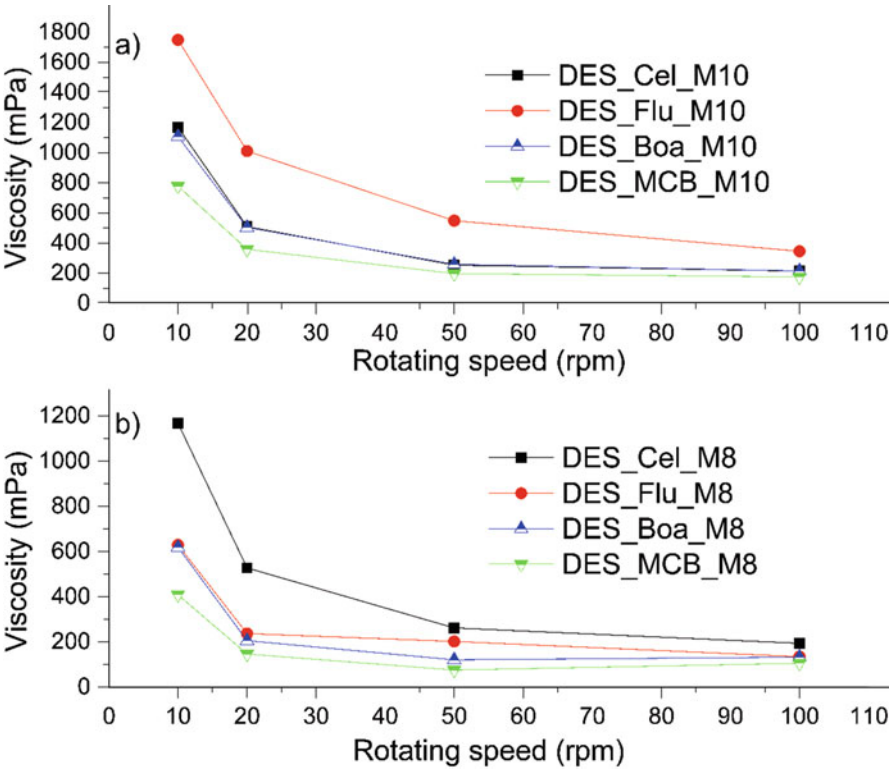

Fig. 4 Rotational viscosities of the CNF hydrogels (DES_Cel, DES_Flu, DES_Boa, and DES_MCB) and Masuko-ground pulps (**a**) after the 10th pass, and (**b**) after the 8th pass of the Masuko grinder at a consistency of 0.5%

of cellulose nanoparticles [51], and the higher the viscosity, the thinner and longer the nanofibrils are for a given concentration [52]. Long and thin nanofibrils are able to form network structures in aqueous phases held together by numerous temporary hydrogen bonds and van der Waals interactions [53]. This effect explains cellulose nanofibril hydrogels' thixotropic and shear thinning behavior that is related to the high aspect ratio of their particles [53, 54].

After eight passes through the Masuko grinder (Fig. 4b), the highest viscosity was observed for the CNF hydrogel obtained from virgin reference cellulose. However, all hydrogels showed high viscosity levels with shear thinning behavior after the 10th pass, thereby indicating that high-performing CNF hydrogels could be obtained from recycled fiber material. The use of recycled cellulose materials has a notable cost benefit, since the price of recycled cellulose materials is only around 10% of the price of bleached birch cellulose. In practice, the cost of recycled cellulose materials is only around 80–100 €/t, whereas the cost of bleached birch cellulose is currently around 700–800 €/t.

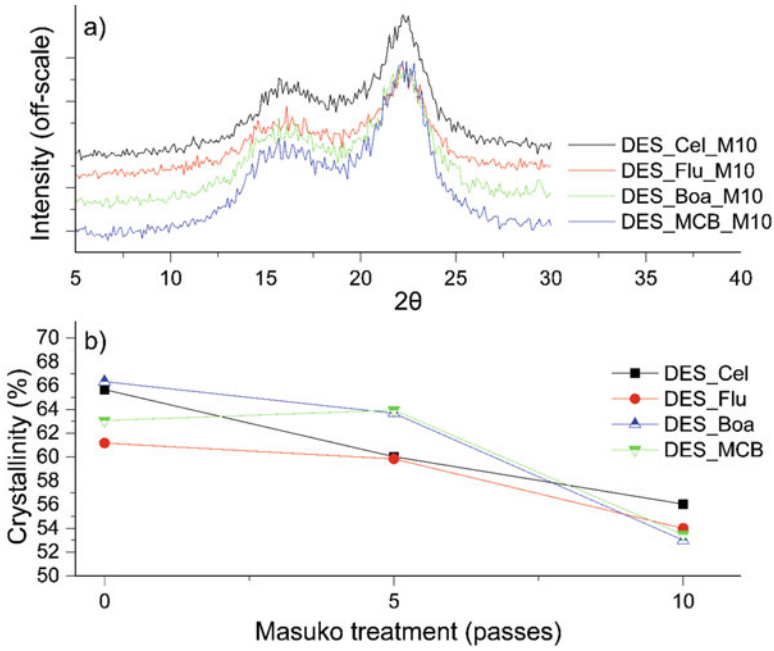

Fig. 5 (**a**) The diffractograms of the CNFs and (**b**) the calculated crystallinity indexes

3.3 X-Ray Diffractometry of the Nanofibrils

The X-ray diffractograms of the CNFs and the calculated crystallinity indexes are shown in Fig. 5a, b. The mechanical shearing caused a reduction in the crystallinity of the CNFs, and the largest reduction was noted after five Masuko grinder passes. The crystallinity index of the CNFs' tenth passes through the Masuko grinder varied from 56% to 53%, indicating that the CNFs still maintained their highly crystalline structure.

3.4 Hydrophobized CNF Sponges

The hydrophobized aerogels were produced from CNF hydrogels using consequent silylation and freeze-drying treatments. The waste cellulose materials (boxboard, milk containerboard, and fluting) were compared to virgin, bleached birch cellulose and found to be of sufficient quality and to present no problems during either chemical modification or fibrillation.

To achieve the porous structure of the CNF sponges (Table 2) and to avoid the need for posttreatment, both silylation agents – MTMS and HDTMS – were mixed with hydrogels before the freeze-drying process to result in cross-linked CNF aerogels while simultaneously improving their hydrophobicity. MTMS is a cross-linking

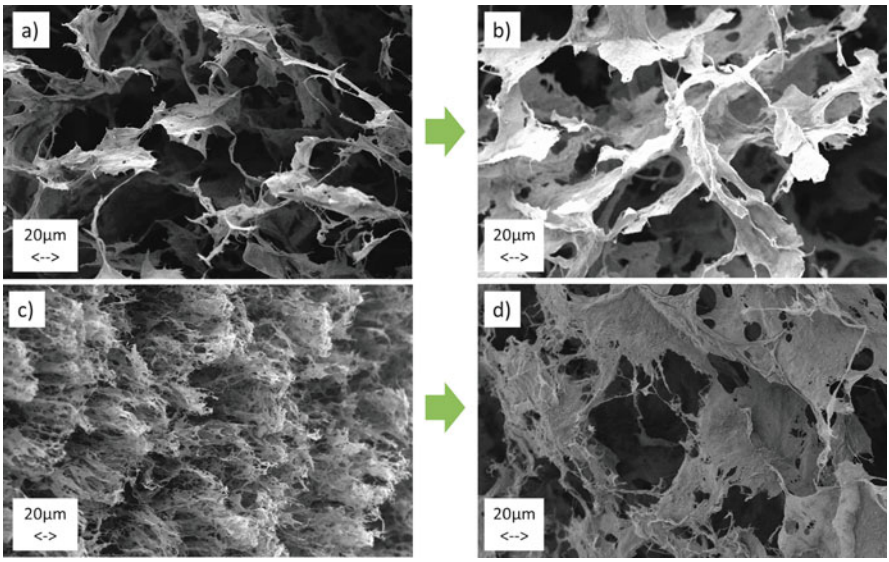

Fig. 6 FESEM images of CNF sponges: (**a**) unmodified DES_Boa (0.5), (**b**) modified DES_Boa (0.5), (**c**) unmodified DES_Cel (0.5), and (**d**) modified DES_Cel (0.5)

agent for cellulose [8, 55], while HDTMS is a silane containing a long carbon chain that can provide hydrophobicity in aerogels. The reaction medium was adjusted to an acidic pH of 4 to favor condensation of the hydrolyzed MTMS and HDTMS with the cellulose surface. At a pH of 4, the hydrolysis of alkoxysilanes has been reported as rapid and the self-condensation limited, which maximizes the concentration of the silanol species available to interact with the cellulosic substrate [56].

Table 2 shows the densities and porosities of the manufactured CNF sponges as a function of their CNF hydrogel solid content. Decreasing the solid content from 1.0% to 0.2% caused the density of the reference CNF sponge (DES_Cel) to decrease from 0.0166 to 0.0029 g/cm^3 and the porosity to increase from 98.91% to 99.81%. Compared to commercial oil absorption materials (i.e., polypropylene from commercial oil absorbent booms), the density of the CNF sponges was up to 28 times less and the porosity more than 8% more (Table 2).

Figure 6 shows the morphologies of the sponges made from recycled board and reference cellulose CNFs (DES_Boa and DES_Cel) with and without hydrophobic modification. Without silylation, the DES_Boa sponge possessed a continuous three-dimensional (3D) porous structure (Fig. 6a) that was formed by randomly entangled nanofibrils. Hydrophobic modification with the aid of a cross-linking agent resulted in the formation of a continuous, sheetlike coating. As demonstrated, the porous structure was well maintained (Fig. 6b, d). In addition, the waste board celluloses formed a well-structured texture when compared to the virgin cellulose aerogel (Fig. 6a–d).

Table 3 Water contact angles (WCAs) of various CNF aerogels with 0.5% solid content

Aerogel	WCA (deg)	WCA (std)
DES_Cel	142.9	6.65
DES_Flu	159.0	4.58
DES_Boa	107.2	4.45
DES_MCB	129.4	4.90

To indicate the hydrophobicity of silylated CNF sponges, their WCAs were determined (Table 3). All aerogels were evidently hydrophobic (i.e., WCA $> 90°$), and a sample of fluting celluloses (DES_Flu) could even be characterized as superhydrophobic (i.e., WCA $> 150°$). Based on visual observations, the water droplets easily rolled off the silylated CNF aerogels when the sliding angle was increased slightly, thereby confirming the hydrophobic nature of all silylated CNF sponges.

3.5 The Silylation Level of the Prepared CNF Sponges

Effective oil/water selectivity is essential for oil absorbents [9]. It should be noted that freeze-dried CNF sponges cannot be directly used as oil absorption materials due to the large number of hydrophilic hydroxyl groups in unsilylated cellulose fibers. Hydrophilic aerogels disintegrate rapidly in water because water penetrates the aerogel, destroying the hydrogen bonds between the CNFs and causing the aerogel structure to collapse.

The silylation of sponges was confirmed and quantified using X-ray photoelectron spectroscopy (XPS). Without silylation, the surface concentration of silicon in various DES-treated CNF sponges varied from 0.46 to 0.76 at.%, whereas after silylation, a strong peak of silicon was noted, and the surface concentration of silicon in these samples varied from 4.47 to 6.27 at.% (Table 4). In addition, the present study analyzed the spatial distribution of silicon on the top phase, the inner phase, and the bottom phase of the aerogel. The silicon contents were very similar (variation within 0.4%), except for that of DES_MCB (variation of 0.76%), which confirmed the successful, homogenous silane treatment of the aerogels (Table 4).

3.6 Diesel Oil Sorption Selectivity of CNF Sponges in Oil–Water Mixtures

To investigate the selectivity of oil sorption of various CNF sponges, a mixture of marine diesel oil and water was prepared. Figure 7 shows the oil absorption capacities of various DES-treated hydrophobic CNF sponges. All CNF sponges investigated demonstrated similar proclivities against porosity (i.e., solid content). With a solid content of 0.5%, all materials had nearly the same oil absorption capacity (from 88 to 97 g/g), while at higher porosities (i.e., $<0.5\%$), DES_Cel had the highest

Table 4 Silicon content of various CNF aerogels with 0.5% solid content

Aerogel	Surface concentration of Si on unmodified samples (at.%)[a]	Surface concentration of Si in silylated samples (at.%)[b]
DES_Cel	0.47	4.47 ± 0.27
DES_Flu	0.74	5.00 ± 0.34
DES_Boa	0.74	6.27 ± 0.36
DES_MCB	0.46	4.80 ± 0.76

[a]Silicon concentration (atomic weight) of aerogels prepared without silanes according to XPS analysis
[b]Silicon concentration (atomic weight) of silylated aerogels according to XPS analysis

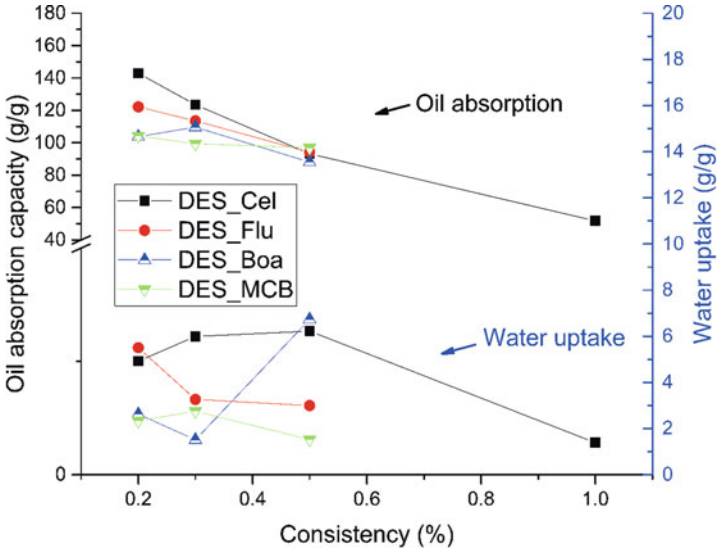

Fig. 7 Oil absorption capacities (left y-axis) and water uptake (right y-axis) of various CNF aerogels

capacity. Evidently, with increased DES_Cel sponge porosity (i.e., solids content from 1.0% to 0.2%), the absorption capacities for marine diesel oil increased significantly, from 52 to 143 g/g. Therefore, the CNF sponges with lower density and higher porosity possessed higher oil absorption capacities.

The water uptake, or water absorption, of various CNF aerogels was also determined, and the results are presented in Fig. 7 (right y-axis). In all cases, the water absorption of various CNF sponges was very low (<7 g/g) when compared to their marine diesel oil absorption (left y-axis of Fig. 7), suggesting that the various DES-treated hydrophobic CNF sponges had excellent selectivity toward diesel oil. Compared to the capacity of DES_Cel (0.3) to absorb water (6.0 g/g), DES_Cel capacity to absorb marine diesel oil could be as much as 21 times higher.

To achieve a very high absorption capacity (>100 g/g), CNF sponges should have the highest possible porosity and clear hydrophobicity. When porosity beyond 99.8% was achieved, problems were encountered because the strength of the CNF sponges was so diminished that handling them was a challenge. Another problem was that absorbed oil easily poured out from the aerogel structure after the oil sorption test, meaning that in practice the aerogel cannot retain all the oil that it absorbs.

3.7 CNF Sponges' Absorption Capacities for Various Oils and Solvents

The present study also investigated the capacity of hydrophobic CNF sponges to absorb a wide range of other oils and organic solvents, as shown in Fig. 8. Overall, the CNF sponges exhibited excellent oil absorption capacities. For example, DES_Cel (0.3) had a capacity of 124 g/g for marine diesel oil, 90 g/g for kerosene, 92 g/g for gasoline, 120 g/g for motor oil, and 150 g/g for linseed oil.

All CNF sponges also showed ultrahigh capacities to absorb a wide range of organic solvents, ranging from 65 g/g for hexane to 205 g/g for chloroform, depending on the density of the liquid (Fig. 8). These capacities could be attributed to the high porosity (99.72%) and hydrophobicity of the material. Comparing the results obtained for CNF sponges to those for commercial reference absorption materials (Ref (strip) and Ref (plug)), all the CNF sponges created had notably higher

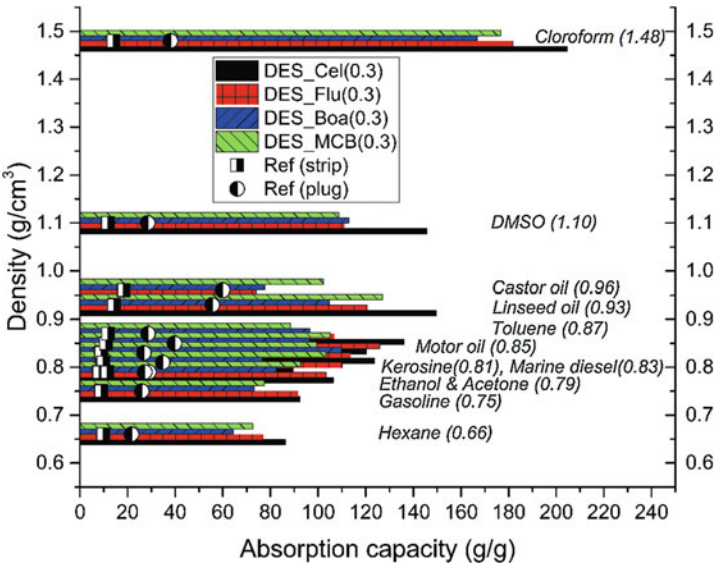

Fig. 8 Absorption capacities of various CNF aerogels and reference materials by the densities of oils and solvents

capacities to absorb all oils and organic solvents investigated. For instance, the DES_Cel (0.3) sponge had an absorption capacity of 120 g/g for motor oil and 136 g/g for toluene, while the DES_Boa (0.3) sponge had an absorption capacity of 96 g/g for motor oil and 97 g/g for toluene. In contrast, the Ref (strip) had an absorption capacity of only 11 g/g for motor oil and 12 g/g for toluene, and the Ref (plug) had values of 40 g/g and 29 g/g for these two liquids, respectively.

3.8 Reusability of CNF Sponges to Absorb Marine Diesel Oil

Figure 9 shows the absorption and reusability performances of the hydrophobic DES_MCB (0.5) sponge in absorbing marine diesel oil. Figure 9a shows how a water droplet stayed on the cleavage plane of the aerogel, thus indicating the CNF

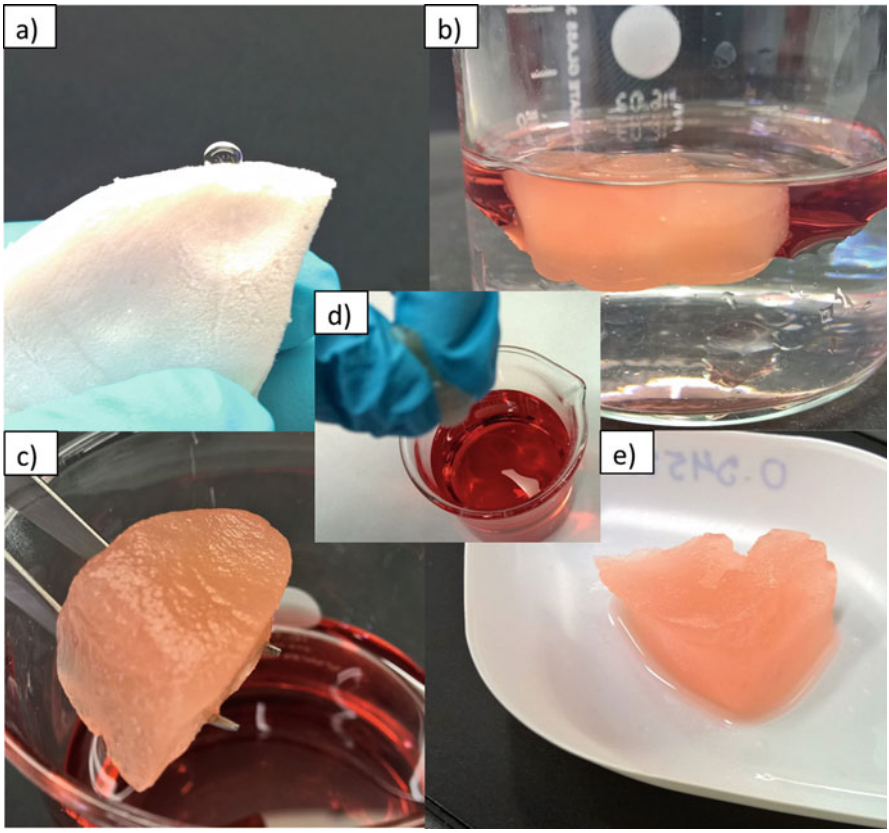

Fig. 9 High oil recovering efficiency and absorbent reusability of the hydrophobic DES_MCB (0.5) sponge. (**a**) Hydrophobic cellulose aerogel, (**b**–**c**) absorbing marine diesel oil, (**d**) squeezing absorbed oil, and (**e**) aerogel after 30 cycles of mechanical squeezing and reabsorption of marine diesel oil

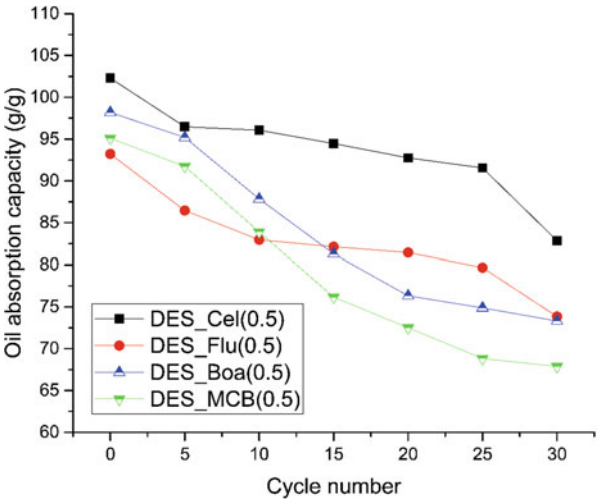

Fig. 10 Reusability of hydrophobic CNF sponges to absorb marine diesel oil

sponge's hydrophobicity. The sponge could be saturated with marine diesel oil in less than 30 s (Fig. 9b), thereby exhibiting its high absorption efficiency. In addition, the absorbed oil could easily be recovered by simple mechanical squeezing (Fig. 9c, d). Furthermore, the squeezed sponge could quickly reabsorb more oil over a period of about 30 s and recovered most of its volume without any posttreatment. Figure 9e demonstrates the appearance of DES_MCB (0.5) after 30 cycles of mechanical squeezing and reabsorption of diesel oil, demonstrating the sponge's efficiency in recovering oil and its reusability.

All DES CNF sponges could be reused, and the absorbed oil could be recovered by simple mechanical squeezing. Figure 10 shows the sponges' oil absorption capacities remaining after 30 squeezing-and-absorbing cycles. The oil absorption capacities of hydrophobic DES_Cel and DES_Flu sponges decreased by about 20 g/g, indicating their high reusability. Although the absorption capacities of the DES_Boa and DES_MCB sponges decreased to about 26 g/g, they retained more than two-thirds of their absorption capacities after 30 squeezing-and-absorption cycles. This performance has significant implications for various practical applications.

Compared with other methods of recovering or reusing absorbents, including distillation (heating) [57], rinsing (solvent extraction) [8, 58], combustion (burning) [59], and vacuum filtration [60], squeezing is probably the simplest and most sustainable in terms of its use of energy, materials, and chemicals. Many of the other methods of recovering oil and reusing absorbents, including distillation, solvent extraction, and burning, are complicated, time-consuming, inefficient, and energy intensive. Carbon fiber aerogels made from raw cotton [61] and waste pulp [62] have previously been mechanically squeezed to recover oil and then reused, but their

absorption capacity decreased dramatically in the second cycle, dropping to less than 55% of their original capacity. Therefore, mechanical squeezing could not be meaningfully applied to carbon absorbents in order to recover oil and reuse materials. Here, more than 70% of the absorbed diesel oil was efficiently recovered by facile, mechanical squeezing without the addition of other methods. Furthermore, the sponges could be reused for at least 30 cycles and maintained very high absorption capacities without sustaining significant structural damage. Oil absorbents with both ultrahigh absorption capacity and high efficiency in terms of their oil recovery and sorbent reusability are highly desired. Therefore, CNF sponges derived from waste cellulose using a green DES treatment prove to be promising for the cleaning of oil and chemical spills.

3.9 Comparison of Various Absorbents

Some of recently developed absorbents and their absorption capacities for various oils and organic solvents are listed in Table 5. Among them, carbon absorbents – either from carbon blocks, such as carbon nanotubes (CNTs) [63] and graphene [59, 64–66], or directly from carbonized materials, such as cotton fibers [61], cellulose fibers [62], and nanobacterial fibers [67], represent novel superabsorbents, demonstrating ultrahigh absorption capacities. Absorbents made from nanocellulose hydrogels exhibited low density and high absorption capacity for various oils and organic solvents (up to 200 g/g), arising from the good dispersion and stable suspension of CNF or CNC [8, 14, 68, 69]. The absorption capacity of nanocellulose fiber-based absorbents was slightly lower than that of carbon materials, but was considerably higher than that of other sorbents obtained from synthetic polymers (14–84 g/g) [70, 71].

In the present work, the marine diesel oil absorption capacity of the hydrophobic CNF aerogel prepared from CNF hydrogels was ultrahigh (88–143 g/g), and for chloroform it was up to 205 g/g, which was much higher than that of cellulose fiber-based absorbents, and was even comparable to that of most carbon absorbents (as listed in Table 5). Similar absorption capacities as found in the present research have been achieved using carbon nanotubes and graphenes [59, 64, 65], but the cost of carbon nanotubes could be as high as 100,000–600,000 €/t, and price of graphenes can be even higher. Furthermore, this research has demonstrated that absorbed marine diesel oil could be recovered in a fast and straightforward manner through simple mechanical squeezing and that the hydrophobic CNF sponge could be reused extensively without requiring any other posttreatment. The oil recovery method, absorbent recyclability, and costs were preferable to those of most of carbon-based absorbents. Therefore, as an ultralight, cost-effective, and highly recyclable superabsorbent, the hydrophobic CNF sponge has been demonstrated to be a possible alternative to carbon-based absorbents for the removal of spilled oil and organic pollutants from marine environments.

Table 5 Comparison of various superabsorbents developed recently

Year	Reference	Cost estimation	Absorbent	Oil recovery method	Absorption capacity (g/g)
2012	[63]	++	B-doped CNT sponge	Burning	25–125
2012	[64]	++	N-doped graphene framework	Burning	200–600

–	Present work	–	CNF aerogel	Squeezing	65–205

"–" low cost, "+" high cost, "++" very high cost

4 Conclusion

The chapter describes basic principle of manufacturing CNF hydrogels, which can be further processed into hydrophobic cellulose aerogels. Nanofibrillation, silylation, and freeze-drying are combined to create a porous, hydrophobic, superabsorbent CNF sponges. Utilization of renewable resources, low-cost raw materials, and simple and environmentally friendly manufacturing process makes these superabsorbents possible alternative for cleaning oil and chemical spills.

Contents

Abstract

During the past decades hydrogels have gained considerable interest and reviewed from different points of view, because of their unique properties. The hydrogel 3D structure, porosity, swelling behavior, stability, gel strength, as well as biodegradability, nontoxicity, and biocompatibility are properties which are widely variable and easily adjusted, making them suitable for many versatile applications, especially in the field of medicine and biotechnology. Generally, hydrogels possess the huge potential to be used as a matrix for incorporation of different types of nanoparticles. Namely, hydrogels in the swollen state provide free space between cross-linked polymer chains, in which the nucleation and

1 Introduction

Nanotechnology is one of the fastest growing new areas in science and engineering. It is a cross-interdisciplinary area which involves the precise control and manipulation with atoms and molecules in order to create novel materials with unique unusual and/or enhanced properties. This technology requires detailed understanding of physical and chemical processes, across a range of disciplines, at the range below 100 nm. The main goal is production of new materials, devices, and systems tailored to meet the needs of a growing range of scientific and engineering applications. Moreover, the commercial application of such materials is probably one of the most important driving forces for so huge global activity in nanotechnology.

Polymer-based nanocomposites are being considered as versatile materials in many scientific applications leading to technological advancements. This is due to the fact that incorporation of the nanoparticles into polymer matrix significantly affects its optical, thermal, and electrical properties while retaining its inherent characteristics. It opens a new gateway in developing the materials for improved performance in many potential applications.

Polymers are considered to be a good host material for incorporation of inorganic nanoparticles. During the synthesis of nanoparticles, the atoms tend to coalesce into clusters, which grow into bigger particles or eventually into precipitates. The control of particle size can be achieved by the use of polymers such as capping agents. Functional groups of polymers ensure the anchoring of the molecule at the particle surface, while the polymeric chains protect particles from coalescing with other ones and thus inhibit at an early stage further coalescence through electrostatic repulsion or steric hindrance [1]. On the other hand, incorporation of nanoparticles, due

to their high surface to bulk ratio, can significantly affect the properties of the polymer matrix.

In the recent years, the novel and very attractive class of materials are the nanocomposites in which cross-linked polymer networks, i.e., hydrogels, are used as a carrier for the incorporation and organization of nanoparticles. The properties of such nanoscale devices can be tuned according to the required functions and applications. The "soft" mesoporous network of hydrogels is suitable matrix for incorporation of metal nanoparticles (Ag, Au) [2–5], magnetic particles (Fe_3O_4) [6, 7], as well as semiconductor nanoparticles (CdS, PbS) [8, 9]. Most of the technologies used to incorporate nanoparticles into polymeric matrix involve either chemical methods such as reduction, synthesis of complex compounds, mixing of preformed particles with polymers, or complicated physical techniques. Recent research efforts are directed toward exploiting possibilities for the *in situ* synthesis of nanoparticles within polymeric network architectures in order to produce enhanced and new hybrid nanomaterials. Three-dimensional network hydrogels are more suitable as templates for the production of nanoparticles than conventional nonaqueous or polymeric systems especially for biomedical applications, considering their exceptional compatibility with biological molecules, cells, and tissues. Hydrogels in the swollen state provide free spaces within the network, which can also serve for nucleation and growth of nanoparticles. In this way, the carrier-hydrogel system acts as a nanoreactor that also immobilizes nanoparticles and provides easy handling [10–14].

Beyond various techniques, the gamma irradiation-induced synthesis offers many advantages over the conventional physical and chemical methods. Radiolytic method is highly suitable for formation of three-dimensional polymer network, i.e., hydrogels, as well as for generation of nanoparticles in a solution (especially metal nanoparticles). This method provides fast, easy, and clean synthesis of hydrogel nanocomposites. Moreover, and probably the most important from the biomedical point of view, is the possibility of simultaneous formation of nanocomposite hydrogel and its sterilization in one technological step.

Despite all the mentioned advantages of radiolytic method, there are not so many investigations and literature related to nanocomposite materials based on nanoparticles incorporated in a hydrogel matrix. Therefore, some achievements in the field of radiolytic synthesis of nanocomposite hydrogels and their properties will be presented in this chapter.

2 Hydrogels

Hydrogels are two- or multicomponent systems consisting of a three-dimensional network of polymer and water that fills the space between macromolecular chains. Depending on the properties of the polymers used, as well as on the nature and density of the network joints, such structures in equilibrium can contain various amounts of water. Typically, in the swollen state, the mass fraction of water in the hydrogel is much higher than the mass of polymer. The hydrophilicity of the network

is due to the presence of chemical groups such as hydroxyl (–OH), carboxyl (–COOH), secondary amide (–CONH–), primary amide ($–CONH_2$), sulfonic ($–SO_3H$), and others that can be found within the polymer backbone or as lateral chains [15]. Nevertheless, it is also possible to produce hydrogels containing a significant portion of hydrophobic polymers, by blending or copolymerizing hydrophilic and hydrophobic polymers [16]. Hydrogels are one of the most promising materials for biomedical applications and have several advantages for wound dressing, contact lenses, drug delivery systems, etc. because of their biocompatibility with blood, body fluids, and tissue [17].

Two classes of hydrogel can be defined: physical gels or pseudogels and chemical or permanent hydrogels. In physically cross-linked gels, the macromolecular chains are connected by transient junctions that arise from either polymer chain entanglements or physical interactions such as ionic interactions and hydrogen bonds. Such types of gels are nonpermanent, and usually they can be converted to polymer solutions by heating. On the other hand, in chemically cross-linked hydrogels, covalent bonds are present between different polymer chains (permanent junctions). Therefore, they are stable and cannot be dissolved in any solvents unless the covalent cross-link points are cleaved [18, 19]. While physically cross-linked hydrogels have the general advantages of forming gels without the need for chemical modification or the addition of cross-linking entities, they also have limitations. It is difficult to decouple variables such as gelation time, network pore size, chemical functionalization, and degradation time; this restricts the design flexibility of a physically cross-linked hydrogel because its strength is directly related to the chemical properties of the gel constituents. In contrast, chemical cross-linking results in a network with a relatively high mechanical strength and, depending on the nature of the chemical bonds in the building blocks and the cross-links, relatively long degradation times. Chemically cross-linked gels are also mechanically stable owing to the covalent bond in these gels.

A special class of hydrogels, which is called stimuli-responsive or intelligent or smart hydrogels, shows an active and significant response (undergo reversible volume phase transitions or gel-sol phase transitions) to small changes in the surrounding environment [20]. Many physical and chemical stimuli have been applied to induce various responses of the smart hydrogel systems. The physical stimuli, which include temperature, solvent composition, light, pressure, sound, electric and magnetic fields, and mechanical stress, will affect and alter molecular interactions at critical onset points. Chemical stimuli, such as pH, ionic factors, and chemical agents, will change the interactions between polymer chains or between polymer chains and solvent at the molecular level. Recently, biochemical stimuli have been considered as another category that involves the responses to antigen, enzyme, ligand, and other biochemical agents. Some systems combine two stimuli-responsive mechanisms into one polymer system, the so-called dual-responsive polymer systems. Smart hydrogels have been used in diverse applications, such as drug delivery systems, in making actuators [21, 22] and valves [23, 24], in the immobilization of enzymes and cells [25, 26], in sensors [27, 28], and in concentrating dilute solutions in bioseparation [29].

3 Radiation Technology

In general, chemical or material engineering mostly applies high temperature and/or high-pressure processes for material synthesis/modification, and quite often a catalyst is required to speed up the reaction. On the other hand, radiation is the unique source of energy which can initiate chemical reactions at any temperature, including ambient, under any pressure, in any phase (gas, liquid, or solid), without use of catalysts [30].

Since the pioneering work of Wichterle and Lim in 1960 [31], the hydrogels have been of great interest, especially in the biomaterials field. In fact, hydrogels have been prepared by chemical methods for a long time. However, in recent years, irradiation techniques have been recognized as highly suitable tool to aid in the formation of hydrogels and being used increasingly around the world. This technology is convenient because the properties of hydrogels can be easily manipulated and adjusted by controlling the radiation dose and rate, and the process of synthesis is very reproducible [32]. The radiation process has various advantages, such as easy process control, the possibility of joining hydrogel formation and sterilization in one technological step (especially important for biomedical application), and the lack of necessity for initiators and cross-linkers, which are possibly harmful and difficult to remove. The radiation technique is clean, because it does not require any extra substances, does not leave some unwanted residues, and does not need any further purification. Moreover, this method has a relatively low running cost. All these qualities make irradiation the method of choice in the synthesis of hydrogels.

Hydrogels can be obtained by radiation technique in a few ways, including irradiation of solid polymer, monomer (in bulk or in solution), or aqueous solution of polymer. Irradiation of hydrophilic polymer in a dry form is rarely applied, so it will not be discussed here. More frequently used method is irradiation of monomer solution. This way is possibly most convenient when the chosen monomer is easily available but its polymer is not. In this method polymerization takes place in the first stage, followed by cross-linking of the formed chains. In this case, particular care has to be taken when using this method for the formation of hydrogels for biomedical use, because many of the monomers used are harmful or even toxic (contrary to the corresponding polymers). After irradiation of such systems, all unreacted residues have been fully extracted afterward, in a separate operation.

Among all methods, the most convenient method of radiation-induced synthesis of hydrogels is the irradiation of polymers in aqueous solution. Such systems, containing neither monomer nor cross-linking agent, are easier to control and to study. Also, with the application of this method, lower number of usually unwanted processes occurs, and hydrogels formed in this way are suitable for biomedical use with no need of further purification (synthesis and sterilization in one technological step) [33].

3.1 Synthesis of Hydrogels

When monomer or polymer solution is subjected to ionizing radiation, reactive intermediates are formed. This can result from direct action of radiation on the

monomer unit or polymer chains and from indirect effect, i.e., reaction of the intermediates generated in water with monomer or polymer molecules. Since the fraction of energy absorbed by each component of the monomer-water or polymer-water system is proportional to its electron fraction, which can be well approximated by the weight fraction, in dilute and moderately concentrated solutions, the indirect effect dominates [34].

It is well known that under the irradiation of aqueous solution, short-lived reactive intermediates of the water radiolysis, such as hydrated electrons (e_{aq}^-), hydroxyl radicals ($OH^\bullet$), and hydrogen atoms ($H^\bullet$), were formed first, and they react with the monomer units or polymer chains. Among these reactive species, hydroxyl radicals are the main species responsible for reactivity transfer from water to the monomer units or polymer chains. They abstract hydrogen atoms from monomer units or macromolecules, and thus monomer or polymer radicals are formed. In the case of monomer radicals, the processes of polymerization and cross-linking occur simultaneously, while the polymer radicals simply cross-linked to form polymer network [35, 36].

For the formation of hydrogels, the most important reaction of macroradicals is intermolecular cross-linking, i.e., recombination of radicals localized on two different macromolecules. Also, the other various reactions in systems can occur, and their importance and role in the competition with intermolecular cross-linking is not always fully recognized. These other reactions include reactions between two radicals, as intramolecular cross-linking as well as inter- and intramolecular disproportionation, and also processes involving one radical, as hydrogen transfer or chain scission. These processes do not result in joining the polymer chains; thus they do not lead to the formation of macroscopic gels [37].

However, during synthesis of hydrogels, an influence on the competition between inter- and intramolecular cross-linking always occurs (Fig. 1). At high polymer concentration (above the critical hydrodynamic concentration, which depends on the molecular weight), the probability that two recombining radicals are localized on different chains is relatively high. In such systems some physical entanglements may become permanent when the entangled chains become joined to the network in at least two points encompassing the entanglement site. The probability of intermolecular recombination decreases by the lowering of polymer concentration to a range where the macromolecules are separate (usually having a coil conformation). Besides concentration, another parameter of which is important for this competition is the way of irradiation, i.e., the dose rate. The combination of high dose rates (pulse irradiation with electron beam) with low polymer concentration may lead to the formation of several tens of even more than a hundred radicals located on every single chain. In these conditions the probability and yield of intermolecular recombination is greatly reduced [38].

Typical examples of simple polymers used for hydrogel formation by this method are poly(vinyl alcohol) (PVA) and poly(vinylpyrrolidone) (PVP). As already mentioned, the irradiation of an oxygen-free aqueous solution induces the radiolysis of water and generation of primary radicals (Eq. 1) [39]:

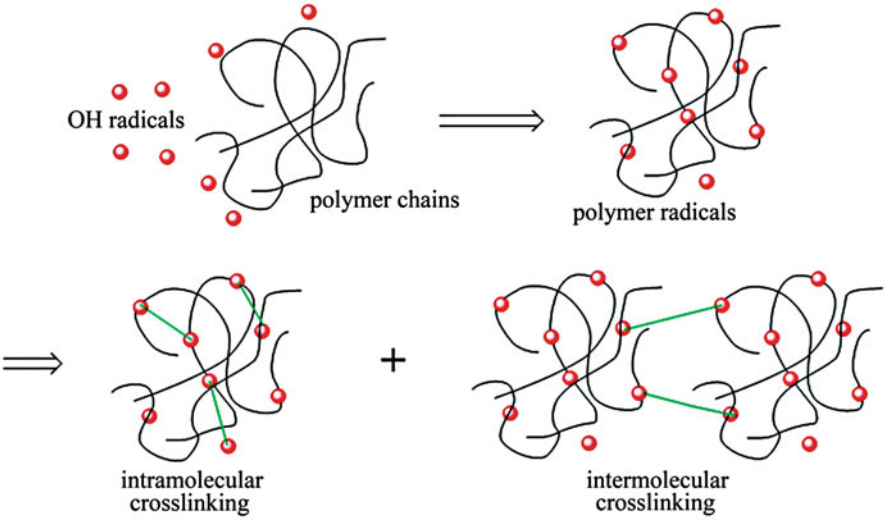

Fig. 1 Schematic representation of polymer cross-linking process (creation of intra- and intermolecular connections)

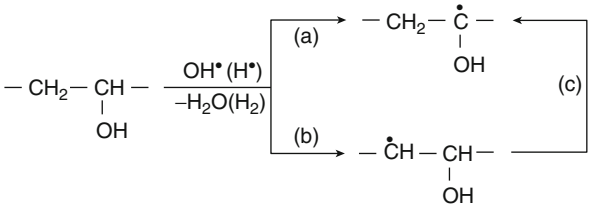
$$H_2O \rightsquigarrow e_{aq}^-, OH^\bullet,\ H^\bullet,\ H_3O^+,\ H_2,\ H_2O_2 \tag{1}$$

In the presence of PVA, both species ($OH^\bullet$ and $H^\bullet$ radicals) abstract preferentially a hydrogen atom in α-position to the hydroxyl group (–CH(OH)–) forming the tertiary radical (~70%) (Eq. 2a), but also from methylene group (–CH_2–) forming secondary radical (~30%) (Eq. 2b). The C-H bond dissociation energy of the secondary hydrogen is somewhat higher than that of the tertiary hydrogen, and therefore the process of radical activity transfer occurs (Eq. 2c) [40, 41].



(2)

These PVA radicals may interact with one another by recombination, disproportionation, and chain scission (by β-fragmentation) [42]. In the case of PVA, the degradation cannot be totally avoided, but its yield is low, and formation of polymer network occurs without any difficulty (G-value for intermolecular cross-linking is 0.48).

Similar situation occurs in the cross-linking process of PVP. The investigations of the reactivity of the primary products of radiolysis with polymer chains in the

process of hydrogel formations have indicated that the rate of reactions of solvated electrons is relatively low, with the rate constant in the range of 10^6 dm^3 mol^{-1} s^{-1}. Comparing this value with constant rate of reactions of hydroxyl radicals, which was determined as higher than 10^8 dm^3 mol^{-1} s^{-1}, it can be concluded that those radicals are the main species of water radiolysis which react with polymer chains [32, 38]. In argon-saturated aqueous solution, $OH^{\bullet}$ radicals attack PVP macromolecules by abstracting hydrogen atoms and thus producing macroradicals. It was suggested that the majority of macroradicals (about 70%) was localized on the main chain of a polymer and formed as a result of hydrogen abstraction at the methylidyne group. Moreover, hydrogen atom abstraction occurs also at methylene group adjacent to the nitrogen at pyrrolidone ring [43, 44]. The result of recombination of produced macroradicals is the formation of polymer network, i.e., hydrogel.

As already mentioned, irradiation can be used to synthesized the hydrogel from the monomer solutions. For example, hydrogels of poly(N-isopropylacrylamide/itaconic acid) (P(NiPAAm/IA)) can be synthesized by radiation-induced simultaneous polymerization and cross-linking of an aqueous solution of the monomers without any additional materials such as initiator and/or cross-linker [45]. In this case, monomeric radicals are generated by both the direct effect of radiation and the indirect effect based on the reaction of the products of water radiolysis with the monomers [35, 36]. In this way, first short-lived reactive intermediates of the water radiolysis, such as hydrated electrons (e_{aq}^-), hydroxyl radicals ($OH^{\bullet}$), and hydrogen atoms ($H^{\bullet}$), were formed and they react with the monomers. The double bonds of −C=C− on NiPAAm and of IA were broken, and generated free radicals react with each other and start copolymerization [46]. At low irradiation dose, the polymer network consists of chains united through multifunctional junctions with no or just few closed effective cross-links, thus forming giant molecules with branches and entanglements. But, by further irradiations, these reactive species can also abstract hydrogen from the growing polymer chains, producing thus polymer radicals that may further react and finally form cross-linked polymer network [36, 47, 48]. Radiation-induced copolymerization of NiPAAm and IA is a free radical process and can be represented by Fig. 2.

3.2 Synthesis of Nanoparticles Within Hydrogels

In general, the obtained polymer network possesses the huge hydrated space between cross-linked polymer chains and can be used as a matrix for formation of nanoparticles (NPs). In colloidal chemistry, the process of particle growth usually occurs through the Ostwald ripening mechanism. As a result, the particle size increases continuously during growth because the larger particles grow on account of dissolution of smaller ones [49]. A convenient procedure to restrict their growth is the *in situ* synthesis of nanoparticles within the polymer matrix with an improved architecture, i.e., within the three-dimensional network of hydrophilic polymers. Thus formed nanoparticles are entrapped in polymer network, and as a result, a novel inorganic/organic hybrid cross-linked nanocomposite was obtained.

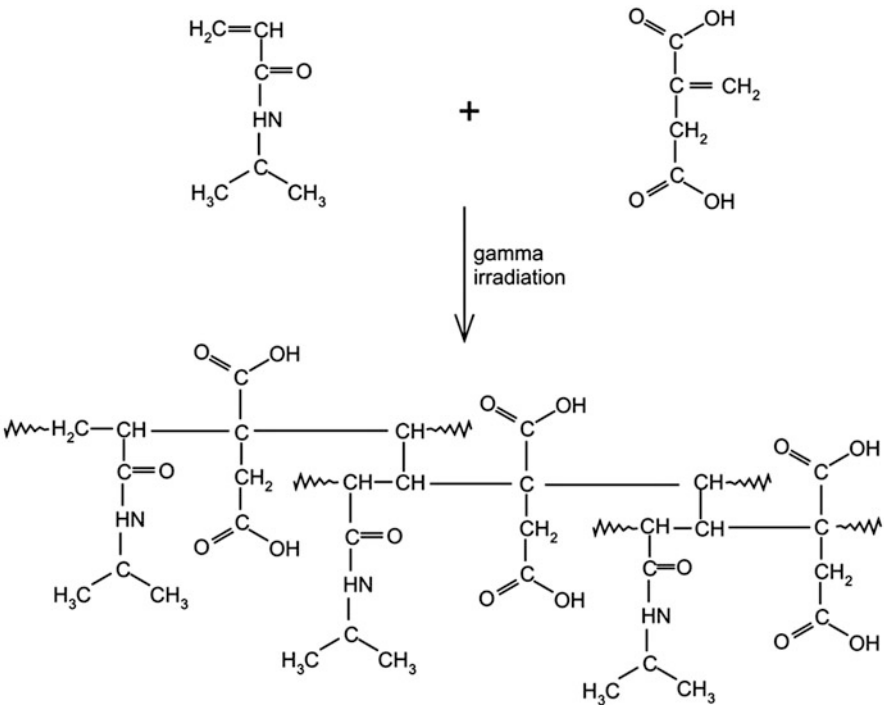


Fig. 2 Schematic representation of formation P(NiPAAm/IA) polymer network [45]

Synthesis of nanocomposites based on different types of nanoparticles incorporated into polymer network, i.e., hydrogels, can be conducted by several various pathways [50]. Not the easiest, from the practical point of view, but probably most convenient is the two-step synthesis procedure (Fig. 3) due to several advantages. The process of polymer cross-linking, as a separate step, in the absence of nanoparticles or their precursors (ions) allows formation of polymer network with the defined and stable 3D structure, further used as a template for incorporation of different types of nanofiller. On the other hand, in the second step of irradiation (synthesis of nanoparticles), this predefined structure of the polymer matrix and applied experimental conditions (absorbed dose and dose rate) can provide a control of size of nanoparticles and their homogeneous 3D distribution through the polymer network [51].

The preparation of metal nanoparticles has received increasing attention due to their unique properties. Noble metal particles such as silver and gold are of great significance due to their size-dependent optical properties [52–54]. Moreover, size effect was also observed for antibacterial activity of silver nanoparticles [55]. A large number of synthetic procedures have been employed in order to synthesize metal nanoparticles and/or nanocomposites. It has been shown that morphology, particle size distribution, stability, and properties of metal nanoparticles as well as corresponding nanocomposites are strongly dependent on the method of

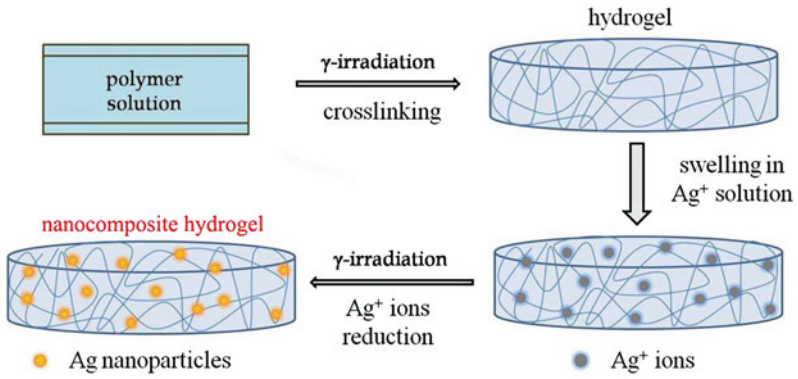

Fig. 3 The two-step irradiation-induced synthesis of nanocomposite hydrogels

preparation and specific experimental conditions. However, the synthesis of nanoparticles of desired shape and uniform size distribution within the matrix remains challenging.

The radiolytic method is suitable for generation of metal particles, particularly silver, in solution. The radiolytically generated species, solvated electrons and secondary radicals, exhibit strong reducing potentials, and consequently metal ions are reduced at each encounter, while the control of particle size is commonly achieved by the use of capping agents such as polymers [56–58].

The ions of noble metals, as well as of many electronegative metals, can be reduced by exposing their aqueous solutions to γ-irradiation. The main reactive radicals among the primary products are solvated electrons (e_{aq}^-), hydroxyl radicals ($OH^\bullet$), and hydrogen atoms ($H^\bullet$). The solvated electrons (e_{aq}^-) and hydrogen atoms ($H^\bullet$) are strong reducing agents, while the hydroxyl radicals ($OH^\bullet$) are able to oxidize the ions or the atoms into a higher oxidation state and thus to counterbalance the reduction reactions. For this reason, an $OH^\bullet$ radical scavenger is added in the solution. Among various possible molecules, the preferred choice is for solutes whose oxidation by $OH^\bullet$ yields radicals that are unable to oxidize the metal ions but, in contrast, themselves exhibit strong reducing power, such as the radicals of secondary alcohols. Most commonly used scavenger is 2-propanol which converts $OH^\bullet$ and $H^\bullet$ radicals into 2-propanol radicals ($(CH_3)_2C^\bullet OH$) (Eqs. 3 and 4) [57]:

$$(CH_3)_2CHOH + OH^\bullet \rightarrow (CH_3)_2C^\bullet OH + H_2O \quad (3)$$

$$(CH_3)_2CHOH + H^\bullet \rightarrow (CH_3)_2C^\bullet OH + H_2 \quad (4)$$

At the argon-saturated solutions, for example, Ag^+ ions are reduced into zero-valent Ag atoms (Ag^0) with strongly reducing hydrated electrons (Eq. 5), 2-propanol (Eq. 6), and the polymeric radicals (Eq. 7), formed in the hydrated polymer network structure as primary and secondary reactive species during gamma irradiation:

$$Ag^{+} + e_{aq}^{-} \rightarrow Ag^{0} \tag{5}$$

$$Ag^{+} + (CH_3)_2C^{\bullet}OH \rightarrow Ag^{0} + (CH_3)_2CO + H^{+} \tag{6}$$

$$Ag^{+} + \text{polymer}^{\bullet} \rightarrow Ag^{0} + \text{polymer} + H^{+} \tag{7}$$

The produced Ag^0 atoms are homogeneously dispersed throughout the hydrogel network. Because the binding energy between two metal atoms is stronger than the atom-solvent or atom-ligand bond energy, these Ag^0 atoms tend to dimerize (Eq. 8) when they encounter and/or associate with an excess of ions (Eq. 9) and by cascade of coalescence processes progressively grow (Eq. 10), yielding the formation of metal clusters with higher nuclearities:

$$Ag^{0} + Ag^{0} \rightarrow Ag_2 \tag{8}$$

$$Ag^{0} + Ag^{+} \rightarrow Ag_2^{+} \tag{9}$$

$$Ag_n + Ag^{+} \rightarrow Ag_{n+1}^{+} \tag{10}$$

The fast collision reactions of ions with atoms or clusters play very important role in the mechanism of cluster growth. Reduction processes of free and adsorbed Ag^+ ions (may be reduced at any stage of the coalescence) are competitive, and they are controlled by formation rate of reduction radicals. Therefore, the formation of clusters by direct reduction, accompanying with collision, is dominant at higher dose rate, when the nanoparticles with smaller dimensions were obtained [59, 60].

Furthermore, besides the metal nanoparticles, the irradiation method can be used for synthesis of semiconductor nanoparticles [9]. The mechanism of gamma irradiation-induced synthesis of semiconductor nanoparticles, in the presence of thiol, has already been known [61–63]. The thiol reacts with the solvated electrons (Eq. 11) and $OH^{\bullet}$ radicals (Eq. 12) to form hydrogen sulfide anion (HS^-) and thiyl radicals ($CH_3(CH_2)_{11}S^{\bullet}$), respectively:

$$CH_3(CH_2)_{11}SH + e_{aq}^{-} \rightarrow CH_3(CH_2)_{10}CH_2^{\bullet} + HS^{-} \tag{11}$$

$$CH_3(CH_2)_{11}SH + OH^{\bullet} \rightarrow CH_3(CH_2)_{11}S^{\bullet} + H_2O \tag{12}$$

When the gamma irradiation occurs in acidic solution (pH ≈ 5), thiol also can react with $H^{\bullet}$ atoms instead with solvated electrons (Eq. 11), but according to the rate constants, the reaction with solvated electrons is favored [63]. The thiyl radicals produced via reaction (12) dimerize to produce disulfide ($(CH_3(CH_2)_{11}S)_2$). Finally, the PbS molecules formed through reaction (13) and then coalesce to form nanoparticle (Eq. 14):

$$Pb^{2+} + HS^{-} \rightarrow PbS + H^{+} \tag{13}$$

$$n\text{PbS} \rightarrow (\text{PbS})_n \tag{14}$$

The final size of PbS nanoparticles can be controlled by concentration ratio of thiol/lead ions, as well as by the dose rate and total absorbed dose.

4 Nanocomposite Hydrogels

4.1 Nanocomposite Hydrogels with Silver Nanoparticles

Silver nanostructures, due to their size-dependent properties, exhibit significantly improved catalytic and electronic properties, and distinctive shape-dependent optical properties [52, 64], making them highly attractive for the use in the development of modern technologies. Morphological anisotropy of nanoparticles induces anisotropic optical absorption properties, bringing difference in the color, as well as optical absorption spectra, associated with the collective oscillations of the conduction electrons [65]. Silver, having the highest electrical and thermal conductivity among all metals, is an important material that has been used in various commercial applications [66, 67]. However, zero-charged nanocrystalline silver, i.e., silver nanoparticles (AgNPs), exhibits powerful antimicrobial capabilities and broad inhibitory biocidal spectra for variety of microbes, including bacteria, viruses, and eukaryotic microorganisms. Enhanced antibacterial properties of silver nanoparticles have been demonstrated both *in vitro* and *in vivo* [68–70].

From the practical point, nanocomposite systems with incorporated silver nanostructures are one of the most investigated new materials. Among all of them, special attention is paid to the nanocomposite hydrogels due to a wide range of applications. Hydrogels have the possibility to absorb large amounts of water and biological fluids; they are biocompatible, and therefore, they are often used in patient care and wound dressings [20]. Hydrogels facilitate autolysis and may be beneficial in the management of ulcers containing necrotic tissue. For example, debridement with hydrogels is more effective than standard wound care for healing diabetic foot ulcers [71]. A potential problem for the biomedical application of hydrogels is that microorganisms may grow in hydrogel materials because of their natural biocompatible properties. Therefore, the incorporation of antibacterial agents is required. However, the emergence of antibiotic-resistant bacteria as a result of the excessive use of antibiotics has led to a demand for newer antimicrobials. The increasing need to develop new formulations to solve this problem has led to considerable interest in the use of nanomaterials as new types of antimicrobials. It is well known that nanosilver has been proven to be probably the most effective antimicrobial agent. The multilevel antimicrobial mode of silver is particularly important for the treatment of wound infections in diabetic patients, which are usually polymicrobial, with the majority of infections being caused by aerobic Gram-positive *cocci* (predominantly *Staphylococcus aureus* and hemolytic *streptococci*) [72, 73].

The recent studies suggest that Ag nanoparticles exert toxicity to bacteria and other organisms not by direct particle-specific effect but by released Ag^+ ions [74]. When the pathways in the antibacterial activity and eukaryotic toxicity of Ag nanoparticles involve the Ag^+ ions and its soluble complexes, Ag nanoparticles

behave in analogy to a drug delivery system, in which the particle contains a concentrated inventory of an active species, the ions [75]. Although the importance of Ag^+ ions in the biological response to Ag nanoparticles is widely recognized, there is significant potential to improve nano-Ag technologies through hydrogel-controlled release formulations. Moreover, for the use of nano-Ag-loaded hydrogels in biomedicine, it should be possible to modulate the release of Ag^+ ions, which could be delivered to the patient at a controlled rate. This would allow the achievement of adequate concentrations and prolonged effectiveness. In general, it is known that the release of a soluble drug entrapped in a hydrogel should be closely related to the swelling characteristics of the hydrogels. That is because the release occurs only after the fluid penetrates into the polymeric network and dissolves the drug; this is followed by diffusion along the aqueous pathways to the surface of the device [76].

Krstić et al. [4] investigated the nano-Ag/PVA hydrogel device, synthesized by *in situ* gamma irradiation method, with the aim of designing a hydrogel-controlled release system of Ag^+ ions for antibacterial purposes. The *in vitro* Ag^+ ion release study showed sustained and controlled release in a solution with a pH similar to the biological fluids, with the release profiles of silver similar with the other drugs. Therefore, the elements of the drug delivery paradigm were applied for the study of Ag^+ ion release kinetics. It was found that the release of Ag^+ ions was predominantly controlled by a diffusion process, i.e., by the mass transport rate due to a concentration gradient of Ag^+ ions (Fickian diffusion). Moreover, the Ag^+ ion release can be adjusted by the concentration of AgNPs as well as by their size. The investigated nano-Ag/PVA nanocomposite hydrogels showed antimicrobial activity against Gram-positive *Staphylococcus aureus* and Gram-negative *Escherichia coli* [4].

Silver shows bactericidal activity at concentrations as low as 0.035 ppm without toxic effects to mammalian cells [77]. However, the typical minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) against standard reference cultures and multidrug-resistant organisms are 0.78–6.25 and 12.5 ppm, respectively [78]. A silver concentration of up to 1.2 ppm has no cytotoxic effect on fibroblasts *in vitro*, which play a critical role in wound healing. However, in general, cytotoxic effects seem to be dose-dependent [79]. The maximum toxic concentration for human cells is around 10 ppm. However, some authors have suggested that for topical use, Ag nanoparticles induce apoptosis at concentrations of up to 250 μg/mL (ppm), which could favor scarless wound healing [78]. Except for their use as antimicrobial topical dressings, nano-Ag/hydrogel systems could be applied for orthopedic implants, such as artificial cartilage, intervertebral discs, and artificial meniscus or tissue expander devices [80, 81].

When developing novel biomaterials, it is necessary to evaluate their biocompatibility and functionality, the latter of which is often related to certain biomechanical properties. Investigations of material functionality can be carried out by exposure of the material to *in vivo* conditions or to biomimetic simulations *in vitro*, followed by determination of the mechanical properties. *In vitro* conditions exhibit advantages in providing precise control and avoiding the complex *in vivo* environment. This type of investigation can be performed in biomimetic tissue engineering bioreactors. Bioreactor that mimics conditions in articular cartilage

and combines dynamic compression and medium flow through the cultivated tissue [82] was used to examine the mechanical behavior of Ag/PVP nanocomposite hydrogels [83]. Mechanical properties of investigated hydrogels varied from series to series, suggesting relative inhomogeneity of the PVP network and significant dependence of its properties to random processes of polymer cross-linking by radical polymerization and Ag^+ ion reduction. Having in mind high compression moduli of human articular cartilage [84], PVP and Ag/PVP nanocomposite hydrogels have not exhibited mechanical properties necessary for the use as soft tissue implants, but they meet requirements needed for the mechanical properties of wound dressings [83].

Biocompatibility of Ag/PVP nanocomposites was investigated by cytotoxicity assays in peripheral blood mononuclear cell (PBMC) and human cervix carcinoma cell (HeLa) cultures [79]. It was shown that the cytotoxicity of AgNPs released from Ag/PVP nanocomposites is dose-dependent, so that slight cytotoxicity is induced by Ag/PVP nanocomposites synthesized from 1 mmol dm^{-3} $AgNO_3$ solution. Kinetics of silver release was examined under static conditions, continuous SBF perfusion (in perfusion bioreactors), and under dynamic compression coupled with SBF perfusion (in the biomimetic bioreactor simulating *in vivo* conditions in articular cartilage). Diffusion was the dominant mechanism of silver release in static conditions and under SBF perfusion, while a slight contribution of dynamic compression was observed in the biomimetic bioreactor. Silver release kinetics modeling provided estimation of the time allowed for PBMC to be safely exposed to Ag/PVP nanocomposites under static and perfusion conditions (e.g., as wound dressings) of about 3 days. In wound dressing applications, it is a reasonable time for dressing replacement. In addition, it is estimated that concentrations of silver released from an Ag/PVP nanocomposite implant in articular cartilage in a knee joint would be well below the levels that would cause even slight cytotoxicity as determined in this study [79].

Among stimuli-responsive or intelligent hydrogels, from a biomedical point of view, thermo- and pH-sensitive polymers are the most frequently studied, because the temperature and pH are two factors that are most often changed in a physiological, biological, and chemical systems. Many previous works have been focused on the thermosensitive polymers because of their fundamental and technological interest [85, 86]. Poly(N-isopropylacrylamide) (PNiPAAm) is one of the most investigated thermosensitive polymers with a sharp lower critical solution temperature (LCST) between 30°C and 35°C for PNiPAAm (depending on the detailed microstructure of the macromolecules) [87]. The LCST represents the temperature at which the hydrophobic forces (due to interaction of the $-NCH(CH_3)_2$ groups), which lead to insolubility in an aqueous environment, are balanced by H-bonding with water, which maintains a polymer in solution. Below the LCST value, a hydration shell around the hydrophobic groups is formed by hydrogen bonds between the hydrophilic groups in the side chains and water, causing water uptake and swelling of the PNiPAAm. If the external temperature increases above the LCST, the scission of the hydrogen bonds occurs and hydrophobic interactions prevail, causing the leaching of water and collapsing of PNiPAAm, indicating the occurrence of phase separation and volume change. In general, it is well known that

the volume phase transition temperature (VPTT) of PNiPAAm-type hydrogel can be adjusted very near to human body temperature (between 37 °C and 41 °C, which is the temperature range of body in response to some diseases) by copolymerization or utilization of additives, which makes them suitable for *in vivo* applications. The addition of hydrophilic ionic comonomers, such as itaconic acid (IA), maleic acid (MA), or methacrylic acid (MAA), may provide that thermosensitivity of PNiPAAm can be controlled by pH value of the external media [88–91].

Spasojević et al. investigated dual-responsive, i.e., thermo- and pH-sensitive, Ag-P(NiPAAm/IA) nanocomposite hydrogel obtained by irradiation method [45]. It was shown that increasing of IA content in polymer network increases equilibrium swelling degree value of hydrogels, but it is also increases the VPTT. For the P(NiPAAm/IA) hydrogels, VPTT increases in the range from 30 °C to 42.8 °C with increasing of IA content in network from 0 up to 4.5 wt%. The same trend can be observed also for Ag-P(NiPAAm/IA) nanocomposite hydrogels, but with somewhat lower values of VPTT, in the range from 30.5 °C to 38.5 °C. Such results indicate that the fine-tuning of VPTT values can be achieved by incorporation of AgNPs in copolymer network.

The investigated homopolymeric hydrogels did not show pH dependence of the swelling degree, as expected. In contrast, the swelling of the copolymeric hydrogels was strongly dependent on the pH value of the external medium. At low pH values, the swelling degree was low because the carboxylic groups in the side chains were not ionized and intermolecular complexation via H-bonds occurred. This complexation results in increased hydrophobicity of the network and lower SD values [92]. As the degree of ionization increased above nominal pKa values of IA (pKa1 3.85 and pKa2 5.44) [93], the greater swelling degree was observed due to the three reasons: most of the H-bonds are broken, COO^- ions are more hydrophilic than COOH groups, and the electrostatic repulsion between the COO^- ions pushes the network chains apart. The most pronounced pH sensitivity was observed for the samples with highest IA content. Moreover, the incorporation of AgNPs induced slightly decrease in swelling capacity, in comparison with corresponding hydrogels without AgNPs. This was probably caused by the restriction of the large-scale segmental motion of the polymer chains and partial occupation of free space by AgNPs [4, 45]. Furthermore, by increasing of IA content, copolymeric hydrogels become weaker, and such mechanical behavior is in agreement with obtained network parameters. On the other hand, incorporation of AgNPs into polymer matrix improves mechanical properties, especially for systems with a higher IA content. As expected, investigated Ag-P(NiPAAm/IA) hydrogel nanocomposites showed good antibacterial potentials against both Gram-positive and Gram-negative bacteria [45].

4.2 Nanocomposite Hydrogels with Semiconductor Nanoparticles

Semiconductor nanoparticles or quantum dots, such as lead sulfide (PbS), cadmium sulfide (CdS), and zinc sulfide (ZnS), have specific optical and electronic properties

because of their quantum size and dielectric confinement effects. These properties are tunable by varying the size and the morphology of the particles. Nowadays, the challenge is to control these two factors in order to reach the best conditions, permitting the synthesis of adequate materials for advanced technologies.

Among semiconductor nanoparticles, PbS has been used in several areas such as light-emitting diodes, infrared detectors, optic fibers, infrared lasers, solar energy panels, window coatings, and environment as Pb^{2+} sensors [94, 95]. This wide range of applications is due to its interesting physical properties. The particularly narrow bandgap of PbS gives the possibility to tune the optical absorption in a large domain by reducing the size to the nanometric scale. But, the challenge is not only to synthesize extremely small PbS nanoparticles but also monodispersed ones. Several methods have been used to produce PbS nanoparticles in different environments such as zeolites, glasses, polymers, and inverse micelles or in colloidal state. The radiolytic method has been proven to be an adequate tool to synthesize monodispersed and size-controlled semiconductor nanoparticles. The particle size can be tailored by controlling the irradiation dose. In this way, PbS, CdS, and ZnS particles have been synthesized in the presence of mercaptoethanol [61–63].

Recent research describes a simple and effective method for preparation of PbS/PVA hydrogel nanocomposite [9]. Namely, the radiolytic *in situ* synthesis of PbS nanoparticles within the PVA hydrogel, previously cross-linked also by gamma irradiation, was achieved. The obtained PbS/PVA nanocomposite hydrogel shows the optical properties characteristic for semiconductor nanoparticles (quantization effects). The incorporated PbS nanoparticles are around 5 nm in diameter, with the bandgap energy of 1.84 eV. Incorporation of these nanoparticles into PVA hydrogel induces the slightly decreasing of swelling capacity of PbS/PVA nanocomposite hydrogel compared with PVA hydrogel. This probably occurs because the incorporated PbS nanoparticles can act as some sort of additional junction point in polymer network [96, 97]. Therefore, the thermal stability of PbS/PVA nanocomposite hydrogel is slightly enhanced.

This class of nanomaterials can be used for the fabrication of novel photonic materials and "solid-state" solar devices where the spacing between nanoparticles can be tuned for optimum photovoltaic efficiency. In particular, *in situ* growth of PbS nanoparticles in PVA 3D hydrogel matrix could produce soft 3D material nanocomposites with optical nonlinearity (metamaterials), opening perspectives for its application in special optical devices requiring small bandgap semiconductors embedded almost in water (optical properties of PVA are similar to water) [98, 99].

4.3 Nanocomposite Hydrogels with Magnetic Nanoparticles

The combination of magnetic nanoparticles with polymers in order to obtain colloidal or composite stable systems had attracted much interest. Magnetic nanoparticles are investigated in different areas because they are used in a wide range of applications in science, industry, and medicine. In particular, magnetic nanoparticles are used in data storage, medical drug delivery, hyperthermia, and bioseparation

[100]. Magnetic field sensitive gels (ferrogels) are new promising class of nanocomposite hydrogels. Zrinyi et al. developed magnetic field sensitive gels in which magnetic particles of colloidal size are dispersed and incorporated into the gels [101]. These ferrogels combine the magnetic properties of magnetic fillers and the elastic properties of gels. When the gels were placed into a spatially nonuniform magnetic field, forces act on the magnetic particles, and as result of strong interaction between magnetic particles and polymer chains, they all move together as a single unit. The coupling of hydrogels and magnetic particles has potential application in soft actuators such as artificial muscles [102]. On the other hand, recently the use of magnetic sensitive hydrogels has been explored for hyperthermia applications. The polymer networks have properties which make the hydrogels suitable for applications in controlled drug delivery systems, while the magnetic particles, with ferromagnetic or superparamagnetic properties, are used for magnetic hyperthermia [103].

In order to obtain magnetic sensitive hydrogels, magnetic nanoparticles can be incorporated in polymer network by loading coprecipitation technique as well as by radiation reduction technique [7]. In the both case, the hydrogel matrix was firstly obtained by irradiation-induced cross-linking of polymer chains. The synthesized quasi-spherical magnetite (Fe_3O_4) nanoparticles were well dispersed in the polymer matrix, with the average particle size around 30 nm. Investigated ferrogels possessed good loading capacity toward doxorubicin hydrochloride (model drug), while the releasing behavior was highly dependent on the pH values of the normal and tumor cells. The anticancer drug release was also affected by the difference between normal tissue that contains tightly connected endothelial cells which prevents the diffusion of the nanomedicines outside the blood vessel and tumor tissue which contains large fenestration between the endothelial cells allowing the nanomedicines to reach the matrix and the tumor cells [104]. These results may offer a suitable way for the preparation of anticancer drug carriers for tumor combination therapy aiming to increase anticancer activity and lower toxicity.

Moreover, ferrogels can be prepared by irradiation-induced cross-linking of polymer chains in the presence of magnetic nanoparticles [6]. In this case, the magnetite nanoparticles were synthesized by coprecipitation method, dispersed in the PVA solution, and exposed to the gamma irradiation to obtain nanocomposite hydrogel. This study shows that irradiation cross-linking of polymer in the presence of particles doesn't interrupt processes of intra- and/or intermolecular cross-linking of PVA chains, giving PVA/Fe_3O_4 ferrogel.

5 Conclusion

In general, nanocomposite hydrogels can be defined as cross-linked polymer network, swelled by water, with entrapped nanoparticles. The incorporated nanoparticles add unique physicochemical properties to polymer hydrogels such as responsiveness to mechanical, optical, thermal, sound, magnetic, electric stimulation, etc. These unique properties lead to applications in such different fields, such

as in the electronics, optics, sensors, actuators, and microfluidics sectors, as well as catalysis, separation devices, drug delivery systems, wound dressings, soft tissue implant, and many other biomedicine and biotechnological areas. The huge success of hydrogel systems as biomaterials lies in their resemblance to living tissue because of their high water content which minimizes the frictional irritation of surrounding tissue. Additional advantages of those materials are their nontoxicity, non-irritability, and chemical stability.

Nanocomposite hydrogels can be synthesized by different chemical and physical methods. Among them, irradiation-induced synthesis offers a number of advantages. This method provides fast synthesis and easiness of process control. Moreover, it is green and eco-friendly synthesis because there is no need to use the initiators, cross-linkers, and reducing agents; all reactions in the system are initiated by the product of water radiolysis. Probably the most important, from the biomedical point of view, is the possibility of simultaneous nanocomposite hydrogel synthesis and their sterilization in one technological step.

Despite all the mentioned advantages of irradiation-induced synthesis as well as the nanocomposite hydrogels prepared by this method, research in this area is not so much widespread.

6 Future Scope

In the field of nanocomposite hydrogels, as a relatively new class of hybrid materials, lies tremendous potential for future investigation and applications in many different fields. It is well known that using irradiation for synthesis and modification of nanocomposite hydrogels has numerous advantages, especially for production of biomaterials. On the other hand, it is still a long way to transfer research knowledge into production facilities, in order to extend the use of these materials. However, since the healthcare is one of the main priorities, it seems that research in this area will become even more important and the radiation technology will get an opportunity to show all possibilities.

Abstract

This review presents the past and current efforts with a brief description on the featured properties of conductive and smart hydrogel fabricated from biopolymers and natural ones for different applications. Many endeavors have been exerted during the past 10 years for developing new smart hydrogels. This review mainly focuses on the effect of different irradiation methods for improving the properties of smart hydrogels. As the hydrogels with single component have low mechanical strength, recent trends have offered composite or hybrid hydrogel membranes to achieve the best properties. So this chapter provides the reader good information about the irradiation effects on producing the smart conductive hydrogels and perspective on further potential developments.

Keywords

Hydrogel · Conductive · Smart · Irradiation · Cellulose

1 Introduction

Hydrogels are cross-linked polymeric networks that have the ability to swell when suspended in water. These absorbent polymers have a wide range of applications, such as sustained-release drug delivery systems, contact lenses, biosensors, personal care products, and medical, pharmaceutical, and agricultural fields. Hydrogels are macromolecular networks able to absorb and release water solutions in a reversible manner, in response to specific environmental stimuli. Such stimuli-sensitive behavior makes hydrogels appealing for the design of "smart" devices, applicable in a variety of technological fields. However, the functional hydrogel displays poor biocompatibility and biodegradability due to petrochemical products as the raw material. Therefore, using renewable resources as raw materials to prepare hydrogels is getting more and more attention. Temperature- and pH-sensitive hydrogels were prepared successfully by using natural polymers and their derivatives, such as chitosan, sodium alginate, dextran, cellulose, etc., as base materials. Cellulose and its derivatives have demonstrated to be versatile materials with unique chemical structure which provides a good platform for the construction of hydrogel networks with distinctive properties as respects swelling ability and sensibility to external stimuli. Indeed, the high density of free hydroxyl groups in the cellulose structure makes them become a solid substrate that can undergo functionalization, allowing the production of new materials for novel advanced applications. From the last decades, there is a growing demand for conductive devices with high performance due to the fast development of electronic industry. Lightweight, high conductivity, and flexibility as well as environmental friendliness are some requirements for these products. Considering the extensive possibilities to use the new materials, this chapter introduces the information on the intelligent conductive cellulose hydrogels, which are able to respond to environmental changes by modification of their characteristics, and finally presents their possible applications in different fields. From this reason, the

present chapter covers the applications of conductive cellulose-based hydrogels in different fields of industry such as the pharmaceutical and biomedical area. Moreover, a series of initiated techniques have been proposed for the production of cellulose-based hydrogels, such as chemical initiation, chemical cross-linking, UV-curing technique, and microwave, plasma, and gamma-ray irradiation. So this chapter provides the reader good information about the irradiation effects on producing the smart conductive hydrogels and perspective on further potential developments.

2 Hydrogels

Hydrogels are three-dimensional, hydrophilic, polymeric networks capable of absorbing large amounts of water or biological fluids. Due to their high water content, porosity, and soft consistency, they closely simulate natural living tissue, more so than any other class of synthetic biomaterials. Hydrogels may be chemically stable, or they may degrade and eventually disintegrate and dissolve. Hydrogels are called "reversible" or "physical" gels if molecular entanglements and/or secondary forces such as ionic, H-bonding, or hydrophobic forces play the main role in forming the network [1].

These absorbent polymers have a wide range of applications in biomedical area, such as sustained-release drug delivery systems; contact lenses; food; cosmetics; high water-absorbing resin; corneal implant; substitutes for the skin, tendons, ligaments, cartilage, and bone; biosensors; wound dressings; tissue engineering; and hygiene products (Fig. 1). Also, super porous hydrogels have been successfully used as soil improvers, slow-release fertilizers, and pesticide-release devices [2].

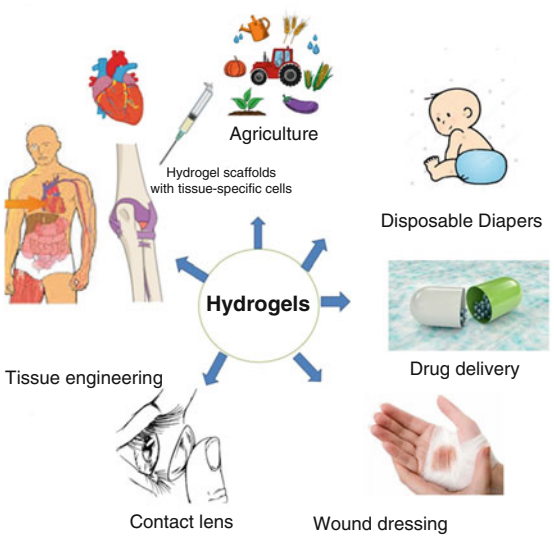

Fig. 1 Application of hydrogels in different branches of industry

The chemical cross-linking, physical entanglement, hydrogen bonds, and ionic bonds are responsible to achieve the network of hydrogels. They can be obtained from the synthetic and natural polymers and depend on various parameters, including the preparation method, charge, as well as mechanical and structural characteristics. It has been reported that the swelling of hydrogels is a complex process comprising of a number of steps. In the first step, the polar hydrophilic groups of the hydrogel matrix are hydrated by water, which appears in the form of primary bound water. In the second step, the water also interacts with the exposed hydrophobic groups, which appear in the form of secondary bound water. The primary bound water and the secondary bound water both form the total bound water. In the third step, the osmotic driving force of the network toward infinite dilution is resisted by the physical or chemical cross-links, so additional water is absorbed. The water absorbed into the equilibrium swelling is called the bulk water or the free water, which fills the spaces between the network or chains and the center of the larger pores. The amount of water absorbed by a hydrogel depends on the temperature and the specific interaction between the water molecules and the polymer chains, which can be explained by the Flory-Huggins theory [3].

It is worth noting that natural polymers have better biocompatibility and less latent toxic effect than most synthetic polymer hydrogels, so pure natural polymer hydrogels would be more suitable for biomaterials. Indeed, polysaccharide-based hydrogels behave as smart materials and offer a variety of properties that can be exploited in several applications. According to those abovementioned, cellulose represents the most abundant renewable and biodegradable polymeric material, being considered as the main constituent of plants and natural fibers. Also, cellulose is an environmentally friendly alternative to conventional materials and exhibits properties that make them very attractive in many applications. Nowadays, cellulose derivative-based hydrogel has gained a great popularity in agriculture and pharmaceutical industry and become more and more important in these fields, owing to the production of the new derivatives with extended applications [4, 5].

On the other hand, intelligent hydrogels, which exhibit sensitive responses to environment, such as temperature, pH, salt, electric field, and chemical environment, are widely applied in sensors, drug release, tissue engineering, and other fields. Various initiated techniques have been proposed for the preparation of smart hydrogels in the past few decades which include chemical initiation, UV-curing technique, microwave or gamma-ray irradiation, etc., but most of the chemical technologies had residual monomers and initiators and in some cases high energy consumption [6].

2.1 Cellulose Hydrogels

Most of the hydrogels are made from synthetic hydrophilic polymers such as poly (acrylic acid) or its copolymer with poly (acrylamide), but due to their biodegradability and low cost, the demand for using natural hydrogels such as starch, cellulose, chitosan, and alginate is continuously increasing. Cellulose is the

most abundant natural polymer and a very promising raw material with low cost for the preparation of its various derivatives [7].

Cellulose is the most abundant naturally occurring polymer of glucose, found as the main constituent of plants and natural fibers such as cotton and linen. Some bacteria (e.g., *Acetobacter xylinum*) are also able to synthesize cellulose. Microbial or bacterial cellulose (BC) is chemically identical to plant cellulose (PC), although possessing different macromolecular structures and physical properties. In both BC and PC, the glucose units are held together by 1,4-β-glucosidic linkages, which account for the high crystallinity of cellulose (usually in the range 40–60% for PC and above 60% for BC) and its insolubility in water and other common solvents. However, BC biosynthesis yields nano-sized fibers, which are about two orders of magnitude smaller than PC fibers. BC cellulose thus shows a peculiar, ultrafine fiber network with high water holding capacity and superior tensile strength compared to PC. Moreover, BC is totally pure, unlike PC which is usually associated with other biogenic compounds, such as lignin and pectin.

Most water-soluble cellulose derivatives are obtained via etherification of cellulose, which involves the reaction of the hydroxyl groups of cellulose with organic species, such as methyl and ethyl units.

The degree of substitution, defined as the average number of etherified hydroxyl groups in a glucose unit, can be controlled to a certain extent, in order to obtain cellulose derivatives with given solubility and viscosity in water solutions. Cellulose-based hydrogels, either reversible or stable, can be formed by properly cross-linking aqueous solutions of cellulose ethers, such as methylcellulose (MC), hydroxypropyl methylcellulose (HPMC), ethyl cellulose (EC), hydroxyethyl cellulose (HEC), and sodium carboxymethyl cellulose (NaCMC). Among the abovementioned cellulose ethers, only NaCMC is a polyelectrolyte and thus a "smart" cellulose derivative which shows sensitivity to pH and ionic strength variations [8–10].

2.2 Application of Cellulose Hydrogels

2.2.1 Superabsorbents for Personal Hygiene Products

A number of studies have been published in recent years documenting the advantages resulting from the use of superabsorbent materials in personal care products and their safety and effectiveness. In addition to keeping skin dry and preventing diaper rash, the SAP helps control the spread of germs in group care settings. The basic idea of diaper recycling is to recover separately the cellulose, which is biodegradable and recyclable, the plastic cover material, and the SAP, both of which are not biodegradable but might be recycled for other uses. The complexity of such a process has prompted the parallel development of biodegradable diapers, i.e., possessing a biodegradable plastic cover, which, however, still contain the nondegradable acrylate-based SAP. An alternative solution to the problem of SAP recycling has been recently suggested and has been envisaged in the use of cellulose-based hydrogels, which are totally biodegradable. Novel hydrogels, based on sodium carboxymethyl cellulose (NaCMC) and hydroxyethyl cellulose (HEC) cross-linked

with DVS, possess swelling capabilities comparable with those displayed by SAP and high water retention capacities under centrifugal loads. Cellulose radiation cross-linking, which does not require the use of further chemicals, might be of value in the development of novel environmentally friendly superabsorbents [5].

2.2.2 Water Reservoirs in Agriculture

There is an increasing interest in using superabsorbent hydrogels in agriculture. A few research studies have been carried out to determine appropriate hydrogel amounts and application rates for different environmental conditions and different plant species. It is worth noting that, being acrylate based, most commercial products are not biodegradable. Cellulose-based hydrogels fit perfectly in the current trend to develop environmentally friendly alternatives to acrylate-based superabsorbent hydrogels. Sannino and coworkers recently developed a novel class of totally biodegradable and biocompatible microporous cellulose-based superabsorbent hydrogels. Such hydrogels are able to absorb up to 1 l of water per gram of dry material, without releasing it under compression [5].

2.2.3 Body Water Retainers

Due to the intrinsic biocompatibility of cellulose, together with the biocompatibility and the versatile properties displayed by hydrogels in biomedical applications, cellulose-based hydrogels are appealing materials for a number of applications in vivo. For example, hydrogels hold promise as devices for the removal of excess water from the body, in the treatment of some pathological conditions, such as renal failure [5].

2.2.4 Devices for Controlled Drug Delivery

Cellulose ethers have long been used in the pharmaceutical industry as excipients in many drug device formulations. Their use in solid tablets allows a swelling-driven release of the drug as physiological fluids come into contact with the tablet itself. The cellulose ether on the tablet surface (e.g., HPMC) starts to swell, forming chain entanglements and a physical hydrogel. As swelling proceeds from the swollen surface to the glassy core of the tablet, the drug progressively dissolves in water and diffuses out from the polymer network. The rate of drug release depends on the water content of the swollen hydrogel, as well as on its network parameters, i.e., degree of cross-linking and mesh size. Controlled release through oral drug delivery is usually based on the strong pH variations encountered when transitioning from the stomach to the intestine [5].

2.2.5 Scaffolds for Regenerative Medicine

Due to their large water content, hydrogels are highly biocompatible, possess rubbery mechanical properties close to those of soft tissues, and usually allow the incorporation of cells and bioactive molecules during the gelling. In the last decade, the use of cellulose and its derivatives as biomaterials for the design of tissue engineering scaffolds has received increasing attention, due to the excellent biocompatibility of cellulose and its good mechanical properties. Nonetheless, it is well known that

a bio-durable material or a too slow degradation may lead to undesired biological responses (e.g., a foreign body reaction) in the long term, which limit the possible applications of cellulose in regenerative medicine. The mechanical stiffness of the hydrogel is also dependent on the degree of cross-linking and should be designed according to the tissues being addressed. Furthermore, the carbodiimide-mediated cross-linking reaction holds promise for the functionalization of cellulose with several biomolecules, able to promote specific cell functions, due to the ability of the carbodiimide to cross-link various polypeptides. This opens a wide range of possibilities for the design of biomimetic, cellulose-based hydrogel scaffolds for tissue engineering [5].

2.2.6 Wound Dressings

Appropriate wound dressings are designed to promote healing while protecting the wound from infection. Various types of hydrogel dressings have been patented so far and are commercially available, based on synthetic or natural polymers, or a combination of them. Due to its purity and high water retention capacity, bacterial cellulose (BC) has been widely investigated for wound healing, and a series of BC-based wound dressings are currently marketed. To the best of our knowledge, gel-forming cellulose derivatives, such as NaCMC, are included in the formulation of some commercially available hydrogel dressings, usually in combination with propylene glycol, which works as a humectant and a preservative [5].

3 Smart Hydrogels

Intelligent hydrogels, which exhibit sensitive responses to environment, such as temperature, pH, salt, electric field, and chemical environment, are widely applied in sensors, drug release, tissue engineering, and others.

3.1 Temperature- and pH-Sensitive Hydrogels

The most important kind of intelligent hydrogels has been paid special attention. Conventional preparations for temperature- and pH-sensitive hydrogels are radical polymerization, interpenetrating to introduce thermosensitive or pH-sensitive monomers, such as *N*-isopropyl acrylamide (NIPAAm) and acrylic acid (AA), and then the temperature- and pH-sensitive hydrogels with three-dimensional network are formed under the effect of cross-linking agents. However, the functional hydrogel displays poor biocompatibility and biodegradability due to petrochemical products as the raw material. Therefore, using renewable resources as raw materials to prepare hydrogels is getting more and more attention. Temperature- and pH-sensitive hydrogels were prepared successfully by using natural polymers and their derivatives, such as chitosan, sodium alginate, dextran, and cellulose as base materials, and all showed good performance. Moreover, hemicellulose, one of the three major components in plant biomass, exists in all cytoderm of plants (constituting about 20–30% of the

biomass). Statistical information shows hemicellulose is one of the most abundant and cheapest renewable resources. But as a result of the complexity and diversity of its structure, the application in intelligent hydrogels was rarely reported [5, 6].

3.1.1 pH-Responsive Hydrogels

Some researchers reported polymeric hydrogels with ionic pendant groups that can accept or donate protons in response to an environmental pH change. In a pH-responsive hydrogel at a specific pH, the degree of ionization known as pKa or pKb is dramatically changed. This rapid change in the net charge of the ionized pendant group causes a sudden volume transition by generating electrostatic repulsive forces between the ionized groups, which creates a large osmotic swelling force. There are two types of pH-responsive hydrogels: anionic and cationic hydrogels. Anionic hydrogels have pendent groups such as carboxylic or sulfonic acid, where deprotonation occurs when the environmental pH is above the pKa leading to the ionization of the pendent groups, which, in turn, increases the swelling of the hydrogel. On the other hand, cationic hydrogels contain pendent groups such as amine groups, where ionization takes place below the pKb, which increases swelling due to the increased electrostatic repulsions [5, 6].

3.1.2 Temperature-Responsive Hydrogels

Temperature-sensitive hydrogels are defined by their ability to swell and shrink when the temperature changes in the surrounding fluid, which means the swelling and deswelling behavior mostly depends on the surrounding temperature. Temperature-responsive hydrogels can be classified as positive or negative temperature-responsive systems [5, 6].

Positive Temperature Hydrogels

Positive temperature hydrogels are known by the upper critical solution temperature (UCST).

This means that when the temperature is below the UCST, the hydrogels contract and release solvents or fluids from the matrix (dehydration). At temperatures higher than the UCST, swelling takes place. In view of the above, it can be concluded that these types of hydrogels are retrogressive at negative temperatures. Positive temperature hydrogels shrink at low temperatures because of the formation of a complex structure by the hydrogen bonds. The structure dissociates at a high temperature due to the breaking of the hydrogen bonds, and the gel will swell to the maximum possible extent rapidly above the UCST. There are a lot of polymers and copolymers that are positively temperature dependent, such as poly (AAm-co-BMA) acrylic acid (AA) and *N*-isopropyl acrylamide (NIPAAm) as monomers and *N*,*N*-methylene double acrylamide (MBA) as cross-linking agents [5, 6].

Negative Temperature-PHGs

This kind of hydrogel has a critical parameter called low critical solution temperature (LCST), which means that the hydrogels will shrink when the temperature increases above the LCST and will show a swelling behavior when lower than the LCST.

The LCST is the most important parameter for negative temperature-sensitive hydrogels and can be changed in different ways, such as by mixing a small amount of ionic copolymer in the gels or by changing the solvent composition. In general, the LCST of a polymer with more hydrophobic constituent shifts to lower temperatures. By changing the ratio of hydrophobic to hydrophilic content of the structure of hydrogels, the LCST will be changed. Such hydrogels have two parts: the first is the hydrophilic part, CONH, and the second is hydrophobic part, R. At temperatures lower than the LCST, water or fluid interacts with the hydrophilic part by forming hydrogen bonds. Because of these hydrogen bonds, the dissolution and swelling will improve. As the temperature increases to greater than the LCST, the hydrophobic interaction with the hydrophobic part will be stronger, while at same time, the hydrogen bonds will become weaker. Therefore, shrinking of sample will occur due to the interpolymer chain association, and the absorbed fluid will go out through a deswelling process. An example is the PVP/PNIPAAm-based negatively thermosensitive drug release hydrogel [5, 6].

3.2 Stimuli-Responsive Hydrogels

Stimuli-responsive hydrogels respond to environmental stimuli and experience unexpected changes in their growth actions, network structure, mechanical strength, and permeability, hence called environmentally sensitive, smart hydrogels. Physical stimuli include light, pressure, temperature, electric fields, magnetic fields, mechanical stress, and the intensity of various energy sources, which change molecular interactions at critical onset points. Chemical stimuli include pH, ionic factors, and chemical agents, which change the interactions between polymer chains and solvents and between polymer chains at the molecular level.

Another class, which is called dual-responsive hydrogels, results from a combination of two stimuli-responsive mechanisms in one hydrogel system. Polyacrylic acid-co-polyvinyl sulfonic acid is an example of a dual-responsive polymer system. A biochemical stimulus involves the responses to ligand, enzyme, antigen, and other biochemical agents. So, stimuli-responsive hydrogels are attractive biomaterials for pharmaceutical, biomedical, and biotechnology applications [5, 6].

4 Conductive Hydrogels

Electroconductive hydrogels (ECHs) are polymeric blends or components that combine integrally conductive electroactive polymers (CEPs) with vastly hydrated hydrogels. Electroconductive hydrogels belong to the general class of multifunctional smart materials. As an emergent class, these materials seek to creatively combine the inherent properties of constituent materials, to give rise to technologically relevant properties for devices and systems as a bio-recognition membrane layer in various biosensors. In one instance, an electroconductive hydrogel that was synthesized from a poly(HEMA)-based hydrogel and poly(aniline) was fashioned

into a biosensor by the incorporation of the recombinant cytochrome P450-2D6. This electroconductive hydrogel was subsequently fully characterized for its electrical, switching, and optical properties and demonstrated faster switching than its purely CEP counterpart. In another instance, an electroconductive hydrogel fashioned from poly (hydroxyethyl methacrylate) [poly(HEMA)] and polypyrrole (PPy) was investigated for its potential application in the clinically important biomedical diagnostic biosensors, by the incorporation of analyte-specific enzymes. Among the various devices for which electroconductive hydrogel polymers were investigated are neural prosthetic and recording devices, electro-stimulated drug release devices, and implantable electrochemical biosensors. In all cases, these polymeric materials, which are both electronically and ionically conductive, provided a non-cytotoxic interface between the device and native living tissue or cell culture medium [3].

Conducting polymer hydrogels (CPHs) represent a unique class of materials that synergize the advantageous features of both the hydrogels and organic conductors. Conducting polymer hydrogels provide an excellent interface between the electronic-transporting (electrode) and the ionic-transporting phases (electrolyte), between natural and synthetic biological systems and between soft and hard materials. As a result, conducting polymeric hydrogels demonstrated promising results for a broad range of recent applications, ranging from energy storage devices, such as biofuel cells and super capacitors, to molecular and bioelectronics and medical electrodes. CPHs have been shown to provide excellent process ability and can be easily cast into thin films and any desired shapes at its gelation stage. CPHs can also be ink-jet printed or screen printed into micro-patterns. Hydrogels, based on conducting polymers, combine the several characteristics of polymeric hydrogels with the electrical and optical characteristic of metals or semiconductors, thus offering an array of features, such as intrinsic 3D microstructured conducting frameworks that promote the transport of charges, ions, and molecules [11].

5 Application of Smart and Conductive Hydrogels

Polyaniline (PANi), polypyrrole (PPy), and polythiophene (PTh) structures are some suitable raw materials. The synthetic routes toward conducting polymeric hydrogels include synthesizing a conducting polymer/monomer within a three-dimensional network of hydrogel. Through these methods, nonconductive hydrogels can be converted into conducting hydrogels via in situ polymerization technique of the electrically conductive polymers (ECPs) into the preformed hydrogel three-dimensional network.

Tang et al. developed poly(acrylateaniline)-based conducting hydrogels by employing in situ polymerization procedure [12, 13]. The first step includes the preparation of cross-linked polyacrylamide hydrogel in powder form, followed by in situ polymerization of absorbed aniline in the swollen hydrogel powder by employing potassium persulfate as an initiator. Furthermore, conducting polymer hydrogels (CPHs) have been prepared by various methods, such as the use

of electrically conductive polymer nanoparticles encapsulated into the three-dimensional hydrogel network. Recently, a few novel conducting hydrogels were developed based on only one material, such kind of materials (e.g., polyaniline (PANi), polypyrrole (PPy), polythiophene (PTh), etc.) as the continuous phase (conducting polymeric hydrogels).

Conducting polymer hydrogels (CPHs) have been applied as potential candidates in chemical mimicry of neural networks, implantable electrochemical biosensors, electro-stimulated drug release, etc. CPHs have been proposed as potential conductive flexible electrodes for super capacitor applications, and also it can be used for bioelectronics and energy storage devices and as glucose enzyme biosensors with high sensing speed and sensitivity applications. CPHs have promising applications in lithium-ion battery technology due to their excellent electronic and electrochemical properties. For instance, CPHs can be used to address the challenges faced by next-generation high-capacity alloy-based anodes, such as silicon and germanium. CPHs are a special class of polymeric hydrogels with potential advanced application in bioactive electrode coating, actuators, and tissue engineering field. Another important application has been found in biosensors, which integrate biological sensing elements, such as enzymes, antibodies, nucleic acids, cells, etc. with an electronic transducer equipped with an electronic amplifier.

CPHs possess a number of advantages, such as providing improved electrode interface between the electronic and ionic transport phases, a possibility of casting into different, complex, and flexible shapes and the possibility for the preparation of micro-patterns by ink-jet printing or spray coating [11].

To assist in identifying the utility of novel materials in drug delivery applications, one study investigated the use of bacterial cellulose (BC), a natural biopolymer, in the synthesis of hydrogels for drug delivery systems. The results of swelling and in vitro drug release studies revealed the hydrogels to be both thermo and pH responsive. Such thermo and pH responsiveness, in addition to their morphological characteristics, suggests that these BC/AA hydrogels are promising candidates as controlled drug delivery systems [14].

In the other research, graphene oxide reinforced regenerated cellulose/polyvinyl alcohol (GO–RCE/PVA) ternary hydrogels have been successfully prepared via a repeated freezing and thawing method in NaOH/urea aqueous solution. The effect of GO content on the mechanical properties, swelling behavior, and water content of composite hydrogels was investigated. With the addition of 1.0 wt% GO, the tensile strength was increased by 40.4% from 0.52 MPa to 0.73 MPa, accompanied by the increase of the elongation at break (from 103% to 238%). Meanwhile, GO–RCE/PVA ternary hydrogels performed the excellent pH sensitivity, and the higher pH leaded to higher swelling ratio. With 0.8 wt% GO loading, the swelling ratio of GO–RCE/PVA ternary hydrogel was improved from 150% (pH = 2) to 310% (pH = 14). In addition, a slight increase in the water content of the ternary hydrogel was achieved with increasing concentrations of GO. It is believed that this novel ternary hydrogel is a promising material in the application of biomedical engineering and intelligent devices [15].

In the other research, conductive hydrogel composed of microcrystalline cellulose (MCC) and polypyrrole (PPy) was prepared in ionic liquid; and hydrogels showed relatively high electrical conductivity, up to 7.83×10^{-3} S/cm [16].

Lignosulfonate (Lig), a biopolymer derivative, is a good candidate to be used as super capacitor electrode material because of its electroactive components. The methoxy and phenolic functional groups in Lig can convert to quinone groups through the redox process and function for energy storage. However, it is difficult to directly utilize Lig's electro activity, because of its insulativity. So a composite of Lig/graphene hydrogel (Lig-GH) has been fabricated from a mixture of Lig and graphene oxide (GO) via convenient hydrothermal process by Xiong et al. The results disclosed that the Lig-GH prepared at a mass ratio of Rm = 3:4 and temperature of 180 °C exhibited excellent electrochemical performance. The as-prepared hydrogel possessed high specific capacitance of 549.5 F g^{-1} at a current density of 1 A g^{-1} in 0.1 M $HClO_4$ electrolyte. It also showed excellent cycling stability: 83.7% capacitance retention after 1000 cycles at 20 A g^{-1}. This work provides an innovative strategy to prepare high-performance Lig-GH super capacitor electrodes material by introducing renewable and inexpensive biopolymers [17].

Chang et al. prepared superabsorbent hydrogels from carboxymethyl cellulose sodium (CMC) and cellulose in the NaOH/urea aqueous system by using epichlorohydrin (ECH) as cross-linker. The prepared hydrogels exhibited smart swelling and shrinking in NaCl or $CaCl_2$ aqueous solution, as well as the release behavior of bovine serum albumin (BSA) that could be controlled by changing CMC content [18].

New stimuli-responsive hydrogels have been invented based on inclusion of cellulose nano whiskers (CNW)-polyacrylamide (PAAm) copolymer in poly *N*-isopropyl acrylamide (PNIPAm) semi interpenetrating network (IPN) hydrogel. These hydrogels exhibit the highest equilibrium swelling ratio (ESR) in acidic medium (pH 4). Meanwhile they perform good swelling behavior and hydrophilicity at a temperature of 32 °C [19].

In the other research, electrically conductive hemicellulose hydrogels (ECHHs) have been successfully synthesized by a straightforward and robust approach by introducing the conductive aniline tetramer (AT) into hydrophilic, nontoxic, and biocompatible hemicellulose networks. By increasing the AT content, the SRs were tuned from 548% to 228% [20, 21].

In the other research work, a highly conductive nanocomposite was made with multiwalled carbon nanotubes (MWCNTs) and chitin nanofibers (ChNFs). It was found that the resultant ChNF/MWCNT gel-film exposed much more MWCNT areas forming denser structure due to the shrinking of ChNFs after the gelation treatment. Compared with ChNF/MWCNT film, the one treated under hydrogel system (ChNF/MWCNT gel-film) exhibited almost twice higher conductivity (9.3 S/cm for 50 wt% MWCNTs in gel-film, whereas 4.7 S/cm for 50 wt% MWCNTs in film) [22].

In many revolutions of the cellulose-based conductive materials, the most significant one was the developed material could be either directly used as a working electrode or used as the underlying substrate for the electrochemical deposition metal

electrodes. An in situ polymerization of aniline monomer onto the porous structured cellulose scaffolds has been carried out by Tian et al. and then electrodeposition of Ag nanoparticles on the obtained conductive composites directly by using it as electrode. The Ag nanoparticles were deposited homogeneously on the matrix of polyaniline (PANI)/cellulose gels. The conductivity of PANI/cellulose nanocomposite gels containing Ag nanoparticles was increased to 0.94 S C m^{-1}, which was higher than that of pure PANI/cellulose composites (3.45×10^{-2} S/Cm). Furthermore, it could be used as electrode for the super capacitors, and the highest specific capacitance of the cellulose/PANI/Ag aerogels was 217 F g^{-1}. This approach offered a facile method for improving the electronic conductivity of native polymer nano-hybrids and suggested a new strategy for fabricating nanostructured polymer nano-hybrids for application in energy storage [23].

The other research showed that the covalent incorporation of CNT into acrylate hydrogels composed of AAm and polyethylene glycol dimethacrylate (PEDGMA) as plasticizing monomer and cross-linker is a valuable strategy for the preparation of electroresponsive drug delivery systems suitable as topical devices (e.g., wound dressings) [24].

6 Irradiation Methods

The network of hydrogels, particularly those based on natural polymers, can be formed by different methods as chemical initiation or ionizing radiation from one component or two components by copolymerization, interpolymer complexes, and semi-interpenetrating polymerization. The irradiation methods are glow discharge, gamma-ray irradiation, electron beam irradiation, microwave, and ultrasonication. Aforementioned in the previous section, the pretreatment mechanism of each process is different according to the method applied. Physically cross-linked hydrogels usually show good biocompatibility but poor mechanical strength and stability. On the other hand, chemically cross-linked hydrogels usually exhibit enhanced mechanical strength and better stability but suffer from potentially harmful side reactions. Ionizing irradiation presents several advantages as it can occur without the need to add chemical initiators/cross-linking agent with subsequent separation of side reaction products. Moreover, the final products can be sterilized during hydrogel formation. Ionizing irradiation of polysaccharides leads to the chain scission and/or cross-linking reaction as a function of different parameters such as irradiation dose, irradiation phase, polymer concentration in aqueous solution phase, and the presence of oxygen. Usually, ionizing irradiation of polysaccharides at solid and non-concentrated solution states causes the breakage down of the chemical bonds between the repeated units of these polymers with consequent formation of lower-molecular-weight fragments. Moreover, the radiation dose can be easily controlled, and the experimental condition is simple for mass production of products. In addition, the product is free from undesirable chemical impurities such as residues from initiators, retarders, and/or accelerators for initiation and manipulation of the cross-linking reaction in chemical cross-linking methods.

6.1 Glow Discharge

The glow discharge owes its name to the fact that the plasma is luminous. This luminosity is produced because the electron energy and number density are high enough to generate visible light by recombination and excitation collisions. Glow discharges are used in a large number of applications. The light-emitting character of glow discharge has several applications such as in the light industry (the classical electrical discharge tube used in fluorescence lamps, neon discharge tube for advertisements, etc.), as the pump source for gas lasers, and as flat plasma display panels for the new generation of flat, large-area television screens. Besides, there are other important applications such as those in the microelectronic industry and in the material processing technology. These include surface treatment, etching of surfaces (for the fabrication of integrated circuits, etc.), plasma polymerization, plasma modification of polymers, and the deposition of thin protective coatings. Other forms of glow discharge for industrial applications are DC parallel plate plasma reactors, electron bombardment plasma sources, etc. In the simplest case, glow discharge is formed by applying a potential difference (of a few 100 V to a few kV) between two electrodes that are inserted in a cell or chamber filled with gas (an inert gas or a reactive gas) at a pressure ranging from a few mTorr to atmospheric pressure. Due to the potential difference, the electrons are accelerated away from the cathode and increase the collisions with the gas atoms and molecules. The collisions may produce processes such as excitation, ionization, dissociation, etc. The excitation collisions create excited species, which can decay to lower levels by the emission of light, and this is responsible for the characteristic name of the "glow" discharge. The ions are accelerated toward the cathode, and they release secondary electrons when bombarding at the cathode surface. These secondary electrons are accelerated away from the cathode, and they can give rise to more ionization collisions. Ionization collisions create ion-electron pairs, and this ion-electron multiplication process makes glow discharge a self-sustained plasma [25].

6.2 Gamma-Ray Irradiation

Gamma ray is a high-energy ionizing radiation in electromagnetic spectrum that easily penetrates most materials. This irradiation is extremely large high-frequency waves and largely depends on the radiation source. This technology is commonly applied in radiotherapy as a tracer in food and medical apparatus sterilization. Recently, the utilization of this technology has gain great attention especially in a biomass and biofiber pretreatment for liquid biofuel production. Radioactive nuclides such as cobalt-60 and cesium-137 are the common radioactive used in this pretreatment. The main goal of this irradiation is to decrease intra- and intermolecular order in cellulose due to the breakdown of the intermolecular hydrogen bonds. In this process, the radiation will travel from the seal source and penetrates (bombard) the biomass and biofiber. The energy carried by gamma radiation is transferred to the biomass component by collision of radiation, resulting to the loss of electron by

the atom and leading to the ionization. Under exposure to radiation, the biomass component mainly cellulose macromolecules undergoes scission, and various short- and long-lived radicals are formed. Also, the content of fragments with a low degree of polymerization generated from the process gradually increases, leading to the alteration of biomass structure, thus providing ease of access for subsequent process such as enzymatic saccharification process. The potential of gamma irradiation technology in biomass and biofiber pretreatment has been studied on various types of biomass, for instance, jute fiber, poplar sawdust, wheat straw, and cotton cellulose. There were only scanty studies on gamma irradiation pretreatment on tropical biomass and biofiber that have also been reported. A study on gamma irradiation of empty fruit bunches (EFB) indicated that the pretreatment has reduced the lignin and increased the cellulose content in the EFB. Scanning electron microscopy-EDX (SEMEDX) analysis showed that there is a significant change on the carbon and oxygen content in the EFB biomass. Typically, untreated EFB contains high carbon and low oxygen content, while the study found a decrease of carbon (9% increment) and decrease of oxygen content (16% decrease), indicating the reduction of lignin content in the EFB. A comparison of gamma-ray irradiation pretreatment on soft- and hardwood has also been carried out using different levels of dosage ranges between 10 and 100 kGy. The study found that the most suitable condition for softwood was at 40 kGy, while higher dosage is required to pretreat hardwood (90 kGy). The study also concluded that gamma-ray pretreatment process is species dependent, wherein higher dosage is needed to disrupt hardwood cell structure compared to softwood [26].

6.3 Electron Beam Irradiation

Electron beam is one of the irradiation pretreatments used to pretreat biomass prior to enzymatic saccharification. This technology has been widely used in various applications such as welding, drilling, and surface treatment. For commercial use, the most important characteristics of an accelerator are its electron energy and average beam power. Therefore, industrial electron accelerators are usually classified according to their energy ranges, which are divided into low (80–300 keV), medium (300 keV–5 MeV), and high energy ranges (above 5 MeV). In the electron beam pretreatment, the biomass and biofiber are exposed to a highly charged stream irradiation pretreatment of tropical biomass and biofiber for biofuel production electron. The electron is emitted from an electron beam gun and accelerated by accelerator. In this pretreatment process, the electron energy can be controlled and modulated by varying the irradiation dose. The high-energy electrons emitted travel into biomass and biofiber component and transfer the energy within the materials. The heating process initiates chemical and thermal reaction in the biomass including cellulose depolymerization and production of carbonyl group, resulting from the oxidation of the biomass. Cross-linking of biomass component has also been reported to occur when the biomass is exposed to irradiation beam. Also, reduction of the biomass mechanical strength has been observed from the biomass exposed to

electron beam. This could be due to the disruption of hydrogen bond between cellulose chains making it less crystalline and more amorphous [26].

6.4 Microwave Irradiation

Microwave is electromagnetic waves between the frequency range of 0.3–300 GHz, and most of the microwave systems used for industrial and domestic purposes range between 0.9 GHz and 2.45 GHz. Microwave radiation is a radiating wave movement and takes a straight-line path type of energy. This radiation does not require any medium to travel through and could penetrate nonmetal materials such as plastic and glass. Microwaves can affect the material thermally and nonthermally. Thermally, microwaves heat the material by the interaction of the molecules of material with electromagnetic field produced by microwave energy. Nonthermally, microwaves affect and interact with the polar molecules and ions in the materials causing physical, chemical, and biological reactions [26].

6.5 Ultrasonication

Another irradiation pretreatment that is widely used to pretreat biomass and biofiber for biofuel production is ultrasonication. This process can be performed either using probe-type ultrasonication or an ultrasonic bath. In this process, ultrasonic waves can be generated via piezoelectric or magnetostrictive transducers in the frequency range of 20–1000 kHz, in which the waves induced provide pressure difference in the medium. The pressure wave that travels through the liquid medium has high-pressure (compression) and low-pressure (rarefaction) regions. The rarefaction of the cycle can stretch the liquid molecules apart and create cavities also known as bubbles. As the wave cycles through the liquid, the bubbles expand and contract with the rarefaction and compression of the wave, respectively, drawing more liquid molecules into the bubbles as they grow. The bubbles that either continue to expand and then float to the surface are subjected to coalescence due to the forces or collapse during compression of the wave. This collapse is almost adiabatic and can result in localized temperatures of around 5000 K and pressures of 1000 atm. The collapse results in the formation of radicals through dissociation of the molecules within and around the bubbles, luminescence due to excited molecules formed losing energy, and micro jets shooting out of the bubbles of speeds in the realms of hundreds of km per hour [26].

7 Glow Discharge Effects on Hydrogels

Various initiated techniques have been proposed for the preparation of hydrogels in the past few decades which include chemical initiation, UV-curing technique, microwave or gamma-ray irradiation, etc., but all these trigger technologies had residual

monomers and initiators, high energy consumption, etc. Glow discharge electrolysis plasma (GDEP), which belongs to the nonequilibrium plasma, exhibits the characteristics of non-faraday because it produces numerous highly active particles in plasma electrolysis, such as $HO^{\bullet}$, $H^{\bullet}$, $HO_2^{\bullet}$, e_{aq}^{-}, and H_2O_2.

In addition, GDEP was used in organic synthesis, wastewater degradation, surface modification, and other fields due to its simple equipment, low energy consumption, and no environmental pollution [6]. The temperature/pH dual sensitivity reed hemicellulose-based hydrogels have been prepared through glow discharge electrolysis plasma (GDEP). The experimental apparatus of the GDEP is shown in Fig. 2. The effect of different discharge voltages on the temperature and pH response performance of reed hemicellulose-based hydrogels was inspected by Zhang et al., and the formation mechanism and deswelling behaviors of reed hemicellulose-based hydrogels were also discussed. In this research, hemicellulose as backbone, hydroxyl radicals which were produced by GDEP as initiators, acrylic acid (AA) and *N*-isopropyl acrylamide (NIPAAm) as monomers, and *N*,*N*-methylene double acrylamide (MBA) as cross-linking agents have been used to prepare temperature/pH dual sensitivity reed hemicellulose-based hydrogel. It turned out to be that all reed hemicellulose-based hydrogels had a double sensitivity to temperature and pH, and their phase transition temperatures were all approximately 33 °C, as well as the deswelling dynamics met the first model. In addition, the prepared hydrogel in this research, under discharge voltage 600 V, was more sensitive to temperature and pH and had higher deswelling ratio. In the process of glow discharge, joule heat, produced by electric current, makes the solution vaporize gas sheath around the electrodes rapidly. When the discharge voltage is high, gas water vapor molecules in the gas sheath layer produce sustained plasma. Many highly active components within plasma such as $HO^{\bullet}$ and $H^{\bullet}$ distributed in solution provide reactive intermediate source for solution chemistry reaction. The hydrogen of the hemicellulose

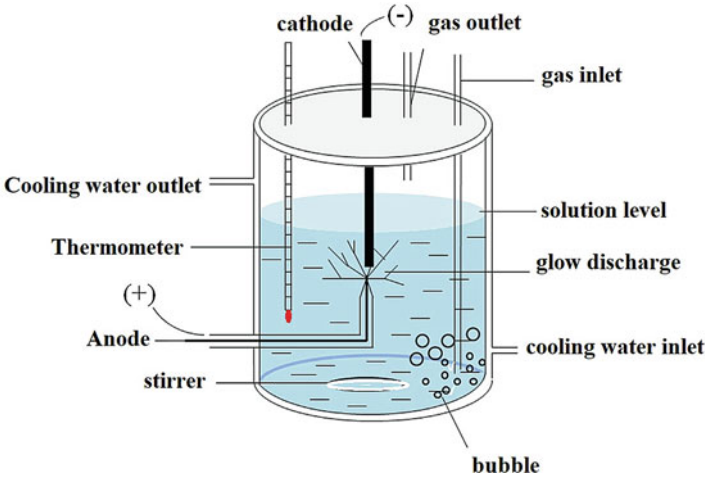

Fig. 2 The experimental apparatus of the glow discharge electrolysis plasma [6]

hydroxyl groups is seized by highly active components for the purpose of making it a main chain with active free radicals. What is more, the copolymerization with acrylic acid (AA) and *N*-propyl acrylamide (NIPAAm) eventually occurs in the solutions, and the three-dimensional network structure of reed hemicellulose-based hydrogel is obtained [6].

Glow discharge electrolysis plasma (GDEP) is emerging as a potential alternative to conventional technologies for the formation of hydrogels due to its low costs, high efficiency, easy operation, and mild reaction conditions. GDEP is a kind of non-faradaic electrochemical process and exhibits the characteristics of non-faraday, which produces numerous highly active particles in plasma electrolysis, such as $HO^{\bullet}$, $H^{\bullet}$, $HO_2^{\bullet}$, e_{aq}^{-}, and $H_2O_2^{\bullet}$. The yield of HO is more than 12 mol per mol electron of electricity in the process of glow discharge electrolysis, which suggests that GDEP is a rich source of free radical in aqueous solution and can be applied to induce some unusual chemical reactions by taking place of chemical initiator in solution. In recent years, a series of adsorbing composites were prepared by GDEP technology and showed some excellent properties. However, there were few studies directly on the preparation of cellulose-based hydrogels with multi-stimulus response properties by GDEP technology. Novel ionic hydrogels have been prepared successfully from cellulose in the NaOH/urea aqueous system by a glow discharge electrolysis plasma (GDEP) technique by Zhang and his coworkers. The results showed that the swelling behavior and the network structure of the ionic hydrogels could be controlled by changing discharge voltage or discharge time, whereas we obtained the maximum absorbency of 898 g g^{-1} for distilled water at 570 V and 90 s. Shrinkage of the network hydrogels took place at higher or lower pH. Relative to the Na^{+} buffer solution, hydrogels were more sensitive to Zn^{2+} and Fe^{3+} buffer solutions and showed network shrinkage and lower swelling ratio. In Na^{+} ionic solution, the swelling ratios of hydrogels are higher and more different. This work provided a new pathway for preparation of cellulose-based hydrogels with environmental friendliness, high water absorption capacity, and rapid and multiple responses to pH and ions, which may allow their use in the biomaterial area [27].

8 Gamma Irradiation of Hydrogels

In recent years there has been a growing interest in hydrogel systems prepared by gamma-ray irradiation. Gamma-ray irradiation is an available technique for the modification of the chemical and physical properties of polymeric materials. The gamma-ray irradiation method has advantages, such as relatively simple manipulation without the need of any extra agents for polymerization and cross-linking; by contrast, the thermal activation method requires radical initiators and cross-linkers. For these reasons, gamma-ray irradiation method is useful for preparing hydrogels for medical applications, for which even a small contamination is undesirable, and is often used to sterilize biomedical devices for medical and veterinary applications. Natural polysaccharides such as hyaluronic acid (HA) have been extensively studied in medical applications since they provide intrinsic biological activity when used as

basis for biomaterials. Zhao and his coworkers prepared hyaluronic acid (HA) and chondroitin sulfate (CS) and the synthetic polymer, poly (vinyl alcohol) (PVA), hydrogels using gamma irradiation. All HA/CS/PVA hydrogels showed relatively high water contents of greater than 90%. These hydrogels reached an equilibrium swelling state within 24 h [28].

Polysaccharides such as cellulose, starch, chitin/chitosan, and their water-soluble derivatives have been known as degradable-type polymers under action of ionizing radiation. However, it was reported that water-soluble polysaccharide derivatives such as carboxymethyl cellulose (CMC) would undergo radiation cross-linking in a high concentrated aqueous solution (more than 10%, paste-like state). It has been proposed that radiation formation of cross-linking of these polysaccharides was mainly due to the mobility of side chains. Side-chains radicals were formed mostly via indirect effects, by the abstraction of H atoms by the intermediate products of water radiolysis. The idea was to apply high concentrated aqueous solutions of the polymer of high degree of substitution. It was assumed that the hydrogel formation of polysaccharide derivatives by radiation was mainly due to the mobility of side chains. Side-chains radicals were formed mostly via indirect effects, by the abstraction of H atoms by the intermediate products of water radiolysis [29].

$$H_2O \xrightarrow{\text{Gamma irradiation}} e_{aq}^{-},\ OH^{\bullet},\ H^{\bullet},\ H_2O_2,\ H_2$$

Plungpongpan et al. prepared hydrogels from polymer blend between poly (*N*-vinyl pyrrolidone) (PVP) and methyl hydroxyethyl cellulose (MHEC) via gamma irradiation. The cross-linking structures in the hydrogels were induced by varying the irradiation doses from 10 to 40 kGy. The gel fraction and the swelling ratio of hydrogels were characterized. The results showed that the swelling ratio of hydrogels increases with increasing the irradiation dose [29].

In the other point of view, water sources like lakes, sea, groundwater, etc. are becoming polluted by different kinds of contaminants, including toxic heavy metals (e.g., Cr, Pb, Cu, Ni, Cd, Fe, etc.) accidentally and deliberately discharged into these surface waters by commercial and industrial establishments. The resulting environmental hazards are undesirable, and therefore heavy metal ions must be appropriately removed using new/improved techniques. In a novel research work, sodium carboxymethyl cellulose (CMC Na)/sodium styrene sulfonate (SSS) hydrogels with grafted and cross-linked polymeric networks were prepared by gamma radiation at atmosphere condition (Fig. 3). The metal ion adsorption capacity of CMC/SSS gel was investigated. The grafted gel effectively removed metal ions, especially Cr and Pb [30].

In similar research work, thermo- and pH-sensitive Ag-P(NiPAAm/IA) hydrogel nanocomposites were prepared by in situ reduction of Ag^{+} ions with gamma irradiation [31].

Also, Yang et al. prepared inorganic/organic hybrid poly (*N*-isopropylacrylamide) (PNIPAM) hydrogels based on polyhedral oligomeric silsesquioxanes (POSS) via gamma-ray irradiation in one step. The swelling and deswelling behavior of PNIPAM

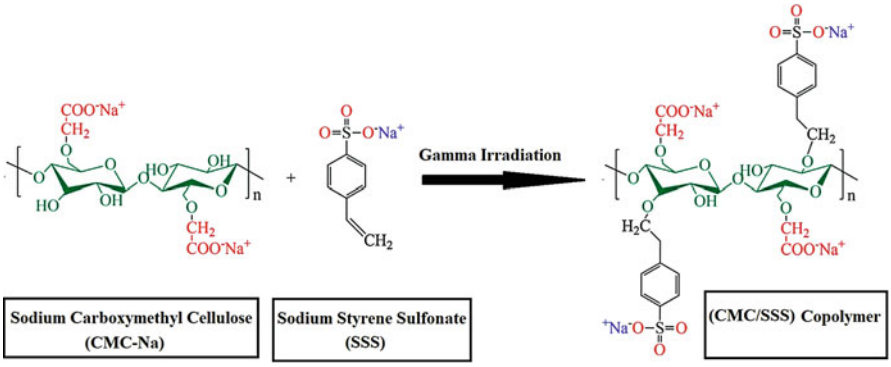

Fig. 3 A brief proposed mechanism for induced grafting of SSS onto CMC [30]

hydrogels indicated that POSS-containing hydrogels had a good water absorption capability and rapid water release capability. Thus, these thermal-responsive POSS-containing hydrogels would have some potential applications such as biological fields [32].

In similar research, gamma irradiation synthesis of silver/poly(vinyl alcohol) (Ag/PVA) hydrogels has been carried out by exposing the mixture of PVA and $AgNO_3$ in double-distilled water to gamma irradiation for 25 kGy dose. The swelling properties of the Ag/PVA hydrogel were compared with the PVA hydrogel by Swaroop et al. Significant increase in the swelling percentage of Ag/PVA hydrogel was observed in comparison to PVA hydrogel [33].

Application of polymers cross-linked by gamma irradiation on cutaneous wounds has resulted in the improvement of healing. Chitosan (CH)- and poloxamer 407 (P407)-based hydrogels confer different advantages in wound management. To combine the properties of both compounds, a gamma-irradiated mixture of 0.75/25% (w/w) CH and P407, respectively, has been obtained. Its thermo-reversibility and gelation properties at a low temperature allow for easy application to the wound, while the ability to swell in the presence of human serum permits the control of excessive exudate for skin wound application [34].

In similar research, poly(vinyl pyrrolidone) (PVP), poly(ethylene glycol) (PEG), and agar have been used for preparing wound dressing under gamma irradiation [35].

If a biomaterial is to be implanted in the body, it must be subjected to a sterilization procedure which often involves gamma irradiation. Magda et al. reported results for the effects of gamma irradiation on the glucose response of a hydrogel with glucose-binding boronic acid moieties. This "smart" hydrogel is of a type suitable for use in nonenzymatic glucose sensors. Exposure to gamma rays reduces the glucose-response sensitivity by over 50%, possibly due to the formation of additional hydrogel cross-links [36].

In the other research, interpenetrating network based on poly(acrylamide-aniline)-grafted gum ghatti has been synthesized under gamma irradiation using

N,*N*′-methylenebis-acrylamide (MBA). The optimum grafting was observed when the reaction mixture containing 10 ml solvent, 0.324×10^{-1} molL^{-1} MBA, and 1.08 molL^{-1} monomer was exposed to 1.5 kGy dose of gamma radiation. The electrical conductivity of doped IPN structures increased with an increased concentration of HCl. However, a high concentration of HCl led to a decrease in electrical conductivity, which may be due to the over protonation of PANI chains in the cross-linked networks [37].

A network of covalently cross-linked wax hydrogel bearing acidic and amide groups using gamma irradiation has been successfully developed by Ghobashy et al. He found that it has a promising application in dye removal [38].

9 Effect of Electron Beam on Hydrogels

Electron beam cross-linking is a clean and safe technology, especially for biomedical application, since it does not require any external initiators and cross-linkers. The irradiation-induced cross-linking technique provides sterilization and hydrogel cross-linking in a single step. The physical properties of hydrogels produced in this manner are dependent on the degree of cross-linking and polymer composition. This method also provides an alternative to the use of chemical initiators and cross-linkers, which can be harmful and difficult to remove. Recently bacterial cellulose/acrylic acid (BC/AA) hydrogels synthesized by electron beam irradiation and investigate its wound healing potential in an animal model. Vivo experiments indicated that hydrogels promoted faster wound healing, enhanced epithelialization, and accelerated fibroblast proliferation compared to that in the control group. These results suggest that BC/AA hydrogels are promising materials for burn dressings [39, 40].

In the other research, electron beam irradiation has been applied to prepare a chemically cross-linked hydrogel based on tyramine conjugated gum tragacanth. The gel content of the prepared hydrogels was in the range of 75–85%. Equilibrium swelling degree of the hydrogels decreased from 51 to 14 with increasing polymer concentration and irradiation dose. Moisture retention capability of the hydrogels after 5 h incubation at 37 °C was in the range of 45–52 that is comparable with that of commercial hydrogels. The cytotoxicity analysis showed the good biocompatibility of hydrogels. These results indicated that electron beam irradiation is a promising method to prepare chemically cross-linked tyramine conjugated gum tragacanth hydrogels for biomedical applications. Also, the versatility of electron beam irradiation for cross-linking of a variety of polymers possessing tyramine groups was demonstrated [41].

In the other research, Choi and his coworkers prepared eggshell membrane (ESM)-based hydrogel by incorporating with polyvinyl alcohol (PVA) via an electron beam irradiation technique. Hen egg shell membrane (ESM) is an abundant natural protein resource and can be readily obtained almost anywhere as a waste. ESM is a thin, highly collagenized fibrous membrane formed by types I, V, and X collagen, making up 88–96% of its dry weight. It has been used as a biomaterial, particularly as a matrix for absorption of heavy metal ions, a template for the formation of ordered

tube networks, a platform for enzyme immobilization, and a scaffold material for tissue engineering. The internal 3D porous network structure, the high absorption capacity, and the possible microbial sterilization due to EBI are the main features of the introduced hydrogel, which make it a suitable candidate for biomedical applications such as wound dressing, drug delivery, tissue scaffolds, etc. More importantly, the preparation strategy could be considered as a cost-effective method which could eliminate the use of toxic chemicals to prepare hydrogel for biomedical applications. We hope, this method can be extended to fabricate a variety of polymer hydrogels for different applications [42].

In similar research, the temperature- and pH-responsive characters of hydrogels prepared from aqueous solutions containing 4.2% and 25% (w/v) carboxymethyl cellulose (CMC) and acrylic acid (AAc), respectively, under the effect of accelerated electrons was investigated. Even though the initial content of hydrogel solution is constant, the swelling in water and responsive characters was greatly dependent on electron beam irradiation dose. In this regard, the percentage swelling in water of the hydrogel prepared at 50 kGy is relatively higher than that prepared at 80 kGy. However, both hydrogels displayed super water-absorbing behavior at room temperature in the range of ∼3500–4000%. The swelling of CMC/AAc hydrogel prepared at 50 kGy was found to substantially increase with increasing pH values from 3 to 10; the hydrogel prepared at 80 kGy was found to display pH-responsive character below and above 7 [43].

Park and his coworkers found that the pure keratin (human hair and wool) aqueous solution was not gelled by EBI, while the aqueous keratin solutions blended with PVA were gelled at an EBI dose of more than 90 kGy. Furthermore, in the presence of PEI, the aqueous keratin solution blended with PVA could be gelled at a considerably lower EBI dose, even at 10 kGy [44].

Blend hydrogels based on aqueous solutions of plasticized starch and different ratios of cellulose acetate (CA) and carboxymethyl cellulose (CMC) were prepared by electron beam irradiation (EB). The blends before and after EB irradiation were characterized by thermos gravimetric analysis (TGA) and differential scanning calorimetry (DSC). The physicochemical properties of blend hydrogels prepared by electron beam irradiation were improved compared to unirradiated blends [45].

10 Microwave Irradiation of Hydrogels

The microwave irradiation is one technique, which is used for preparation of the hydrogel in several researches. Microwave heating process has high temperatures for attack the solution with relatively short times and thus creates reactions faster than under conventional thermal conditions [46].

Microwave irradiation is a special heating energy, and it has some significant advantages over the conventional thermal methods in preparation of colloid particles. Omprakash used microwave irradiation followed by hydrothermal method for synthesizing ZSM-5 type of zeolite and found that zeolite synthesized by microwave irradiation method only took half the time for ZSM-5 crystallization of 100%

crystallinity to that of conventional hydrothermal heating method. Hence, microwave treatment method is economic and time saving. Li et al. used microwave irradiation synthesis method for the preparation of thermosensitive poly(*N*-isopropylacrylamide) (PNIPAAm) hydrogels. He found that the PNIPAAm hydrogels synthesized using microwave irradiation had much higher swelling ratios at 10.0 °C below the (lower critical solution temperature) LCST [47, 48].

Cross-linked acrylamide-based thermosensitive hydrogels are interesting candidates for biomedical or pharmaceutical applications, such as drug release because they change volume and expel a significant amount of its inner solution when a transition is induced by external action. These kinds of materials based on smart hydrogels could also be used in chemical or mechanical actuators as well as environment sensors for technological applications. It has been shown that the in situ polymerization water-soluble monomers (aniline or pyrrole) inside a hydrogel produce nanocomposite with conductive and dielectric domains. The nanocomposite suffers a phase transition by externally changing the temperature of the gel or by microwave absorption. Upon microwave irradiation, the conductive polymer absorbs the radiation and heats up driving the phase transition of hydrogel which involves a clear volume decrease and inner solution expulsion. It is found that the amount of water released correlates well with the surface temperature of the materials upon microwave irradiation [49].

Li et al. studied the swelling and deswelling kinetics of poly(*N*-isopropylacrylamide) (PNIPAAm) hydrogels separately synthesized by means of microwave irradiation and normal water bath heating. As compared with the PN hydrogel synthesized by the conventional method, the PM hydrogel synthesized by microwave irradiation had larger swelling and deswelling rate constants as well as lower swelling/deswelling activation energy due to its higher surface area and larger pore sizes, and thus it had faster response behavior. Also he found that the use of microwave irradiation method to prepare the hydrogel not only made it more porous but also made its pores more uniform and deeper [50].

In the other study, microwave irradiation technique has been used to synthesize poly(acrylamide-co-2-hydroxyethyl methacrylate)/poly(vinyl alcohol) (P(AM-co-HEMA)/PVA which are separately synthesized by using one-pot polymerization and two-step polymerization techniques. The hydrogel prepared by one-pot polymerization technique exhibited the highest swelling ratio and reduced step of polymerization, compared with the hydrogels prepared by two-step polymerization technique. The hydrogel of 50% HEMA-PM showed the maximum mass swelling percentage (the mass swelling percentage has higher than 900%) [46].

To prepare a novel biodegradable hydrogel for use in tissue engineering, pHEMA hydrogel has been synthesized by microwave-assisted polymerization using 2-hydroxyethyl methacrylate (HEMA) as the raw material, potassium persulfate as the initiator, and PCLX as the cross-linking additive. Biodegradation studies showed 75% uniform bulk degradation of the hydrogel over a period of 17 days. In addition, the biodegradable hydrogel had no observable cytotoxicity toward L-929 fibroblast cells. Therefore, this novel bioresorbable pHEMA can play an important role as a scaffold for tissue engineering applications [51].

11 Ultrasonication of Hydrogels

The radiation synthesis is a kind of new technology which was highly effective and eco-friendly. And because of its high temperatures for attacking the solution with relatively short times and thus creating reactions faster than conventional thermal conditions, microwave irradiation has been used for preparation of the hydrogel in several researches. Also ultrasound has been investigated for the initiation of polymerization reactions to prepare polymer hydrogel since it can be used both for dispersion of monomer droplets and for generation of free radicals. The use of ultrasonic irradiations during the hydrogel synthesis not only can control the molecular weights but also can improve the swelling ratio. Wang et al. synthesized the hydrogels based on gelatin cross-linked with chitosan (CS) and polyvinyl pyrrolidone (PVP) using microwave and ultrasonic coupling technique. This interpenetrating polymer network (IPN) hydrogels were cross-linked by glutaraldehyde and 1,2-Epoxy-4-vinylcyclohexane. The results showed that the hydrogel prepared with microwave and ultrasonic exhibited the highest tensile strength (86.68 MPa), compared with the hydrogel prepared with traditional method and only microwave reactive field. The FT-IR and XRD results showed that the chemical reactions occurred between the eNH2 of chitosan and the eCOOH of gelatin and the introduction of ultrasound can improve the reaction rate. The hydrogel film gained in microwave and ultrasonic coupling field has the best combination properties. Therefore, the new microwave-ultrasonic coupling technique is the potential technology to prepare the new hydrogel due to less synthesis time [52].

In the other research, Wang et al. successfully prepared a series of (sodium lignosulphonate) SLS-based hydrogels by ultrasonic-assisted synthesis which is green, fast, and convenient relative to other methods. The swelling capacity of SLS-based hydrogels was measured in various experimental conditions like pH, SLS content, and different electrolytes. The results demonstrated that the water uptake capacity achieved the maximum when containing 1 wt% sodium lignosulphonate. It was worth mentioning that the maximum of swelling capabilities could reach 1328 g g^{-1} and 110 g g^{-1} in deionized water and 0.9% NaCl solution, respectively. It was found through the exploration that the swelling behavior in aqueous solution was consistent with the pseudo-second-order kinetic model. At the same time, SLS-based hydrogel was selected as an adsorbent to remove Ni^{2+} from an aqueous solution, and the maximum adsorption capacity reached about 293 mg g^{-1} under the optimal experimental condition. The adsorption capability of SLS-based hydrogel was influenced by pH, temperature, and adsorption time as well as initial concentration. The mechanism of adsorption was evaluated by fitting adsorption data to different kinetic models and adsorption isotherms, and the findings revealed that the adsorption behavior was endothermic and spontaneous as well as multi-molecular layer chemisorption [53].

Nowadays adsorption of dyes is carried out with superabsorbent hydrogels due to their high water absorption property. Lignin is a biodegradable, eco-friendly, low-cost, and renewable raw material and is strongly reactive due to its aromatic nature and functional groups (carboxyl and phenol groups), which can potentially be

used for high performance as adsorbent. However, its adsorption amount and adsorption rate need to be further improved for practical applications. Ultrasound-irradiation has been investigated for the initiation of bulk polymerization reactions to produce polymer hydrogel since it can be used both for dispersion of monomer droplets and for generation of free radicals. The use of ultrasonic irradiations during the hydrogel synthesis not only can control the molecular weights which are attributed to the high shear gradients generated by cavitational events but also can improve the dispersion of the clay with enhancement in the mechanical properties and adsorption capacity of hydrogels. A novel hybrid hydrogel has been synthesized from grafting of acrylamide and *N*-isopropyl acrylamide onto lignin by incorporation of montmorillonite under ultrasonic irradiation (lignin-g-p(AM-co-NIPAM)/MMT). This hydrogel was employed for the removal of methylene blue from the aqueous solution, and it exhibited good swelling-deswelling property. The initial swelling kinetic was Fickian-type diffusion, and the whole swelling process was good fit for Schott's pseudo-second-order model. The adsorption process was found to be highly pH and temperature dependent and followed the pseudo-second-order rate model [54].

In the other research, hen egg white lysozyme (LZM) cross-linked with ultrasonic-treated tragacanth (US-treated TGC) under mild Maillard reaction conditions. Since this gum is extensively used in food industry and application of LZM as a natural antimicrobial agent in different food systems is recommended and practiced in some countries, the results of this study indicate that a conjugated product of these two polymers combines different properties into one macromolecule and improves the property of each. These properties may make the conjugate an attractive food ingredient [55].

Ultrasonic radiation is used in a vast range of applications. More commonly this includes imaging (industrial and medical), physiotherapy, and welding of metals and plastics. High frequencies are commonly used for imaging, whereas low frequencies (less than 500 kHz) provide strong physical and chemical interaction with materials. The physical effects of low-frequency (high power) ultrasound include high shear rates, free radical production in solution, and heat generation. This has been utilized for fragmentation and dissolution of solids, biological techniques, the preparation of nanomaterials, various synthetic sonochemical reactions, thermal applications such as plastic welding, and environment remediation. Ultrasound has also been investigated for many polymer-based applications. These include polymer synthesis through the generation of free radicals, activation of free radical initiators, degradation of polymers in solution by high shear rates, and physical mixing of heterogeneous emulsion/suspension polymerization systems. Several acrylic hydrogels have been prepared via ultrasonic polymerization of water-soluble monomers and macromonomers by Cass et al. Ultrasound was used to create initiating radicals in viscous aqueous monomer solutions using the additives glycerol, sorbitol, or glucose in an open system at 37 °C.

Ultrasound was found to be an effective method for the polymerization of water-soluble vinyl monomers and for the production of hydrogels. This occurs rapidly in the absence of a chemical initiator. The water-soluble additive was essential for the

preparation of hydrogel. We propose that its effect is attributed to the enhanced viscosity increasing the free radical production as well as reducing the polymer solubility and hence retarding depolymerization. The most effective additive for the preparation of hydrogels was glycerol. Such a technique may find application in the field of biomaterial synthesis to avoid problems associated with cytotoxic initiators. In combination with techniques such as high intensity focused ultrasound, the polymerization method described here may also allow the formation of hydrogels in vivo [56].

12 Conclusion

Without a doubt, there are a number of significant features of hydrogels that qualify and allow them to exhibit extraordinary characteristics, which enables them to be employed as essential tools for applications in almost all the fields, such as biomedical, agricultural, industrial, and environmental areas. From time to time, significant modifications are made to revolutionize the field of hydrogels for their comprehensive applications. Nowadays, smart and electrical conductive hydrogels play very important role in different branches of industry. Although extensive research is ongoing in order to provide new kind of hydrogels for future necessities, novel conceptual assimilation of hydrogel preparation such as different irradiation methods may lead to tailored properties, translating its innovative applications in the diversified fields. Above all, an economical way to improve the efficacy of the hydrogel system will be the most demandingly needed approach.

Cellulose-Based Composite Hydrogels: Preparation, Structures, and Applications

21

Liying Qian

Contents

Abstract

In this chapter, cellulose-based composite hydrogels were summarized in three categories according to the components. Synthetic polymer/cellulose composite hydrogels combine the advantages of synthetic polymers and cellulose. Soluble cellulose derivatives are feasible to construct the composite hydrogels with polyacrylamide, polyvinyl alcohol, polyacrylic acid, and so on. The composite hydrogels are normally applied as superabsorbents for heavy metal ions and dyes because the abundant functional groups in the hydrogels can act as binding sites. Due to most of the crosslinked polymeric hydrogels suffering from poor

mechanical performance, low breaking strain, and sensitivity to fracture, cellulose nanocrystal can be combined into the hydrogels to enhance the mechanical properties significantly in order to obtain the mechanically strong, tough, or highly stretchable nanocomposite hydrogels. Natural macromolecules/cellulose composite hydrogels have a great potential for applications in tissue engineering, drug delivery, sensors, and purification for their excellent biocompatible, biodegradable, and nontoxic properties. Cellulose hydrogels have high mechanical strength and good permeability for liquids, gases, and electrolytes, the composite hydrogels which combine cellulose and extracellular matrixes are very promising scaf folds for the tissue repair and regeneration. Chitosan, alginate, and other polysaccharides are popular natural macromolecules for the composite hydrogels. Inorganics/cellulose composite hydrogels have recently received considerable attentions in both academic research and industrial application due to their excellent hybrid properties. Montmorillonite, clay, and bentonite are traditional inorganic minerals to fabricate the composite hydrogels as superabsorbents for water treatment, personal care, and agriculture. Nanoparticles of ZnO and Ag are also incorporated into the cellulose hydrogels to render the antimicrobial activity to biomedical materials. Recently, the novel cellulose-based composite hydrogels with graphene oxide, carbon nanotube, and carbon dots show potential applications in supercapacitors and biosensors.

1 Introduction

Cellulose composite hydrogels can be prepared from cellulose and macromolecules or inorganic materials with physical and chemical crosslinking. Physical hydrogels are formed by molecular self-assembly through ionic or hydrogen bonds, while chemical hydrogels are formed by covalent bonds [1]. Cellulose can take part in the formation of 3D network or act as reinforcement. Interpenetrating polymer networks (IPNs) are common structures for cellulose-based composite hydrogels, especially for synthetic polymer/cellulose composite hydrogels. IPNs can be divided into two types: sequential IPN and semi-IPN. For sequential IPN, cellulose is used as the first network, and the second network is formed by polymerizing in the presence of the cellulose network. When cellulose or its derivative is linear or branched in a crosslinked network, it is called as semi-IPN hydrogel [2]. Nanocellulose is an excellent reinforcement for both synthetic polymer and natural macromolecule hydrogels. Inorganic/cellulose composite hydrogels combine the advantages of both components which are very promising materials in biomedicals, tissue scaffold engineering, superabsorbent, and so on. The main purposes of incorporation of inorganics are reducing production cost, improving the properties, and rendering special features. This chapter discusses about cellulose-based composite hydrogels

including synthetic polymer/cellulose, natural macromolecules/cellulose, and inorganics/cellulose composite hydrogels with the emphasis on the latter two categories.

2 Synthetic Polymer/Cellulose Composite Hydrogels

2.1 Water-Soluble Cellulose Derivatives

Naturally available cellulose is not water-soluble due to the hydrogen bonding between molecular chains; the strong intermolecular and intramolecular hydrogen bonds between the hydroxyl groups not only limit the water solubility but also lead to the poor reactivity of cellulose. However, water-soluble cellulose can be prepared by esterification and etherification reaction of the hydroxyl groups. Methyl cellulose (MC), hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and carboxymethyl cellulose (CMC) are common water-soluble cellulose derivatives. The concentrated aqueous solution of cellulose derivatives can be crosslinked under irradiation to prepare cellulose-based hydrogels [3]. It is feasible to incorporate some synthetic polymers with cellulose to fabricate the composite hydrogels by chemical crosslinking via crosslinker and irradiation, physical crosslinking, and ionic crosslinking.

CMC is a representative cellulose derivative, which is manufactured by reacting sodium monochloroacetate with cellulose in alkaline medium. It is the most popular cellulose derivative to prepare the composite hydrogels with synthetic polymers. In situ free-radical solution polymerization of acrylate monomers onto CMC is one of main methods to introduce synthetic polymers into CMC hydrogels. By this method, acrylic acid (AA) [4–6], acrylamide (AM), and N-isopropylacrylamide (NIPAM) can be grafting polymerized on CMC and chemically crosslinked to the composite hydrogels by chemical crosslinker [7, 8] or irradiation [9–11]. Methylenebis acrylamide (MBA) always acts as a chemical crosslinker or a crosslinking enhancer agent in irradiation [12–15]. Polyacrylic acid (PAA)/cellulose composite hydrogels have been widely reported for the applications of drug delivery and adsorbent. The negative carboxyl groups in PAA/CMC composite hydrogels facilitated the removal of cationic dyes via electrostatic interactions [16]. Cyclodextrin (CD) and CMC were grafting polymerized with AA to prepare CD/CMC-g-PAA hydrogels with pH sensitive as drug delivery system [17, 18]. A double crosslinking PAA hydrogel via visible-light-trigger polymerization, with CMC as initiator and the first crosslinker and MBA as the second crosslinker, showed a remarkably rapid recovery in both successive and intermittent cyclic tensile tests [19]. Hydrogels based on AM monomer and CMC were synthesized by gamma irradiation with MBA as a crosslinking enhancer agent for drug release system [20] and agrochemicals [21]. Interpenetrating double network was formed by chemically crosslinked polyacrylamide (PAM) network and physically crosslinked CMC network (Fig. 1). This shape memory hydrogels exhibited excellent tunable mechanical properties [22], which are similar to PAA/CMC composite hydrogels [19]. Both AM and AA were grafted onto CMC and further ionic coordinated to fabricate a tough hydrogel actuator with

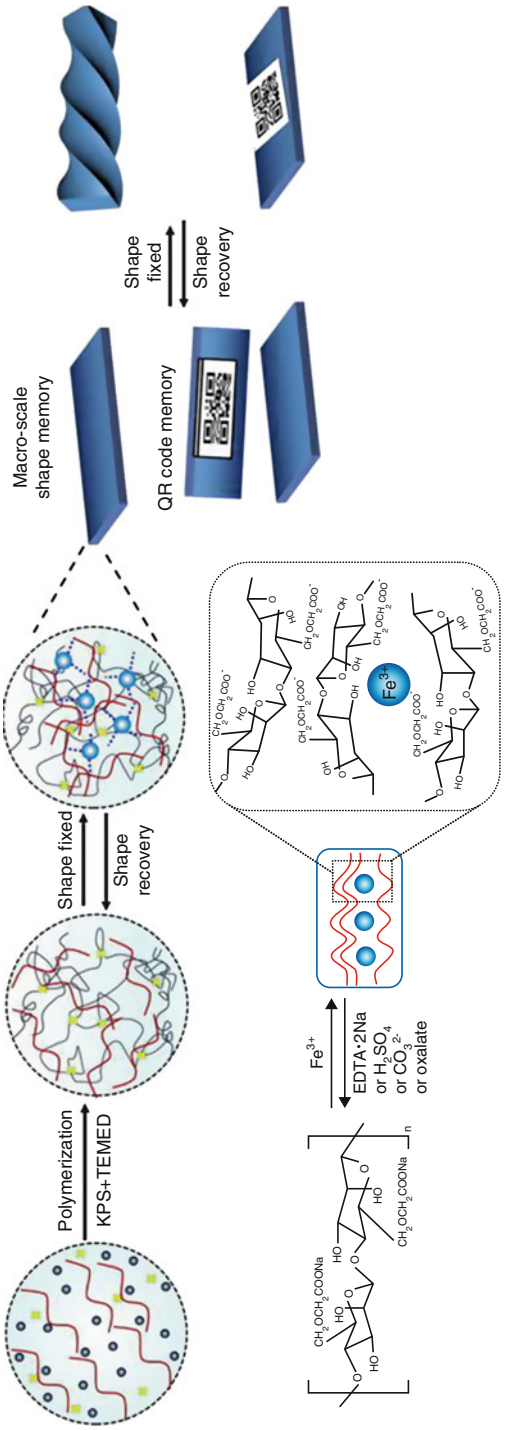

Fig. 1 Scheme of PAM/CMC hydrogels with excellent shape memory effect. (Reproduced from [22])

programmable folding deformation which showed great application prospect in soft machine. The ionic coordination was utilized to not only trigger the locally folding deformation of the hydrogels but also reinforce the mechanical property significantly [23]. By grafting poly(N-isopropylacrylamide) (PNIPAM) onto CMC, the self-association of grafted chains led to a thermothickening effect compared to the physical blends [24]. PNIPAM/CMC composite hydrogels with thermo- and pH responses are promising materials for protein and drug delivery [25, 26]. pH, thermo-, and redox ternary-responsive composite hydrogels were prepared by free-radical polymerization using methacrylated carboxymethyl cellulose (MACMC) and NIPAM as monomers [27]. PNIPAM and CMC were functionalized with hydrazide or aldehyde functional groups and mixed using a double-barreled syringe to create in situ gelling and hydrazone-crosslinked composite hydrogels, which provided a highly adaptable method of engineering injectable, rapidly gelling hydrogels for potential in vivo applications [28]. CMC can also be incorporated with some synthetic polymers to fabricate the composite hydrogels for medical and super-absorbent applications [29, 30].

MC is normally obtained by heating cellulose with a solution of sodium hydroxide and methyl chloride to replace the hydroxyl groups of cellulose by methoxyl groups. MC can form a thermoreversible physical hydrogel itself. At low temperatures, the hydrogen bonds formed and the polar water molecules form cages around the hydrophobic methoxyl groups of MC; upon heating, the hydrogen bonds and the water cages were broken to expose the hydrophobic side groups of MC chains, inducing hydrophobic associations and thus gelation [31]. MC-based injectable hydrogels for postoperation anti-adhesion were fabricated by mixing CMC, polyethylene glycol (PEG), and chitosan sulfate (CS-SO_3) in the MC matrix with a low critical solution temperature (LCST) at 36 °C [32]. PAM/MC/montmorillonite (MMT) composite hydrogels were obtained through chemical polymerization of the AM monomer in aqueous solution containing MC and MMT which were appropriate for the controlled release of fertilizers with very high fertilizer loading in their structures [33]. PAM/MC semi-IPNs composite hydrogels were prepared by aqueous radical polymerization at room temperature, and MBA was used as a crossliking agent [34, 35]. Frontal polymerization (FP) was exploited as an alternative and convenient technique to prepare PAM/MC composite hydrogels swollen either in water or glycerol [36]. MC was modified with functional methacrylate groups and photocrosslinked to produce hydrogels for potential applications in plastic and reconstructive surgery [37]. Polythiophene-g-poly(dimethylaminoethyl methacrylate)-doped MC hydrogel behaved like a polymeric AND logic gate [38].

HPMC is produced by the addition of methyl and hydroxypropyl groups to the cellulose backbone. PAM/HPMC composite hydrogels were synthesized by radical polymerization technique which demonstrated controlled drug release behavior due to the hydrophobicity as well as lower rate of erosion [39, 40]. Thermosensitive PNIPAM/HPMC hydrogels were prepared, and swelling ratio of the hydrogel decreased with increasing temperature [41]. HPMC hydrogels containing PEG as crosslinks were prepared by reacting HPMC with polyethylene glycol dichloride which was a promising drug delivery system for the drugs to be delivered to the colon [42].

HEC is obtained by reacting cellulose with sodium hydroxide, and hydroxyl groups of cellulose are replaced by hydroxyethyl groups. Double-layered gels, consisting of HEC cryogel core and poly(ethylene oxide) (PEO) hydrogel shell, were synthesized with UV irradiation which were used as carriers for immobilization by entrapment of cells [43]. Composite hydrogels from poly(N-vinyl pyrrolidone) (PVP) and methyl hydroxyethyl cellulose (MHEC) were obtained via gamma irradiation [44]. PAA/HEC composite hydrogels were prepared by in situ method, and moduli of the composite hydrogels were improved dramatically compared to HEC [45]. HEC-g-PAA/vermiculite superabsorbent nanocomposites were prepared by radical solution polymerization among HEC, AA, and vermiculite in the presence of MBA as crosslinker [46]. PNIPAM/HEC composite hydrogels were prepared by copolymerization with NIPAM onto HEC, and LCST of hydrogels was enhanced by the introduction of HEC [47].

HPC is synthesized by chemical modification of cellulose with an etherifying agent, propylene oxide, which results in the introduction of hydroxypropyl side chains onto cellulose chains. Composite hydrogels with HPC and two methacrylate compounds were obtained by irradiation with γ-rays. Radiation-induced change of optical properties made them to be good candidates of a new type of radiation dosimeter utilized in radiation therapy [48]. Thermally sensitive hydrogels were prepared by crosslinking HPC with polyethylene glycol diglycidyl ether which swelled at low temperature and contracted at high temperature [49]. Ternary system thermoresponsive hydrogels, poly(N-isopropylacrylamide-co-hydroxyethyl methylacrylate polycaprolactone)/HPC (P(NIPAM-co-HEMAPCL)/HPC), were prepared via "alkynyl/azide" click chemistry between the azide-modified graft copolymer P(NIPAM-co-HEMAPCL-N3) and the alkynyl-modified HPC (Fig. 2). The composite hydrogels exhibited reversible swelling-deswelling behavior after three "swelling-deswelling" cycles [50]. Comb-shaped copolymer composed of HPC backbones and low-molecular-weight PNIPAM side chains were prepared via atom transfer radical polymerization (ATRP) for smart hydrogels in biomedical applications [51]. Methacrylic anhydride/HPC (MA/HPC) composite hydrogels for adipose tissue engineering applications were prepared and made to be biocompatible to human adipose-derived stem cells [52]. PAM/HPC composite hydrogels were prepared by in situ graft polymerization for heavy metal removal due to the capacity of both chemicals for forming chelates with metals [53]. PAA/HPC composite hydrogels were also fabricated via free-radical polymerization as absorbent, and a phase separation was revealed in the hydrogels [54].

2.2 Nanocellulose

Nanocellulose (NC) with high aspect ratio is partially to fully crystalline and exhibits impressive mechanical properties and tunable surface chemistries. Recently, the use of NC as a reinforcing agent for hydrogels has attracted significant research interest, especially in applications of tissue engineering scaffolds, wound healing materials, and drug delivery systems. There are three main reasons for the improved

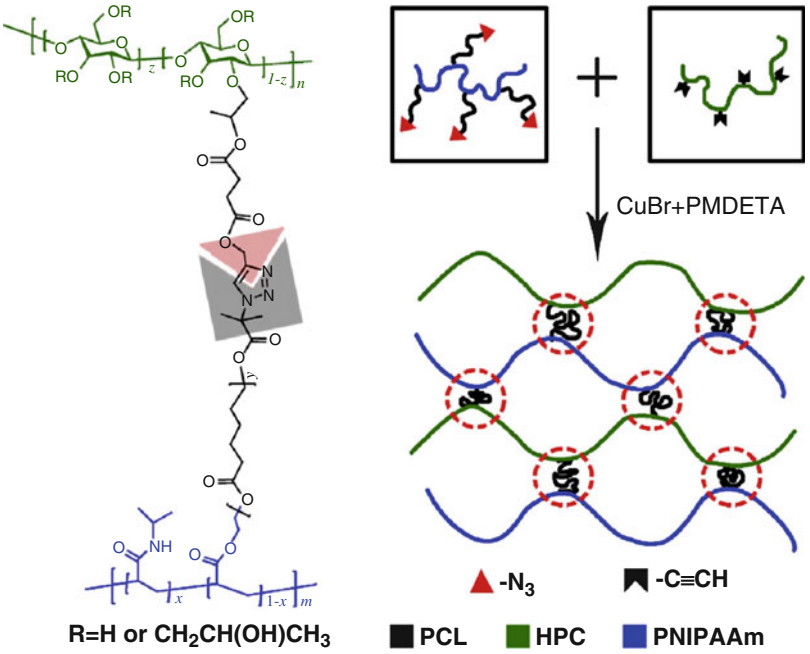

Fig. 2 Preparation of the P(NIPAM-co-HEMAPCL)/HPC hydrogels via click chemistry [50]

performance of the polymer hydrogels by incorporating NC, i.e., increased relative surface area (aspect ratios) and its associated quantum effects exhibited by NC, which formed polymer-filler interactions such as hydrogen bond, enhanced the elastic modulus with the rigid nanofibrils [55]. NC can be physically entrapped in the polymer network as a filler or chemically crosslinked with the polymer matrix in the composite hydrogels. Due to their rigidity and mechanical strength, NC acts as effective fillers in the composite hydrogels, and the majority of the NC composite hydrogel research has focused on the physical incorporation of NC as fillers. Common preparation methods include simple homogenization and physical entanglement of polymer networks, free-radical polymerization of polymeric species within NC suspensions, and UV/ion-mediated crosslinking of the polymeric network around the NC and cyclic freeze-thaw processing [56].

Incorporation of NC into synthetic polymer hydrogels can significantly improve the degradation and the mechanical strength of the hydrogels. The orientation of the reinforcing NC from the anisotropic to highly isotropic state under applied stress is the main mechanism of strain-dependent behavior of the composite hydrogels [57]. Polyvinyl alcohol (PVA) is among the most promising polymer candidates for the composite hydrogels because it is biocompatible, nontoxic, and readily crosslinked polymer. With the increase of NC concentration in PVA hydrogels, the composite hydrogels greatly improved the mechanical strength while maintaining remarkable ductility [58, 59]. PVA/NC composite hydrogels obtained by freezing-thawing (F-T)

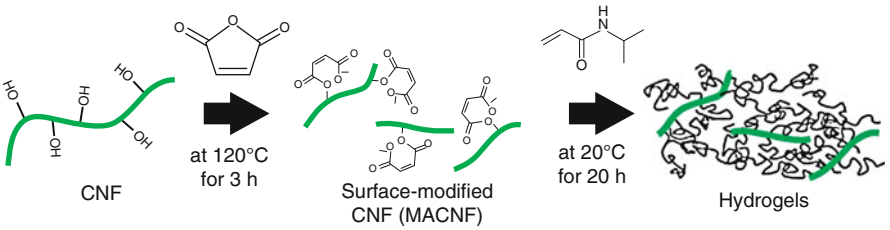

Fig. 3 Surface modification of NC with MA and the following hydrogel formation via in situ polymerization of NIPAM [71]

technique revealed increased thermal stability, mechanical properties [60], and proper water vapor transmission rate in the potential application of wound dressing [61]. The porous structure of PVA/NC hydrogels can be controlled by adding PEG with various molecular weights [62]. Hyperelastic, rubberlike PVA/NC composite hydrogels mimicking collagenous soft tissues are promising materials for ophthalmic applications [57, 63, 64]. The stiffness of PVA/NC composite hydrogels was significantly enhanced by utilizing three-component recognition-driven supramolecular crosslinks [65]. NC can also be chemically crosslinked with PVA to obtain the composite hydrogels [66, 67]. NC can be incorporated into PVA/chitosan [68] or PVA/alginate [69] to form the ternary composite hydrogels.

PNIPAM is a thermoresponsive polymer and has a LCST very close to the human physiological temperature. Incorporation of NC into PNIPAM hydrogels could obtain stimuli-responsive composite hydrogels which are promising in drug delivery. PNIPAM/NC composite hydrogels obtained by in situ radical polymerization of NIPAM monomer on the surface of modified NC (Fig. 3) could be elastically stretched to more than 700 times their original length [70] which attributed to the sustainer effect of the highly aligned NC fibers in the stretched hydrogels [71]. MBA was used to crosslink NC with PNIPAM by concurrent free-radical polymerization of monomers [72–75]. Additionally, the negatively charged carboxylate groups on oxidized NC would favorably interact with hydrophilic amide groups in PNIPAM to form the network structure. AM, AA, and HEMA are common monomers to fabricate the PAM/NC [76–85], PAA/NC [86–89], and PHEMA/NC [90–92] composite hydrogels via in situ polymerization of monomers in the presence of NC.

3 Natural Macromolecules/Cellulose Composite Hydrogels

3.1 Polysaccharides

3.1.1 Chitosan

Chitosan is a linear copolymer obtained by deacetylation of chitin, and it is a polycation that has one amino group in the repeating glucosidic residue. The backbone of chitosan is very similar to cellulose excepted that some amino groups replace the hydroxyl groups on the C2 position. Chitosan is the most important

polysaccharide which incorporated with cellulose to form the composite hydrogels with many applications. The chemical crosslinking is assuredly a highly versatile method to create chitosan/cellulose composite hydrogels with stable structure and effective swelling. According to the mechanism, crosslinking reactions between chitosan and cellulose can be classified into two types: (1) crosslinking with crosslinkers such as epichlorohydrin (ECH) and ethylene glycol diglycidyl ether (EGDE) and (2) crosslinking by the reactive groups in chitosan and cellulose or their derivatives. Chemical crosslinkers form covalent bonds and link chitosan with cellulose into network. ECH is a common etherifying crosslinker resulting in formation of ROR bonds. Etherification generally involves reactions in aqueous alkaline conditions (alkali catalysis) for the deprotonation of hydroxyl groups in order to make them highly nucleophilic and reactive with the crosslinker [93]. HEC and cationic modified chitosan can be crosslinked by ECH to prepare a double-network structure for loading anionic modified β-cyclodextrin (β-CD) via electrostatic interaction (Fig. 4). Incorporation of β-CD not only increased the mechanical strength of the composite hydrogels but also encapsulated hydrophobic guest substances by the host-guest interaction, and guest molecules could adsorb rapidly in the composite hydrogels and sustain the release in aqueous solution [94]. A water-soluble hydroxyethyl chitosan and cellulose were employed to fabricate the composite hydrogel scaffolds with bubble-like porous structure by a combination of chemical crosslinking with ECH, particle-leaching technique using silicon dioxide particles as porogen, and freeze-drying method. ECH mediated the chemical reactions between the hydroxyethyl or amino groups of chitosan and the hydroxyl groups of cellulose. The compressive modulus, equilibrium swelling ratio, and elasticity of the composite hydrogels were improved. In vitro biocompatibility evaluation demonstrated that the composite scaffolds could well support the attachment spreading, viability, and proliferation of cells [95]. EGDE with double epoxide groups was used to obtain the composite hydrogels with significant improved mechanical strength and chemical stability. The chitosan/cellulose composite hydrogel beads had high adsorption capacities for Cu removal which mainly involved the nitrogen atoms in chitosan to form surface complexes [96]. Thiourea-formaldehyde resin crosslinked chitosan and cellulose firstly, and AA was grafting polymerized on the composite hydrogels to obtain the superabsorbent in controlled release of soil nutrients [97]. Genipin, a biobased crosslinker, was used to crosslink amino groups of chitosan in the presence of CMC in order to form stable nanoparticles with semi-IPN

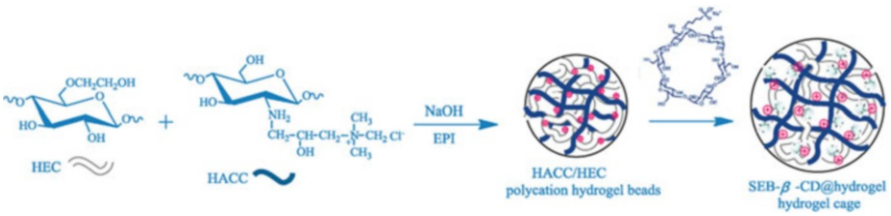

Fig. 4 The synthetic route of SEB-β-CD at hydrogel beads. (Reproduced from [94])

structure, and magnetite was lastly synthesized within the composite particles by the coprecipitation method to obtain hybrid nanoparticles which exhibited the responsiveness to a magnetic field [98].

There are an abundance of amino groups in chitosan molecules, and they are feasible to react with aldehyde groups in oxidized cellulose derivatives to form a Schiff base which is an important chemical crosslinking to produce chitosan/cellulose composite hydrogels. Sodium periodate is a normal agent to cleave the C2-C3 bond of the anhydroglucose unit in cellulose and results in the formation of two aldehyde groups. Hydrogen peroxide was also used as an oxidant which oxidized CMC in the presence of sulfate copper, and the amount of aldehydes increased with the $CuSO_4$ [99]. Due to the good water solubility, CMC was extensively employed to be oxidized to dialdehyde carboxymethylcellulose (DCMC) and self-crosslinked with chitosan or its derivatives based on Schiff base formation [100–103]. The chitosan/DCMC composite hydrogels displayed significantly better thermostability, swelling capacity, and cytocompatibility compared with glutaraldehyde (GA) crosslinked carboxymethyl chitosan [100]. Chitosan/cellulose composite hydrogels with gelation driven by Schiff base reactions are highly porous materials which are capable of loading various potential therapeutic agents including cells, drugs, and growth factors, as drug delivery carriers of an anticancer drug, drug loading and releasing can be easily modulated by tuning the composition of the composite hydrogels. Protonation of carboxylic groups in the microsphere matrix at acidic conditions resulted in an accelerated release of doxorubicin, which is desired for treating tumors [101]. Chemical stability of the composite hydrogels was improved remarkably by grafting chitosan onto cellulose hydrogels prepared by dissolution-regeneration in LiOH/urea [104].

Irradiation is a useful method for the formation of covalent bonding between chitosan and cellulose to obtain the composite hydrogels. The advantages of this method are high purity of the hydrogel products without crosslinkers and tedious process to prepare polymer derivatives. High concentrated paste-like condition was favorable for irradiation crosslinking of chitosan or cellulose; meanwhile, degradation of the polymer chains competed with crosslinking during irradiation [105]. Carboxymethyl chitosan/CMC composite hydrogels were prepared by γ-irradiation of a high concentrated mixture solution revealing the high-adsorption capacities for metal ions. It was found that the maximum strength depended on the composition of the composite hydrogels. The behavior of the tensile strength of the composite hydrogels with increasing dose was similar to that of pure hydrogels [106–108]. Additionally, MBA as a radical crosslinker could be added to the mixed solution before irradiation to enhance the gelation efficiency [109]. It was reported that macroradicals emerged preferentially in weakened C1 and C4 positions of cellulose as a result of the fracture of C-H bonds upon irradiation, while macroradicals of the derivatives were created in the side chains during radical crosslinking [110, 111].

Chitosan/cellulose composite hydrogels can be fabricated by physical interactions as well such as hydrogen bonds, electronic or hydrophobic associations, chain entanglements, and van der Waals forces. Cellulose ethers such as MC, HEC, and HPMC are the most important water-soluble derivatives of cellulose which can form

physical crosslinking composite hydrogels with chitosan via hydrophobic associations and hydrogen bonding. HPMC and MC are temperature-sensitive and will undergo abrupt change in solubility in response to increases in environmental temperature at LCST which is governed by the balance of hydrophilic and hydrophobic moieties on the polymer chains. At the LCST, phase separation occurred because the balance of hydrophilic and hydrophobic moieties on the polymer chain was broken which resulted in a more hydrophobic structure of the polymer. Thermoreversible chitosan/HPMC composite hydrogels were fabricated, and LCST was increased with the increment of chitosan proportion in the composite hydrogels. For HPMC gelation, hydrophobic associations among the macromolecules possessing the methoxy group are the main mechanism. As temperature increases, hydrated and simply entangled polymer chains gradually lose their water of hydration with hydrophobic associations and form the hydrogel network. By adding chitosan, the concentration of HPMC was decreased, and hydrogen bond between the OH groups of HPMC and NH_2 groups of chitosan enhanced the interactions of two macromolecules. The ionization of the amino groups extended the distance between the chitosan molecules through cationic repulsion and favored the osmotic flow of the water into the network. Therefore, the hydrophilicity of the composite was enhanced resulting in the increased LCST [112]. The composite hydrogels displayed excellent thermal stability and good mechanical properties [113]. The composite hydrogels physically crosslinked by hydrogen bonding of carboxymethyl chitosan with HEC and MC were prepared for controlled drug release system. Better interaction is demonstrated in HEC composite hydrogels than that in MC composite hydrogels, owing to stronger intermolecular hydrogen bonding [114]. Polyol was also introduced into chitosan/HEC composite hydrogels to strengthen the hydrophobic interactions resulting in the incorporation of hydrophobic network into the hydrophilic network via IPN. The hydrophobic microenvironment can not only limit the swelling degree of the composite hydrogels but also act as reservoir of the drug [115]. The pH-responsive composite hydrogels slowed down the drug release rate by the moieties formed by hydrophobic network which was a promising approach to cover up the drawbacks of drug burst-release kinetics from the hydrogels [116]. The gelation temperature of CS-SO_3/MC/CMC was around body temperature which made it a good candidate for injectable thermosensitive hydrogels for postoperation anti-adhesion [32]. Chitosan/cellulose composite hydrogels can also be fabricated through the different solubilities of the macromolecules in various solvents. Both cellulose and chitosan can be dissolved in ionic liquid and coagulated to composite hydrogels by adding certain antisolvents such as water and ethanol. By this method, the lipase could be entrapped into chitosan/cellulose composite hydrogels with higher immobilization yields than cellulose hydrogels [117]. Chitosan/cellulose composite hydrogels also exhibited good cell compatibility and non-cytotoxicity. Magnetic hybrid hydrogels were obtained by coating cellulose and chitosan in ionic liquid on the surface of Fe_3O_4 which revealed high adsorption capacities for different heavy metal ions [118].

The amino groups of chitosan can be ionized in acid conditions to make it positively charged and form the composite hydrogels with negative-charged

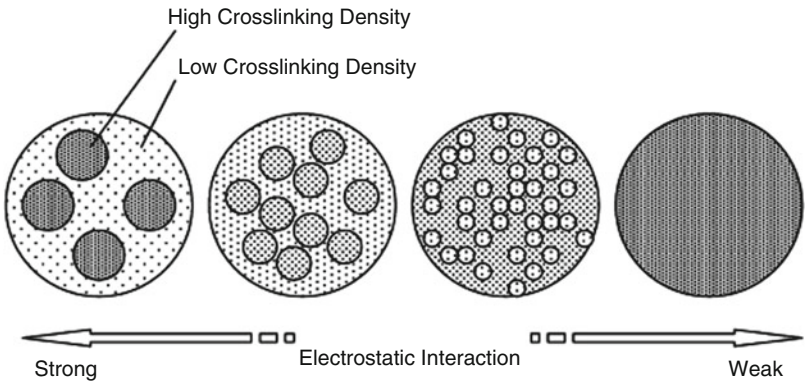

Fig. 5 Scheme representing heterogeneity of the chitosan/carrageenan/NaCMC composite hydrogels [120]

cellulose derivatives such as CMC via electrostatic interaction. Chitosan/CMC composite hydrogels showed pH-responsive swelling behavior. In acidic solution, amino groups of chitosan were protonized to NH^{3+} groups which coagulated with COO^{-} to form the condensed network, whereas in alkaline solution, the amino groups were neutralized, and electrostatic linkages between the two functional groups disappeared which resulted in the swelling of the hydrogels by the electrostatic repulsion between carboxyl groups. In vitro evaluations of capsaicin from chitosan/CMC composite hydrogels showed the reduced flux of capsaicin compared to the single-component hydrogels [119]. Chitosan/CMC/carrageenan ternary composite hydrogels were prepared by ionic crosslinking between NH^{3+} of chitosan with COO^{-} of CMC and SO_3^{-} of carrageenan. Both pH and addition of salt influenced the degree of swelling by changing the crosslinking density and/or the homogeneity of the network. As shown in Fig. 5, the composite hydrogels have the phase-separated structure, which is changed by the electrostatic interaction among three kinds of polyelectrolytes. The homogeneity of the composite hydrogels strongly depended on the composition of carrageenan/CMC and the salt concentration. When the chitosan or salt concentration was low, highly crosslinked part appeared in a relatively low crosslinked network. Increasing the chitosan or salt concentration, the difference in the crosslinking density in the homogeneous composite hydrogels would be small [120]. Chitosan/CMC composite hydrogels with core-shell structure were obtained by ionic crosslinking CMC with the Zr tetravalent metal ions firstly and further complexing with chitosan for the potential applications in bone tissue engineering [121].

3.1.2 Alginate

Alginate, a water-soluble polysaccharide composed of D-mannuronic and L-guluronic acid residues, is an abundantly available biopolymer extensively used for hydrogels, and the ionotropic gelation of alginate can be achieved with several cations. Alkaline earth metals, transition metals, and certain post-transition metals

are normally applied to form alginate hydrogels. Most of alginate/cellulose composite hydrogels were fabricated by utilization of the gelation of alginate with calcium ions, and cellulose was incorporated by dispersing in the composite hydrogels without taking part in forming the network. Water-soluble CMC is feasible to be mixed with alginate and crosslinked by Ca^{2+} to form alginate/cellulose composite hydrogels in order to remove some heavy metal ions such as Zn(II) [122], Chromium (VI) [123], and Hg(II) [124]. Both alginate and CMC are anionic in nature due to the presence of negatively charged carboxyl groups at pH $>$ 5. These negative charges allow the polymers to shrink in the acidic pH and to swell when they are exposed to neutral or basic pH. Therefore, alginate/CMC composite hydrogels prepared by the ionic gelation are good candidates of the drug delivery [125]. The crosslinking rate for trivalent ions was faster than that of divalent ions due to their higher valency; the Al^{3+} crosslinked alginate/MC composite hydrogels improved not only the drug encapsulation efficiency but also drug release in alkaline media [126]. Addition of CMC to alginate gel significantly improved the yield of lactase immobilization and the activity of the fixed enzyme [127]. CMC and its grafted copolymer were also incorporated into the alginate hydrogels by ionic crosslinking at the presence of inorganics to form the ternary composite hydrogels [128, 129].

Recently, alginate/bacteria cellulose (BC) composite hydrogels are gaining more and more attentions as scaffolds for tissue engineering by combining beneficial properties of both BC and alginate. BC has advantages in terms of biocompatibility, nontoxicity, high mechanical strength, high swelling ability, and high stability to pH variations. Alginate can provide mechanical integrity in tissue engineering applications for its hydrogel properties. Several therapeutic agents, including antibiotics, enzymes, growth factors, and DNA, have already been successfully incorporated in alginate hydrogels in order to maintain high biological activity [130]. Normally, the BC pellicles were crushed to form BC slurry and mixed with the alginate solution, then crosslinked by Ca^{2+} to obtain the composite hydrogels for scaffold. The compression strength and chemical stability of the alginate/BC composites were increased compared with the alginate hydrogels [131]; cell proliferation and migration on the surface of the scaffolds were promoted as well [130, 132]. Silver sulfadiazine particles, topical antibacterial agents, were embedded into the alginate/BC composite hydrogels to render the enhanced antibacterial property for utility as potential wound dressings [133]. Multi-walled carbon nanotube was incorporated into alginate/BC composite hydrogels to get a pH and electric field dual-stimulus responsive drug delivery system [134]. Alginate/BC composite hydrogels were also good immobilization carriers of lipase [135] and yeast [136]. In application in lipase immobilization, a novel in situ method was employed. Alginate solution was mixed with *G. xylinus* suspension firstly, and the resulting mixture was then added into $BaCl_2$ solution to gain the hydrogels. *G. xylinus* entrapped in the hydrogels successfully produced BC with a narrow distribution of fiber diameters. The prepared alginate/BC nanocomposite hydrogel beads showed consistent sizes and regular spherical shapes [135].

Alginate/cellulose composite hydrogels can be fabricated by ionic crosslinking by some trivalent cations with both macromolecules taking part in the formation of

network. Trivalent cations such as Fe^{3+} and Al^{3+} can induce the gelation of alginate; meanwhile, CMC can produce hydrogels by coordinating with these trivalent cations [137] due to numerous carboxyls and hydroxyls in the molecular chains. The trivalent iron can be a more suitable crossliking agent for alginate/CMC composite hydrogels than divalent metal ions in drug delivery system due to the faster crossliking rate which can result in the higher load capacity and sustained release [128, 138]. Protein, drugs, and some bioactive compounds can be encapsulated into the composite hydrogels and controlled released from them. Albumin was embedded into the Fe^{3+}-crosslinked alginate/CMC composite hydrogels, encapsulation efficiency was higher, and protein release was reduced in the gastric environment because of the pH sensitivity, which demonstrated that the alginate/CMC composite hydrogels presented a promising protein therapeutic carrier for the oral delivery [139]. The composite hydrogels also exhibited pH sensitive for delivering metformin hydrochloride (MH); the swelling degree and in vitro release profiles were higher by two orders at gastric conditions compared to an acidic environment [140]. Hesperidin-loaded efficiency in the alginate/CMC composite hydrogels was high, and in vitro release of hesperidin was prolonged. The composite hydrogels exhibited the ability to protect the encapsulated flavonoid glycoside during its passage through the simulated gastric environment, while under the simulated intestinal conditions, the transportation systems exhibited a pH-triggered release behavior [141]. The alginate/CMC composite hydrogels are also good absorbents to remove lead ions by physical, chemical, and electrostatic adsorptions [142].

Besides the ionic crosslinking, alginate and cellulose can be chemically crosslinked via some crosslinking agents to form the IPN composite hydrogels. There are numerous hydroxyl groups in both alginate and cellulose macromolecular chains; aldehyde groups of GA can form ether linkage with hydroxyl groups of alginate and cellulose as a result of the crosslinking reaction. Alginate/CMC composite hydrogels were prepared by crosslinking with GA and used for the delivery of carbaryl with higher entrapment efficiency. By increasing of exposure to GA or concentrations of GA, the crosslink density of the composite hydrogel matrix was changed to more compact network with increase in crosslink density resulting in reduced free volume and difficult diffusion of the carbaryl molecules [143]. AM was grafted onto HEC by free-radical polymerization and blended with sodium alginate to prepare pH-sensitive IPN composite hydrogels using GA as a crosslinking agent (Fig. 6). The covalent crosslinking leads to reduced swelling and introduces specific properties such as structural strength along with thermal and mechanical stability. In vitro release of diclofenac sodium was decreased with increasing GA content in the matrix due to the formation of a more tightly crosslinked rigid network structure [144]. ECH was also used as a crosslinker to react with the hydroxyl groups of cellulose and alginate chains through nucleophilic attack of the alcoholate anion, whereas a new epoxide formed by chloride displacement (Fig. 7). The combination of cellulose containing semi-stiff chain and alginate containing carboxyl groups created macroporous structure in the crosslinking hydrogels where cellulose contributed to support the pore wall and alginate acted as an expander of the pore size [145].

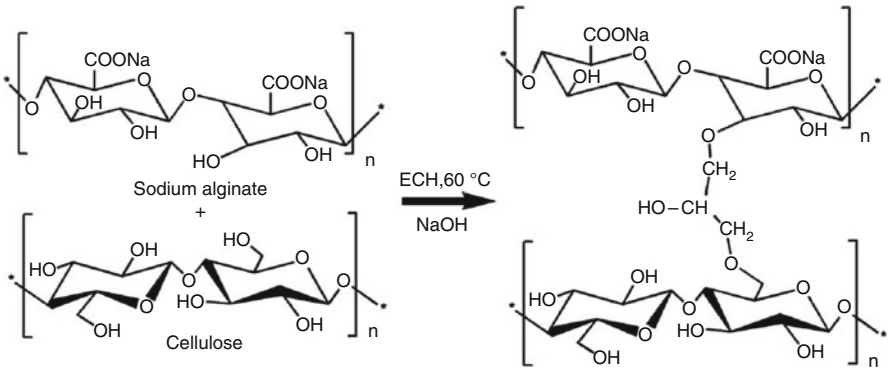

Fig. 7 Proposed mechanism for crosslinking reaction of cellulose and alginate with ECH [145]

3.1.3 Starch

Starch is an abundant renewable resource with low cost and broad-ranged capability in food and nonfood products. Starch granules have a semicrystalline structure, mostly composed of two different polysaccharides, amylose and amylopectin, with complicated internal structure. Starch/cellulose composite hydrogels can be prepared in chemical and physical crosslink of the network as well as with high-energy irradiation. Injectable adhesive hydrogels composed of starch and CMC were developed. Firstly, CMC was modified with tyramine to introduce crosslinking site, then the in situ hydrogel was prepared by an enzyme-mediated reaction of tyramine-immobilized CMC with horseradish peroxidase (HRP) and hydrogen peroxide (H_2O_2). Starch was added to the hydrogel solution to be incorporated in the cellulose

network as semi-IPN composite hydrogels. Starch can improve adhesiveness to the wound area and accelerate biodegradation of the hydrogels as injectable in situ anti-adhesive agents [146]. Starch/CMC/SiO_2 composite hydrogels were fabricated using aluminum sulfate octadecahydrate as an ionic crosslinker which increased the water restoration capability of agricultural soil [147]. Starch-g-PAA/NC composite hydrogels were obtained by in situ copolymerization of AA onto starch and crosslink with MBA (Fig. 8). The large amounts of active -OH groups on the surface of NC can take part in the polymerization reaction as well as the construction of 3D polymer network [148, 149]. Composite hydrogels were prepared with cellulose from tea residue [150] or pineapple peel [151] in ionic liquid, followed by incorporating soluble starch by mixing the cellulose hydrogel with starch. Addition of soluble starch exhibited good cell compatibility and non-cytotoxicity to the composite hydrogels. The composite hydrogels from HPMC and starch demonstrated the typical behavior of "filled" composite systems having poor adhesion between the surface of the elastic starch "filler" and the continuous HPMC phase [152].

High-energy irradiation technique is becoming an important approach in the crosslinking of polymers as it can efficiently replace the chemical crosslinking agents and produce hydrogels with high purity that do not need the removal of hazardous chemical crosslinkers. It allows the chemical crosslinking without the use of crosslinking agents which provides a convenient approach to crosslink polysaccharide at high concentrated aqueous solution mainly due to the mobility of side chains [153–155]. Side-chain radicals were formed mostly via indirect effects, by the abstraction of H atoms in the intermediate products of water radiolysis. Electron beam irradiation (EB) was used to prepare composite hydrogels from aqueous solutions of plasticized starch (PLST), cellulose acetate (CA), and CMC. A semi-IPN structure could be formed in which the network was mainly formed by crosslinked CMC and CA with PLST physically included [156]. Carboxymethyl sago pulp (CMSP)/carboxymethyl sago starch (CMSS) hydrogel was also synthesized by electron beam irradiation to produce the composite hydrogels with sustained release of drugs. The radicals on CMSP and CMSS chains can combine and form the intermolecular crosslinking between the molecular chains [157]. Gamma irradiation was also applied to prepare starch/CMC composite hydrogels as superabsorbent gels, in which the starch granules also participated in the

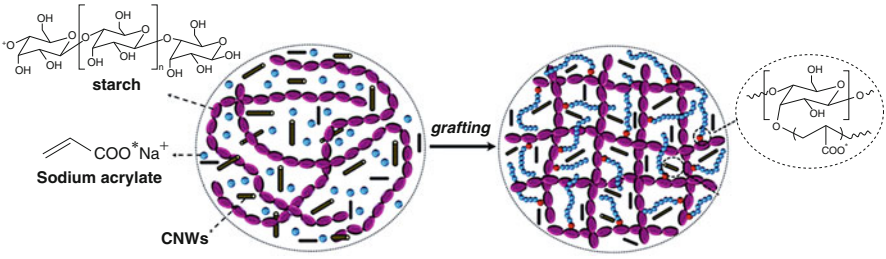

Fig. 8 Illustrative scheme for the structure of starch-g-poly(sodium acrylate)/CNWs composite hydrogels. Reproduced from [149]

crosslinking process resulting in the improved gelation. CMC chains reacted with the granule surface through the recombination of the radicals, and the reaction was not hindered by electrostatic repulsion during the crosslink formation between two CMC chains. The partial replacement of CMC with starch improved the gel fraction; however, very high starch content had a negative impact on the gelation [158].

3.1.4 β-CD

β-CD is a type of cyclic molecule composed of seven glucose units and derived from starch. β-CD possesses internal relatively hydrophobic cavity and exterior hydrophilic structure. These special structures make β-CD easy to form molecular complexes via interaction with other polymer network by virtue of intermolecular force. There are abundant hydroxyl groups in β-CD molecular; it is feasible to chemically crosslink β-CD and cellulose via some crosslinkers to obtain β-CD/cellulose composite hydrogels. Water-soluble CMC was crosslinked with β-CD via ECH, and the graft reaction involved usually nucleophilic substituent in cellulose. Meanwhile, β-CD of the heptatomic ring chain can attack the epoxy group of ECH and is then converted to a monoether of chloropropanediol [159]. Due to substitute and rearrangement of chloride, β-CD and CMC were linked together, and the network structure was constructed (Fig. 9). The prepared composite hydrogels were sensitive to changes of pH, temperature, and ionic strength [160]. NaOH/urea aqueous solution has been found to be a good solvent for cellulose; β-CD/cellulose composite hydrogels could also be synthesized in NaOH/urea aqueous solutions by crosslinking with ECH. Swelling degree of the composite hydrogels decreased with an increase of the β-CD content. The drug-loading capacity of the composite hydrogels was preferred to the hydrophobic drug due to the formation of complexation; however, only the molecules which can form a stronger inclusion complex with β-CD [161] can promote the release of the drug. The composite hydrogels-adsorbed aniline blue also caused enhanced fluorescence intensity with the potential application as a biological stain [162].

Citric acid (CA) has gained recognition as a nontoxic crosslinking agent for grafting β-CD onto cellulose, and anhydride formation of CA facilitated the ester crosslinks between cellulose and β-CD (Fig. 10). β-CD-grafted HPMC [163] and β-CD-grafted

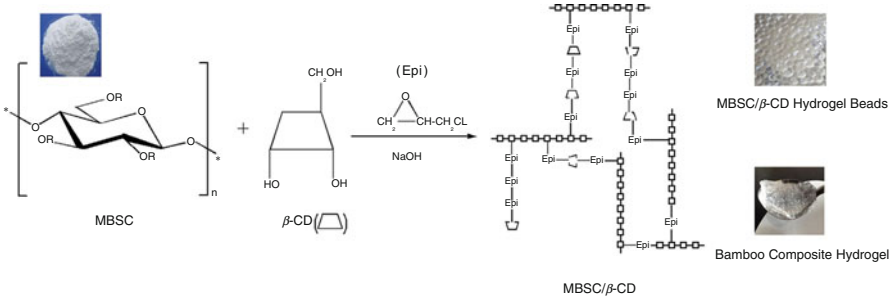

Fig. 9 Synthesis of the β-CD/cellulose composite hydrogels [159]

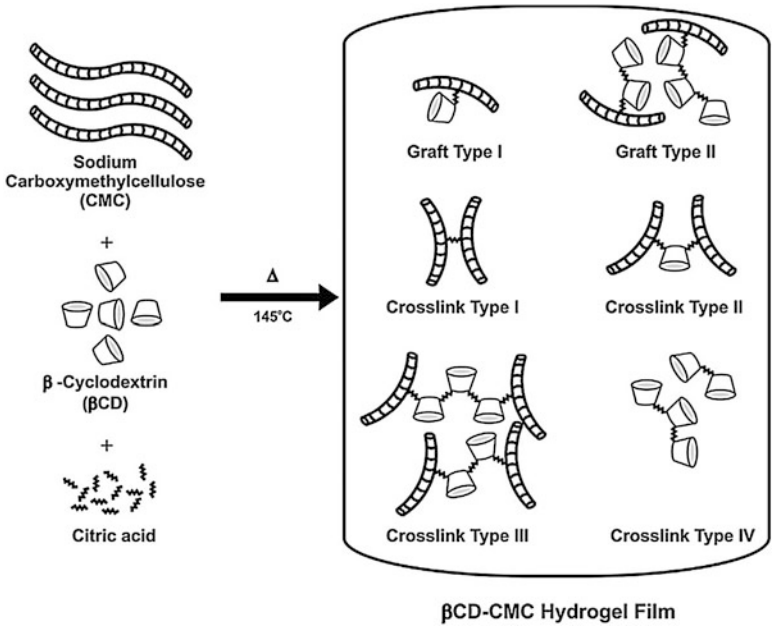

Fig. 10 Schematic representation of the formation of β-CD-CMC hydrogel film [164]

CMC [164] composite hydrogels were obtained with CA, and the controlled delivery of drugs with poor solubility of those composite hydrogels was investigated. The active β-CD content, carboxyl content, and swellability showed major contributions toward improvement of drug loading and retardance of drug release [163].

Hydroxypropyl-β-cyclodextrin (HPβCD) was crosslinked with HPMC via EGDE under mild conditions to prepare β-CD/cellulose composite hydrogels [165]. 1,4-butanediol diglycidyl ether (BDGE) was used as crosslinker to form β-CD/HPMC composite hydrogels which were conjugated with antimicrobial gallic acid to prevent wound infection [166]. β-CD and CMC were graft polymerized with AA, in the presence of MBA as a crosslinker to prepare β-CD/CMC-g-PAA composite hydrogels. The pH-sensitive composite hydrogels were conferred good mechanical properties with improved drug loading and release capability for the antiviral drug acyclovir [18].

β-CD can be incorporated into β-CD/cellulose composite hydrogels by non-covalent interactions as well. Hydrophobic cavities of β-CD can act as moieties capable of generating physical crosslinks, by making inclusion complexes with hydrophobically modified polymers or with amphiphilic polymers with hydrophobic chains, which combined to form host-guest complexes networks. β-CD can also be modified by some anionic or cationic groups to make it charged and form the composite hydrogels with opposite charged polymers via electrostatic interaction.

Cellulose can be dissolved in the mixed solvent of tetrabutylammonium hydroxide (TBAH) and Dimethyl sulfoxide (DMSO) because TBAH is capable to dissolve cellulose at the molecular level with effectively repulsive cellulose-cellulose

interactions. Stiff composite hydrogels were formed when adding β-CD to the cellulose dopes because the formation of 1:1 β-CD:TBA+ host-guest complex [167] destabilized the cellulose solution state and triggered the composite hydrogels formation [168]. β-CD and ferrocene (Fc) were grafted onto cellulose individually to obtain β-CD-cellulose and Fc-cellulose; firstly, the composite hydrogels can be prepared by mixing two solutions by formation of inclusion complexes. The ferrocene forms of the inclusion complexes with β-CD effectively, whereas the oxidized ferrocene is basically impossible. Therefore, the host-guest interaction between the metal ferrocene with β-CD can also be a reversible regulation by oxidation and reduction of the ferrocene which resulted in the controlled sol-gel transition [169]. The hydrophobic lauryl side chains were grafted onto HEC firstly and mixed with water-soluble β-CD polymers. The cavities of β-CD polymers can provide hydrophobic binding sites with C12 side chains to obtain self-assembled composite hydrogels based on the host-guest interaction, and the residual cavities of composite hydrogels can load drugs (Fig. 11) [170]. β-CD-grafted NC was accomplished using ECH as a coupling agent and pluronic polymers were introduced on the surface of NC by means of inclusion interaction between β-CD and hydrophobic segment of the polymers to obtain supramolecular hydrogels [171].

Chitosan/HEC hydrogels were prepared by crosslinking firstly, the negative sulfonatedbutyl (SEB) β-CD (SEB-β-CD) was loaded into the hydrogels simply by immersing the hydrogels into the SEB-β-CD solution. The electrostatic interaction of cationic chitosan and anionic SEB-β-CD was the main driving force to immobilize the β-CD into the hydrogels. Moreover, the encaged SEB-β-CD can be controlled and released from the composite hydrogels with ion-exchange method by immersing it in electrolyte solution readily [94]. In addition, hydroxypropyl-β-CD (HP-β-CD) was immobilized into HEC [172], HPC [173], and HPMC [174] hydrogels at the same time of the crosslinking of cellulose derivatives.

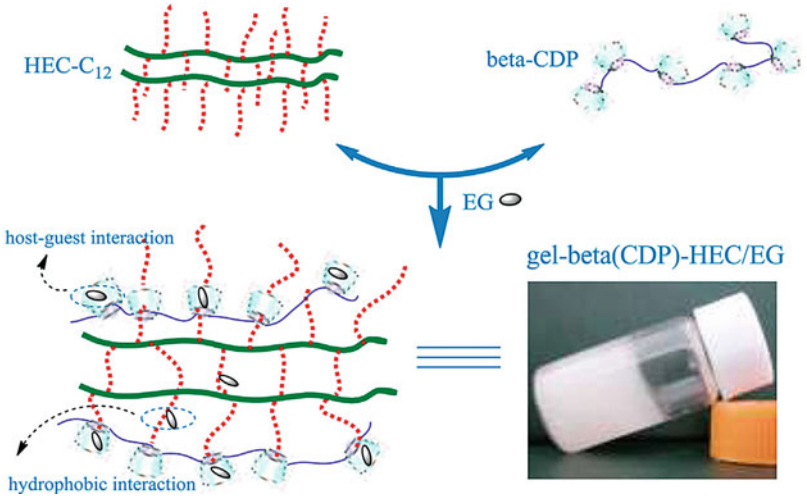

Fig. 11 Scheme of the formation of self-assembled hydrogels and its drug-loading pattern [170]

3.2 Extracellular Matrix

The extracellular matrix (ECM) is the noncellular component presenting within all tissues and organs that not only provides essential physical scaffolding for the cellular constituents but also initiates crucial biochemical and biomechanical cues [175, 176]. The composite hydrogels-combined cellulose and ECM are very promising scaffolds for the tissue repair and regeneration, especially for the injectable self-healing hydrogels with the dynamic interactions. Collagen as a key ECM component for promoting cell cultivation is most widely used to fabricate the composite hydrogels, especially for bone reparation because of its weak antigenicity, excellent biocompatibility, and unique fibril-forming properties. Collagen is a kind of protein forming a characteristic triple helix of three polypeptide chains, and all members of the collagen family form these supramolecular structures in the extracellular matrix although their size, function, and tissue distribution vary considerably [177].

Dialdehyde cellulose is an attractive cellulose derivative because it can react with amino functional groups in collagen by the formation of Schiff base-type compounds [178, 179]. Regenerated cellulose hydrogel was obtained firstly and oxidized by periodate oxidation to obtain 2,3-dialdehyde cellulose (DARC) which presented a porous structure with tangled fibrils and interconnected networks. This unique structure was attributed to the phase separation of the cellulose solution during the regeneration process, where solvent-rich regions contributed to the formation of pores. Collagen was immobilized on cellulose via the Schiff base reaction between -NH_2 in collagen and -CHO in DARC (Fig. 12). The self-crosslinked composite hydrogels showed great potential for use as a tissue engineering scaffold due to its high strength, malleability in situ, good equilibrium-swelling ratio, air permeability, and biocompatibility [180]. DCMC [181] with substantial degradation in periodate oxidization induced the crosslinking of collagen to macroporous structure [182].

The cellulose hydrogels were prepared from cellulose solution dissolved in LiOH/urea aqueous system by crosslinking with ECH and then thermal crosslinked collagen by neutralizing the collagen solution to obtain collagen/cellulose composite hydrogels. The composite hydrogels integrated microfluidics with well-controlled pore size, good mechanical durability, cytocompatibility in cell culture, and excellent dimensional stability [183]. The amino groups in collagen provide Cu(II) binding

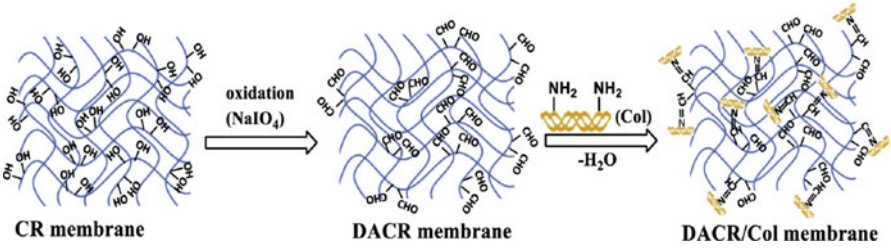

Fig. 12 The schematic diagram of the preparation of DARC/Collagen (DACR/Col) composite film [180]

sites through their chelating performance [184]. Collagen/cellulose hydrogel beads reconstituted from ionic liquid showed high Cu(II) adsorption capacity for removal of it from wastewater [185].

BC displays many unique properties including high water uptake capacity and an ultrafine nanofibril network structure which are essential for scaffolds in tissue engineering. To improve the biocompatibility and cell affinity of BC as wound dressing material, BC can be modified through the incorporation of collagen, and the collagen/BC composite hydrogels are very promising materials in skin tissue engineering. Collagen/BC composite hydrogels can be prepared by simply immersing wet BC pellicle into collagen solution followed by a freeze-drying process. The collagen molecules were not only coated on the BC fibrils surface but also penetrated inside BC, and hydrogen bond interactions were thus formed between BC and collagen [186]. According to the in vivo test and macroscopic evaluation, collagen/BC composite hydrogels showed better reparation ability of wounds and promoted statistically significant differences of tissue repair between treatments after surgery [187]. BC formed semi-penetrate hydrogels with alginate and immobilized collagen to ternary composite hydrogels which supported the growth of human skin fibroblast as deliver vehicles for therapeutic compounds during wound healing [188]. In order to improve thermal and mechanical properties of collagen/BC composite hydrogels, both GA and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride were used as crosslinkers to form the chemical bonds between collagen and BC [189].

3.3 Nanocellulose/Natural Macromolecules

NC can also be incorporated into natural macromolecules hydrogels such as chitosan, alginate, and gelatin which targeted biological or biomedical applications. GA was used as a crosslinker to chitosan because of its high reactivity toward the amine groups, and NC was incorporated into the network to improve mechanical properties and pH sensitivity of the chitosan/NC composite hydrogels [190, 191]. Carboxymethylated chitosan/NC aerogel for dye removal was prepared through Schiff base reaction. NC, bearing aldehyde and carboxylic acid groups, facilitated the crosslinking with chitosan through imine bond formation while providing negatively charged functional groups, and chitosan was modified to accommodate carboxylic acid [192]. Chitosan/NC sponge was prepared by lyophilization to be used as a new absorbable hemostat [193]. The carboxyl groups of NC and amino groups of chitosn were linked with peptide bonds forming stable hydrogel network [194]. Chitosan-g-PAA/NC composite hydrogels obtained by in situ polymerization showed responsive behavior in relation to pH and the salt solution [195]. Chitosan/NC/xanthan [196] and chitosan/BC/MMT [197] ternary composite hydrogels were also fabricated by lyophilization. Chitosan/BC composite hydrogels were prepared by co-dissolution of BC and chitosan in 1-Ethyl-3-methylimidazolium acetate ([Emim][Ac]) and reconstitution with water [198] or in situ method during biosynthesis which showed better effect on cell growth, cell proliferation, and biocompatibility [199].

For alginate/NC composite hydrogels, NC normally acts as reinforcement filler embedded in the alginate hydrogels crosslinked by metal ions. The alginate/NC composite hydrogels are effective absorbents to organic dyes [200], and the reusable composite hydrogels showed more than 97% dye removal efficiency after five successive adsorption-desorption cycles [201]. Alginate/BC hydrogel membrane was also used for separation of ethanol-water mixtures [202]. NC was firstly biofunctionalized by the covalent coupling of an enhanced avidin protein and used to fabricate 3D-printable bioactivated alginate/NC composite hydrogels [203]. IPN hydrogels based on NC in a matrix of alginate/gelatin were prepared via freeze drying and stabilized using $CaCl_2$ and genipin which were potential in load-bearing biomedical applications such as cartilage replacement (Fig. 13) [204]. Double-membrane hydrogels from cationic NC and anionic alginate involved with an internal membrane consolidate by electrostatic interactions. The composite hydrogels with double-layer structures can realize the complexing drugs release with the first quick release of one drug and the successively slow release of another drug [205].

NC was employed to reinforce the cellulose and its derivative hydrogels such as CMC/HEC [206] and MC [207]. Injectable hydrogels based on CMC and dextran, reinforced with rigid rodlike NC as simple fillers and aldehyde-functionalized NC as chemical crosslinkers, were prepared with potential applications such as drug delivery vehicles or tissue engineering matrices [208]. Composite hydrogels based on CMC-g-P(AA-co-AM) and carboxylate NC were prepared by in situ graft polymerization in the presence of NC, and results showed that the composite hydrogels comprised a crosslinking structure of NC and CMC with side chains carrying AA and AM [209]. Gelatin [210, 211], collagen [212–215], and starch [148, 149, 216] were also applied to fabricate the composite hydrogels with NC.

4 Inorganics/Cellulose Composite Hydrogels

4.1 Inorganic Minerals

Layered silicate, such as MMT, can form the microcomposite (Fig. 14a) and nanocomposite (Fig. 14b, c) hydrogels with polymers. The silicate can dispersed in the hydrogel matrix in nanoscale with two main structures: (1) intercalated (Fig. 14b), the polymer chains are inserted into the interlayer spacing of the stacking silicate platelets and (2) exfoliated (Fig. 14c), the individual layers are partitioned and dispersed in the polymer matrix. The exfoliated structure is more effective to improve the properties of the composite hydrogels for its greater phase homogeneity. Moreover, the polymer can act as a crosslinking agent by reacting with the groups on the surface of the inorganic plate. As shown in the Fig. 14d, the silicate platelets provide high surface area for multiple sites of crosslinking; meanwhile the polymer chains are flexible and can adopt random conformations for the long distances between the clay sheets which provide the cushion when the composite hydrogels are stretched or compressed. The performance of the clay composite hydrogels is

largely influenced by the clay content and homogeneous dispersion in the matrix [217]. Compared to the monocomponent hydrogels, composite hydrogels have the combined properties of high mechanical strengths, elongations at break, and high rates of swelling/deswelling.

Vinyl monomers such as AA and AM can be in situ polymerized and grafted onto the chains of cellulose derivatives in the presence of the layered silicate to prepare the composite hydrogels. The obtained superabsorbents revealed that the inorganic particles could be incorporated into the hydrogels matrix by reacting through the active groups on the surface. Silanol groups on the attapulgite (APT) [219] and hydroxyl groups on the MMT [220] make them facilitate to participate in the graft polymerization of CMC side chain of vinyl monomers. The remarkable pH sensitivity swelling behavior of the composite hydrogels was observed. Compared to the effects of cellulose derivates on swelling properties of the composite hydrogels, equilibrium water absorbency and the swelling rate in distilled water and saline solution are always in the order CMC > HPMC > MC > HEC. It was revealed that the influence of functional groups on swelling properties was great and the swelling properties of composite hydrogels were related to the hydrophilicity and the rigidity of functional groups [221]. Carboxyl group is an ion hydrophilic group which can be ionized; therefore, the polymeric network tends to swell, and the space for absorbing and holding water increases due to electrostatic repulsion. Moreover, the higher osmotic swelling pressure and chain relaxation process of CMC make it possess the higher swelling rate than other cellulose derivatives. Therefore, CMC is suitable to fabricate the inorganics/cellulose composite hydrogels for superabsorbent.

MMT is one of the most widely used layered silicates because its lamellar elements display high in-plane strength, stiffness, and high aspect ratio, which are beneficail to the properties of the composite hydrogels such as swelling ability, mechanical strength, and thermal stability. It has a 2:1 layer structure consisting of an octahedral alumina sheet sandwiched between two opposing tetrahedral silica sheets. The bonding between two silica sheets is very weak, which permits the water, exchangeable ions, and polymer chains to enter, and this leads to the development of nanocomposite hydrogels and their swelling capacity. The reactive hydroxyl groups and exchangeable cations on the surface of MMT can also make it act as a crosslinking agent between cellulose chains [220] and in situ intercalative polymerization [222, 223].

Cellulose-g-P(AA-co-AM-co-AMPS)/MMT composite hydrogels for superabsorbent were synthesized by using potassium persulfate as a free-radical initiator, in the presence of MBA as a crosslinking agent. The composite hydrogels comprised a crosslink structure of MMT and CMC with side chains that carried carboxylate, carboxamide, and sulfate [220]. CMC, MMT, and 2-acrylamido-2-methyl-1-propanesulfonic acid (AMPS) could be incorporated into AM hydrogels during free-radical solution polymerization; meanwhile the multifunctional crosslinker such as poly(ethylene glycol)diacrylate was used at the polymerization process to fabricate the highly swollen composite hydrogels [224]. Cellulose-g-PAA/MMT nanocomposite hydrogels were proved to be effective in controlled release of macro- and micronutrients; furthermore, a hydrolysis treatment improved their physicochemical properties. The presence of MMT not only remarkably enhanced their capacities of loading nutrient solutions but also acted as an effective barrier to control and retard the release of nutrients to the medium as well as played an important role in reducing production costs [225]. CMC-g-poly(NIPAM-co-AA)/MMT hydrogels were prepared by graft copolymerization of NIPAM and AA onto CMC in MMT/water suspension media, which were thermoresponsive and pH-sensitive hydrogels for removal of heavy metal ions from aqueous solutions [226]. MC was also used to prepare the nanocomposite hydrogels with PAM and MMT to slowly release of fertilizers [33]. Cellulose/MMT composite hydrogels were fabricated by chemical crosslinking cellulose and CMC with ECH in the presence of MMT nanosheets. MMT was first modified in order to make it take part in the formation of hydrogel network by reacting with cellulose. In this case, cellulose chains entered the galleries of MMT, and intercalated nanocomposite hydrogels were fabricated for highly efficient removal of dye in water [227].

Bentonite is a type of clay mainly composed of the crystalline structure of MMT and other additional crystalline structures. Composite hydrogels were synthesized by the graft copolymerization reaction among cellulose, polymethacrylic acid (PMAA), and bentonite; the inorganic bentonite particles in the network acted as additional network points. The PMAA-g-cellulose/bentonite could be effectively used as an adsorbent for the removal of dyes from water and wastewater [228]. CA-crosslinked CMC/bentonite composite hydrogels were prepared to develop base triggered release formulations of thiamethoxam due to their high swelling sensitivity under the basic pH condition, low cost, and environment-benign nature. Bentonite was added in the composite hydrogels to improve the barrier properties of formulations with enhanced rheological properties [229]. A new composite matrix for the controlled release of herbicides was prepared by adding bentonite or its acid-activated form into CMC gel [230].

Halloysite nanotubes (HNTs) with similar chemical formula as kaolinite possess unique empty lumen tubular morphology with outer diameters of 50 nm and inner lumens of 20 nm and 200–1000 nm long. They are biocompatible and widely available in nature, which make them good candidates for application in biomedicine by protecting the drug from enzyme degradation and delivery of the drugs to enter the cell. HNTs can be easily incorporated via solution mixing for cellulose composite hydrogels. HNTs were mixed into cellulose NaOH/urea solution to prepare

composite hydrogels using ECH crosslinking at elevated temperature, and curcumin-loaded composite hydrogels showed a strong inhibition effect on the cancer cells and good cytocompatibility [231]. HNTs were firstly modified by the reaction of the external silanol groups with maleic anhydride and further reacted with adipic acid dihydrazide to introduce a hydrazine moiety on the clay surface. Functionalized HNTs were mixed with oxidized CMC to form biodegradable hydrazone bond to prepare the injectable composites hydrogels with potential applications in bone medication [232].

Similar to MMT, carclazyte is a layered aluminum silicate with exchangeable cations and reactive -OH groups on the surface. CMC-g-poly(AA-co-AM)/carclazyte composite hydrogels for superabsorbent were synthesized by graft polymerization of AA and AM onto CMC and the introduction of carclazyte. Additionally, ammonium persulfate (APS) and MBA were used as a free-radical initiator and a hydrophilic crosslinking agent, respectively [233]. Medicinal stone is a special igneous rock composed of silicic acid, alumina oxide, and more than 50 kinds of constant and trace elements. Vermiculite is a trioctahedral 2:1-layered silicate similar in texture to mica, and it is abundant and much cheaper in comparison with MMT [234]. Both medicinal stone and vermiculite can be incorporated with HEC-g-PAA to fabricate the composite hydrogels by the free-radical polymerization among HEC and AA which exhibited the enhanced swelling capability, swelling rate, excellent pH-responsive and good deswelling capability as potential water-manageable materials [46, 235].

4.2 Antimicrobial Nanoparticles

The synthesis of cellulose/nanoparticles hybrid composite hydrogels has attracted increasing attention especially for the nanoparticles (NPs) with special functions. Metallic NPs with inherent antimicrobial properties such as Ag, Zn, Au, and Cu are known to have broad-spectrum antimicrobial nature and pose minimum toxicity to humans. Particularly, nanosilver-based wound dressings have received approval for clinical applications, but dermal toxicity was reported [236]; therefore, the combination of hydrogels with silver NPs (AgNPs) is a better choice for the treatment of wounds [237]. There are free spaces within the cellulose hydrogels that could be utilized to incorporate NPs; meanwhile the incorporation of NPs into the hydrogel matrix reduces their agglomeration. Development of cellulose/NPs composite hydrogels is important to control growth of pathogenic microorganisms for the prevention of infectious diseases with good biocompatibility in the medical field. However, NPs have a tendency to aggregate to minimize their surface energy, which decreases their antimicrobial activity [238] and hinders the large-scale production with cost-effective dispersion methods. The methods of composite hydrogels preparation have a great influence on the structure and properties of the resulting composite hydrogels. For the preparation of cellulose/NP composite hydrogels, metals NP can be incorporated via two approaches: (1) ex situ, in which pre-synthesized NPs are incorporated into the cellulose hydrogel matrix and (2) in

situ, in which cellulose matrix acts as a nano-reactor for synthesizing NPs. The antimicrobial NPs must be integrated in isolated and well-dispersed primary NPs inside the cellulose matrix to obtain the homogeneous composite hydrogels with good mechanical strength and enhanced antimicrobial activity.

4.2.1 AgNPs

AgNPs, efficient antimicrobial agents with little toxicity, are utilized in clothing, medical devices, cosmetic and pharmaceutical goods. AgNPs constitute an important component in nano-enabled consumer products available in the market. They are the most desirable antimicrobial NPs to be incorporated into the cellulose hydrogels. The antimicrobial property of AgNPs is governed by their size, shape, aggregation state, and so on. It is widely accepted that smaller the size of AgNPs is more beneficial to the antimicrobial activity due to higher penetration rates. Although the truncated AgNPs appear to be higher antimicrobial efficiency than spherical AgNPs, spherical AgNPs are usually preferred over other shapes due to their ease in synthesis, controlling on particle size, handling, and recovery for use. Hydrogels can afford free spaces between the networks in the swollen stage that serve for nucleation and growth of NPs and act as nanoreactors or nanopots. The crosslink densities were proved to be important in controlling the size and shape of the AgNPs within the hydrogel networks which was a facile synthetic strategy for tuning AgNPs to the desirable morphology (Fig. 15) [239].

CMC [240, 241] and hydroxypropyl CMC [242] can be used as reducing and stabilizing agents for green preparation of AgNPs, the hydroxyl groups form coordination bonds with silver ions, and carboxylic groups have electrostatic interaction with Ag ions which facilitate the reduction of Ag ions by CMC. A two-step process was the most common mechanism for synthesis of AgNPs, i.e., single-atom formation and then polymerization of the atoms to a particle. Firstly, a portion of metal ions in a solution is reduced by the available reducing groups of the cellulose and its derivatives; the produced atoms act as nucleation centers and catalyze the reduction

Fig. 15 Hydrogel networks used as templates to synthesize of silver NPs [239]

of the other metal ions remaining in the bulk of solution. Subsequently, these formed atoms coalesce together to form metal clusters, and the ions attracted to the surfaces of these clusters are reduced further to aggregate to NPs. The formed particles are stabilized by a layer from the polymer matrix, thus preventing further coalescence of these NPs to larger particles [242, 243]. Synthesis procedures using microwave irradiation were also employed to accelerate the process. Microwave radiation of CMC and silver nitrates solution produced uniform AgNPs that were stable for 2 months at room temperature [244].

In situ: Cellulose and its derivatives can be chemically crosslinked into hydrogels, and AgNPs can further be incorporated into hydrogels matrix by in situ synthesis. CMC was converted to hydrogels using ECH as a cross linking agent. Two strategies were employed to obtain the CMC/AgNPs composite hydrogels: the first involved reaction of ECH with CMC in alkaline medium containing silver nitrate to synthesize AgNPs and form CMC networks simultaneously; the second entailed previous preparation of CMC hydrogel and reduction Ag^+ ions into AgNPs within the swollen hydrogels. Both of CMC/AgNPs composite hydrogels showed uniform distribution of NPs in the hydrogels matrix, and the composite hydrogels obtained by the first strategy exhibited high antibacterial activity against Gram-positive and Gram-negative bacteria [237]. Fumaric acid was also used as a crosslinker to prepare the CMC/AgNPs composite hydrogels with the first strategy to render cotton fabrics for antibacterial property with the potential applications in wound dressings [245]. With the second strategy, hydrogels with CMC, PVA, and the crosslinker EGDE were fabricated, and AgNPs were incorporated by using trisodium citrate as a reducing agent under microwave radiation. The hydrogel matrix mainly provides steric protection to the Ag^+ due to the polymeric network by direct bonding with these electron donor sites. The obtained composites hydrogels exhibited high antibacterial activity against urinary tract infection (UTI) pathogens [246]. CMC-poly (diallyldimethylammonium chloride) (DADMAC) hydrogels were fabricated by graft copolymerization of DADMAC onto CMC using APS as a free-radical initiator and MBA as a crosslinker. AgNPs or CuO NPs were incorporated into the hydrogels by immersing the CMC-poly(DADMAC) hydrogels into $AgNO_3$ solution or copper sulfate solution and reducing or oxidizing to NPs in situ. The prepared composite hydrogels can be used in different medical fields, i.e., drug delivery and wound dressing as well as wound healing [247]. Semi-IPN hydrogels based on crosslinked PAM through an optimized rapid redox solution polymerization with MBA in presence of CMC were synthesized, and silver ions were in situ reduced using *Azadirachta indica* (Neem) plant extract under atmospheric conditions. The obtained pH-responsive composite hydrogels were suitable to safely transfer the drug through the stomach with acidic pH and release it successfully in the basic environment of the colon [248]. AgNPs can be transformed into Ag_3PO_4 NPs by the reaction of Ag and HPO_4^{2-} to prepare Ag_3PO_4/cellulose composite hydrogels [249].

Layered double hydroxides (LDHs) which consist of brucite-like sheets containing both bivalent and trivalent cations were employed to prepare physically crosslinked CMC composite hydrogels by intercalating CMC into different LDHs. AgNPs/CMC-LDH composite hydrogels were prepared through in situ formation of AgNPs within

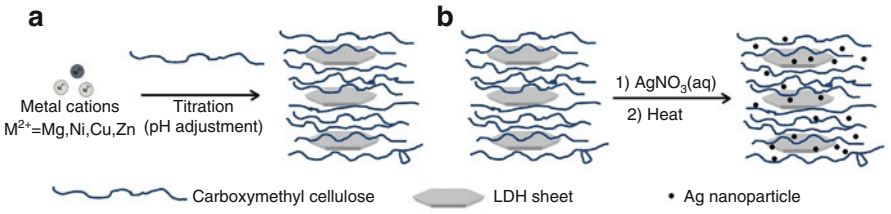

Fig. 16 The schematic representation of the formation of CMC-LDH hydrogels (**a**) and AgNPs/CMC-LDH composite hydrogels (**b**). (Reproduced from [251])

the CMC-LDHs hydrogels. Figure 16a illustrated the formation of CMC-LDH hydrogels through co-precipitation by dropping solution of mixed M^{2+}/Al^{3+} metal ions into alkali-CMC solution in order to precipitate LDH layers and intercalate CMC chains into LDHs. The electrostatic interaction between negative CMC and positive LDH sheets made LDHs act as inorganic crosslinkers in the composite hydrogels. Figure 16b represented the immobilization of AgNPs in the CMC-LDH hydrogels by in situ synthesis of AgNPs by the utilization of CMC as reducing and stabilizing agents. The silver ions are exchanged to the CMC-LDH networks firstly by anchoring through -COONa and -OH groups in CMC chains and then followed by reduction with the existing hydroxyl groups in CMC [31–33]. The LDH surface not only acts as a substrate to anchor and grow AgNPs but also is important in the stabilization of NPs through interactions between NPs and hydroxyl groups of the LDH surface [250]. AgNPs were well distributed within the AgNPs/CMC-LDHs composite hydrogels, and the hydrogels revealed a pH-dependent swelling behavior and good antibacterial activity to both Gram-negative and Gram-positive bacteria [251].

NC can also form the composite hydrogels with AgNPs by in situ reduction of Ag ions [252, 253]. The negatively charged surface carboxylate groups of TEMPO-oxidized NC provide high binding capability to Ag ions which triggers rapid gelation of the NC because transition metals are capable of resulting in carboxylate metal ion complex formation. Simultaneously, Ag^{+} was reduced slowly into AgNPs with prevalent hydroxyl groups on NC without additional reducing agents [252]. BC fibers are assembled by bundles of thinner cellulosic fibers with diameter sizes down to micro- and nanoscale. An extended network is observed via both intramolecular and intermolecular hydrogen bonds [254] enabling the production of sheets with high surface area and porosity. BC network has a very high affinity for water which results in hydrogel-like properties; therefore, BC hydrogel can embed the NPs to fabricate the composite hydrogels. GO-AgNPs/BC hydrogel microfibers were prepared with the microfluidic technology which exhibited a well-defined coaxial cable-like structure, with GO-AgNPs in the inner-core layer and BC hydrogel in the outer-shell layer. GO-AgNPs/BC hydrogel microfibers revealed efficient activity to sterilize both Gram-positive and Gram-negative bacterial strains with low cytotoxicity [255]. AgNPs/BC composite hydrogels could be obtained by UV light irradiation in situ with AgNPs photochemically deposited onto the BC gel network as well as chemically bonded to the cellulose fiber surfaces [256].

Ex situ: The super-macroporous polymer hydrogels based on HPC and PAM were obtained by UV irradiation of moderately frozen systems, using hydrogen peroxide as a source of radicals. H_2O_2 generated hydroxyl radicals during its photo-homolysis which reacted with the polymer molecules giving rise to macro-radicals. The crosslinking occurred by intermolecular recombination of two macro-radicals. AgNPs were immobilized in the channels of the gel by immersing a freeze-dried HPC cryogel in aqueous dispersion of AgNPs or incorporated into the polymer matrix by mixing of the AgNPs dispersion and HPC followed by freezing and subsequent crosslinking. The two types of composite hydrogels exhibited completely different releasing process of AgNPs; the gels containing AgNPs only in the channels could release them immediately by compression, while the gels with AgNPs embedded in the walls exhibited a slow release of Ag for months because AgNPs were physically entrapped within the dense polymer network. Thus, composite hydrogels with different release profiles could be obtained by different ex situ incorporation methods which were beneficial to controllable release of AgNPs [257]. Cellulose-based sponges were developed by freeze drying of regenerated cellulose gels and incorporated the prepared AgNPs by immersing the sponges into the AgNPs suspension. The composite sponges showed excellent antibacterial activity with prolonged release of AgNPs, high sorption of simulated wound fluids, and high water vapor transmission ability due to hydrophylicity of cellulose and porous structure, resulting in the cellulose-based sponges as promising wound dressing materials for fester and infected wounds [258]. AgNPs can also be coated with PEG, sodium dodecyl sulfate, and β-CD before loading into the cellulose hydrogels in order to improve the stability of the NPs and reduce the growth of the particles via trapping of seeds and steric repulsion [259].

4.2.2 ZnO NPs

ZnO NPs possess antibacterial activity to both Gram-positive and Gram-negative bacteria which may be related to the induction of oxidative stress due to generation of reactive oxygen species and the degradation of the membrane structure of the cell. They even have antibacterial activity against spores that are high-temperature-resistant and high-pressure-resistant [260]. Due to the lower cost, lack of color, and UV-blocking properties of ZnO NPs, they are used as alternatives to AgNPs to incorporate with cellulose hydrogels [261, 262]. Like AgNPs, ZnO NPs can be embedded into the cellulose hydrogels by in situ formation or ex situ process.

In situ: CMC hydrogels were prepared by crosslinking with ECH firstly, and ZnO NPs were formed in situ oxidation of the Zn^{2+} ions within swollen CMC hydrogels. Figure 17 represents in situ formation of ZnO NPs in CMC hydrogel network. Carboxylate groups in CMC easily bind to the Zn^{2+} cations in aqueous solutions via electrostatic interactions, and the zinc ions are oxidized to ZnO NPs with the basic agent. ZnO NPs with size range of 30–40 nm were well dispersed in the hydrogels matrix at low zinc nitrate concentration, whereas some aggregation and bigger particle sizes (50–65 nm) could be seen for the CMC/ZnO composite hydrogels at higher concentration. This procedure is facile and economically not requiring heat or any other tools for NP synthesis. The prepared composite hydrogels

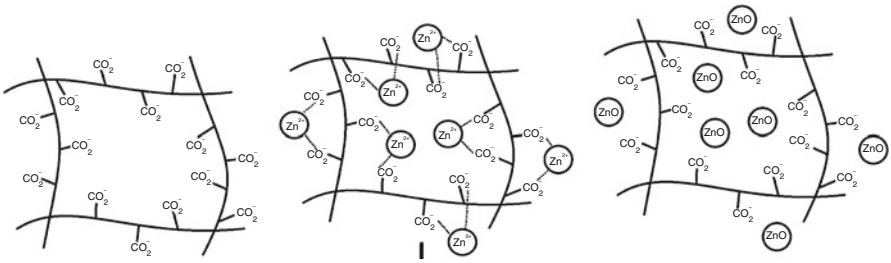

Fig. 17 The schematic representation of in situ formation of ZnO NPs in CMC hydrogel network [263]

showed pH- and salt-sensitive swelling behaviors with excellent antibacterial activity against *Escherichia coli* and *Staphylococcus aureus* bacteria [263]. The multifunctional carboxylic acids such as malic, succinic, and CA were used to crosslink CMC into hydrogels via esterification reaction between the OH group and COOH groups, and dehydration between the COOH groups and adjacent CMC molecules to give rise to strong hydrogen bonding during the thermal treatment [264].

CMC can form complexes with Zn^{2+} due to its large number of coordinating functional groups in its molecular chains, and the precipitations of nuclei start as the concentrations of Zn^{2+} and OH^{-} ions exceed the critical values. The precipitated $Zn(OH)_2$ can be transformed into the ZnO crystals via the simple chemical reaction by heat [265]. ZnO NPs/cellulose composite hydrogel particles were fabricated by using $ZnCl_2$ aqueous solution as both the solvent of cellulose and the zinc source of ZnO nanoflakes. $ZnCl_2$ aqueous solution can effectively dissolve cellulose, and reactive hydroxyl groups in the cellulose chains can accelerate the formation of ZnO nano-structures by reacting with Zn^{2+} to form $Zn(OH)_4{}^{2-}$/cellulose complex through co-gelation process and transforming to ZnO nanocrystals at low temperature. ZnO nanoflakes are hexagonal structured nanoflakes with lamellar thickness of about 100 nm. Cellulose dissolved in $ZnCl_2$ contributed not only to the growth of ZnO nanoflakes but also to restrain the formation of impurity phase [266]. Cellulose solution dissolved in NaOH/urea revealed that the sol-gel transition and intra- and intermolecular hydrogen bonds of cellulose tended to be increased as a result of its strong self-association tendency to cause aggregation and chain entanglements for the gelation [267]. ZnO NPs were grown in the network of cellulose hydrogels in situ to form the composite hydrogels [268]. Like AgNPs, ZnO was also incorporated into BC hydrogel-like pellicle by in situ synthesis of ZnO via solution plasma process without the addition of a reducing agent [269].

Ex situ: CMC was dissolved in distilled water and mixed with ZnO NPs to a homogenous solution; Fe^{3+} ion as a physical crosslinking agent was used to prepare ionic crosslinked CMC/ZnO NPs composite hydrogels by combination of metal coordination and ion exchange interaction between the carboxyl groups of CMC chains and Fe^{3+} cations. The pH-sensitive composite hydrogels showed high drug incorporation efficiency and a sustained release pattern. The release time of drugs from CMC/ZnO beads was prolonged because of a longer path to migrate from

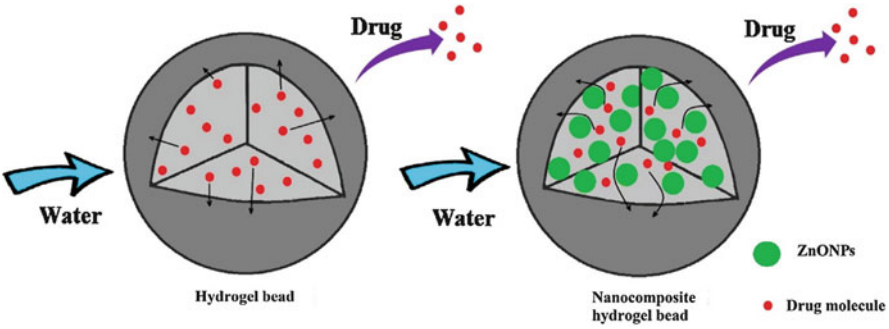

Fig. 18 The drug release of pristine CMC hydrogel and CMC/ZnO composite hydrogel [270]

hydrogels containing ZnO NPs to the buffer solution, shown in Fig. 18. The prepared CMC/ZnO NPs composite hydrogel beads might function as oral drug delivery systems for the controlled delivery of drugs [270]. In order to control the stability of the ZnO NPs, it was loaded on mesoporous MCM-41 through impregnation. ZnO-impregnated MCM-41 was added into CMC solution and further crosslinked with CA to obtain the composite hydrogels. ZnO-MCM-41 highly increased the drug loading, and addition of ZnO-MCM-41 into CMC hydrogels caused a prolonged and continued release of drugs [271]. Both ZnO and ZnO_2 NPs were loaded into the cellulose-chitosan hydrogels by dispersing the NPs into the polymer solutions before crosslinking. Cellulose and chitosan were crosslinked with triethyl orthoformate, which the primary amino group in chitosan and hydroxyl group in cellulose reacted with ethylformate, respectively. The composite hydrogels are potential new materials for tissue engineering applications with enhanced angiogenesis with zinc NPs, and it was proved that ZnO_2-loaded hydrogels supported angiogenesis better than the ZnO-loaded hydrogels because of the difference in oxidation potential [272].

4.3 Carbon Nanomaterials

Graphene and its derivates such as graphene oxide (GO) have been targeted on mechanically or electrically enhanced cellulose hydrogels as nanofillers. Specifically, GO shows the strong functionalities and processibilities due to the oxygen-containing functional groups on its basal planes and edges. The layered structure with oxygen-containing groups, i.e., hydroxyl, epoxide, and carboxyl groups, makes GO to be a favorable candidate for improving the mechanical strength of the cellulose hydrogels.

Normally, GO dispersion can be mixed with the cellulose solutions firstly and fabricated the GO/cellulose composite hydrogels further by crosslinking of cellulose. GO was mixed into cellulose dissolved in NaOH/PEG, and then the composite hydrogels were regenerated with the introduction of hydrochloric acid which neutralized NaOH and caused the reconnect and entanglement of cellulose chains by hydrogen bonds [273]. Both GO and cellulose dissolved in ionic liquids were mixed

and regenerated using water as a coagulant to composite hydrogels which significantly enhanced mechanical strength and thermal stability [274]. CMC could be chemically crosslinked with CA in the presence of GO to obtain the GO/CMC composite hydrogels, and the introduction of GO also significantly improved the adsorption performances of the composite hydrogels toward dyes and heavy metals [275]. GO/CMC-g-PAA and GO/CMC-g-PAM composite hydrogels were fabricated by in situ copolymerization of monomers on CMC backbone with MBA as a crosslinker in the presence of GO as fillers [276, 277]. GO/CMC composite hydrogels via electron beam radiation-assisted polymerization with MBA as a crosslinking agent showed larger gel fraction, higher mechanical strength and swelling capabilities compared to those prepared by solution polymerization with ECH as a crosslinker [278]. Moreover, GO and the dissolved cellulose in the NaOH/urea were crosslinked with ECH; the incorporation of GO chemically increased the compressive strength of the composite hydrogels and significantly improved their adsorption capacities for the metal ions [279].

GO/CMC composite hydrogels physically crosslinked with Fe^{3+} and Ca^{2+} ions were prepared via the coordination between metal ions and the carboxyl groups in the CMC side chains. Due to the biocompatibility and the anionic-exchange properties of GO, the composite hydrogels revealed higher loading capacity and controlled release of the drugs [280, 281]. GO/CMC/PAM composite hydrogels with double networks consisting of ionically (Al^{3+}) crosslinked CMC and covalently crosslinked PAM exhibited superior mechanical properties by combination of double networks and nanofiller reinforcement [282]. In order to decrease aggregation of GO, HPC was grafted onto GO before fabricating the composite hydrogels [283].

The recent emergence of three-dimensional (3D) graphene hydrogels has provided a promising avenue to explore the performance of 3D porous material on electrochemistry [284, 285]. GO/cellulose composite hydrogels could be fabricated by ball milling of the mixture of GO hydrogels and cellulose solution in the presence of hydrazine, template shaping, coagulating, and freeze drying. The hydrogen bond interactions and the shearing force collaboratively resulted in sufficient mixing of GO and cellulose and the subsequent formation of homogenous GO/cellulose hydrogels. It is a scalable preparation method of GO/cellulose composite hydrogels with application in supercapacitors.

GO could be incorporated into BC hydrogels with ex situ composites synthesis [286–288]; however intrinsically 3D structure of BC was broken [289]. In situ BC composites synthesis is becoming a main approach in which reinforcement materials are added to BC culture media at the beginning of the BC synthetic process. Microfibrils of BC become denser with time and produce a network structure that can trap various materials added to the BC synthetic media. The encaged materials become part of the BC fibril network, resulting in BC composites. GO/BC composite hydrogels were prepared by in situ biosynthesis of BC in graphene-dispersed culture medium. The addition of graphene reduced the crystallinity of BC without changing the entangled network structure [289, 290]. GO/BC composite hydrogels followed a non-Fickian diffusion mechanism in the drug release with good cell viability for drug delivery system [291].

Carbon nanotubes (CNTs) demonstrate very interesting properties because of sp2 hybridization of carbon-carbon bonds and the resultant cylindrical arrangement of the graphene sheets. In the realm of drug delivery, CNTs have gained tremendous attentions as promising nanocarriers, owing to their distinct characteristics, such as high surface area, enhanced cellular uptake, and the possibility to be easily conjugated with therapeutics, including both small molecules and biologics, displaying superior efficacy, enhanced specificity, and diminished side effects [292]. Carbon nanodots (C-dots) as new carbon nanomaterials have obtained increasing attentions for the applications of bioimaging, sensing, and catalysis fields, due to their exceptional properties such as highly fluorescent feature, low toxicity, excellent dispersibility in water, flexible functionalization, and good biocompatibility. C-dots possess numerous oxygen-containing functional groups on their surfaces such as hydroxyl groups, carboxyl groups, and epoxide groups, which indicate that C-dots have the promising potential application as physical crosslinkers in the preparation of NC hydrogels [293].

CNT/CMC composite hydrogels were fabricated simply by mixing CMC and CNTs at room temperature by ultrasonication; the strong hydrogen bonding as well as electrostatic interactions between acid groups of CNT and hydroxyl/carboxyl groups of CMC were believed to be the main reasons to form the composite hydrogels [294]. High-strength composite hydrogels were designed and synthesized by introducing CNTs into cellulose/NaOH/urea aqueous solution and chemically crosslinked by ECH [295]. Cellulose nanofibrils and BC were also used to fabricate the CNT/cellulose composite hydrogels [296–300].

5 Conclusions

Three categories of cellulose-based composite hydrogels were summarized in this chapter including synthetic polymer/cellulose, natural macromolecules/cellulose, and inorganics/cellulose composite hydrogels. The composite hydrogels combine the advantages of two components and obtain the new features for broadening applications especially in biomedical and tissue engineering, drug delivery, biosensors, and superabsorbent. It is feasible to incorporate some synthetic polymers with water-soluble cellulose derivatives to fabricate the synthetic polymer/cellulose composite hydrogels by chemical, physical, and ionic crosslinking. In situ free-radical polymerization of acrylate monomers onto cellulose derivatives is one of main methods to introduce synthetic polymers into cellulose-based hydrogels. Nanocellulose with high-aspect ratio can be physically entrapped in the polymer network as a filler or chemically crosslinked with the polymer matrix in order to improve the degradation and the mechanical strength of the composite hydrogels. Chitosan, alginate, starch, and extracellular matrix are popular natural macromolecules for the fabrication of natural macromolecules/cellulose composite hydrogels. Chitosan is the most important polysaccharide to form the composite hydrogels with cellulose by chemical crosslinking. Chitosan can crosslink with cellulose via crosslinkers such as epichlorohydrin or reaction between reactive groups in chitosan

and cellulose derivatives. Inorganics/cellulose composite hydrogels are a kind of special hydrogels combining both inorganic and organic properties. Montmorillonite and other layered silicates can form the nanocomposite hydrogels with cellulose for applications of superabsorbent and controlled release of nutrients. Metallic nanoparticles with inherent antimicrobial properties such as Ag were also incorporated into the cellulose composite hydrogels via ex situ and in situ methods to render antimicrobial. Carbon nanomaterials such as graphene oxide can be incorporated into the cellulose hydrogels as fillers, and the composite hydrogels show potential applications in supercapacitors and biosensors. Cellulose-based composite hydrogels are attracting considerable attentions in both academic research and industrial application due to their excellent hybrid properties.

Surface Functionalization of Nanocellulose-Based Hydrogels

22

Joanna Lewandowska-Łańcucka, Anna Karewicz, Karol Wolski, and Szczepan Zapotoczny

Contents

Abstract

Nanocellulose is the nanostructured product or extract from the native cellulose found in plants, animals, and bacteria. Three main types of nanocellulose may be identified as cellulose nanocrystals (CNCs), nanofibrillated cellulose (NFC), and bacterial nanocellulose (BNC). Due to the very high surface-to-volume ratio,

nanocellulose tends to form hydrogels with exceptionally high water content (>90 wt%). Surface modifications of those nanostructured materials can, e.g., improve their compatibility with different matrices, enable control of water absorption, and release and bring desired chemical functionality expanding utilization of such hydrogel in (bio)nanotechnology-related applications. Various objects including small molecules of biomedical relevance, nano- or microparticles serving as drug carriers, protective/semipermeable coatings, or polymer brushes can be attached onto the surfaces of nanocellulose-based materials in order to prepare various functional nanocomposites. Such composite materials have been successfully applied in, e.g., wound healing and regenerative medicine. Chemical approaches for surface functionalization of nanocellulose-based hydrogels are systematically described in this chapter, together with properties of such formed hydrogel materials and examples of their applications.

Nanocellulose · Nanofibrillar cellulose · Cellulose nanocrystals

1 Introduction

Cellulose is a semicrystalline polysaccharide appearing in nature in the form of fibers of length in the range of 0.5 up to several mm [1]. From molecular point of view, cellulose is composed of β-D-glucopyranose units linked by 1-4-β glycosidic bonds, whereas at the supramolecular level, its chains aggregate and form elementary fibrils composed of alternated crystalline and amorphous domains. These elementary fibrils align and further aggregate into larger microfibrils/macrofibrils with diameter of 10–25 nm, and at the structural level, they stick together in a spiral manner to form the cellulose fibers.

Hierarchical structure of cellulose enables its breaking down into nanoscale cellulose known as nanocellulose with morphology depending on the employed extraction mode and origin of the raw material. Nanocellulose materials are commonly produced using mechanically based methods, but such nanostructured cellulose may be also produced by bacteria offering unique structural characteristics and macroscopic properties. Thus, cellulose nanocrystals (CNCs), cellulose nanofibers (CNF), and bacterial nanocellulose (BNC) are commonly distinguished within nanocellulose materials. The structure of nanocellulose implies its desired mechanical properties for reinforcing nanocomposites and enables better compatibilization due to the larger surface area as compared to typical cellulose materials. It applies especially to hydrogels due to the presence of numerous hydroxyl groups and ease of their modification on the surface of nanocellulose. The fundamentals on nanocellulose and its surface modification methods with special focus on hydrogel formation based on native and functionalized nanocellulose materials are described in this chapter together with their current and potential applications.

2 Cellulose Nanocrystals (CNCs)

Crude cellulose obtained from natural sources is composed of highly crystalline regions mixed with amorphous ones. The degree of crystallinity of naturally occurring cellulose strongly depends on its natural source. High degree of crystallinity was observed in cellulose from algae (up to 90%) and tunicate (about 80%) [2] while slightly lower in bacterial cellulose (65–79%) [3] or cellulose derived from plants (60%) [2]. Natural cellulose subjected to mechanical, chemical, and/or enzymatic treatment results in formation of highly crystalline nanomaterial devoid of amorphous regions (after proper extraction of highly crystalline regions of the cellulose microfibrils), commonly known as cellulose nanocrystals (CNCs). CNCs occur in the form of needle-shaped or rodlike particles consisting of polymer chain segments arranged in highly crystalline structure [4]. The shape, dimensions, and degree of crystallinity of CNCs are strongly determined by material's origin, as well as the method used for their isolation (see Fig. 1). The size of CNCs is usually within the range of 100 nm up to a few microns in length and 4–70 nm in width [2]. Very high aspect ratios of nanocrystals were reported for CNCs derived from maize husk (aspect ratio 157) [5] or tunicate (aspect ratio about 147) [6].

There are a few main isolation methods that lead to CNCs: acidic hydrolysis, enzymatic hydrolysis, oxidation, ionic liquid treatment, subcritical water hydrolysis, and combined processes [2]. Various isolation methods have been presented in details in several review papers [2, 4, 7]; therefore only brief description of acidic and enzymatic hydrolysis will be provided below. Acidic hydrolysis is the most

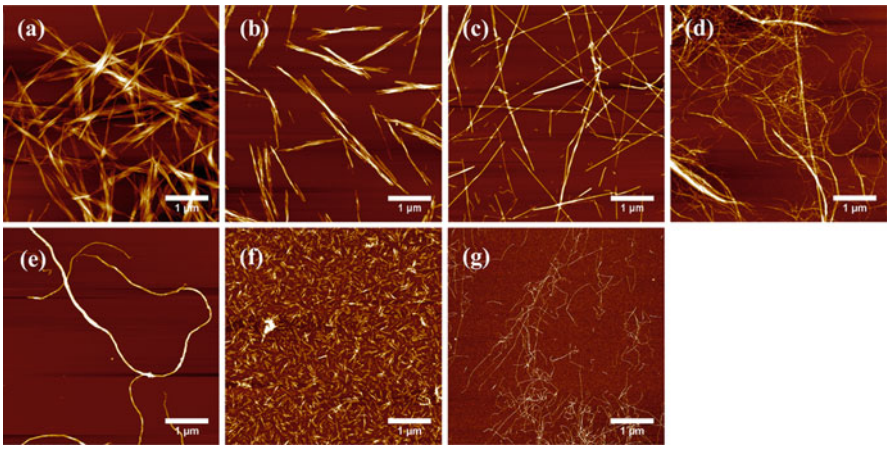

Fig. 1 AFM topography images of CNC derived from bacterial cellulose after HCl (**a**) and after H_2SO_4 treatment (**b**), tunicate cellulose after H_2SO_4 treatment (**c**), wood cellulose after enzymatic (**d**), mechanically refined (**e**), H_2SO_4 (**f**), and TEMPO (**g**) treatments. (Reprinted with permission from Ref. [6])

popular approach among all isolation methods. This process is based on strong acid-induced removal of the amorphous parts in the cellulose microfibrils. Strong acids may preferentially and easily hydrolyze amorphous regions, due to their low level of order, leaving the crystalline regions unaffected [4]. The selection of the acid plays an important role as it determines the properties of the final material. The most popular hydrolysis with sulfuric acid [8, 9] results in formation of CNCs with negative surface charge (due to sulfonation of CNC surface), which may easily form stable colloidal suspension useful for various applications. However, CNC sulfonation promotes degradation of cellulose at higher temperatures [2]. Utilization of hydrochloric acid ensures higher stability but lower charge density at CNC surface and, as a result, poorer dispersibility in aqueous media [1]. Very recently Chen et al. [10] demonstrated that organic acid applied in cellulose hydrolysis resulted in formation of CNCs with moderate dispersibility in water and significantly higher thermal stability than that produced using sulfuric acid.

The process of acidic hydrolysis requires the use of hazardous and toxic materials during CNC production, while enzymatic hydrolysis is much safer and environmentally friendly. As enzymes are much more selective and milder agents, they do not destroy crystalline parts and enable formation of materials with original hydroxyl surface chemistry. However, such treatment ensures lower synthesis yields [11] and it is much slower than acidic hydrolysis.

2.1 Low Molecular Weight Modifications of CNC

CNC surface may be modified in three different ways. The first approach utilizes surface functionality introduced during CNC isolation. As it was mentioned above, depending on the isolation method, CNC surface bears various groups such as sulfate esters after sulfuric acid isolation, hydroxyl after enzymatic or hydrochloric acid treatment, and carboxyl after oxidative isolation in the presence of 2,2,6,6-tetramethyl-piperidinyl-1-oxyl (TEMPO) radicals [12]. Therefore, the choice of isolation method determines surface chemistry of CNC, as well as further synthetic paths for grafting of particular molecules.

The second method is based on adsorption of particular compounds to the surface of CNC. Different surfactant molecules such as stearic acid [13], cetyltrimethylammonium bromide (CTAB) [14], and quaternary ammonium-based compounds [15] were used in such approach in order to increase dispersibility of CNCs in organic solvents and polymers.

The last approach utilizes covalent grafting of particular molecules on the cellulose surface. Figure 2 shows the most frequently used methods for covalent grafting of various low molecular compounds. Hydroxyl groups on CNC may be easily reacted with chloro- and alkoxysilanes [16], isocyanates [17], acid halides [18], acid anhydrides [19], or epoxides [20]. CNCs modified by oxidation of hydroxyl groups (to carboxyl ones) are commonly applied as precursors for amidation reaction [21]. Carboxyl groups in such synthesis are activated in the first step by *N*-hydroxysuccinimide (NHS) and then are reacted with primary amines leading to

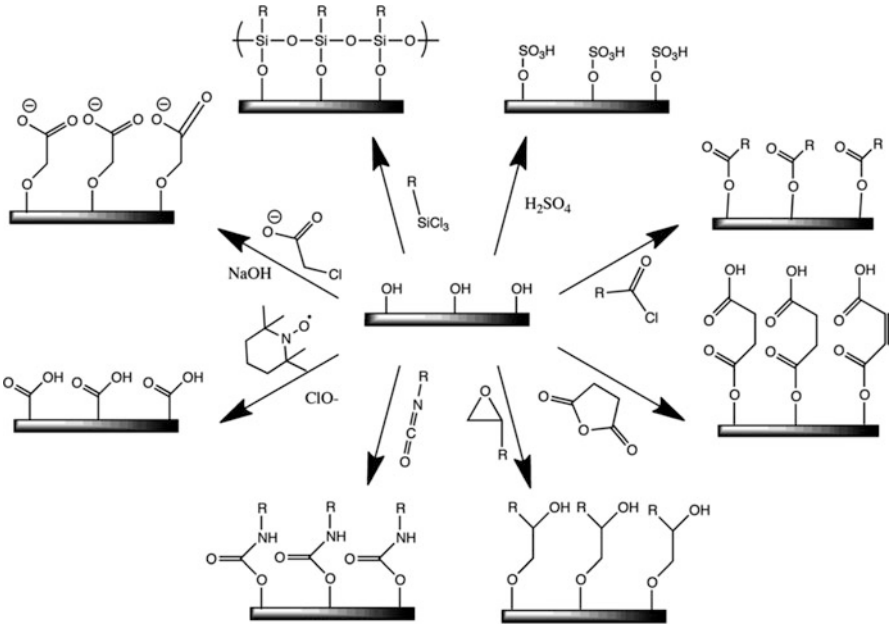

Fig. 2 CNC surface modifications during selected isolation methods together with common synthetic paths to low molecular compound grafting. (Reprinted with permission from Ref. [7])

amides [22]. The mentioned procedure was used also by Filpponen et al. for the synthesis of alkyne-based CNC precursors for the click reaction [23]. It is important to underline that the diversity of modification techniques is far greater, as the presented surface functionalizations may serve as precursors for further modifications.

2.2 Modifications of CNC with Polymers

Cellulose nanocrystals may be functionalized with polymers via either covalent grafting ~~and~~ or adsorption. Electrostatic adsorption of polymers on cellulose enables formation of composite thin films via layer-by-layer (LbL) technique [24]. Very recently Gill et al. prepared LbL-coated CNC (isolated using sulfuric acid-based hydrolysis) containing films with xyloglucan (XG) and polyethyleneimine (PEI) [25]. Interactions responsible for LbL film formation were based on van der Waals forces in XG/CNC system, while for PEI/CNC they were of electrostatic nature. Furthermore, CNC surface is prone to adsorption of amphiphilic polymers as presented by Zhou et al. [26]. The authors showed modification of CNC via adsorption of xyloglucan oligosaccharide-based triblock amphiphilic copolymer. The resulting material exhibited chiral nematic self-ordering of the CNCs with the adsorbed copolymer. Recently Nagalakshmaiah et al. presented surface adsorption of amphiphilic triblock copolymer based on two hydrophilic polyethylene oxide

blocks and one hydrophobic polypropylene oxide block [27]. The applied modification increased thermal stability and aqueous dispersibility of CNCs.

Covalent attachment of polymer chains to CNC is more frequently used and is realized by three main strategies called "grafting through," "grafting to," and "grafting from." First of them is based on grafting via surface-anchored monomer or macromonomer. In this approach polymerization mainly proceeds in solution, and the macromolecules growing there may react with surface-anchored monomers resulting in polymer grafting. This methodology leads to grafted polymers with wide molar mass distribution and low grafting density. "Grafting through" approach represented by free radical polymerization was applied by Atifi et al. for grafting poly(acrylamide) on CNC surface [28]. In the "grafting to" approach, end-functionalized polymer chains are at first synthesized in the solution. Such prepared macromolecules are then subjected to grafting on CNC surface. Attachment of polymers using "grafting to" method utilizes the same chemistry as presented in Sect. 2.1 concerning covalent grafting of low molecular compounds. However, formation of densely packed polymer brushes using this strategy is hindered due to steric impediment created by already attached polymer chains that block active sites on the surface. The main advantage of "grafting to" is the fact that macromolecules synthesized in the solution may be carefully characterized using different methods (not available for grafted polymers) before grafting. Cellulose nanocrystals were modified with different polymers via "grafting to" methodology using click chemistry (CNC-g-poly(ethyl ethylene phosphate)) [29], amidation (CNC-g-polypeptides) [30], or etherification (CNC-g-(poly(ethylene oxide))) [31].

"Grafting from" approach is a first choice method for covalent grafting of polymers on CNC surface. It starts from the initiator-modified surface and utilizes well-controlled surface-initiated reversible-deactivation radical polymerizations (SI-RDRP) such as atom transfer radical polymerization (SI-ATRP), nitroxide-mediated polymerization (SI-NMP), or reversible addition-fragmentation chain transfer (SI-RAFT) [32]. Controlled character of SI-RDRP techniques is due to very fast and reversible activation and deactivation processes of the growing radicals. Instead of SI-RDRP, surface-initiated ring opening polymerization (SI-ROP) may be also applied for polymer attachment via this approach. This methodology enables formation of well-ordered and densely packed brushes. In the most popular SI-ATRP technique, CNC surface is predominantly directly modified with ATRP initiator via esterification reaction (e.g., with α-bromoisobutyryl bromide). Polymerization is started from the initiator-decorated CNC in the presence of monomer, solvent, and activation complex (in basic ATRP composed of transition metal salt and chelating ligand) which ensure controlled character of the process [32]. The description of the mechanism of SI-ATRP and the abovementioned polymerization is beyond the scope of this chapter; therefore only short overview of the very recent CNC modifications done via SI-RDRP and SI-ROP is given below. Comprehensive information is collected in the review papers [32, 33].

SI-ATRP was used for polymerization of styrene from CNC surface in order to increase thermal stability and compatibility of the native material with other polymers [18]. Similarly, Zhang et al. presented a synthetic route for grafting

thermoresponsive poly(*N*-vinylcaprolactam) on CNC using SI-ATRP. Roeder et al. reported for the first-time graft modification of CNCs via SI-NMP [34]. Cellulose surface was functionalized with (4-(diethoxyphosphinyl)-2,2,5,5-tetramethyl-3-azahexane-N-oxyl) (SG1 nitroxide) which served as the initiator. Poly(methyl acrylate) and poly(methyl methacrylate) brushes were then successfully obtained under relatively mild reaction conditions. SI-RAFT method was used for surface-initiated polymerization of vinyl acetate, which resulted in the formation of CNC composite material with promising mechanical properties [35]. SI-ROP technique was also applied for formation of polymer composites with improved mechanical properties. For this purpose CNCs were decorated with poly(L-lactide) and incorporated in poly (lactic acid) matrix [36].

2.3 Hydrogels Containing CNC

High stiffness and mechanical strength of CNCs are recognized as desirable features for creation of stable hydrogel nanocomposites. Lahiji et al. indicated that transverse elastic modulus of an individual cellulose nanocrystal is a few times higher than for Kevlar-49 and it lies in the range of 11–57 GPa [37]. The mentioned traits of CNCs, together with low ability to entangle, unfortunately, hinder formation of single-component CNC gels [38]. However, high concentrations of CNCs in their aqueous suspensions (above 10–12 wt%) may result in formation of gel-like phase [39]. Nevertheless, addition of salts, acids, or multivalent ions may extort gel formation due to destabilizing effect on CNC suspension. It was reported that increased ionic strength of CNCs aqueous suspension led to gelation at significantly lower concentrations of CNCs (about 2 wt%), as addition of salt-limited electrostatic repulsions between particular nanocrystals while promoted their mutual attractive interactions by hydrogen bonding and van der Waals forces [40]. Single-component CNC hydrogels can be also obtained via pH-induced gelation, thanks to modifications of nanocrystal surface with amine or carboxyl groups [41].

In fact, multicomponent hydrogels with CNC as filler or reinforcing agent within polymeric networks have aroused the greatest interest so far [38]. Such nanocomposite hydrogels are produced via physical or chemical entrapment of native or functionalized CNCs by polymeric matrix. The former approach is represented by various synthetic methodologies such as free radical polymerization of monomers within CNC suspension, homogenization, and physical entanglement of polymer networks or UV-mediated cross-linking of the polymeric network around CNCs. Free radical polymerization of sodium acrylate in nanocrystal suspension in the presence of the cross-linker, *N*,*N*-methylenebis-acrylamide, was applied for formation of poly(sodium acrylate) hydrogels with physically entrapped CNCs [42]. Agarose hydrogel with cellulose nanocrystals as a filler was prepared via homogenization process by Osorio-Madrazo et al. [43]. The orientation of cellulose rodlike particles within agarose matrix was found to be dependent on drying process and hydrogel stretching.

In the case of chemical entrapment, CNCs can serve as polymer cross-linkers themselves, while in other cases CNCs are cross-linked to a networked polymer matrix [38]. Yang et al. have presented formation of poly(*N*,*N*-dimethylacrylamide) (PDMA) hydrogel with chemically entrapped nanocrystals via UV-initiated free radical polymerization of *N*,*N*-dimethylacrylamide in CNC suspensions [44]. In the first step, CNC surface was modified with organosilane-bearing methacryloyl group, and then, in the second step, they were subjected to UV-initiated polymerization in the presence of monomer and photoinitiator. As a result CNC-PDMA hydrogel with significantly improved mechanical properties was formed due to combination of chemical cross-linking and physical interactions between modified nanocrystals.

Concentration of CNC in multicomponent hydrogels is usually in the range of 0.1–6 wt% (in reference to the total swollen gel weight). De France et al. reported that poly(oligoethylene glycol methacrylate) (POEGMA) hydrogel with relatively low CNC concentration (4.95 wt%; hydrogel with physically entrapped CNCs) demonstrated about 35 times higher storage modulus (39 kPa) than initial POEGMA hydrogel (1.1 kPa) [45]. Hydrogels with chemically entrapped CNCs generally present lower swelling ability and better mechanical stability than those obtained by physical entrapment methods (as reinforcement effect is more pronounced for similar systems). Mechanical strength of CNC-reinforced hydrogels was found to depend on the content of nanocrystals and aspect ratio as found by Yang et al. [44, 46]. Poly(acrylic acid)-based hydrogels reinforced with chemically entrapped CNCs with different aspect ratios were obtained. The authors have found that hydrogel storage modulus significantly increased together with the growing aspect ratio of the nanocrystals [46].

2.4 Applications of CNC

Surface hydroxyl groups, high surface area, high stiffness, and tensile strength of cellulose nanocrystals make them very attractive nanomaterials for various applications. As-synthesized CNCs (functionalized or nonfunctionalized) can be applied as antibacterial agent (CNCs modified with Ag nanoparticles) [47], adsorbents (carboxylated CNCs were found to present specific adsorption for methylene blue dye) [48], Pickering emulsifier [49], highly transparent nanopaper for flexible electronics [50], or pH sensor (CNC surface modified with pH indicator dye) [51]. However, most of CNC applications are related to their use in different polymer composites, e.g., for drug delivery systems [52], biosensors [53], separators for energy storage [54], biodegradable food packaging materials [55], and transparent conductive membranes [56]. There are a few review papers that gathered most of CNC applications [4, 7, 57], but we focus here on applications of CNCs in formation of hydrogels. Alginate/gelatin hydrogels with CNCs as reinforcing agent were used as injectable tissue scaffolds by Wang et al. [58]. The addition of CNCs reduced degradation of the hydrogel and positively influenced long-term cell proliferation. Very recently Lin et al. have synthesized biocompatible dual-membrane hydrogel

composed of cationic CNCs and anionic alginate [59]. The external membrane was composed of neat alginate, while the internal one contained the hydrogel composed of cationic CNCs and anionic alginate. Two drugs were introduced into those membranes and different drug release characteristics were observed. The authors have demonstrated rapid release of the drug from the outer neat alginate membrane, while prolonged drug release from the inner hydrogel-based one was induced by steric effect resulting from the strong interactions between cationic CNCs and anionic alginate. Recently Zubik et al. have developed CNC/PNIPAM poly(*N*-isopropylacrylamide) thermoresponsive hydrogel with incorporated metronidazole drug for wound dressing applications [60].

CNC hydrogels have found applications not only in the biomedical field. Kelly et al. developed CNC-based responsive photonic hydrogels which had long-range chiral nematic structure [61]. Depending on the applied polymer matrix, materials show changes in iridescence in response to solvent type, pH, and temperature. McKee et al. synthesized three-component hydrogel composed of reinforcing CNC colloidal rods modified with copolymer brushes (via SI-ATRP) bearing naphthyl (guest) group, linear polymer containing methyl viologen functionality (additional guest group), and macrocyclic supramolecular cross-linker (cucurbituril [8], host group), which allowed host-guest interactions leading to selective and simultaneous binding of two guest groups [62]. The obtained supramolecular nanocomposite hydrogel exhibited rapid sol-gel transition (<6 s), high storage modulus (above 10 kPa), and self-healing properties maintained upon aging for even several months.

3 Nanofibrillated Cellulose (NFC)

The cellulose nanofibers are mainly produced by mechanical breaking out the cell wall of fibers and releasing the cellulose fibrils in the form of bundles of elementary fibrils [63, 64]. Nanofibrillated cellulose (NFC), cellulose nanofiber, and cellulose nanofibril are the terms commonly used for the same material [65]. Being composed of a bundle of stretched cellulose chains with long and entangled nanofibers of approximately 1–100 nm in diameter, NFC consists of alternating crystalline and amorphous domains [66]. In order to perform the defibrillation of NFC, intensive mechanical treatment is required. However, depending on the degree of processing and raw material, chemical pretreatments are carried out before mechanical defibrillation [67]. Appropriate pretreatments of cellulose fibers are of great interest since they induce breaking of hydrogen bonds, promote accessibility of hydroxyl groups for modifications, and therefore boost their reactivity [68].

As introduced by Turbak and coworkers in the 1980s [69], the high-pressure homogenization and microfluidization are still the main methods currently used to effectively produce NFC [70, 71]. They include simple mechanical methods, sometimes in combination with enzymatic or chemical pretreatments. The process of isolating NFC consists of disintegration of cellulose fibers along their long axis into substructural fibrils having lengths in the micron scale and widths in the range from

ten to a few hundred nanometers depending on the nature of the plant cell walls [72]. That obtained aqueous suspensions exhibit gel-like features in water with pseudoplastic and thixotropic characteristics even at low solid content. Other technologies, namely, high-intensity ultrasonication [73], high-speed blending [74], and stem explosion [75, 76], were also proposed, but they are still in a very early stage of development and far from scaling up. Employing the abovementioned technologies, NFCs were prepared from numerous cellulosic sources including soft and hard woods [77], sugar beet pulp [78], banana [79], wheat straw [80], bamboo [81], and seaweed [82]. The morphological properties of the resulting NFCs are strongly dependent on the original fibers, and the general tendency is that NFCs from primary cell wall fibers are longer and thinner than those obtained from secondary cell wall fibers.

It should be emphasized that, in spite of very promising potential of multimode applications of NFCs, their scale-up production is still below expectation. One of the major limitations of this development is high energy consumption involved during the mechanical disintegration of cellulose into nanofibers [83]. In addition, fabrication of uniform size NFCs is also challenging. The energy consumption strongly depends on the fiber pretreatment method, and reported values range from 10 up to 100 KWh per kg of dry NFC [84]. This high energy demand is connected with the necessity to operate under high pressure (200–800 bar) with multiple passes until a high fibril ratio degree is achieved. To cope with this issue, the fiber pretreatment prior to the disintegration process is commonly adopted. In this field, the chemical pretreatment seems to be one of the most efficient and popular strategies to enable the breakup of the fiber network by producing ionic or ionizable groups within the internal structure of the cellulose. There are many methods like TEMPO-mediated oxidation [85], carboxymethylation [86], sulfonation with sodium bisulfate [87], periodate oxidation [88], or quaternization [89] which enable to achieve that goal. Another advantage of the pretreatment is the reduction of the risk of clogging during the homogenization/microfluidization processes. It was found that chemical pretreatment approach can significantly reduce the energy consumption for production of NFC; however in many cases, the price of chemicals surpasses the energy costs saved.

3.1 Low Molecular Weight Modifications of NFC

Surface modification of NFCs is essential when considering improvement of their compatibility and homogeneous dispersion within polymer matrices. Both low and high molecular weight modifications, such as polymer grafting, silylation, esterification, cationization, or TEMPO oxidation, have been applied for that purpose [90].

Lu et al. reported the surface modification of nanofibrillated cellulose by use of silane reagents, namely, 3-aminopropyltriethoxysilane and 3-glycidoxypropyltrimethoxysilane [91] leading to formation of Si-O-C bonds at room temperature through –OH groups of cellulose. The wettability of the surface of pristine and modified NFC was investigated, and it was revealed that untreated NFC film was very hydrophilic with the water contact angle of 15° resulting from OH-rich molecular structure. The

silane modification of NFC increases the value of water contact angle to 90° and 64° for 3-aminopropyltriethoxysilane and 3-glycidoxypropyltrimethoxysilane-treated NFC, respectively. NFC was also hydrophobized via partial surface silylation using isopropyl dimethyl chlorosilane as a silylation agent, and it was found that loss of nanostructure occurred when silylation conditions were too harsh [92].

Acetylation is another method adopted by the researchers to modify the surface of cellulose nanofibers. It is based on chemical modification in which acetyl groups react with the hydroxyl groups of the cellulose, making the surface more hydrophobic. Acetylation of NFC was performed to change the wettability of cellulose nanofibers and, as a consequence, to improve the chemical affinity between NFC and nonpolar environments. It was observed that the acetylated nanofibers, being more hydrophobic, formed stable suspension in solvents like acetone or ethanol, while the pristine NFC exhibits tendency to sedimentation in these applied solvents [93]. Tingaut and coworkers studied the impact of acetyl content on the dispersion stability and the influence of chemical modification on the crystal structure of NFC [94]. They found that the obtained powdered nanofibers were easily redispersed in chloroform and formed very stable suspensions. They also observed variations in NFC stability which depended on the percentage (%) of acetylation (Ac); stable suspensions were obtained for NFC with more than 1.5% acetylation. Using wide-angle X-ray diffraction (WAXD) analysis, Tingaut et al. showed that more than 4.5% of Ac strongly affected NFC crystalline structure since grafted acetyl groups caused reduction of hydrogen bonding between the cellulose fibrils.

Cationic modification of NFC films was performed by adsorption of cationic surfactant cetyltrimethylammonium bromide (CTAB) [95]. Employing high-resolution transmission electron microscopy (HRTEM), it was demonstrated that the CTAB molecules adsorbed on the nanofibril surfaces. That was manifested by the presence of black dots (surfactant molecules) only along the surface of nanofibril of modified NFC (see Fig. 3).

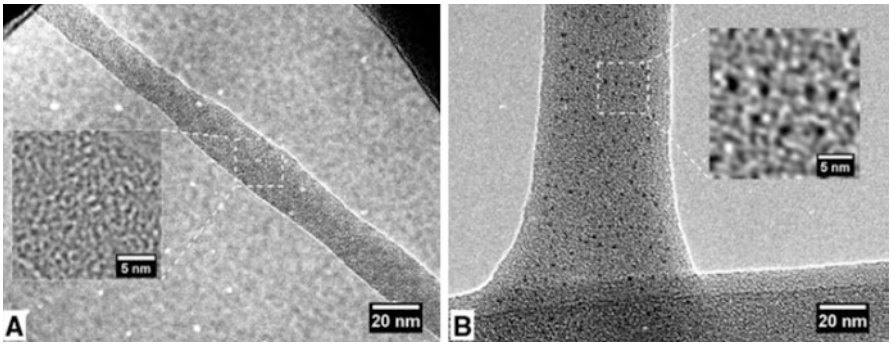

Fig. 3 (**a**) HRTEM of a single nanofibril. (**b**) HRTEM image of a CTAB-modified nanofibril. Note that the images (**a**) and (**b**) were taken at the same magnification, i.e., 100,000. The contrast of the images has been modified for better visualization. (Reprinted from Ref. [95] with permission from Springer)

Yano and coworkers reported on alkali treatment of NFC by immersing the dry sheets of NFC in NaOH aqueous solutions of two concentrations (5 and 20 wt.%). The dispersion was kept at reduced pressure of 0.01 MPa for 2 h and subsequently at ambient pressure for 10 h. It was found that the NFC sheets modified with 5 wt.% NaOH solution did not reveal any changes in dimensions, while 20 wt.% alkali solution treatment resulted in a noticeable reduction in diameter of about 17% as compared to unmodified NFC [96]. Seppala et al. using click chemistry synthesized pH-responsive 1,2,3-triazole-4-methanamine decorated NFC [97]. Reactive azide groups were introduced on the surface of NFC by the etherification of 1-azido-2,3-epoxypropane in alkaline water/isopropanol mixture at ambient temperature. Subsequently the reaction between azide-functionalized NFC and propargyl amine using copper-catalyzed azide-alkyne cycloaddition (CuAAC) was performed to introduce amine groups.

3.2 High Molecular Weight Modifications of NFC

Several studies have reported on graft copolymerization onto NFC. Xiao and coworkers focused on the creation of controllable hydrophobic chains on NFC employing SI-ATRP of butyl acrylate [98]. Li et al. similarly grafted poly(butyl acrylate) (PBuA) on NFC for subsequent application in reinforcement of a biocomposite [99]. A two-step method for grafting polyacrylic acid (PAA) onto cellulose nanofibers was developed by Vega et al. [100]. In the first stage, the cellulose fibers were treated with an epoxide that contains a terminal double bond and subsequently grafting of the PAA onto the cellulosic fibrils with potassium persulfate as a reaction initiator was carried out. Another approach to improve the dispersibility of the hydrophilic NFC in the nonpolar matrix and the interfacial adhesion in the composite material was based on grafting of poly(ε-caprolactone) (PCL) via ring-opening polymerization of ε-caprolactone [101].

Properties of pristine NFC and acrylic monomer-grafted NFC were investigated by AFM technique [102]. It was found that the grafted NFCs exhibit a rougher surface than those of the unmodified NFC; however nanoscale fibrillar structure was retained during the graft copolymerization process. AFM images revealed that the fibrils of the grafted NFC were thicker when compared to those of the pristine sample. This was explained considering large amount of polymer grafted on the NFC surface. In the case of NFC modified with poly(glycidyl methacrylate) (PGMA) with 80% of weight fraction of the grafted PGMA was clearly visible as a granular structure on the nanofibrils. NFC grafted with PGMA and poly(methyl methacrylate) (PMMA) formed a stable dispersion in acetone and THF.

3.3 NFC-Based Hydrogels and their Applications

Design of cellulose-based hydrogels, which combines biodegradability with smart stimuli sensitive behavior, is of great interest [103]. The ability of cellulose to absorb

large amounts of water makes it attractive material in fabrication of various hydrogels. Many factors affect the ability of cellulose to absorb water, and among them the most important are degree of crystallinity, total surface area, and pore volume [104]. NFC with its large surface area, water retention value, transparency, and sustainability is considered as a promising candidate for hydrogel-based material construction [105].

However, the low mechanical characteristics of the NFC native hydrogel – with storage modulus around 10 Pa at 0.5 wt% [106] – significantly limit its application in soft tissue engineering [107, 108]. In order to improve the mechanical strength of the NFC hydrogel, chemical cross-linkers such as ethylenediamine or hexamethylenediamine have been applied; however they might bring the risk of some cytotoxicity [109, 110]. Environmentally friendly methods to adjust the mechanical properties of NFC hydrogel for potential applications in tissue engineering were achieved by controlling the hydrogel swelling capacity [111] or by introducing biocompatible reinforcing agent such as hemicellulose [112]. Liu et al. applied two approaches to use hemicelluloses as cross-linkers to tune the structural and mechanical properties of NFC hydrogel scaffolds and investigated the effect of these properties on the cellular behavior during wound healing application. Different types of hemicellulose, namely, galactoglucomannan (GGM), xyloglucan (XG), and xylan, were introduced into NFC network via presorption and in situ adsorption to reinforce the NFC hydrogels. They reported that the charge density of NFC, type and amount of incorporated hemicellulose, and the swelling time of the hydrogels affected the pore structure, the mechanical strength, and thus the cells' growth on the composite hydrogel scaffolds. Among all employed hemicelluloses, the XG showed the highest adsorption capacity on the NFC and the highest reinforcement effect, and it promoted cell growth. The conclusion was that the polysaccharide composite hydrogels fabricated by presorption method may work as promising scaffold in wound healing applications to provide supporting networks and to promote cells adhesion, growth, and proliferation.

Recently, there has been great interest in the use of NFC in improving the physical properties of hydrogels. Owing to large surface area and high stiffness and strength, NFC has been used to reinforce various polymer matrices, like poly(styrene-co-butyl acrylate) and poly(vinyl acetate) latexes [113], polyurethane [114], hydroxypropyl cellulose [115], and poly(lactic acid) [94]. Nair and coworkers [116] developed nanocomposite hydrogels based on nanofibrillated cellulose cross-linked with poly (methylvinylether-co-maleic acid) and polyethylene glycol. The resulted hydrogels showed enhanced water sorption and gel content with the addition of nanocellulose. Moreover, the thermal stability, mechanical strength, and modulus increased with an increase in the amount of nanocellulose in the hydrogels. It was explained considering the efficient cross-linking between the nanocellulose and the matrix. The improved physical characteristics confirmed that by cross-linking interactions between the NFC and polymeric matrix distinctively unique hydrogels that are not just blends of starting materials are formed.

Eyholzer et al. fabricated biocomposite hydrogels with carboxymethylated, nanofibrillated cellulose (c-NFC) powder by UV polymerization of N-vinyl-2-

pyrrolidone with Tween 20 trimethacrylates as a cross-linking agent [117]. This composite was designed to serve for replacement of the native, human nucleus pulposus (NP) in intervertebral disks. The swelling ratios and elastic moduli of neat and biocomposite hydrogels were investigated for various c-NFC concentrations and degree of substitution. The resulted biocomposite hydrogels were shown to successfully mimic both the mechanical and swelling behavior of the NP. Moreover, the presence of the c-NFC in hydrogels improved material relaxation properties compared with neat hydrogels, what was demonstrated by lower strain values after cyclic compression tests.

Wen et al. developed superabsorbent composites based on poly(acrylic acid)/nanofibrillated cellulose [118]. NFC was introduced to the system during the UV-induced polymerization process of acrylic acid, so that the obtained composites can reveal enhanced water absorbency and swelling rate. It was demonstrated that even on addition of a small amount of NFC, substantial increase in both water absorbency and swelling rate of the PAA/NFC hydrogel composite was observed. The water absorbency of the obtained composite increased from 380 to 525 g/g at 1 wt% of NFC addition, whereas the swelling rate in deionized water increased by 25% when compared to the control.

In the recent years, NFC-based hydrogels were successfully used by many researchers, especially in the field of various biomedical applications. Nanofibrillated cellulose composite hydrogel was developed for the replacement of NP [117, 119]. It was reported that composite hydrogels reinforced with cellulosic nanofibers can be potentially useful as NP implants. It was shown that their satisfactory swelling ratio may restore the annulus fibrosus loading, while enhanced mechanical properties could possibly restore the height of the intervertebral disks. NFC was also applied as a material for the development of nanocomposite scaffolds for use in artificial ligaments or tendon substitutes [120]. It was found that resulted nanocomposites exhibited excellent cytocompatibility required for biomedical applications and mechanical properties similar or better than the natural ligaments and tendons. Cellulosic nanofibers were also employed to reinforce collagen-based implantable scaffolds, what resulted in better mechanical properties and dimensional stability without affecting the biocompatibility of pristine collagen [121]. NFC-based hydrogels were also studied for potential wound healing applications. It was demonstrated that NFC is non-cytotoxic [109] and exhibits ability to impair growth of common wound bacteria [122] and to reduce inflammation and promote wound healing [108]. All these qualities are suitable for wound healing applications.

The high swelling ability of the NFC hydrogels opens the opportunity to incorporate biomolecules, e.g., peptide, nucleic acids, enzymes, or even whole living cells, into their porous structures for future release or supporting cellular processes in biomedical applications. The adjustable porous structure and stiffness of the NFC-based materials can therefore meet the required pore size and mechanical strength for various cellular activities, such as cell adhesion, proliferation, as well as transportation of nutrients and metabolites [123].

4 Bacterial Nanocellulose (BNC)

Nanocellulose produced as a result of bacterial biosynthesis (BNC) stands out as chemically very pure and structurally significantly different from the nanocellulose obtained from plants. The structure of BNC can be described as a reticulate network of fine fibers with the diameter of 0.1 μm, which is about 100 times smaller than that of plant-derived fibers. BNC shows the whole spectrum of desired properties, including high degree of crystallinity, high density, good shape retention, and high water-binding capacity, which makes it a perfect material for various applications in textile, paper, and food industries, waste treatment, broadcasting, mining, and refineries [124]. Recently a special attention is given to its possible utilization as a biomaterial in tissue engineering, wound dressings, drug delivery, and vascular grafts. Due to high requirements imposed on biomaterials for advanced biomedical applications, most of the currently developed BNC modifications are focused on this area of research.

4.1 BNC Modified with Low Molecular Weight Compounds

Due to its high purity, chemical stability, good mechanical properties, excellent biocompatibility, and ability to form hydrogels, BNC meets practically all the requirements of materials for the modern wound dressing. It does not, however, possess any bacteriostatic or antimicrobial activity, which seems a key property, especially in dressings used in chronic wounds. Various low molecular weight compounds were introduced on BNC surface or entrapped inside its matrix in order to solve this issue, including ibuprofen [125], benzalkonium chloride [126], or silver sulfadiazine [127]. One of the most promising compositions for chronic wound healing seems to be combining BNC with octenidine. The latter is a cationic surfactant known for its broad antimicrobial activity against both Gram-positive and Gram-negative bacteria, as well as plaque-forming bacteria, and fungi. It possesses excellent skin compatibility and does not induce resistance [128]. Moritz et al. [129] introduced octenidine into the BNC matrix by 48 h incubation of the BNC fleeces with 0.5% aqueous solution of octenidine at 20 °C with constant mixing (70 rpm). SEM analysis demonstrated that the presence of the drug, confirmed by weight increase of the samples, did not change the structure of BNC. Octenidine release was followed using spectrophotometry. Release profile was exponential with high initial burst (up to 82% of the drug) within the first 8 h. The equilibrium conditions were reached after 24 h and the total release was around 92%. The rapid release of the significant amount of loaded octenidine should allow to effectively eliminate bacteria and other microbials and seems advantageous. On the other hand, the fact that release has practically stopped after only 24 h is not preferable, especially for long-healing chronic wounds, as the frequent dressing change should be rather avoided. Authors performed also the stability tests over up to 6 months, combined with tests of antimicrobial activity of the new and aged samples. The aluminum
