The primary functions of antioxidants include the regulation of the redox potential within a cell and the reduction of potential initiators of cell death and carcinogenesis. Hence antioxidants are anti-carcinogenic agents. The redox potential refers to the balance of the reducing and oxidizing reactions that occur within the cell. Redox changes within a cell are able to trigger various molecular responses such as induction of cell death and activation of signal transduction (the transfer of messages between cells and within a cell). Therefore, redox regulation of physiological and pathological processes is important in optimizing health and disease prevention [40, 43]. Other functional antioxidant compounds are able to bind to toxins or carcinogens in the intestinal tract, such as the binding of *N*-nitroso compounds by polyphenols in tea, thereby preventing their transformation or even absorption [40].

The lipid-lowering mechanism of phytosterol and stanols occurs by sequestering cholesterol in the intestinal tract and reducing its absorption. Epidemiological and experimental studies suggest that dietary phytosterols may offer protection from most of the common cancers in western societies such as colon, breast and prostate cancers [44]. The possible mechanism by which phytosterols offer this protection include its effects on membrane structure, tumor and host cell tissues, signal transduction pathways that regulate tumor growth and apoptosis, immune functions of the host and cholesterol metabolism by the host [21, 22]. Phytosterols are precursors for lactogogues. Lactogogues are generally prescribed to lactating mothers to augment milk production and also acts as a precursor for hormones required for

reproductive growth. Other phytosterols including stigmasterol, sitosterol and kampesterol are also precursors for hormones. These compounds increase the estrogen production, which in turn stimulates the proliferation of the mammary gland ducts to produce milk [45].

The structural similarity between several isoflavone metabolites and those of estrogens and estradiols suggests the possibility of estrogen-like biological activities in isoflavones. Isoflavones or phytoestrogens, however, exhibit antagonist estrogen activity resulting in lower overall exposure to estrogen in premenopausal women and reducing breast cancer risk [46–48]. In postmenopausal women, phytoestrogen-rich diets reduce hormone-sensitive plasma cholesterol levels and bone loss [49, 50].

Similarly, the induction of enzyme systems that detoxify toxic chemicals including the phase I (example, cytochrome P450 group of oxidases) and phase II (e.g., *N*-acetyl transferase, glutathione *S*-transferase, *UDP*-glucoronyl transferase, etc.) detoxifying enzymes is thought to reduce one's susceptibility to mutagenic effects. Functional food components with antioxidant functions are able to activate phase II detoxifying enzymes via the antioxidant responsive element pathway such as the nuclear factor [erythroid-derived 2]-like 2 also known as Nfe2l2 or Nrf2 signaling pathway [40, 42, 51]. Organo-sulfur compounds such as isothiocyanates, in particular sulforaphane, are potent mono-inducers of phase II detoxifying enzymes [52] while diallyl sulfides from garlic preparations are inducers of both phases I and II detoxifying enzymes [53].

A primary mechanism for immune-modulation is the multiple antioxidant capability of polyphenols, tocopherols, carotenoids, isothiocyanates, and allyl sulfides, lycopene being the most active oxygen neutralizer with potential chemo-preventive activities. Together, these compounds are able to reduce the deleterious effects of reactive oxygen species (ROS) and free radicals, which cause premature death of immune cells [54]. Garlic is found to be a superior phytochemical in the reduction of total cholesterol levels [55] and is also reported to control arterial stiffness by increasing the good cholesterol: high density lipoprotein (HDL) and decreasing the bad cholesterol: low density lipoprotein (LDL). It also inhibits inducible nitric oxide synthase by reducing the protein and *m*RNA and thus promotes vasodilatation of blood vessels. Garlic has strong immunopotential capacity and enhances the natural killer (NK) activity and proliferation of T-lymphocytes by delaying the hypersensitivity reaction [40].

Aged garlic extract is found to be a promising immune modifier with internal body regulatory functions, particularly in the control of sarcoma-180 and lung carcinoma as well as inhibition of platelet aggregation. Both the oil- and water-soluble components of garlic extract have shown health benefits. Specifically, its oil extract reduces serious mental disorder and prevents blood coagulation even in diabetics while its water extract is effective in cell cycle and viability of human hepatoma cells (HG2) [6]. Since garlic extract reverses oxidant responses it seems likely that it protects tissues from oxidative damages [56].

2.2.2 Sources

Carrots, squash, sweet potato, and spinach contain abundant beta-and alpha-carotene and the dark green leafy vegetables such as kale, spinach, mustard greens, and green

beans are good sources of lutein. Lycopene is found predominately in tomatoes. Other bioactive components in tomato are kaempferol or chlorogenic acid, which have anti-mutagenic activities. This suggests that tomato suspension have a protective effect on colon cancer which is mediated by the modulation of different biological pathways during carcinogenesis [57]. Typical dietary sources which are rich in tocopherol and tocotrienols include vegetable oils, nuts and the germ portion of grains [58].

Among the foods that have been shown to have beneficial immunomodulatory effects are broccoli, garlic, onions, vegetable oils, almonds, and walnuts [5, 6]. Similarly, garlic, soy bean, cabbage, ginger, licorice root extract (extract of the root of *Glycytthiza glabra*) and umbelliferous vegetables (vegetables that grow or produce its plant beneath the ground, e.g., carrots) have been identified as foods and herbs with the highest anticancer activity. Citrus in addition to providing an ample supply of vitamin C, folic acid, potassium and soluble fiber contains a host of active phytochemicals [58].

Green tea enhances humoral and cell-mediated immunity while decreasing the risk of certain cancers and cardio-vascular disease. On the other hand, ginseng enhances the production of macrophages and T-cells, natural killer cells and colony forming activity of bone marrow [59]. Soy bean, garlic, ginger and green tea which have been suggested, in epidemiological studies, to reduce the incidence of cancer may do so by inducing programmed apoptosis (cell death). Soybean extract has been shown to prevent the development of polycystic kidneys [60]. Turmeric is most potent against skin tumors [61].

Moringa oleifera is a rich source of a variety of functional components (phytochemicals) in its leaves, pods and seeds. Moringa is reported to contain 7 times more vitamin C than oranges, 10 times more vitamin A than carrots, 17 times more calcium than milk, 9 times more protein than yoghurt, 15 times more potassium than bananas and 25 times more iron than spinach [62]. In addition, it contains other phytochemicals such as tannins, phenolics such as flavonoids, sterols, terpenoids, saponins, anthraquinones, alkaloids and reducing sugar as well as other anti-cancerous agents like glucosinolates, isothiocyanates, glycoside compounds, glycerol-1-9-octadecanoate and about 76% poly-unsaturated fatty acids such as linoleic acid, linolenic acid and oleic acid [45].

2.3 Probiotics and Prebiotics

(a) **Probiotics** are the beneficial live microorganisms, which, when administered in adequate amounts, confer health benefits on the host [63], examples Lactic acid bacteria (LAB), Biofidobacterium.

(b) **Prebiotics** are the non-digestible food ingredients that stimulate the growth and activity of probiotics in the digestive system in ways claimed to be beneficial to health. Thus, prebiotics are healthy non-digestible food ingredients that make their way through our digestive system and help the beneficial or good bacteria grow and flourish [63, 64].

2.3.1 Functions

Probiotics are believed to protect humans in two major ways. The first is the role that they play in human digestive tract. Human digestive tracts need a healthy balance between the good and bad microorganisms. But our lifestyles such as poor food choices, emotional stress, and lack of sleep, antibiotic over-use, other drugs, and environmental influences can shift the balance in favor of the bad microorganisms [65]. When the digestive tract is healthy, it filters out and eliminates things that can damage it, such as harmful microbes, toxins, chemicals, and other waste products. On the flip side, it takes in the things that the human body needs (nutrients from food and water) and helps deliver them to the cells where they are needed. The idea is not to kill off all of the microbes. Human bodies do have a need for the bad ones and the good ones. The problem is when the balance is shifted to have more bad than good. An imbalance has been associated with diarrhea, urinary tract infections, muscle pain, and fatigue [65].

The second major benefit of probiotics is the impact they have on the immune system. The immune system protects against pathogens. When it doesn't function properly, one can suffer from allergic reactions, autoimmune disorders (for example, ulcerative colitis, Crohn's disease, and rheumatoid arthritis), and infections (for example, infectious diarrhea, *Helicobacter pylori*, skin infections, and vaginal infections). By maintaining the correct balance from birth, these ailments are prevented [63, 66]. During delivery through the birth canal, a newborn picks up the beneficial bacteria from his/her mother. These good bacteria are not transmitted when a Caesarean section is performed and have been shown to be the reason why some infants born by Caesarean section have allergies, sub-optimal immune systems, and lower levels of gut micro-flora [65].

Some of the specific mechanisms by which probiotics exclude undesirable microorganisms include the production of inhibitory substances, blocking of adhesion sites, competition for nutrients, degradation of toxin receptors, and stimulation of immunity [66].

Prebiotics stimulate the growth of beneficial and healthy microorganisms (probiotics) in the gut with a resultant increased resistance to invading pathogens. This positive impact of prebiotics, in an unaltered form, in the human intestine is known as the *prebiotic effect*. However, such prebiotic effect is manifested when there is increase in the number and activity of probiotics. This effect is induced by consuming functional foods that contain prebiotics. The prebiotic definition does not emphasize a specific microbial group.

2.3.2 Sources

Dietary supplements and fermented food products have been advertised as containing beneficial cultures. These cultures are what would now be considered probiotics [67]. Other foods currently claimed to provide probiotics are cereal juice, frozen yogurt, granola, candy bars, and cookies. While they may contain probiotics, there is no guarantee that they have them in optimal levels. Only the manufacturer of the product can confirm if there are any studies to support his specific claims [65].

The most common types of prebiotics are non-starchy carbohydrates such as soluble dietary fiber (e.g., β-glucans, inulin, etc.) and other oligosaccharides such as fructo-oligosaccharide (fructans), galacto-oligosaccharide, etc. Many of the plants frequently eaten as vegetables – asparagus, garlic, leek, onion, artichoke – are excellent sources of inulin. β-Glucans and inulin are common in many plants containing dietary fiber and fructans. Traditional dietary sources of prebiotics also include soybeans, raw oats, unrefined wheat and unrefined barley. Some of the oligosaccharides that naturally occur in breast milk are believed to play an important role in the development of a healthy immune system in infants through the prebiotic-probiotic relationship.

3 Food as Medicine

Since ancient times, plants have always been the common sources of food and medicines, either in the form of traditional herbal preparations or as pure active principles [68]. Many herbal extracts have been tested in numerous systems to assess their chemopreventive and chemotherapeutic efficacy [69]. Similarly, there is growing evidence that functional components (phytochemicals) play an integral role in the link between food and health thereby providing disease-fighting foods for the prevention of chronic degenerative pathologies or in support of traditional remedies [18]. Most of the observed therapeutic effects of plants have been linked to their potent phytochemical content especially anti-oxidants. Healing of diseases or maintenance of a healthy lifestyle based on antioxidant activity could be the scientific basis of traditional herbal medicines [70].

In this regard, the eastern civilizations of Asia and the oriental cultures including the Chinese, Japanese, Indians and Egyptians were the few civilizations that explored these healing powers of food phytochemicals for thousands of years and provided evidences which supported claims that functional phytochemicals in foods can be effectively used to prevent the risk of developing diseases and promote well-being [71, 72]. However, a diet can only be adjudged healthy if its combination of individual food types is appropriate and their nutritive and non-nutritive metabolites are biologically available for cell absorption and utilization. Table 2 gives the effect of some physiological factors on the bioavailability of functional components. Limiting certain food types or components such as sugars, salts and saturated or trans-fatty acids alone or simply delivering an intake of pure nutrients alone may not be regarded entirely as a healthy diet. Therefore, while it is easy to recommend a healthy diet, it is much harder to define it for a particular need [9].

Hence, in this era when the role of a healthy diet in preventing non-communicable diseases are well accepted, the borderline between food and medicine is becoming very thin [9]. Thus, the concept of food has obviously gone beyond basic nutrition only. While products intended to cure diseases are classified as medicine, a healthy diet consisting of foods with functional components can help promote well-being and even reduce the risk of developing certain diseases [70].

Table 2 Effect of some physiological factors on the bioavailability of functional components[a]

S/N	Factors	Effect
1.	Food matrix	Functional components are compartmentalized, bound in cell walls and are unavailable
2.	Food preparation	Cutting, mashing, grinding, peeling, trimming activate enzymes, e.g., polyphenol oxidase, allinase. Improves availability of antioxidants
3.	Food processing: Thermal/non-thermal processing, (NTP example high pressure processing (HPP), pulsed electric field (PEF))	Mild heat treatment (steaming, blanching) over short period improves antioxidant content but this decreases with severe treatment (boiling, cooking). NTP has positive effect on polyphenols and negative effect on carotenoids
4.	Food mixtures	Enhances availability of polyphenols with sugars, ascorbic acid, fat and stabilizing effects of polyphenols on other phytochemicals
5.	Gastric digestion	De-polymerization of large polyphenols, hydrogen bonding of polyphenols to proteins
6.	Small intestine	Micelle formation, increased role of uptake and efflux transporters (cell to gut lumen to basolateral to cell), transition from matrix to oil phase
7.	Colon	Phase I/II interactions, influence of micro-flora on phytochemicals, colonic absorption, increased formation of metabolites and phase I/II products
8.	Tissues	Biotransformation, phase I and II metabolism, interaction with transporters in certain tissues (blood-brain barriers, placenta, testis) or excretory organs (liver, kidney)

[a]Bohn et al. [15]

4 Healing Powers of Functional Components

Some properties which link functional components to potential health-modulating roles and functions can be classified into antioxidation, anti-cancerous, anti-diabetic, anti-inflammatory, prevention of cardio-vascular diseases, anti-microbial, immune-modulatory and anti-hypertensive [20, 73, 74].

4.1 Anti-oxidation Properties

Free radicals in the form of reactive oxygen species (ROS) or reactive nitrogen species (RNS) are the usual by-products of body metabolic activities which involve

oxidation and reduction reactions in cells. It is expected that at low concentrations, these reactions have beneficial effects on cellular responses and immune functions [75]. However, at high concentrations they cause the condition known as oxidative stress which is harmful to cell structures. In simple terms, oxidative stress is defined as the condition whereby the balance between formation and removal of free radicals is shifted towards formation of more free radicals rather than their removal [76]. It is generally believed that oxidative stress plays a major role in the development of chronic and degenerative diseases such as cancer, diabetes and cardio-vascular diseases [75, 77]. The human body has its own endogenous anti-oxidant system designed to combat oxidative stress which is supported and strengthened by exogenously supplied anti-oxidants in diets [75]. In this regard, phytochemicals such as phenolic compounds are believed to play key role in protecting the body against oxidative stress and its effects due to their well-known anti-oxidant properties. The antioxidant capacity or activity of phytochemicals, in vitro, is well reported in literature and serves as an indicator of the potential ability of dietary antioxidants to combat oxidative stress [78, 79]. This has been determined mostly through free-radical scavenging ability although other assays have been used such as inhibition of lipid peroxidation and metal ion chelating capacity. Similarly, the potential of anti-oxidants to combat oxidative stress have been demonstrated in vivo, mostly in rats. This involved the monitoring of activities of anti-oxidant enzymes or anti-oxidant molecules within the experimental animal on feeding it with the phytochemical of choice [79–81]. Overall, anti-oxidant supplementation reduced lipid peroxidation and enhanced anti-oxidant capacity of blood (plasma), heart, kidney, testes, lung and pancreas. It is therefore acceptable that oxidative stress is a precursor for the development of various chronic and degenerative diseases. It has been suggested that free radicals are involved in the pathology of more than 50 human diseases, including aging [82]. However, it is also important to note that free radicals are not harmful at all times, rather, their toxicity depends on several factors including the type of ROS/RNS, their concentration and localization, and the kinetics of their production and elimination [83].

4.2 Anti-cancer Properties

Various reports provide some evidence of potential anticancer properties of functional components of food. These properties have been demonstrated in vitro through assays including their effects on oxidative stress (free-radical scavenging activity), inhibition of DNA damage, anti-proliferative effects on cancer cell lines and phase II enzyme induction [84]. Methoxylated 3-deoxyanthocyanins was found to be the most potent inducer of quinine oxidoreductase, a phase II detoxifying enzyme [85]. The effects of functional components on oxidative DNA damage have been reported [86]. Higher total phenolic contents including flavonoids and non-flavonoids such as rutin and quercetin increased the inhibition of oxidative DNA damage. Similarly, the inhibition of hydroxyl radical-induced DNA damage by an anthocyanin has also been reported [87].

4.3 Anti-diabetic Properties

Diabetes is associated with various conditions including oxidative stress, impaired insulin secretion and insulin resistance due to malfunctioning of β-cells of the pancreatic islets of langerhan, leading to defective utilization of carbohydrates as energy source [88]. Due to their anti-oxidant properties, phenolic compounds may reduce oxidative stress conditions and also protect pancreatic β-cells. Another widely used way of demonstrating anti-diabetic effects of functional components is by determining their inhibitory effects against starch-degrading enzymes such as α-amylase and α-glucosidase. Phytochemicals have been shown to possess inhibitory effects against α-amylase and α-glucosidase [89, 90]. Some in vivo studies on the anti-diabetic effects of phytochemicals have also been reported. Diets high in phytochemicals could protect against hyperglycemia and alloxan-induced oxidative stress through the restoration of levels of endogenous enzymatic superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GP_X), and glutathione reductase (GR) and non-enzymatic (vitamins E and C) anti-oxidants in diabetic rats [91].

4.4 Anti-inflammatory Properties

Inflammation may be described as an immune response to cellular or tissue injury or infection by pathogens [92]. The condition of inflammation itself is not considered a disease. However, if left unchecked to become chronic, there can be exacerbated tissue damage and modulation of various cell-signaling pathways [93]. Chronic inflammation causes life style diseases, such as obesity, metabolic syndrome, arterial sclerosis, and cancer [94–98]. The process of inflammation consists of a wide and complex range of cellular and molecular pathways and reactions involving a host of enzymes [92]. These enzymes include cyclooxygenase, lipoxygenase, phospholipase A2 and nitric oxide synthase. Cytokines such as IL-1, IL-2 and TNF-α and nitric oxide are important pro-inflammatory products of cellular reactions [16, 73]. Phytochemicals can modulate inflammatory processes by inhibiting pro-inflammatory enzymes [92] which influence the production of the cytokines and nitric oxide. The anti-inflammatory properties of dietary phytochemicals may be determined by their inhibitory activities against the pro-inflammatory enzymes and by monitoring the production of pro-inflammatory cytokines. Simple nitric oxide radical scavenging capacity could also be used as an indicator of anti-inflammatory properties. In vitro and in vivo anti-inflammatory activities have been widely reported [80, 81, 99].

4.5 Cardio-vascular Properties

The oxidation of LDL seem to trigger-off the onset of coronary heart disease [100]. The oxidized LDL is taken up by macrophages (foam cells) and smooth muscle cells leading to the formation of fatty streaks and eventual development of arteriosclerosis [101]. The prevention of the oxidation of LDL may be a potential prevention of

cardiovascular disease. The ability of functional components including phenolics to prevent LDL oxidation by exerting anti-oxidant effects such as cholesterol lowering effects through the suppression of LDL-cholesterol and the elevation of HDL cholesterol that is important for the prevention of cardiovascular disease has been reported in literature [102]. The effect of supplementation of phytochemicals from a pseudocereal (quinoa) in a fructose containing diet on some cardiovascular disease parameters in male Wistar rats was studied by Pasko et al. [103]. Rats fed with quinoa had reduced serum total cholesterol, LDL, triacylglycerol, glucose and plasma total protein. Those fed fructose had decreased HDL but this decrease was reversed on feeding with quinoa. The reduction in LDL and prevention in decrease in HDL on feeding with quinoa suggests potential ability of the phytochemicals in quinoa to prevent cardio-vascular disease [73]. The observed hypo-cholesterolemic effects may be due to synergistic effects of high crude fiber and high anti-oxidant concentrations such as quercetin. Thiol-containing compounds and phenolics were shown to inhibit rat microsomal lipid peroxidation which may be significant for the prevention of LDL oxidation and hence prevention of arteriosclerosis and cardiovascular disease [104]. Oxidative stress-mediated conditions such as cardiovascular disease are also accompanied by loss of endogenous antioxidant compounds such as glutathione-glutathione disulfide ratio [77].

4.6 Anti-hypertensive Properties

Functional components possess therapeutic capacity to decrease blood pressure [105]. These non-nutritive food factors such as flavonoid polyphenols (flavonols example quercetin; flavones example lutelin; and isoflavones example coumesterol) and carotenoids are scavengers of free radicals like superoxide anions, lipid proxy radicals, and lipid oxidation of LDL cholesterol, hence are anti-atherogenic (decreasing the formation of atherosclerotic plaques and arterial stiffness) thereby making arteries more responsive to vasodilation thereby lowering blood pressure [106]. Low risk of stroke is associated with high intake of plant food materials including fruits and vegetables and thus prevents hypertension [105]. In addition, several plant sources in the forms of herbs and spices including *Allium sativum* (Garlic), *Camellia sinensis* (Tea), *Hibiscus sabdariffa* (Roselle), *Nigella sativum* (Black cumin), *Panax* (Ginseng), *Cymbopogon citratus* (Lemon grass), *Zingiber officinale* (Ginger) contain non-nutritive secondary metabolites which have been demonstrated to possess vaso-relaxant, anti-oxidant, anti-proliferative, anti-inflammatory, and diuretic functions which play anti-hypertensive roles [107].

5 Optimal Health and Well-Being

Health and well-being or wellness are terms which are often used interchangeably, but their meanings are no doubt different. According to the World Health Organization, health is a state of "complete" physical, mental and social well-being and not

merely the absence of disease or infirmity. Health is therefore a dynamic condition resulting from a body's constant adjustment and adaptation in response to stress and changes in the environment for the maintenance of a homeostatic inner equilibrium [108]. Accordingly, the primary determinants of health include social, economic, and physical environments, as well as the individual's personal characteristics and behaviors. This definition has attracted serious criticisms for being overtly inclusive and practically unattainable, especially as it relates to the word "complete." However, "complete" medically expands the definition of health beyond the mere absence of diseases [109]. The maintenance and improvement of health, accordingly, depends not only on external or environmental factors (including the health care systems) but also on the efforts and lifestyle choices of the person involved [110]. On the other hand, optimal health is a level of health where the body's natural defense mechanisms are activated to function maximally. Optimal health turns off all chronic infections and oxidative stress. It prepares the body to respond quickly and effectively to any invasion by pathogens, toxins and other infections thereby preventing the onset of degenerative diseases including cancer, hypertension, stroke, diabetes, etc.

Although variously defined, depending on the context of usage, well-being generally depicts a healthy balance of the mind, body and spirit (state of comfortability or happiness) which results in an overall feeling of wholesomeness. However, according to the National Wellness Institute, wellness is considered as an active process through which people become aware of, and make choices towards, a more successful existence based on a conscious, positive and affirming, self-directed and evolving process of achieving full potential; a multidimensional and holistic lifestyle, encompassing mental and spiritual well-being, and the environment. Therefore, in understanding the difference between these two terms, health could be regarded as a state of being – both physical, mental, and social – whereas wellness aims to enhance this state of being by living a healthy lifestyle [110].

6 Mode of Action of Functional Components and How they Impact on Optimal Health and Well-Being

The mechanisms through which functional components impact on human health are not completely clear and seem to be multiple [18, 111]. Some identified multiple molecular targets of functional components include pro- and anti-apoptotic proteins, cell cycle proteins, cell adhesion molecules, protein kinases, transcription factors, metastasis and cell growth pathways [112–114]. Phytochemicals such as epigallocatechin-3-gallate (EGC-3-G) from green tea, curcumin from turmeric, and resveratrol from red wine tend to aim at a multitude of molecular targets. These multiple characteristics may have contributed to the unavailability of definitive mechanisms of action despite decades of research [115]. Specifically, the main mechanisms suggested for phenolics include an improvement in the lipid profile of plasma, an increase in its antioxidant activity as well as an enhancement of the endothelial function by exerting anti-inflammatory effects, reducing LDL oxidation, inhibiting

endothelial NADPH oxidase, modulating nitric oxide synthase activity/expression and increasing nitric oxide status [116, 117].

Data from in vitro studies suggest a protective interaction of flavonoids with lipid bilayers against oxidative damage, as a result of their localization in lipoprotein domains and cell membranes thus explaining the possible in vivo role phenolics in protecting LDL from oxidation. Moreover, it has been hypothesized that bioactive compounds, once absorbed and metabolized, may accumulate inside the cell membrane modifying the membrane composition, fluidity and functionality [83, 118]. In vivo, plant antioxidants are generally assessed for their effects on the activity of endogenous antioxidant enzymes or oxidative damage biomarkers before and after induction of oxidative stress in experimental animals. Some of these commonly used methods directly evaluate the enzymatic activity of endogenous anti-oxidants such as SOD, CAT, GPx and GR, while other methods involve quantification of oxidative damage biomarkers. The formation of specific end products resulting from interaction of ROS with biologically important macromolecules such as DNA, protein and lipids is measured by quantifying oxidative damage biomarker methods. DNA damage is determined by measuring the 8-hydroxydeoxyguanosine content. Carbonyl and aldehyde such as malondialdehyde contents are measured as biomarkers of protein and lipid oxidation, respectively [119]. Potential health benefits of functional components of food are summarized in Fig. 10.

Several claims have been made, evaluated and approved by various regulatory agencies in different parts of the world in respect of the health benefits and positive effects of functional components of food such as soluble DF including β-glucans on health and well-being [120]. Such approvals include those by the US Food and Drug Administration (FDA) in 1997 [121]; the Panel on Diabetic Products and Nutrition and Allergies of the European Commission in 2009 and 2011, respectively [122, 123]; the Joint Health Claims Initiative (JHCI) expert committee and council of the UK [124] and in Sweden [28]. These approvals were based on recommended dose of 3.0 g day^{-1} of β-glucans to attain health benefits including maintenance of gut health and normal blood cholesterol level, reduction of energy and post-prandial glycemic responses. Processed β-glucans are effective food supplement which has no side effects irrespective of level of consumption and therefore generally recognized as safe (GRAS) [125].

7 Effect of Processing on Functional Components of Food

Processing exercises some effects which could be positive or negative on phytochemicals and other functional components of food. While some food processing techniques increase the concentration of these functional components in food, others decrease them (Table 2). It has been shown that the length of post-harvest storage, steam blanching, and thermal processing all influence the retention of functional compounds in allium vegetables [126]. However, losses of about 30-80% of bioactive isothiocyanates through heat processing have been reported

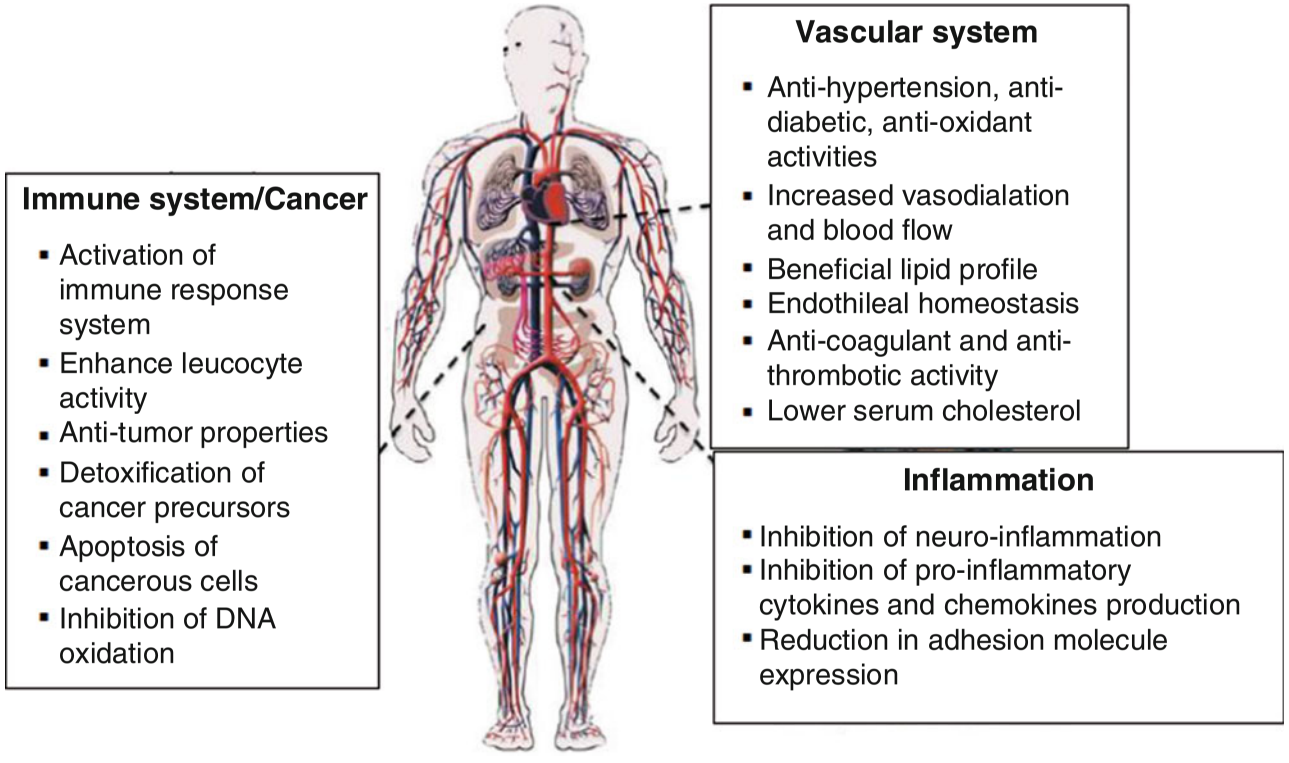

Fig. 10 Potential health benefits of functional components

[120]. In addition, high temperatures (100 °C and above) inactivates key enzymes such as myrosinase in cruciferous vegetables and allinase in allium vegetables, thereby reducing the amount of functional components in these food materials. However, temperatures associated with normal cooking have shown little evidence of substantial loss of isothiocyanates. Leaching of glucosinolates and their hydrolysis products also results in a reduction in total phytochemical content following cooking. Research has shown that heating garlic in a microwave oven for 30-60 s or heating it to a temperature of 60-100 °C results in significant losses of its anti-inflammatory, anti-cancerous, anti-microbial and anti-oxidant activities [127].

The bioavailability of carotenoids and other lipid-soluble functional food components have been shown to improve with processing techniques that increase surface area, such as size-reduction, example, cutting and chopping, as well as heat treatment that breaks down protein and carbohydrate matrix [128, 129]. Also, the brewing of tea leaves, whether black or green, releases 69-85% of their bioactive flavonoids within 3-5 min in hot water [129].

In contrast, drying pre-treatment before boiling was found to reduce cooking time thereby leading to less leaching of anti-oxidants in edible Irish seaweed *Homanthalia elongata*. In terms of extract, drying followed by boiling of *Homanthalia elongata* had the most significant effect on phytochemicals as its total phenolic content increased by 174%. However, this processing treatment reduced its anti-microbial activity compared to extracts from fresh samples [130]. Table 3 below gives a summary of the effect of some processing techniques on the anti-oxidant content of some foods.

Table 3 Effect of processing on antioxidant content of some foods compared to nonprocessed foods[b]

S/N	Food	Type of processing	Effect (%)
1.	Apple	Peeling	(−) 33–66%
2.	Carrots	Steaming	(+) 291%
3.	Carrots	Boiling	(+) 121–159%
4.	Cucumbers	Peeling	(−) 50%
5.	Asparagus	Steaming	(+) 205%
6.	Broccoli	Steaming	(+) 122–654%
7.	Green cabbage	Steaming	(+) 448%
8.	Red cabbage	Steaming	(+) 270%
9.	Green pepper	Steaming	(+) 467%
10.	Red pepper	Steaming	(+) 180%
11.	Potatoes	Steaming	(+) 105–242%
12.	Tomatoes	Steaming	(+) 112–164%
13.	Spinach	Boiling	(+) 114–184%
14.	Sweet potatoes	Steaming	(+) 413

[b]Hadvorsen et al. [131]

8 Conclusion

It is a widely held view that the consumption of a healthy diet can help prevent non-communicable degenerative diseases. This is as a result of the presence of non-nutritive or secondary metabolites known as functional components especially in plant based foods. Similarly, there is also growing evidence that functional components including phytochemicals and bioactives play an integral role in the link between food, optimal health and well-being. Epidemiological data support this preventive and protective effects of food against chronic degenerative pathologies such as cancer, diabetes, and cardiovascular diseases as a result of their functional components. Such functional components include dietary fibers, fucoidans, carotenoids, phenolics, phytosterols, tocopherols/trienols, organo-sulfur compounds, prebiotics and probiotics.

Increasing scientific evidence indicate that insufficient functional components in diets through the low consumption of foods such as fruits, vegetables, nuts, whole grains, spices is among the risk factors which contribute to increased incidence of noncommunicable "silent killer" diseases in the world today. Some properties which link functional components to potential health benefits can be classified into antioxidation, anti-cancerous, anti-diabetic, anti-inflammatory, cardiovascular, anti-microbial, immunomodulatory and anti-hypertensive, anti-coagulant and anti-thrombotic activity of blood plasma, anti-virus, reduction of blood lipids including cholesterol, anti-complementary properties, activity against hepatopathy, uropathy and renalpathy, protective effects on gastric organ and gastric mucosa.

Thus, the idea of food these days has obviously gone beyond mere provision of biochemical building blocks necessary to refresh and nourish life in the form of primary nutrients to cells of an organism. While products intended to cure diseases could be classified as medicine, a healthy diet consisting of appropriate food types with functional components can serve as a scientific alternative to reduce the risk of developing certain diseases. Obviously, functional components of food will play an important role in health maintenance in the future as a result of their medicinal properties. However, their bioavailability and levels required in humans are critical factors necessary to optimize their potential benefits. Hence, in this era when the role of a healthy diet in preventing non-communicable diseases is well accepted, the borderline between food and medicine is becoming very thin.

Acknowledgements The author expresses grateful acknowledgement to Dr. Elena Barascu of Department of Food Engineering, Valahia University, Targoviste, Dambovita, Romania and Prof. Lavinia Buruleanu, the Editor-in-Chief, Annals Food Science and Technology for granting kind permission to reuse the original article, Current developments on β-glucans as functional components of food: a review published in volume 14, issue 2, and pages 217–229 of its 2013 edition in this work. It is further acknowledged that the journal article, Functional components and medicinal properties of food: a review which was first published in the Journal of Food Science and Technology, volume 52, issue 5, pages 2522–2529 in 2015 also contributed to this book chapter project.

Abstract

There has been a growing interest on functional foods, markedly recognized as being able to provide additional benefits on health promotion, wellbeing maintenance, and disease prevention. Based on this scenario, food industries have been increasingly focused in developing added-value foodstuffs, being dairy foods one of the most currently used food products for functional purposes. extraction and encapsulation technologies have been used to obtain target food bioactive ingredients and to ensure an effective functionalization of dairy products, respectively. Probiotics, prebiotics, mushrooms, and plant food bioactive extracts comprise the most commonly used food ingredients to produce functional dairy foods, mostly fermented milk, yogurt, and cheese. In fact, dynamic and promissory biological effects have been documented for these functional dairy foods, among them antioxidant, cardioprotective, antihypertensive, immunomodulatory, antimicrobial, antidiabetic, anti-inflammatory, neuromodulatory, and even bone protection. However, besides the impact of health benefits on consumers' acceptance and subsequent consumption of functional dairy foods, other factors, such as consumers' familiarity with new products and functional ingredients used on their formulation, consumers' knowledge and awareness about the credibility of shared health effects, and finally the organoleptic and sensory evaluation of the developed functional dairy foods, have also a determinant role. Anyway, consumers are considered self-contributors for this promising food innovation. Thus, the concept of functional dairy foods may represent an upcoming multiniche market and sustainable trend to be exploited.

Functional foods · Dairy products functionalization · Food ingredients · Extraction/encapsulation technologies · Consumers' acceptance

1 Introduction

Consumers' perception about the real importance of a balanced diet and healthy lifestyle on disease prevention, health maintenance, and longevity promotion has driven the development of multiple and increasingly deepen studies [1, 2]. Foods, food ingredients, and even bioactive molecules with health-promoting abilities present a large demand by worldwide consumers [3]. In fact, biotechnological and agro-food industries have been increasingly focused on the development of highly specific methodological procedures to incorporate certain bioactive molecules on daily products, making them more safe, effective, bioavailable, and even able to confer certain additional biological attributes [4, 5]. Despite the inexistence of a general consensus, these food products are commonly referred as functional foods, i.e., "*foods that when included in the normal diet display one or more target functions in the human body, being able to improve the health status and/or to reduce the likelihood of some disorders occurrence*" [6]. Thus, functional foods make part of daily diet, both as natural, whole, or unmodified foods; however, they may also be used and/or incorporated as food constituents, added and/or removed by technological or biotechnological procedures that modulate their bioavailability, focusing on the improvement of their biological effects [6, 7]. Several food groups, such as meat and fish products, ice cream, cheese, yogurt, and other dairy products present very interesting chemical characteristics and nutritional composition that

triggers the focus of researchers to the incorporation and application of bioactive molecules in those food matrices [3].

Dairy products are amongst the most commonly tested and selected food groups toward the incorporation of food ingredients for functional purposes. Milk, cream, yogurt, kefir, powdered milk, condensed milk, ricotta, butter, casein, fermented dairy drinks, infant milk formula, colostrum, cheese, and ice creams are the most common traditional dairy products considered as functional foods [8, 9]. All these products have on their chemical composition recognized ingredients that provide, besides the nutritional benefits, a considerable improvement on human health and well-being [8]. Numerous nutrients are present on dairy food products, being vitamins, minerals, and proteins the most abundant ones. However, some preparations present active ingredients with low availability and/or nutritional deficits of these constituents, being milk fortified with calcium and vitamin-D (fortified product) one of the most representative examples of this situation [10, 11]. Moreover, the incorporation of milk supplements and milk-based food products, such as probiotic bacteria and prebiotic polysaccharides, omega-3 fatty acids, and other compounds, is becoming increasingly common (enriched product) [10, 11]. Moreover, there are some situations in which some deleterious components need to be removed, reduced, or replaced by another substance with beneficial effects, for example, fibers as fat releasers in ice cream products (altered products) [10, 11]. Curiously, functional dairy foods are virtually found in all these types of functional food categories, despite they are not homogeneously scattered over all segments of the growing market.

In this sense, the present chapter aims to provide an overview on functional dairy foods, emphasizing the role of biotechnological and agro-industrial prospects in their development, describing the most commonly used plant food bioactives on functional dairy foods formulation, and lastly their bioactive and health-promoting abilities.

2 Dairy Food Products: An Overview

Innovations in the agro-food sector are mostly focused on the improvement of the currently available food products, always taking into account some specific criteria, such as the quality, safety, and even distinct characteristics related with bioactive and health promoter effects conferred by these matrices [12–15]. Besides, the information about nutrients, ingredients, and food additives should also be prioritized [12, 14]. Specifically, the food industry has been the target of intensive and impressive innovative processes along with different parts of the food chain, being the most evident ones classified in five distinct sectors: (1) new food ingredients and materials; (2) innovation in fresh foods; (3) innovation in food quality; (4) new food process techniques; and (5) new packaging methods [12]. All these innovative aspects result from consumers' demand that trigger the search and development of highly effective products, techniques, and services by food science and technology researchers in articulation with the food industry (Fig. 1). Within the scope of food

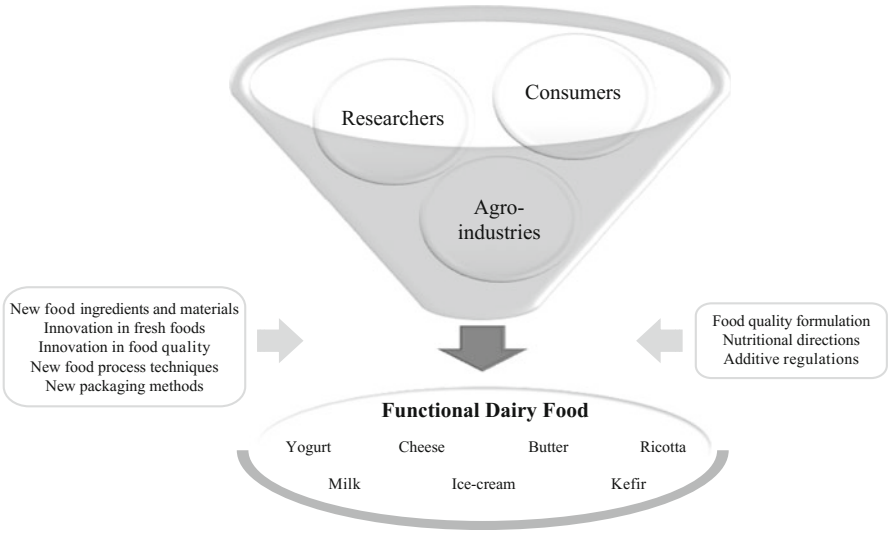

Fig. 1 Main actors and factors involved in the development of functional dairy foods

science and technology, the market of dairy products has gained a renowned niche of demand and recognition by consumers, besides of their increasing research interest and innovation procedures.

Milk is one of the most widely consumed dairy product, being used over centuries as part of daily diet [15, 16]. Despite a growing evidence showing that their unlimited ingestion is associated with several disorders, including some forms of cancer, asthma, diabetes, obesity, cardiovascular diseases, and even osteoporosis, more recent clinical data have demonstrated that calcium supplementation helps to promote bone health besides other benefits [9, 15, 17]. Nevertheless, there are some data that still remains inconclusive concerning to the linkage between high dietary calcium intake from milk and prevention of osteoporosis and bone loss [16]. On the other hand, and considering that many people are lactose-intolerant or even allergic to milk, the interest was progressively driven to milk fermented products, such as yogurt and cheese [16, 18, 19]. Fermented dairy products contain live beneficial microorganisms that can digest lactose and other nontolerable milk constituents, exert cholesterol-lowering effects, and also contribute to cancer risk reduction [15]. These promising modulatory effects are mainly reached through action of those microorganisms, namely probiotic bacteria, that significantly enhances the health-promoting abilities of dairy products, contributing for a longer and healthier lifetime [9, 16]. Not least important to highlight is that the benefits of probiotic bacteria may be achieved both directly and/or indirectly, being all these aspects carefully described in a specific section of this chapter.

Considering the recent findings on this field, milk and other dairy products, and more specifically fermented dairy products, may have a crucial and determinant functional role in contributing to health and well-being of worldwide population.

This aspect has driven an increasing interest of researches in developing functional foods based on milk and other dairy products, which are known by humanity since medieval times due to their health benefits. More recently, the biologically active constituents have been increasingly studied and their benefits reported, remaining, however, the interest to deepen knowledge on this field, in order to promote their strengthening and valorization.

3 Functional Foods: Innovative Trends on Dairy Products

Functional foods have been the target of an intense investigation by researchers, highly demanded by consumers as also with increasingly strict regulatory processes applied to agro-industries. Despite dairy products present a broad history of use, in the last years a high demand by consumers for enhanced-dairy foods with additional health-promoting abilities has been observed [20, 21]. The large evidence that foods in general, and specifically dairy foods with balanced-enriched nutritional composition, may confer additional health benefits has stimulated the development of novel formulations of dairy products containing active ingredients [9, 18, 22]. Until now, prebiotics, probiotic bacteria, vitamins and minerals, flavoring agents, plants, fruits, and even its derived extracts are amongst the most frequently used food ingredients in the design of functional dairy food formulations (Fig. 2). In fact, the development and formulation of functional dairy foods are on the top of the current studies, being yogurt, followed by cheese, butter, milk through different preparations (powdered,

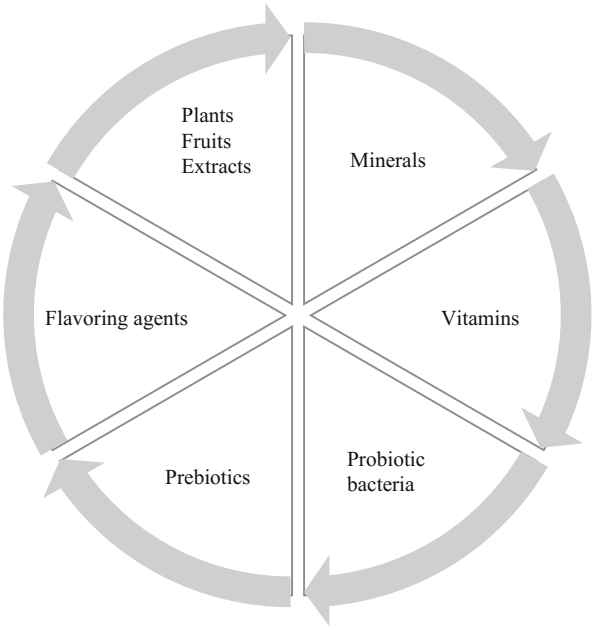

Fig. 2 Most commonly used ingredients in the formulation of functional dairy foods

processed, condensed, and even milk-based foods), ice cream, kefir, and ricotta the most widely investigated toward the incorporation of the previous mentioned ingredients for different functional purposes (Fig. 1). This information is briefly summarized in Table 1 and described in detail in the following paragraphs.

Studies with probiotics are on the top of dairy products' investigations, including the use of microorganisms, such as *Bifidobacterium, Lactobacillus, Streptococcus*, and *Saccharomyces*, individually or in cocultures [4, 14, 18]. Very interesting results have been reported related with food quality characteristics, effectiveness, and acceptance by consumers [4, 18]. There is an increasing evidence related with the effective biological potential and health benefits of probiotic bacteria, namely on the prevention of gastrointestinal disorders, microbiota modulation, selective inhibition of opportunistic microorganisms, on the metabolism of toxic substances, as anti-carcinogenic/antimutagenic agents, and even on the reduction of cholesterol levels and of lactose intolerance [3, 4, 7]. This last one has received a pivotal attention by food industries, due to the increasing rates of lactose intolerance, which directly interfere with food selection by worldwide consumers [4]. Different levels of lactose intolerance require specific dietary recommendations, including to avoid dairy products and derivatives [16]. Therefore, the incorporation of probiotic bacteria in various matrices of dairy products to reduce lactose intolerance is very important. Yogurts and cheeses are amongst the most investigated dairy products toward the incorporation of probiotic bacteria for functional purposes [4].

The incorporation of vitamins and minerals on dairy foods is not less common, both in bioavailable, stable, and soluble forms to enrich the nutritional value as also to extend the shelf life of dairy products [17]. Calcium, iron, and vitamins C, D, and

Table 1 Types of food ingredients commonly incorporated in the formulation of functional dairy foods

Types of food ingredients	Detailed food ingredients	Dairy products incorporation
Prebiotics	Milk proteins, lactose, saccharose, lactulose, fructo-, glyco- and galactooligosaccharides, arabinose, galactose, inulin, raffinose, mannose, lactulose, staquiose, xylooligosaccharides, isomaltulose (palatinose), isomaltooligosaccharides, and soy oligosaccharides	Cheese, yogurt
Probiotics	Species: *Bifidobacterium, Lactobacillus, Streptococcus* and *Saccharomyces*	Cheese, yogurt
Vitamins and minerals	Calcium, iron, vitamins C, D, B2, B9, and B12	Milk, cheese, yogurt
Flavoring agents	Polyphenols, flavonoids, carotenoids	Milk, cheese, yogurt
Plants, fruits, and its derived extracts	Chamomile, fennel, honey, mushrooms, chestnut, lemon balm, rosemary, basil	Cheese, yogurt
Others	Omega-3 fatty acids are linoleic acid (LA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA); β-carotene	Milk, yogurt

B12 are among the most frequent ones [9]. Other B vitamins, such as folate and riboflavin, have been also used; some of them are even synthesized from various nonvitamin precursors through action of certain bacteria in plant and dairy foods [14]. Although several years ago synthetic formulas were the most common, presently the incorporation of natural ingredients rich on these nutrients are on the top of agro-industrial selection and consumers' preference [3]. A similar scenario is observed for the addition of flavors and aromas, in which essences, plant fruits and/or plant fruit extracts, and even honey have been increasingly used, while artificial flavoring agents become secondary in the formulation of dairy products [2, 23, 24]. The addition of plants and fruits and/or its derived extracts seems to present modulatory effects on gut microbiota, i.e., favors the growth of beneficial bacteria and limits the growth of opportunistic microorganisms [14]. Still, these active ingredients are also able to contribute for the improvement of the dairy products shelf life at large extent, being therefore currently used for different purposes [25].

Plants and fruits are *per* definition, composed by a rich and complex pool of chemical molecules, most of them already characterized and properly identified as having important bioactive effects at different levels [26]. Within the different classes of bioactive molecules, phenolic compounds have received a special attention, due to their well-known antioxidant properties [26]. Nevertheless, most of these bioactive molecules present inactive forms, being transformed into active forms by metabolic processes; in this field lactic acid bacteria (*Lactobacillus* and *Streptococcus*) display a very important role, favoring the conversion of inactive phenolic compounds into their biologically active forms, via expression of glycosyl hydrolase, esterase, decarboxylase, and phenolic acid reductase enzymes [14]. These biochemical reactions lead to the formation of several biologically active molecules, namely pyranoanthocyanidins and 3-desoxypyranoanthocyanidins that display determinant and regulator effects as health promoters and disease preventers [14]. Once again, probiotic bacteria seem to exert multiple contributing effects when combined with other food ingredients in dairy functional products' formulation. However, besides plant extracts, several other ingredients, such as milk proteins, inulin, oligosaccharides, and lactulose, have been incorporated for prebiotic purposes, i.e., to promote the growth of *Bifidobacterium* and other probiotic bacteria, to ensure gut health, to keep harmful bacteria under control, and to enhance immune system [9, 27]. Besides prebiotic effects, these active ingredients also show other important functions, such as improvement of minerals and vitamins absorption, decrease of triglycerides and cholesterol levels, and due to their high contents in dietary fiber, improvement of fecal transit time and stool weight, crucial to prevent constipation [9, 22]. Not least important to point out is that the above referenced health conditions are amongst the most common disorders observed in modern society.

The latest studies performed on this area have investigated different parameters related with the general quality and acceptability of the incorporation of honey to produce functional yogurts [2], mushrooms on functional cheese formulations [23], and even phenolic extracts derived from different plant parts on dairy functional

yogurts and cheese formulation [25, 28–36]. Nevertheless, further studies are necessary to evaluate the feasibility, efficacy, effectiveness, and bioavailability of bioactive ingredients used to functionalize dairy products, and not least important to evaluate the consumers' acceptance.

4 Functional Dairy Foods: Agro-Industrial and Biotechnological Prospects

A balanced and healthy diet is a key determining factor for overall quality of life, which has been increasingly evident for worldwide consumers [6]. In fact, the perception about the real importance of some specific foods and even food ingredients in the daily diet is increasingly common, up to a point that the consumers' demand of healthy and functional foods reached exponential levels [13, 14]. Being consumers directly involved on food selection, development, and evaluation of its overall quality and acceptability, the food industry is increasingly focused on the formulation of foods with abilities to improve the health and well-being of consumers, at the same time that favor digestive system (which is considered a key factor for overall quality of life), besides other physiological and metabolic effects [9, 11]. Therefore, the development of functional dairy foods provides a great opportunity to contribute to the improvement of food quality and consumers' health and well-being.

Among the wide variety of food ingredients, there are three main groups that have become increasingly common in functional foods formulation, such as: probiotics (live bacteria), prebiotics (compounds as fibers), and antioxidants [27, 37]. The latest group of antioxidants mainly includes vitamins, minerals, plants and fruits, and even its derivatives (Table 1). Most of the food ingredients currently incorporated in functional dairy foods formulation naturally occurs on these dairy matrices, such as bioactive peptides, probiotic bacteria, antioxidants, vitamins, specific proteins, oligosaccharides, organic acids, highly absorbable calcium, conjugated linoleic acid, and other biologically active components [9, 37]. Notwithstanding, and despite their natural occurrence, a limited content of bioactive compounds is present, which can compromise the effective value of these products [31]. Therefore, the incorporation of these active ingredients in the functionalization of milk and dairy products is of the utmost importance. Using these food ingredients, new functional dairy products may be formulated, through modification of the traditional formulas, adding, eliminating, or even substituting some constituents, and even though the addition of some wholesome compounds.

For example, Caleja et al. [31] observed that the incorporation of antioxidants from natural origin (from chamomile and fennel extracts) in yogurts not only improved their biological activity but also satisfied consumer demands, in comparison with the synthetic additive, potassium sorbate [31]. Also important to highlight is that the yogurt functionalization did not alter significantly its nutritional profile, external appearance, pH, and even fatty acids content, being therefore suitable for upcoming use both in food industry and in the dairy sector, where synthetic additives

are commonly used [31]. On the other hand, Heleno et al. [36] performed an experiment using *Agaricus bisporus* extracts obtained by ultrasound-assisted extraction, and ergosterol, to incorporate in dairy beverages at concentrations mimicking those that commercially occur in phytosterol-added yogurts. The authors observed that samples incorporated with the extract and with ergosterol showed a higher antioxidant capacity at same time that protected yogurt from oxidation, improving therefore their shelf life, without modifying the nutritional value in comparison with the original product [36]. Similar findings were reported by Carocho et al. [34] using chestnut flowers, lemon balm, and its respective aqueous extracts (decoction) to incorporate into "Serra da Estrela" cheese, aiming not only to assess their ability to maintain its nutritional value but mainly to promote additional characteristics toward new dairy foodstuffs formulation [34]. Caleja et al. [25] and Carocho et al. [34] incorporated, respectively, fennel in cottage cheese [38] and basil in "Serra da Estrela" cheese [35], aiming to assess their functional and preserving abilities. The authors found that both samples did not alter significantly the nutritional value of cheeses, at same time that improved their antioxidant properties, preserved the contents in unsaturated fatty acids and proteins, as also exerted a prominent functionalizing and preservative effect.

Concerning the incorporation of prebiotics and probiotics in functional dairy products formulation, multiple findings have reported that, by one hand the incorporation of prebiotics not only conferred protection but also improved the viability of probiotic bacteria, presupposing therefore there action as symbiotic ingredients [39]. On the other hand, it was also shown that the incorporation of stingless bee honey in goat yogurt containing *Lactobacillus acidophilus* positively affected several characteristics, among them the color, syneresis, viscosity, sensory acceptance, and even purchase intention [2]. But besides to these aspects, probiotic bacteria also exert other highly valuable biological effects, such as being responsible for reinforcing natural intestinal flora, decreasing serum triglycerides, cholesterol, transaminase, and total bilirubin levels, exerting immunomodulatory effects, protecting against gastrointestinal pathogens, contributing for lactose metabolism, infantile diarrhea, besides reducing the incidence of urogenital and respiratory diseases and preventing the occurrence of some cancers [3, 40].

It is clearly evident that these food ingredients may provide considerable nutritional and sensory attributes of quality and acceptability, despite having a great market potential to be exploited considering the functional properties. In this sense, and considering that the top research areas in the Food Science and Technology comprises the extraction and characterization of new natural ingredients with biological effects for further incorporation into functional foods formulation, it is very important to use proper extraction methodologies and even effective technologies in functional foods preparation. Therefore, there is not only interest in ensuring a proper extraction of the bioactive constituents, but also the use of effective encapsulation methodologies toward the preservation of all the characteristics presents in the developed functional food until the physiological site of action is reached.

Considering the existence of a wide variety of bioactive molecules with suitable characteristics for upcoming use as food ingredients on functional foods

formulation, it is mandatory to select the most appropriate extraction methodology aiming to achieve the highest extraction yield, without affecting both the chemical composition and even the final bioavailability and subsequent biological activity. The quality of the bioactive compounds is closely dependent on the suitability of the extraction process and the proper selection of separation steps, which will also affect the subsequent identification and characterization of those biomolecules [3, 4]. In this sense, the selected extraction technique will also need to convert bioactive compounds into more suitable forms both for detection and subsequent characterization, but also to provide a strong and reproducible method to be used in other molecules belonging to the same group [3, 4]. There are a wide variety of extraction techniques, but the most commonly used are briefly described in Table 2, namely Soxhlet extraction (SoE), Ultrasound-assisted extraction (UAE), Supercritical-fluid extraction (SFE), Accelerated solvent extraction (ASE), and finally Shake extraction (ShE).

Table 2 Most commonly used extraction technologies in functional foods formulation

Extraction techniques	
Soxhlet extraction (SoE)	Commonly used to extract lipophilic compounds (hexane or petroleum ether as solvents), but can be also used to extract polar compounds, such as some specific phenolic compounds that are effectively extracted using methanol. More recently has been also applied to extract volatile compounds. *Bioactive molecules*: carotenoids, phenolic compounds, sterols, and aromatic compounds.
Ultrasound-assisted extraction (UAE)	Based on ultrasonic vibrations, being a fast and simple method, allowing the extraction of multiple samples at same time. The solvent extraction used (mainly methanol, acetone, water, and ethyl acetate) displays a crucial role, but also sample size, pH, temperature, and pressure determines extraction quality and yield. *Bioactive molecules*: carotenoids, polysaccharides, proteins, phenolic compounds, aromatic compounds, and sterols.
Supercritical fluid extraction (SFE)	Currently considered a "green" methodology, this technique is used on the extraction of multiple nutraceutical ingredients, usually performed using carbon dioxide under high pressure. This technique allows the use of low temperatures, presents a high selectivity, needs low solvent volume, small samples, short extraction times, and great automation procedures. *Bioactive molecules*: carotenoids, sterols, tocopherols, and phenolic compounds.
Accelerated solvent extraction (ASE)	This technique is carried out under high pressure and temperatures, presenting, however, some advantages in relation to the previous ones, such as enable the extraction of fresh samples, short extraction times, higher automation procedures, and good extraction rates. *Bioactive molecules*: vitamins, phenolic compounds, and carotenoids.
Shake extraction (ShE)	This technique needs the use of a shaking device, allowing more effective extractions at short times. The main advantage is to increase the surface where solvent extraction interacts with the sample material. *Bioactive molecules*: phenolic compounds.

Encapsulation technique is a complex process that includes the creation of a barrier, more or less complex, that acts covering bioactive components inhibiting the occurrence of chemical interactions, protecting against environmental factors (i.e., temperature, pH, enzymes, and oxygen), and even allowing the progressive release of the active components under certain conditions [3, 4].

There are three main groups of encapsulation techniques, i.e., microencapsulation, nanoencapsulation, and even emulsions, as briefly described in Table 3. The selection of a specific encapsulation procedure mainly depends on two distinct characteristics: the type of core material and characteristics of the final product where the technique will be applied. Moreover, the material of capsule wall, size, shape, and structure of capsule particles also determines the stability of the bioactive molecules during production, storage, and even releasing during consumption [3, 4]. However, the encapsulation technologies mainly aspire in ensuring a proper stabilization of the bioactive compounds, warranting that they reach consumers in appropriate levels, maintaining their bioavailability, avoiding the formation of harmful and unpleasant compounds and even to mask some undesirable sensorial attributes characteristic from some bioactive substances [3, 4].

5 Mushrooms and Plant-Food Bioactives: Key Factors on Functional Dairy Products Formulation

The world of plant-food bioactives has received a pivotal attention in the last years, being the assessment of their pharmacological effects and related biotechnological applications an exponential niche of market to be exploited. Regarding particularly their biotechnological applications, the sector of food industry and specifically the subsector of development of new food ingredients and materials are under dynamic innovation and overall exploitation. Inside this subsector, the area of functional foods' formulation is of largest demand not only by consumers but also of the utmost interest of researchers and industries (Fig. 1). Moreover, being the group of dairy products one of the most widely recognized food categories for functional purposes, considering the presence of promissory molecules with multiple benefits, a pivotal attention and intensive research work has been carried out on this field. On the other hand, and despite probiotics and prebiotics have been on the top of the latest studies on this area, a great attention has been given to plants, fruits, and its derived extracts on fortification of dairy food products and subsequent functionalization. As briefly described in Table 1, different plant, fruits, derived extracts, and even other food constituents have been used to functionalize dairy products. Yogurt and cheese are the most commonly selected to be investigated. Also interesting to point out is that these food ingredients are not only used to improve the nutritional value, health-promoting effects, and to confer additional benefits to dairy food products but also to improve their shelf life and even to remove some unpleasant and even nonbeneficial, nontolerated, and unaccepted characteristics by consumers.

Concerning the use of plant food bioactives in the development of functional dairy foods, chamomile and fennel have been incorporated both in yogurt [31] and

Table 3 Most commonly used encapsulation technologies in functional foods formulation

Encapsulation technologies	
Microencapsulation	
Spray drying	This is the most commonly used preparation, destined to prepare dry and stable food additives and flavors. It is based on the injection of a liquid suspension of the bioactive compound at the top of a vessel, drying the droplet into a fine powder particle concomitantly with hot air. Then, liquid droplet solidified and entraps the bioactive molecule. The technique is economic, flexible, and suitable to be used in a continuous operation, besides to provide a high protection to short exposure periods to acids, humidity, and oxygen.
Freeze drying	Commonly known as lyophilization or cryodesiccation. This technique is great to be used in a wide variety of heat-sensitive ingredients. It consists in homogenize core materials from the initial solution and then originates colyophilizes, i.e., irregular particles. This technique is suitable to encapsulate water-soluble essences, natural aromas, and even drugs.
Coacervation	This technique is based on the phase separation of hydrocolloids present in an initial solution and further deposition of the newly formed coacervates around the suspended or emulsified bioactive molecule. It is considered an expensive method, being particularly suitable to be used in high-value and sensitive functional ingredients (i.e., polyphenols).
Liposome entrapment	This technique consists in the formation of a lipid membranous system that encapsulates a hydrophilic space, leading to the formation of a suitable place to encapsulate water-soluble, lipid-soluble, and amphiphilic functional ingredients. With this technique, it is possible to control the release rate and exact point of incorporated materials delivery. Encapsulated materials through this technique are protected from stomach digestion, so ensuring their subsequent bioavailability and bioactivity in the next section of the gastrointestinal tract.
Cocrystallization	This technique consists in the modification of the sucrose structure, leading to the formation of an irregular agglomerated crystal. Bioactive ingredient is therefore incorporated into the porous matrix of the newly formed microsized crystals. This technique improves the solubility, homogeneity, dispersibility, hydration, anticaking, stability, and flowability of the encapsulated functional ingredients. It also allows the conversion of liquid materials into powders, which facilitates their subsequent application in pharmaceutical industry.
Yeast-encapsulation	This technique is based on the use of yeast cells (*Saccharomyces cerevisiae*) as the encapsulating material, being also usually applied to essential oils, flavors, and polyphenols. The target ingredients can pass across cell wall and remains inside the cells, being also ensured the control of the diffusion of the incorporated functional ingredients. Finally, this technique is also embroiled with green chemistry principles, once no additives besides water, yeast, and target functional ingredients are used. It is also a low-cost technique that allows the processing of high volumes of bioactive ingredients.
Cold gelation	This is a recent method, consisting from an alternative way to develop protein microparticles in food industry. No organic solvents are necessary, being encapsulation achieved under mild conditions, minimizing the destruction of sensitive nutraceutical compounds. Moreover, it is also possible to denature, dissociate, and even aggregate under different conditions of pH, ionic strength, and temperature.

(*continued*)

Table 3 (continued)

Encapsulation technologies
Nanoencapsulation
This technique is more complex that microencapsulation, mainly because of the intricate morphology of the capsule and core material, and the demand in controlling the release rate of the nanoencapsulates. It involves the incorporation, absorption, or dispersion of the bioactive compounds and subsequent formation of the functional ingredients encapsulated in small vesicles (<100 nm). Nanoparticles ensure a greater surface area, increase the solubility and enhance the bioavailability of the target ingredients, due to their subcellular size and improved controlled release. They can also easily penetrate tissues through fine capillaries, crossing epithelial lining fenestration, being therefore efficiently taken up by cells and allowing and efficient delivery of the active compounds in the target sites of body.
Emulsions
In a broad sense, an emulsion is a mixture of at least two immiscible liquids, usually oil and water, where one of the liquids is dispersed as small spherical droplets in the other. Therefore, emulsions are turbid, with small droplets sizes ranging from 0.2 mm to 10 mm, may remaining stable for a considerable time-period, despite being classified as thermodynamically unstable systems. Emulsions may be also classified into two distinct groups: microemulsions and nanoemulsions. Microemulsions are systems consisting from a mixture of water, hydrocarbons and amphiphilic compounds, forming kinetically and thermodynamically stable compounds, transparent, homogeneous, and isotropic solutions, ranging particle sizes from 5 nm to 100 nm. Nanoemulsions consists from fine dispersed emulsions and submicron emulsions, that in contrary of microemulsions, are not thermodynamically stable. They are produced by microfluidization or micelle formation techniques, exhibiting poor solubility and low bioavailability.

cheese [25, 30, 38] samples for subsequent analytical and methodological studies. Lemon balm [33, 34], rosemary [32], chestnut [33, 34], and basil [35] were incorporated in cheese samples, while honey [2], wild blackberry [41], and seaweed extracts [42] were used to functionalize yogurt samples. More recently, dairy beverages were tentatively functionalized with pure ergosterol and mycosterols from *Agaricus bisporus* extracts [36], as an alternative to phytosterol-based beverages; and also incorporated antioxidant extracts from two mushrooms species, namely *Suillus luteus* (L.: Fries) and *Coprinopsis atramentaria* (Bull.), acting as food ingredients in the functionalization of cottage cheese [23]. Interestingly, in all the above described experiments, prominent results were achieved both in terms of protection against oxidation, improving consequently the shelf life of the functionalized dairy products, as also in terms of nutritional value, stronger antioxidant activity, moisture and sensory attributes, such as external color, syneresis, and viscosity [31, 32, 34]. Moreover, organoleptic characteristics also display a crucial role in overall sensory acceptance and purchase intention, which was achieved though the functionalization of these dairy products that provide beneficial characteristics both for consumers (contributing for healthier lifestyles) and producer industries (commercialization of added-value products) [2, 33]. From the point of view of consumers, two additional aspects should be also considered. The first one is related with the healthier substitution of artificial preservatives from natural ones, improving consequently the acceptability, quality, and security of the final product

[11]. In fact, modern consumers are increasingly focused on the consumption of naturally-derived and safer products and formulated with natural food ingredients. The second one is related with the health-promoting abilities attributed to the consumption of these functional dairy foods; it has been increasingly documented and widely recognized that daily diet exerts a determinant role in health maintenance and disease prevention [8, 22].

The last aspect that is not least important is related with the high interest by food industry in always searching for new products, being this goal markedly driven by the production of cheaper food products, but healthier for consumers also looking for longer storage periods [7, 14, 33]. Therefore, consumers' acceptance and subsequent selection of a specific functional dairy product is markedly determined by a host of factors. The first one is related with the primary health concerns, as already highlighted, the consumers' familiarity with the new functional dairy food and with the functional food ingredients used on their formulation (i.e., nature of the carrier product, delivery of health effects, etc.) [11, 43]. On the other hand, consumers are awareness about the health effects of multiple substances and food ingredients, being thus essential to provide specific and credible information about the latest documented studies on the area. Finally but also determinant is the overall organoleptic and sensory evaluation carried out by consumers about the new product. In fact, different surveys have been applied to consumers, being clearly evident the key conditions for acceptance, such as taste, product quality, price, convenience, and even the reliability of health claims [11, 43, 44]. Therefore, during the development of a functional dairy food, all these aspects should be taken into consideration, besides to ensure their added value in terms of biological activity.

6 Bioactive Effects of Functional Dairy Foods

There is a widespread knowledge about the real benefits of functional dairy foods at the level of health promotion, well-being maintenance, and longevity [27, 44]. By themselves dairy products can confer several biological effects due to the naturally occurrence of biologically active constituents on its chemical composition, such as bioactive proteins, lipids, oligosaccharides, immunoglobulins, enzymes, hormones, antimicrobial peptides, cytokines, growth factors, among others [37]. Nevertheless, these constituents exist in limiting quantities, being therefore extremely usefulness their incorporation in dairy products functionalization [31]. Furthermore, it has been increasingly clear that some fermented dairy foods promote human health not so much directly attributable to the starting materials, but instead from the outcomes of fermentation, thus conferring additional properties beyond basic nutrition [14].

In fact, the formulation of dairy food products able to promote health and well-being is one of the main key research priorities by food industries, that has mostly favored the selection and subsequent consumption of foods enriched with physiologically active components, such as probiotics, prebiotics, and more recently plant food bioactives [3, 14, 37]. One of the main and most widely recognized biological effects of functional dairy products are their recognized modulatory activities, through the action of probiotic

Table 4 Biological activity of functional dairy foods

Bioactive effect	Detailed activity	Functional dairy food
Cardiovascular disease	Improvement of total cholesterol, non-HDL-C, and LDL concentrations	Fermented milk
Hypertension	Antihypertensive peptides acting as angiotensin-converting-enzyme (ACE) inhibitors	Fermented milk, Cheese, Yogurt
Immunomodulatory	Stimulation of the natural immunity, modulation of the production of cytokines, inhibition of carcinogenic effects, gut fermentation, metabolites	Yogurt, Cheese, Kefir
Infection control	Peptides exerting antimicrobial effects, reduction of the incidence of fever and constipation	Fermented milk
Inflammatory bowel syndrome	Reduction of symptoms of flatulence, abdominal pain, cramps, and stomach rumbling	Fermented milk, yogurt
Mood and brain activity	Modulation of the activity of brain regions responsible for controlling central processing of emotion and sensation	Fermented milk
Muscle soreness	Suppression of muscle soreness	Fermented milk
Obesity	Improvement of body fat percentage, waist circumference and waist-to-hip ratio, lean body mass	Yogurt, Fermented milk
Osteoporosis	Increase of bone mineral density and short-term changes in turnover	Kefir
Type-2 diabetes	Decrease of insulin resistance and increase of insulin sensitivity, improving glucose tolerance, and metabolism	Yogurt, Fermented milk

bacteria, also existent in fermented milk products [14, 37]. Besides other aspects, they exert an important role in gut fermentation metabolites, and therefore contributes to local and systemic beneficial effects in humans, not only at a level of digestion, absorption, and metabolism but also elimination, once favor a healthy bowel movement [14, 15]. More interestingly is that the functional effect of dairy products may be achieved directly through the action of probiotic bacteria or even indirectly because of their metabolic activity, i.e., microbial metabolites, such as vitamins, proteins, peptides, oligosaccharides, organic acids, and bacteriocins [14, 37]. In fact, the modulatory effects conferred by probiotic bacteria are both related with the stimulation of the natural immunity as also modulation of the production of cytokines, antimicrobial peptides, and inhibition of the carcinogenicity of multiple substances [45]. Another pronounced bioactive effect of functional dairy products is their ability to minimize the incidence of hypertension [14, 46]. In fact, dairy products, such as milk and cheese, contain significant amounts of antihypertensive peptides, including lactopeptides isoleucine-proline-proline and valine-proline-proline, that mainly acts as antihypertensive angiotensin-converting-enzyme (ACE) inhibitors [14, 46, 47]. On the other hand, whey and casein fractions of yoghurt have also shown strong antihypertensive effects being documented by several studies their role in curtail several syndromes among which in controlling blood pressure [46]. Other studies have even revealed that other peptides from dairy fermented products also exert antithrombotic, satiety, opioid,

immunomodulatory, antimutagenic, osteogenic, and antioxidative effects [14, 48]. Additionally, interesting reports have revealed a positive association between fermented dairy foods' consumption and weight maintenance and body fat reduction, besides their ability to reduce the risk of type 2 diabetes and other metabolic disorders, and overall morbidity and mortality, mainly from yogurt consumption. The effects on glucose metabolism seems to be mainly related with the improvement of glucose metabolism and insulin sensitivity, and reduction of muscle soreness [14, 46]. The positive effects on inflammatory bowel diseases and other immune-related pathologies, including arthritis, sclerosis, fibromyalgia, migraine, and depression have been also increasingly evident, as also their modulatory effects at a level of brain and mood [14, 49], still, however, being essential to deepen knowledge on this field. All the above described biological effects are briefly summarized in the Table 4.

7 Concluding Remarks

The world of functional foods development has led to one of the most promising and dynamic development on a specific segment of food industry. The increasing consumer awareness and demands for healthy products, in association with the latest advances on the area of food science and technology are the most important factors supporting the new revolution on food science and innovation. Nevertheless, consumers' acceptance and preferences are not homogenous, being observed a large distribution and differences on functional foods acceptance. Specifically, the development and commercialization of functional dairy products is not easy, it involves complex, expensive, and specific requirements. Besides the consumers' demand, during the development of a dairy functional product, the technical conditions as also legislation conditions should also be considered. Special requirements stablished to apply during the development and marketing of functional dairy foods should be met, as also their economic potential; health impact, acceptance, and overall interest should not be forgotten. Particularly, consumers' acceptance has been considered a key success factor on market orientation, brand new product introduction, and consumer-led product development, besides to be successful in negotiating market opportunities. Therefore, by purchasing functional dairy foods, consumers may have the overall health benefits of functional foods, besides to achieve a positive and valuable impression of themselves. In fact, they are self-contributors for this achievement, once they interfere both on selection, formulation, evaluation, and overall qualification of these products. Besides to the highlighted aspects, consumers may follow a balanced diet and acquire a healthy lifestyle, which differ from the conventionally stablished healthy diet. Finally and not least important is that the concept of functional dairy foods may represent a sustainable trend in a multiniche market to be exploited.

Abstract

Seafood comprising of finfish and shellfish significantly contribute to world food security. Seafood species are nutritious since they are rich in proteins and other nutrients including peptides, essential amino acids, long-chain omega-3 polyunsaturated fatty acids, carotenoids, vitamins including vitamin B_{12}, and minerals such as calcium, copper, zinc, sodium, potassium, selenium, iodine, and others. Commercial fish processing generates about 30 million metric tons of discards consisting of shell, head, bones, intestines, fin, skin, etc. These discards are rich in several nutraceuticals and biologically active compounds, which include oils containing omega-3 PUFA; carotenoids such as astaxanthin and β-carotene; proteins including myosin, collagen, and gelatin; enzymes; essential amino acids and peptides; polysaccharides and their derivatives including chitin, chitosan, glucosamine, and glycosaminoglycans; and mineral-based compounds. These compounds, depending on their nature, can have varying physiological functions including antioxidant, anti-inflammatory, anti-allergic, antitumor, anti-obesity, anticoagulant, antimicrobial, immunomodulatory, and other activities, which are valuable in healthcare. Marine biotechnology offers several techniques to isolate these nutraceuticals from seafood and their processing discards. This article briefly surveys nutrients and nutraceutical contents of seafood and their potential benefits in human nutrition and healthcare and current commercial status.

1 Introduction

Seafood, in a broader perspective, comprises of both finfish and shellfish items from marine, estuarine, brackish, and freshwater habitats and forms a sizeable component of the total world food production. According to the State of World Fisheries and Aquaculture, published by the FAO, in the year 2014, an amount of 167.2 million metric tons (MMT) of seafood was globally available, supplying about 20 kg of fish per capita [1]. The major finfish species include anchovies, mackerel, tuna, herring, cod, whiting, and others, while shellfish include two major groups, crustaceans and mollusks, based on their structural features. Shrimp, lobster, crayfish, crab, and krill belong to crustaceans, while mollusks are composed of bivalves (consisting of mussels, oysters, clams, and scallops), cephalopods (squid, cuttlefish, and octopus), and gastropods (abalone, sea snail, cockle, and whelks). Increasing consumer demand has resulted in aquaculture of 73.8 MMT of preferred seafood items in 2014, consisting of 49.8 MMT of finfish, 16.1 MMT of mollusks, and 6.9 MMT of crustaceans [1]. Commercial fishing operations often result in large volumes of bycatch having poor consumer appeal, which is mostly used as landfill, fertilizer, or animal feed. Commercial seafood processing leads to huge volume of discards weighing as high as 50% of total landings, consisting of shell, head, bones, intestines, fin, skin, and others [2, 3]. High-value seafood, bycatch, and processing discards are all rich in many nutrients including peptides; essential amino acids; long-chain omega-3 polyunsaturated fatty acids (PUFAs); carotenoids; vitamins A, B_3, B_6, B_{12}, and D; and various minerals such as calcium, copper, zinc, sodium, potassium, selenium, iodine, and others [4]. Besides, they contain many nutraceuticals, which may be nitrogen, lipid, polysaccharide, or mineral based. These compounds may be proteins including collagen and gelatin; protein hydrolyzates; peptides having interesting bioactivities; lipids rich in long-chain PUFA; hydrocarbons such as squalene; carotenoids; polysaccharides such as chitin, chitosan, glycosaminoglycans, and their derivatives; and mineral-based products such as bone powders. These, depending upon their nature, have interesting bioactivities offering potentials for development of functional foods and uses as natural food additives, medicinal drugs, and encapsulation as well as carrier materials for nutraceuticals [4–7]. With changing consumer interests toward natural bioactive compounds for healthcare and rapid developments in biotechnology, there is a vast scope for secondary processing of seafood and their processing discards for isolation of nutraceuticals. Such an attempt also helps total utilization of seafood for human consumption favoring minimizing seafood-associated environmental problems. This article discusses various nutrients, nutraceuticals, and other bioactive compounds present in both edible portions and processing discards of seafood products. At the onset, a brief discussion on nutraceuticals and functional foods is provided.

2 Nutraceuticals and Functional Foods

The term *nutraceutical* is a contraction form that links both the words nutrition and pharmaceutical, coined in 1989 by Dr. Stephen L. DeFelice, founder and chairman of the Foundation for Innovation in Medicine (FIM), Crawford, New Jersey. It is

defined as any substance that may be considered a food or part of a food which provides medical or health benefits including the prevention and treatment of disease and includes isolated nutrients and compounds that are used as dietary supplements [8–10]. The term *functional food* was coined in Japan in the mid-1980s and is defined as "foods for specified health uses." These foods contain ingredients that can address diseases such as hypertension, allergy, etc. [11]. A food can be regarded as functional if it is satisfactorily demonstrated to benefit one or more target functions in the body, beyond adequate nutritional effects, in a way that is relevant to either improved health or well-being or to a reduction in the risk of disease [12]. Plaza et al. [13] emphasized three important characteristics of a functional food, namely: (i) the functional effect is different from that of normal nutrition, (ii) the functional effect will be demonstrated satisfactorily, and (iii) the benefit can result in an improvement of physiological function or in a reduction of risk of developing a pathological process. It is now well recognized that dietary habit is one of the most important determinants of chronic diseases. This has led to an increased interest of the consumers toward natural bioactive compounds as nutraceuticals. Fish and shellfish are well recognized to possess appreciable nutraceutical potential to protect human health. This aspect will be broadly covered in this chapter. At the beginning, nutrient contents and nutritional value of seafood are considered.

3 Nutrients from Seafood

The percentage of edible lean tissue in aquatic species is appreciably greater than that in beef, pork, or poultry. About 50–60% of the weight of fish is constituted by its muscle. The proximate composition of fish muscle gives a general idea on its nutrient contents. The proximate composition of fish muscle varies greatly among species, their age, sex, habitats, and season. Information on proximate composition of fish and shellfish are provided by various databases. These include the global database of FAO/INFOODS [14], the USDA [15], the US National Marine Fisheries Service [16], the Department of Health UK [17], and FSANZ [18]. Besides, several authors have also discussed proximate compositions and nutrients in various fish and shellfish [19–24]. Information is also available on the website, SELFNutritionData [25]. The muscle contains water (52–82%), proteins (16–21%), lipids (0.5–2.3%), ash (1.2–1.5%), and a small proportion (about 0.5%) of carbohydrates. The various nutrients present in seafood are briefly discussed below.

3.1 Proteins

Seafood items are rich in Proteins. More than 50% of the world's seafood catch come from developing countries. Therefore, people from these countries derive much of their protein requirements from fishery products [1]. In the year 2014 an amount of 146.3 MMT of seafood was used as human food, giving a per capita seafood consumption of 20.1 kg, which contributed to about 20% of total average per capita

intake of animal protein [1]. Proteins in finfish are distributed in both light and dark muscle. Demersal fish such as cod and haddock have low percentage of dark muscle, which is present under the skin on both sides of the body. On the other hand, in pelagic fish, such as herring and mackerel, the proportions of dark muscle are high, with more vitamins and fats, providing energy for their rapid movement. Light muscle is more abundant in demersal fish. There are three main fractions of muscle proteins in fish and shellfish, namely, myofibrillar (structural proteins) consisting of myosin, actin, and others; sarcoplasmic (soluble proteins) consisting of myoglobin, hemoglobin, globulins, albumins, and various enzymes; and stroma (connective tissue) proteins consisting mainly of collagen, elastin, and gelatin. These fractions constitute 70–80%, 20–30%, and 3% of total muscle proteins, respectively. Muscle proteins are conveniently characterized by their solubility properties. Sarcoplasmic proteins are defined as those soluble when the muscle is extracted with water or solutions of low ionic strength, physiological or less. Myofibrillar proteins are soluble at elevated ionic strengths (> 0.3). Myofibrillar proteins correspond to 65–75% (w/w) of the total protein in fish and shellfish muscle [4, 22]. These proteins consist mainly of myosin (which account for 65–78%) and also actin (F and G types), tropomyosin, M protein, α-actinin, β-actinin, C protein, as well as troponins I and C, which are involved in muscle contraction. The myosin molecules resemble a thread (2 nm x 160 nm) with two globular heads (19 mm long) attached at one end to a tail portion. Fish myosins, compared to myosins from terrestrial animals, are more unstable. A novel protein, paramyosin (molecular weight 200 to 250 kDa), is also found at varying levels in invertebrate myofibrils, but not in vertebrate myofibrils. The protein is involved in catch contraction of bivalves [22]. Fish meat, unlike bovine meat, contains much less stroma proteins, which are the least soluble. When heated, fish muscle connective tissue proteins dissolve more readily and soften, contributing to softness of the cooked meat, in comparison with the tough connective tissue of land animals [24].

The contents of proteins vary from 18% to 23% depending on the seafood items, on the habitats (marine water, freshwater, or brackish water), and on the depth, i.e., pelagic (fast-moving species on surface waters such as tuna, herring, mackerel, sprat, anchovy, and sardine) or demersal (slow-moving species in deep waters such as cod) [21, 24, 26]. Shellfish, in general, contain slightly more proteins than finfish. The reported average protein contents (g%, raw meat) of various shellfish are shrimp, 17.0–22.1; scallop, 14.8–17.7; squid, 13.2–19.6; crab, 15.0–18.4; lobster, 18.2–19.2; krill, 12.0–13.0; clam, 9.0–13.0; mussel, 12.6–13.0; cuttlefish, 16.6–17.3; and oyster, 8.9–14.3 [16–22]. Myofibrillar proteins are the major fractions of the foot and mantle of the clam, constituting 31 to 40% [26]. The claw meat and hepatopancreas of the green crab (*C. mediterraneus*) had protein levels of 17.8–18.2% and 13–14%, respectively [27]. The raw meat of brown shrimp (*Crangon crangon*) from the Black Sea has a protein content of about 18.5% [28]. The white shrimp has higher protein contents than black tiger shrimp, the former having higher amounts of stromal proteins with greater pepsin-soluble collagen [29]. Marine snail meat and hepatopancreas are important sources of protein [30]. The edible portion of common octopus (*O. vulgaris*) has appreciable level of proteins

[31]. Protein contents of some raw shellfish species from Indian waters vary from 14.0 to 21.6% [32].

An adequate diet must contain an appropriate level of nutritive protein to support long-term health. Fish muscle proteins are considered nutritionally equivalent or slightly superior to meat proteins due to their lower collagen contents and higher sensitivity to proteolytic digestion [33–35]. The nutritive value of a protein is determined by its primary structure, amino acid composition, contents of essential amino acids, susceptibility to enzymatic digestion, and chemical changes during processing such as thermal treatment. Most seafood proteins show a digestibility above 90% associated with release of copious proportions of essential amino acids (EAAs) (lysine, methionine, threonine, tryptophan, isoleucine, leucine, phenylalanine, and valine), suggesting high nutritive value of the proteins [35, 36]. Enzymatic digestion of proteins in the human digestive system gives rise to many peptides and amino acids, which can be absorbed in the intestine in the form of single amino acids and oligopeptides [25, 33, 34]. Animal feeding experiments are used to determine nutritive value of proteins. These include the nitrogen balance method based on protein digestibility, determination of protein efficiency ratio (PER, weight gained per g of protein consumed), net protein utilization (NPU, ratio of amino acid converted to protein to the ratio of amino acids intake), and biological value (a measure of absorption and utilization of protein by the living organism). These studies have suggested the high nutritive value of fish proteins [37]. It is generally accepted that the relative content of EAAs is the major factor determining the nutritional value of a food protein. Most animal proteins have a satisfactory essential amino acid (EAA) pattern required to satisfy amino acid requirements. The amino acid score (AAS) of a protein is indicative of its nutritional quality; an AAS score of 100 means high protein quality. Proteins of seafood including shellfish, cooked under moist heat, have AAS scores as high as 100 indicating their high nutritional quality [25, 38]. The protein digestibility-corrected amino acid score (PDCAAS) is based on the amino acid content of food protein, its digestibility, and its ability to supply EAAs according to requirement [19, 25]. The PDCAAS of shrimp is 1, indicating its good protein quality [38]. Shellfish proteins have PER values that are slightly above that of casein, the major milk protein [22, 24].

Dietary fish proteins, rich in arginine, glycine, and taurine, may have ability for improved resolution of inflammation in the muscle, attributed to their ability to decrease the production of major pro-inflammatory cytokines (TNF-α, IL-6) and to limit the accumulation of pro-inflammatory macrophages at the site of injury. Cod protein promotes growth and regeneration of the skeletal muscle after trauma, partly because of the improved resolution of inflammation [39]. Krill meat concentrate has 78% protein and 8% fat on dry weight basis. The protein has PDCAAS and PER equal to casein and hence is a promising protein source for human consumption [40]. Spray-dried protein powder from threadfin bream *(Nemipterus japonicus)* has a PER value of 3.52 ± 0.27 and trypsin and pepsin digestibility up to 80% [41]. In view of their nutritional properties, seafood proteins are able to enhance the nutritive value of proteins from plants, legumes, grains, nuts, seeds, and vegetables, which may be deficient in one or more of the essential amino acids [42, 43]. Fish meat and also

other commonly consumed protein foods are also significant sources of nutrients such as calcium, vitamin D, potassium, iron, and folate [35, 44].

3.2 Amino Acids

Seafood items are important sources of both EAAs and nonessential amino acids. The predominant EAAs in seafood are lysine and leucine, and within the nonessential, aspartic and glutamic acids are more abundant. The nonprotein nitrogen fraction of fish and shellfish muscle, which is usually higher than that of terrestrial animals, contains amino acids in addition to small peptides, creatin, creatinine, trimethylamine oxide, and nucleotides. Glycine, taurine, alanine, and lysine are generally present in relatively higher amounts. Certain nonessential amino acids, such as aspartic acid, glycine, and glutamic acid, necessary for growth and maintenance in humans, are present in seafood, as revealed by the amino acid compositions of 60 commercially important fish and shellfish [45].The whole body tissues of Atlantic halibut, yellowtail flounder, and Japanese flounder contain all the EAAs [46]. The freshwater fish, carp, has high content of free amino acids, irrespective of the area of breeding, the dominant amino acids being histidine, methionine, cysteine, phenylalanine, tyrosine, lysine, and threonine [24].

Crustaceans have more amino acid contents than finfish. The amino acids alanine, glutamic acid, and glycine are mostly responsible for the flavor of cooked shellfish. Alanine and glycine contribute to sweet tastes and glutamic acid to the "umami" taste of crustaceans [47]. Shrimp has good contents of glycine (up to 1% of the fresh muscle), alanine, and proline [16]. The major EAAs of shrimp are arginine, lysine, leucine, and methionine, while the nonessential amino acids are glutamic acid, aspartic acid, proline, and glycine [48]. Glutamic acid and glycine contents were greater in black tiger shrimp meat, while white shrimp had good levels of hydroxyproline. Arginine, leucine, isoleucine, and proline were predominant in both shrimps [29]. The Norway lobster has threonine, leucine, valine, lysine, and arginine, each at levels of about 40 mg% of raw meat. It has also glycine, alanine, and glutamic acid at 58, 57, and 31 mg%, respectively. Besides, the lobster also contained the dipeptide anserine at 53 mg% of raw meat [49]. Edible tissues of the marine snail are good sources of EAAs, particularly aspartic acid [30]. Green crab meat is balanced in EAA contents, except for tryptophan [50]. Fish sauces are products that contain significant amounts of peptides and amino acids [52].

Cooking, in general, enhances the digestibility of fish proteins. Mild cooking causes little loss of protein with only a slight loss in available lysine, whereas drastic heating can significantly reduce the protein quality. Boiling has little effect in the composition of shellfish. Moisture, protein, fat, ash, and carbohydrate contents of the cooked horse mackerel ranged from 56 to 61%, 21 to 24%, 13 to 20%, 1.7 to 2.5%, and 1 to 4%, respectively. The changes in amino acids in the fish were significant after frying, grilling, and steaming. Cooking increased the contents of essential and nonessential amino acids compared to raw fish. Amino acid contents of grilled horse mackerel were higher than those found in fried and steamed fish [52]. Literature on

the influence of processing on nutritional value of seafood has been reviewed by Venugopal [22].

Taurine (2-aminoethanesulfonic acid) contents were relatively high in flatfish and ray and low in silver pomfret, yellow croaker, and baby croaker. Although humans synthesize taurine from methionine and cysteine, aging lowers production of taurine in the body, necessitating supplementation of the amino acid. Shellfish and other seafood are good sources of taurine; its contents in the muscle of mussel, oyster, cuttlefish, and squid vary between 7.5 and 12.0% of total amino acids [32]. Taurine acts beneficially on glucose metabolism and also lowers blood pressure by reducing cholesterol absorption [43, 53, 54]. Processed fishery products may be supplemented with taurine, the added taurine retaining in the product without adversely affecting the sensory acceptability [55].

3.3 Lipids

The contents of lipids in fishery products vary depending on the species, season, geographic location, age, gender, and diet. Feed has a strong influence on the lipid contents of fishery products including cultured items [20]. The lipid content can vary from 4% to more than 30% in Atlantic mackerel and from 2 to 25% in Atlantic herring, depending on the season. Species living in temperate waters have more lipid contents in their flesh than leaner tropical fish [24]. Contrary to terrestrial animals, which deposit their lipids in the adipose tissue, fish have lipids in the liver, muscle, and perivisceral and subcutaneous tissues. Lipid content in dark muscle is much higher than in white muscles. Pelagic fish, which contain more dark muscle, have more fat than the demersal species such as cod, which have higher proportions of white meat. Depending on the fat content, fish are classified as lean (less than 2% fat), low-fat (2–4% fat, such as cod and hake), medium-fat (4–8% fat), and fatty fish (more than 8% fat, such as mackerel and herring).

The fatty acid composition of seafood is different from red meat, vegetable, and dairy products and also showing marked variability within and between species. The fatty acids are present as triglycerides, which are prone to hydrolysis by lipases. The phospholipids of tropical fish are more saturated than those from cold water. The major phospholipids include phosphatidylcholine, phosphatidylethanolamine, and sphingomyelin. In contrast to red meat, marine fish lipids have appreciable proportions of n-3 (omega-3) long-chain PUFA, particularly eicosapentaenoic acid (EPA) ($C_{20:5w3}$ *cis*-5,8,11,14,17) and docosahexaenoic acid (DHA) ($C_{22:6w3,}$ *cis*-4,7,10,13,16,19). Fish obtain these from PUFA-rich phytoplankton used as feed by the animal. Fatty fish such as herring and mackerel contain more omega-3 PUFAs (particularly EPA and DHA) than leaner species. Saturated fatty acid (SFA) content is comparatively less. Freshwater fish generally contain lower proportion of n-3 PUFA than marine fish [47]. Marine steroids are composed of cholesterol, which is present at 20 to 50 mg per 100 g raw meat of finfish and 250 to 650 mg per 100 g in roe [21].

Shellfish items have low crude lipid contents, generally up to 2% (w/w) of their raw muscle. The contents of EPA and DHA in shellfish usually range between 300 and 500 mg% of raw muscle; their contents are generally lower than those of oily finfish such as Atlantic mackerel and sardine [19, 21]. Shellfish lipids, like those of finfish, are rich in PUFA generally exhibiting a ratio of n-3 PUFA to n-6 PUFA above 1.0 [22, 56]. The Mediterranean giant red shrimp (*Aristaeomorpha foliacea*) has good levels of n-3 PUFA, particularly EPA and DHA [57]. The lipids of the shrimp spp. (*P. longirostris* and *A. antennatus*) and Norway lobster (*N. norvegicus*) contain 42–48% PUFA, 26–35% MUFA, and 23–27% SFA [48]. The crude fat (1%, w/w) of brown shrimp (*C. crangon* L) meat consisted of 33% SFA, 22% MUFA, and 29% n-3 PUFA. The SFA and MUFA fractions have 21% palmitic acid and 14% oleic acid, respectively. The PUFA consisted of EPA and DHA at 41% and 32%, respectively [28]. The n-3 PUFAs of white shrimp (*P. vannamei*) and black tiger shrimp (*P.monodon*) are 42 to 44% of crude lipids. PUFAs of the white and black shrimps have DHA-to-EPA ratios of 1.05 and 2.15, respectively [29]. Ozogul et al. [58] reported that the common cuttlefish (*S. officinalis*), European squid (*L. vulgaris*), common octopus (*O. vulgaris*), and musky octopus (*E. moschata*) had PUFA, SFA, and MUFA contents of 43.6–56.5%, 28.2–35.3%, and 4.4–9.5%, respectively. The fatty acids of the common octopus (*O. vulgaris*) consisted of 58.6% of n-3 PUFA (composed of 20.1% EPA and 26.3% DHA), 25.9% SFA, and 15.4% MUFA [31]. The mussel (*M. coruscus*) has higher contents of PUFA than SFA and MUFA, with DHA and EPA comprised of 12–18% and 10.8–14.6% of total fatty acids, respectively [59]. Crustaceans, bivalves, and cephalopods may contain total sterols at 150–250 mg%, w. wt. [16, 19, 28].

The changes that take place in fats during heat processing greatly depend on the fatty acid composition. Unsaturated lipids are very susceptible to oxidation. Enzymes such as lipoxygenase, peroxidase, and microsomal enzymes can potentially initiate lipid peroxidation producing hydroperoxides, which decompose to a wide range of compounds. These compounds, which include aldehydes, ketones, alcohols, small carboxylic acids, and alkanes, give rise to very broad odor spectrum and also yellowish discoloration to the product. These substances are formed slowly at normal frying temperatures in pure fats, but their formation is catalyzed by traces of metals such as iron and copper present in the fish. The common dietary antioxidants vitamin E (tocopherol), vitamin C, polyphenols including flavonoids, and carotenoids are able to control lipid oxidation (see also Sect. 3.4**)**.

The human diet contains long-chain PUFA belonging to the n-6 and n-3 families. Major dietary n-6 PUFAs include linoleic, $C_{18:2w6}$ (18:2); γ-linolenic, $C_{18:3w6}$ (18:3); and arachidonic, $C_{20:4w6}$ (20:4) acids, whereas major dietary omega-3 PUFAs include α-linolenic, $C_{18:3w3}$ (18:3), EPA, and DHA. Linoleic, α-linolenic, and γ-linolenic acids are present in large quantities in foods of plant origin. Arachidonic acid originates from muscle and organ meats or may be synthesized within the body from linoleic acid. In comparison with n-6 PUFA, n-3 PUFA can have significant health benefits. The cardioprotective role of n-3 PUFA has been determined by several studies [60, 61]. Other benefits include their antidepressive, antiaging, and antiarthritic effects, among others [61] (see also discussion on Sect. 4.2.1). The mode

of action of EPA and DHA is attributed to their ability to give rise to a class of pharmacologically important groups of compounds, such as prostaglandins, prostacyclins, thromboxanes, and leukotrienes (collectively called eicosanoids). Both n-3 and n-6 PUFAs are precursors of eicosanoids. Whereas eicosanoids derived from n-6 PUFA, such as arachidonic acid, have pro-inflammatory functions, eicosanoids derived from n-3 PUFA have anti-inflammatory properties. The n-3 PUFA-derived eicosanoids antagonize the formation of inflammatory eicosanoids such as prostaglandin E_2, derived from arachidonic acid and other n-6 PUFAs. The n-3 PUFAs impart their anti-inflammatory effects via reduction of nuclear factor-κB activation. This transcription factor is a potent inducer of pro-inflammatory cytokine production. Through these actions, the n-3 PUFAs alter cell and tissue functions that favor disease prevention and maintenance of health [61, 62].

3.4 Carotenoids

Carotenoids are a group of pigments that contribute to the yellow, orange, and red color of aquatic organisms. Carotenoids exist in mollusks (oyster and scallop), crustaceans (shrimp, lobster, crayfish, and crab), and finfish (salmon, trout, sea bream, and tuna). They are also present in their processed products influencing consumer acceptability. Animals, including humans, do not synthesize carotenoids de novo and rely upon diet as the source of these compounds. Fish and shellfish accumulate carotenoids in their body tissues from carotenoid-rich plants, which are used as their feeds. The carotenoids may be either hydrocarbons or xanthophylls (the oxygenated derivatives) and include astacene, astaxanthin, canthaxanthin, cryptoxanthin, fucoxanthin, lutein, neoxanthin, violaxanthin, zeaxanthin, alloxanthin, and β-carotene [4, 63, 64]. Astaxanthin, perhaps, is the important pigment present in fishery products. The red-orange color of salmonid fish is due to the presence of astaxanthin. The carotenoids β-carotene and β-cryptoxanthin ingested by the animals may be converted to different compounds, including astaxanthin and vitamin A. In shellfish carotenoid contents vary depending on body parts; they are high in their carapace, followed by the head, while their meat has minimum contents. For example, the total carotenoid contents (mg g^{-1}) of raw meat, head, and carapace of shallow water shrimp (*P. monodon*) are 17.4, 58.4, and 86.6, respectively. Similar pattern is observed in carotenoid contents in the body parts of shallow water shrimps (*M. dobsoni*, *P. stylifera*, and *P. indicus*), deep-sea shrimps, *S. indica*, and A. *alcocki* [64]. Carotenoid content in raw body tissues of scallop ranged from 7 to 60 μg g^{-1}. The pigment contents varied in this order: gonad > mantle > adductor > gill [65].

Antioxidants, defined as substances capable of delaying, retarding, or preventing the development of rancidity or other flavor deteriorations, can inhibit or retard oxidation either by scavenging the free radicals that initiate oxidation or by breaking the oxidative chain reactions. The mechanisms also involve binding of metal ions, scavenging of oxygen, converting hydroperoxides to non-radical species, deactivating singlet oxygen, and thereby suppressing the generation of free radicals and reducing the rate of oxidation. Autooxidation of unsaturated lipids leads to

formation of reactive oxygen species (ROS), which include peroxy radicals ($ROO^{\cdot}$), superoxide anion (O_2^{-}), hydroxyl radical (HO^{-}), and alkoxy radical (RO^{-}), among others. Non-radical derivatives are hydrogen peroxide (H_2O_2), ozone (O_3), and singlet oxygen ($^1O_2$). The hydroxyl radical is the most reactive ROS, followed by singlet oxygen. Reactions of ROS with food components destroy nutrients; change the functionalities of proteins, lipids, and carbohydrates; and lead to the formation of undesirable volatile compounds and carcinogens. Carotenoids are natural antioxidants, which are able to quench singlet oxygen and act as in vivo scavengers of ROS. The antioxidant activities of carotenoids have been attributed to the presence of conjugated double bonds in their structures [66, 67]. The singlet oxygen scavenging ability is the highest for β-carotene, followed by tocopherol, riboflavin, vitamin D, and ascorbic acid [66]. Free radical stress can cause tissue damage and result in an inflammatory response. Adequate intakes of carotenoids and also other antioxidants such as vitamin A, vitamin C, and vitamin E may help prevent free radical-induced adverse oxidative processes in living systems. Carotenoids, in general, also possess anti-inflammatory properties, presumably due to their effects on intracellular signaling cascades, thereby inhibiting production of inflammatory cytokines [67, 68]. Astaxanthin, the major shellfish carotenoid, has the ability to protect body tissues from oxidative damage by UV light. The antioxidant activity of astaxanthin is higher than that of β-carotene, lutein, lycopene, α-tocopherol, and canthaxanthin. It also has anti-inflammatory and cardioprotective properties [69]. The potential health benefits of astaxanthin also include its anticancer, antiaging, and immunostimulating activities. The carotenoid also possesses antidiabetic properties, controls cataracts, and inactivates gram-negative bacteria such as *Helicobacter pylori*, responsible for chronic gastritis [63, 68, 69]. Canthaxanthin and β-carotene protect macrophage receptors from ROS, while β-carotene protects neutrophils, a major class of white blood cells, which use ROS to kill phagocytized bacteria [70].

3.5 Vitamins

Vitamins and minerals are essential for normal physiological functions. Their contents in fishery products vary with the species, age, season, sexual maturation, and geographic area. Fatty fish are excellent source of fat-soluble vitamins A, D, and E, which are more concentrated in their liver, viscera, and eyes but in less amounts in their flesh [21]. The flesh of lean fish contains about 25 to 50 IU of vitamin A, while in fatty fish such as mackerel and herring, the content ranges between 100 and 1500 IU. Vitamins A and D are also present in copious levels in the liver of lean species like cod. In freshwater fish, vitamin A exists mainly in the form of 3,4-dehydroretinol. Considerable amount of vitamin A, as retinol, is found in shark and oysters, as well as in oily fish such as small sardines, herring, and horse mackerel. Fish liver oil is an excellent source of vitamin A. Shrimp, blue mussel, oyster, and scallop are good sources of vitamin A [15–17, 21, 23].

Vitamin D mainly occurs in nature as ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3). Fish obtain their requirements of vitamin D_3 through phyto- and

zooplanktons used as food. Fatty fish like horse mackerel or herring have a higher content of vitamin D than lean species like flounder or marine trout. Contrary to the general belief, there was no significant correlation between contents of fat and vitamin D. Pelagic fish with high fat content provides excellent dietetic sources of vitamin D_3. Shrimp recorded about 0.06 μg vitamin D_3 per 100 g [71]. Fish liver and oils are also rich sources of vitamin D_3 containing up to 300 μg of the vitamin per kg oil [24]. The anticancer properties of vitamin D have been pointed out recently [72]. Vitamin E comprises of four tocopherols, α-, β-, γ-, and δ-tocopherol, all of them are present in seafood and aquacultured products, particularly fatty fish items [73]. Through its potent antioxidant activity, the vitamin quenches free radicals formed by oxidative processes, thereby controlling inflammatory processes; heating processes, boiling, grilling, and frying, caused a decrease in tocopherol contents in fishery products [74]. Fish flesh seems to be considerably rich in the antihemorrhagic vitamin K [24].

Water-soluble vitamins are distributed along the whole fish, with niacin, thiamine, riboflavin, pyridoxine, and B_{12} being the most representative in aquatic organisms [4, 24]. The average content of thiamin varies from 4 to 400 μg per 100 g meat. However, much of thiamin is destroyed by heat and oxygen or is lost in cooking water or when exposed to ionizing radiation. Modest amounts of riboflavin are present particularly in the dark flesh of some species like canned herring, mackerel, and pilchard. Ideal sources of pyridoxine (vitamin B_6) are salmon and tuna and, to some extent, shellfish. Niacin, like thiamine, forms part of a coenzyme essential in the production of energy. The vitamin ranges from 0.9 mg to 3.1 mg per 100 g raw fish flesh. Vitamin B_{12} (cobalamin) is found in significant quantities in fish, particularly fatty fish. In general, seafood items contain 0.89 to 42 μg of vitamin B_{12} per serving (3 oz). Anchovies, clams, herring, oysters, pilchard, and sardines have vitamin B_{12} ranging from 25 to 40 μg per 100 g raw meat. Shellfish species contain all the vitamins, particularly vitamin B_{12}. Oyster, mussels, and short-necked clam have a content of 46.3, 15.71, and 87.0 μg per 100 g, respectively. Contents of vitamin B_{12} are generally higher in muscle tissues of crab and lobster [14]. Certain fish like salmon, sardine, trout, and tuna have a B_{12} content varying from 3.8 to 8.9 μg 100 g^{-1}; however, mollusks and clams have an average of 98 μg 100 g^{-1} of B_{12} [75]. The flesh of Atlantic salmon, European hake, and sardine has folic acid concentrations of 10, 27, and 24 μg 100 g^{-1}, respectively [76].

Vitamins are considered the most susceptible to loss during heat treatment; the magnitude of loss depends on the specific vitamins and the conditions employed. Water-soluble vitamins may be lost due to leaching. A combination of oxygen, light, and heat causes a greater loss of vitamins than any one of these factors individually. Folate and vitamin B_6 are susceptible to destruction due to oxidation. Riboflavin is reasonably stable during cooking but is sensitive to light as it decomposes on exposure to ultraviolet rays. The fat-stable vitamin A and also carotenes are relatively stable at normal cooking temperatures, but the high temperatures used in frying can produce oxidative losses and isomerization of the carotenes, with significant losses of biological activity. Vitamin E is slowly destroyed during frying and is decomposed by light.

3.6 Minerals

Several minerals are essential for life. The process of bone formation, for example, requires adequate and constant supply of nutrients such as calcium, magnesium, vitamin D, vitamin K, and fluoride, besides proteins. The ash contents up to 2.0% (w/w) of seafood carry macroelements such as calcium (Ca), magnesium (Mg), sodium (Na), potassium (K), iron (Fe), and phosphate (Pi) and microelements such as zinc (Zn), copper (Cu), chromium (Cr), manganese (Mn), selenium (Se), fluorine (F), and iodine (I), which are important for human nutrition [15, 16, 19, 35]. Fe, Zn, Cu, and Mn concentrations are generally higher in the liver than in muscle tissues, either being wild or farmed fish. The minimum contents (μg g^{-1} edible fish flesh) of Na, K, Mn, Ca, Cu, Pi, and I are 250, 250, 100,100, 1.1, 250, and 0.1, respectively [21]. Fish is a good source of Zn and Cu that ranged from 7 to 34 μg g^{-1} in wild sea bass and from 3.7 to 76.2 μg g^{-1} in the farmed ones [21]. An average serving of fish can grossly satisfy the total human requirements for essential microelements [21, 24].

Most shellfish are good sources of Na, K, Pi, Fe, Zn, Se, and Cu. Most fresh marine fish may be considered moderately low-sodium foods delivering approximately 140 mg sodium per serving. However, the sodium content of most processed fish and seafood products (frozen, canned, smoked, cured) can be substantially high, ranging from 3 to 9 mg g^{-1}. Seafood is a source of calcium, its contents varying from 60 to 1200 μ per g^{-1} depending upon the species. The iron content of edible tissue may vary as 90 μg g^{-1} in cod, flounder, and pollock and 90–200 μg g^{-1} in carp, catfish, salmon, and trout. Copper, which is necessary for normal blood formation and maintenance of blood vessels, tendons, and bones, is sufficiently available from shellfish. Mollusks and crustaceans contain appreciable levels of Cu and Zn [19]. Oysters are rich in zinc, iron, and copper [21]. Mg, Ca, and Fe are in appreciable levels in white and black shrimps [29]. The contents of Ca, Mg, Pi, and Na in blue crab vary in claw, breast meat, and hepatopancreas [77]. The edible portions of clam are rich in Na, K, Ca, Mg, Fe, Zn, and Cu [26]. The contents (mg 100 g^{-1}) of iron, zinc, and calcium in 55 samples of fresh fishery products from Bangladesh ranged from 0.34 to 19, 0.6 to 4.7, and 8.6 to 1000, respectively. Shrimp had maximum Cu and I contents of 12 and 1.2 μg g^{-1}, respectively [71]. Fish and shellfish are rich sources of iodine, being highest in oysters, followed by clams, lobster, shrimp, and crab followed by ocean fish. Oceanic fish has 0.3 to 3.0 μg g^{-1}iodine and freshwater fish, 0.02 μg to 0.04 μg g^{-1} [20].

3.7 Evaluation of the Nutritional Value of Fishery Products

It is interesting to evaluate the nutritive value of fishery products against the US 2015–2020 *Dietary Guidelines*, which provides consumers of different age and sex guidance to choose a healthy eating pattern to prevent diet-related chronic diseases. The *Guidelines* are designed to meet the Recommended Dietary Allowances (RDA) and the Adequate Intakes for Essential Nutrients set by the Institute of Medicine

(IOM), US National Academies [78]. The *Guidelines* recommend daily intake of the following amounts of nutrients by males aged 19–30, namely:

Protein: 56 g
Total fat: 20–35 g (saturated fat, <10% of total fat)
Macro-minerals (in mg): Na, 2300; Ca, 1000; K, 4700; Pi, 700; and Mg, 400
Micro-minerals (in mg except vitamin D and vitamin B_{12}): Fe, 18; Zn, 11; Mn, 2.3; Cu, 0.9; and Se, 0.055
Vitamins (in mg except vitamin B_{12} which is in μg and vitamin D, which is in IU): A, 900; B_1, 1.2; B_2, 1.3; B_6, 1.3; B_{12}, 2.4 μg; niacin, 16; D, 600 IU; E, 15; K, 0.1; and folate 400
Calories: 2400 to 3000

The daily nutritional goals for other age and sex groups are also given in the Guidelines [78]. Seafood including shellfish can significantly satisfy requirements of almost all of the nutrients, mentioned above. Dayal et al. [38] calculated percent direct value (%DV) (representing ability to satisfy dietary requirement of each nutrient as per recommended values) for various nutrients present in seafood. They reported %DV values of 75 for total EPA and DHA contents and a value of 70 for the essential amino acids methionine, tryptophan, and lysine present in tiger shrimp (*P. monodon*) [38]. Consumption of 100 g of most shellfish can meet at least 50% requirement for proteins by the adult [23]. Compared with suggested amino acid requirements by the FAO/WHO, the hydrolyzates of the little *Loligo* squid (*U. chinensis*) have high nutritional value and are a potential nutritious supplement used in various food products [79]. Selenium has a %DV as high as 110, suggesting that the shrimp fully satisfied the dietary requirement for this mineral [38]. Shellfish and other seafood provide good measures of vitamin B_{12} and vitamin D. A 100 g serving of shellfish, except squid, scallop, and crayfish, can provide appreciable amounts of the vitamin B_{12} necessary to satisfy its dietary requirement. The giant red shrimp, as well as Norway lobster, is a valuable source of nutrients, including proteins and antioxidants, among others, for the human diet [48]. The muscle and gonads of female crab (*C. pagurus*) have favorable n-3 to n-6 PUFA ratios and a well-balanced essential amino acid composition [80, 81]. American and European lobsters have nutritive values compatible with nutritional foods [82]. The mussel *P. viridis* has balanced ratios of essential to nonessential amino acids and also of *n*-3 to *n*-6 PUFA contents [83]. Furthermore, the consumption of mollusks can make an important contribution to the daily dietary intake requirement of Se, Cu, and Zn [84]. The presence of appreciable levels of PUFA (including EPA and DHA), vitamins, minerals, and amino acids qualifies the oyster (*C. madrasensis*) as a potential "health" food. The shellfish has also atherogenic and thrombogenicity indices together with a good hypocholesterolemic to hypercholesterolemic ratio, pointing out its health benefits [85]. The blue crab could be used as a dietary supplement to balance human nutrition [77]. Nutritional claims have also been made with respect to common octopus [31] and Asian hard clam [26]. The nutritional value of seafood has also been pointed out by many studies [19, 23, 35]. The Second International

Conference on Nutrition (ICN2), held in Rome in November 2014, confirmed the importance of seafood including shellfish as a source of nutrition and health [1].

4 Nutraceuticals and Bioactive Compounds from Seafood Discard

Industrial processing of seafood generates voluminous discards such as scales, shells, frames, backbones, viscera, head, liver, skin, belly flaps, dark muscle, roe, and others. Processing discards of crustaceans are composed of the cephalothorax, carapace, and tail; shell discards of shrimp, krill, and crab constitute as high as 50% of the shellfish. Increased aquaculture production of popular shrimp and other shellfish items has led to a significant amount of discards. Depending upon finfish, discards may range from 25 to 50% of the raw material. The backbone accounts for about 15% of the wet weight of fish such as Atlantic cod. In addition, approximately 50,000 tons of scale is produced from the current global fish processing operations [3]. Currently most of these discards are used as landfill or converted into fertilizer or used for animal feed and ensilage. For example, the Norwegian fisheries annually produce more than 615,000 tons of discards; most of it is converted into fish silage and fish meal as animal feed [52]. Furthermore, commercial fishing operations results in a large proportion of bycatch, which has poor consumer value due to inherent problems related to unattractive color, flavor, texture, small size, and high fat content. Most of these underutilized fish belong to the abundantly available pelagic species and are considered as bycatch [86]. Secondary processing of seafood discards can significantly reduce the environmental hazards associated with the industry, besides yielding valuable ingredients for diverse applications.

The important ingredients that can be recovered from seafood discards include proteins including collagen and gelatin and their hydrolyzates, peptides, enzymes, oil, carotenoids, bone calcium, chitin, chitosan, and other compounds, many of which have nutraceutical potentials [2, 36, 87–89]. During the recent years, there is increased consumer interest toward nutraceuticals and natural bioactive compounds as functional ingredients to prevent, alleviate, or treat diverse diseases [88]. An example may be cited. The processing of the Black Sea anchovy gives rise to approximately 32% (w/w) discards consisting of the head, frame, and viscera. These have protein and fat contents ranging from 12 to 17% and 10 to 23.9%, respectively. The discards are also rich sources of lysine and leucine, constituting 6–7% and 5–6% of total amino acids, respectively, PUFA (about 32–40% of total fatty acids, with n-3 fatty acids comprising about 27–34% of total fatty acids), and also various minerals. The anchovy discards are raw material for protein powder, protein hydrolyzates, fish oils, and mineral supplements [90].

Interests in seafood- and other marine-derived compounds stem from the fact that most aquatic organisms have inbuilt mechanisms to survive hostile oceanic environments such as varying degrees of salinity, pressure, temperature, and illuminations. Most marine organisms produce several secondary metabolites, which although are not directly involved in central physiological functions, yet contribute

to their survival. They synthesize novel compounds with interesting bioactivities, which facilitate them to adapt to these conditions. Seafood species, for example, in the extremely low temperatures of the polar region possess enzymes having novel features relating to isozyme distribution, substrate binding, amino acid sequence, low activation energies, high-specific activities, and thermal sensitivities [91, 92]. Besides, most marine organisms also produce several secondary metabolites such as sulfated polysaccharides, peptides, alkaloids, terpenoids, and others, which although are not directly involved in central physiological functions, yet contribute to their survival [4]. These novel compounds may possess a wide spectrum of bioactivities encompassing anticancer, anti-inflammatory, antiviral, antimicrobial, antioxidative, antihypertensive, anti-atherosclerotic and anticoagulant, immunomodulatory, analgesic, antidiabetic, appetite-suppressing, neuroprotective, and other interesting functions. Therefore, during the recent years, the search for nutraceuticals and other medicinal compounds from seafood and other marine organisms such as sponges, tunicates, bryozoans, mollusks, and sea slugs and other organisms has intensified for the potential control of various diseases such as cardiovascular disease (CVD), diabetes, osteoporosis, arthritis, Alzheimer's disease, and others [5, 88, 91]. Recent studies have indicated that specific compounds from fish such as cod, anchovy, eel, and shellfish like mollusks (mussel, oyster, clams, and abalone) as well as sea cucumbers may possess in vivo/in vitro anticancer/antitumor activities, supporting health benefits of these organisms. Some of the compounds can also function as hypotensive agents, cardioactive substances, muscle relaxants, antibiotics, and antiviral agents [4, 92]. Nguyen [93] observed that about 50,000 tons of lobster processing discard by-products can be valuable sources of bioactive compounds having potential applications in nutraceutical, pharmaceutical, and medicine, besides water treatment, agriculture, and other industries. Table 1 shows major nutraceuticals and bioactive components available from seafood.

The remaining part of this chapter is intended to briefly discuss various nutraceuticals and other bioactive compounds from seafood processing discards and underutilized fish. For the convenience of discussion, these compounds are grouped as those of nitrogenous origin, lipid-based compounds, polysaccharides and their derivatives, and mineral-based compounds [6].

4.1 Nutraceuticals of Nitrogenous Origin

4.1.1 Proteins

Seafood proteins, besides notable nutritive properties, as discussed above, also have excellent functional properties, which include solubility, viscosity, water-holding capacity, gelation, adhesion, elasticity, foaming, and oil emulsification capacities, which make them interesting food ingredients [4]. These properties emanate from their compositional and structural features, which include hydrophilic character, hydrodynamic size and shape, and ability for hydrogen bonding and ionic hydration, among others [4]. Seafood processing discards are therefore valuable sources of functionally active proteins. Techniques for isolation of these

Table 1 Major nutraceuticals and bioactive components from seafood

Finfish
Bioactive peptides
Biological calcium
Carotenoids
Enzymes including cold-adapted enzymes
Glycosaminoglycans including chondroitin sulfate, dermatan sulfate, and hyaluronic acid
Long-chain omega-3 polyunsaturated fatty acids (PUFAs)
Phosphopeptide from fish bone
Protein hormones such as calcitonin
Protein isolates including collagen and gelatin
Squalene and squalamine
Shellfish (crustaceans and mollusks)
Bioactive peptides
Carotenoids
Chitin, chitosan, and chitosan derivatives
Enzymes
Glucosamine
Long-chain omega-3 polyunsaturated fatty acids (PUFAs)
Mussel polysaccharides, lipids, and other products
Protein isolates including collagen and gelatin

proteins involve extraction by dilute acids, bases, or isoelectric solubilization/precipitation [94, 95]. Filleting operations of large fish such as hake, seer, and others give rise to frames that carry large amounts of meat portions. Mechanical deboning helps to recover meat from the frames. Thorough washing of the recovered meat gives surimi, which because of its excellent gel-forming properties, is an ideal raw material for the development of restructured imitation seafood [94]. Generally fish protein isolates maintain their properties for about 6 months when stored at 5 °C but loses them rapidly at 30 °C. Deterioration during storage is prevented by lowering the moisture content of the product and by eliminating oxygen from the package [96]. The protein isolate can be used as an ingredient to enhance protein contents of food products and also as a nutraceutical. Fortification of extruded corn snacks with up to 18% fish protein powder and 17% omega-3 fish oil did not influence the sensory attributes of the products when served within 12 weeks of production [96]. Soluble powders recovered from processing discards of Alaska pollock had protein contents ranging from 65% to 79% and nitrogen solubility value as high as 86%. Emulsion capacity (mL of oil emulsified per mg^{-1} protein) and emulsion stability of the pollock protein powders ranged from 29% to 35% and 65% to 78%, respectively, with a maximum fat-adsorption values of 10.6 mL of oil g^{-1} protein. The protein powder was also a good source of K, P, Mg, and also amino acids. Emulsions made with soluble protein powders from pollock exhibited viscoelastic characteristics, suggesting its use as a food fortificant and functional additive [97]. The nutraceutical potential of protein isolates has also

been indicated. For instance, the protein isolate from striped bass (*Morone saxatilis*) has a positive effect in control of CVD [95].

Preparation of fish protein hydrolyzates (FPHs) is a plausible method for utilization of proteins from seafood discards. Currently hydrolyzed fish proteins are used as condiments and sauces in the East Asian countries. FPHs have potential as a functional ingredient and protein supplement for developing formulated ready-to-eat products, which can help increase in protein consumption by the general public for health benefits [98]. In the year 2014, a landing of 7.7 MMT of tuna was recorded [1]. A sizeable portion of tuna is used for canning, which generates as much as 70% solid discards from the fish, consisting of muscle (after loins are taken), viscera, gills, dark flesh, head, bone, and skin. Proteins from these discards can be recovered as FPH for use as food supplement to enhance functional effects such as whipping, gelling, and texturing properties [99]. FPH has also been recognized as potential nutraceutical essentially due to the activity of antioxidant peptides present in the product [99] (see Sect. 4.1.2.). Both in vitro and in vivo studies have shown that certain peptide fractions in FPHs may stimulate the non-specific immune defense system [51]. Preliminary studies have indicated that expression levels of tumor necrosis factor (TNF-α) had a tendency to be lower after the addition of FPH. Furthermore, the combination of FPH and omega-3 fatty acids synergistically decreased expression levels of TNF-α, compared to individual effects of omega-3 fatty acids or FPH [100]. Animal feeding study conducted at Norway suggested the effect of fish protein hydrolyzate as a cardioprotective nutrient. The fish protein treatment reduced plasma cholesterol level and altered the fatty acid composition in liver, plasma, and triglycerol-rich lipoproteins in obese Zucker rats. The ratio of HDL cholesterol to total cholesterol was greater in the animals, compared with casein-fed animals [101]. Although not a nutraceutical, mussels possess specialized proteinous glue, collectively referred to as mussel adhesive proteins (MAPs), which adhere well to surfaces despite the presence of water. The protein is rich in the amino acid, L-3,4-dihydroxyphenylalanine (DOPA). MAPs may be used for surgical tissue adhesion or as components of muco-adhesive drug delivery systems. Another protein, green fluorescent protein (GFP), isolated from the jellyfish in 1962 has interesting applications in biotechnology and cell biology [4].

Frames discarded from fish filleting operations, fins, scales, air bladder, and fish heads are also good sources of collagen. Collagen and its partially hydrolyzed form, gelatin, contain more than 80% nonpolar amino acids such as glycine, alanine, valine, and proline and hence are different in their amino acid contents, in comparison with fish muscle proteins. Collagen-based biomaterials are extensively used as food additives and in ophthalmology, dermatology, drug delivery, cosmetics, and other industries [102, 103]. Fish collagen has lower denaturation temperatures than porcine collagens. Therefore, collagen from fish offal can be a better alternative to mammalian collagen for use in foods, cosmetics, and medicine. Collagen hydrolyzates are beneficial for the treatment of osteoarthritis and other joint disorders. Orally administered collagen hydrolyzate is absorbed intestinally and is accumulated in the cartilage. Ingestion of collagen hydrolyzate stimulates synthesis of macromolecules by chondrocytes in extracellular matrix [104]. Collagens can be easily converted into

gelatin by hot water treatment. Gelatin has found extensive application in the pharmaceutical industry. It is also being used as a matrix molecule for nanoparticle-based drug delivery applications. Most of the current production of gelatin is from porcine and bovine hides, bones, and hooves. The incidents of mad cow disease have made adverse impact on the use of mammalian gelatins. Fish gelatins could be plausible substitutes to mammalian gelatins, since they have properties such as bloom strength (the gel strength equivalent referred to in the industry), viscosity, and solubility comparable with those of mammalian gelatins [102, 103].

Fishery discards such as viscera, liver, and head are sources of proteases, lipases, transglutaminases, amidases, lipases, phospholipase, chitinases, alginate lyases, β-1,3-glucanase and carrageenases, and other enzymes. These can have potential applications in diverse fields such as food processing, pharmaceuticals, textiles, and protein engineering. Enzymes from fish and shellfish from cold habitats are particularly useful since they can function effectively at lower temperatures, thereby saving energy and protecting the food products [105, 106]. For example, pepsin from the gastric mucosa of polar cod has high specific activity at low temperature, and a fish trypsin exhibits high salt stability [107]. Cold-active proteases are useful for controlled protein digestions and extraction of carotenoproteins, which are known to be thermolabile. Transglutaminase is an enzyme that catalyzes cross-linking of glutamine and lysine in proteins through acyl-transfer reaction involving the γ-carboxamide group of peptide-bound glutamine residues and the ε-amino group of lysine residues. The enzyme from cold-adapted organisms can modify texture of protein foods at low temperatures [107, 108]. A number of seafood enzymes can replace conventional seafood processing operations such as isolation and modification of fish proteins and marine oils, production of bioactive peptides, acceleration of traditional fermentation, peeling and deveining of shellfish, scaling of finfish, removal of membranes from fish roe, extraction of flavors, shelf life extension, texture modification, removal of off-odors, and quality control either directly or as components of biosensors; non-fishery applications include use of trypsin from the stomach of tuna for milk clotting, cheese ripening, meat tenderization, and other processes [109]. Table 2 indicates various enzymes from fishery sources and their potential applications.

4.1.2 Bioactive Peptides

Bioactive peptides are protein fragments that have various physiological functionalities in the human body following consumption. These peptides are derived through enzymatic hydrolysis of proteins including food proteins including seafood muscle and the stromal proteins, collagen and gelatin [97, 110]. Enzymatic hydrolysis of fish processing discards under controlled conditions gives rise to peptides, which are separated by ultrafiltration or other suitable techniques [98]. Peptides from marine by-products have high nutraceutical potentials to address important public health issues like obesity, stress, hypertension, and others. These arise from their interesting bioactivities, which are dependent on their amino acid composition and sequences, and include their antimicrobial, antiviral, antitumor, antioxidative, antihypertensive, cardioprotective, anti-amnesiac, immunomodulatory, analgesic,

Table 2 Enzymes from fishery sources and their potential applications

Enzymes	Fishery sources	Characteristics and potential applications
Proteases including chymotrypsin and Cathepsin D	Carp, capelin, carp, Herring, Atlantic Cod, rainbow trout, Scallop, dogfish, squid, prawn, sardine	Milk clotting activity at alkaline pH. Degrade proteins including Myofibrillar proteins. Preparation of FPH
Collagenases	Carp, catfish, cod, Crab species, pacific Rock fish, bivalves	Comparable to mammalian metalloproteinases
Chymosin (rennin)	Carp, seal	Optimal pH 2.0–3.5, possesses high milk clotting activity
Lipases	Atlantic cod, seal, Salmon, sardine, Indian mackerel, Red sea bream	Production of omega-3-enriched triglycerides, flavor enhancement
Transglutaminases	Various fishery products	Comparable to mammalian metalloproteinases
Chitinases	Shellfish, squid Liver, octopus saliva	Optimal pH 2.0–3.5, possesses high milk clotting activity
β-1,3-glucanase, β-galactosidase	Abalone, scallop, Tilapia, sea cucumber	Production of omega-3-enriched triglycerides, flavor enhancement
Lysozyme	Arctic scallop shell, crab shell	Can produce low molecular weight antibacterial chitosans in coordination with cellulase and chitinase
Catalase, Glutathione Peroxidase	Marine mussel and other organisms	Antioxidants
Carbohydrases such as β-galactosidase	Finfish such as tilapia	Deacetylation of chitin

Adapted from Ref. [109]

antidiabetic, antiaging, appetite-suppressing, and neuroprotective activities [7, 70, 98, 110–113]. A major bio-function of many peptides is in the control of CVD. High blood pressure is one of the relevant independent risk factors for CVD. Angiotensin I-converting enzyme (ACE) plays a critical role in the regulation of blood pressure and is a multifunctional enzyme, which promotes conversion of angiotensin I to the potent vasoconstrictor angiotensin II. Inhibition of ACE is considered to be a useful therapeutic approach in the treatment of hypertension. A number of seafood-derived peptides can inhibit angiotensin I-converting enzyme (ACE) (EC3.4.15.1). ACE-inhibitory peptides have been produced from salmon, oyster, squid, sea urchin,

shrimp, snow crab, seahorse, jelly fish, Alaska pollock, bigeye tuna muscle, sea cucumber, sea bream, yellowfin sole, and others [112, 113]. A number of peptides from fishery sources are capable of scavenging free radicals and reactive oxygen species, thereby preventing oxidative damage [110, 112]. Fish and shellfish are also good sources of antimicrobial peptides, which are described in the hemolymph of spider crab, oyster, American lobster, shrimp, and green sea urchin [110]. A novel anticancer peptide from the shellfish *C. gigas* exhibited cytotoxic activity, inducing death of prostate, breast, and lung cancer cells [114]. Table 3 gives peptides from various fishery sources and their bioactivities.

4.2 Lipid-Based Compounds

4.2.1 Fish Oils

Processing discards, particularly the liver of fish such as albacore, cod, salmon, shark, haddock, and tuna, are good sources of oil and rich in omega-3 PUFA and vitamins A and D. The oil of fish species, such as Atlantic mackerel, shark, anchovies, menhaden, and Atlantic sardine, can have up to 35% omega-3 fatty acids, with EPA and DHA at around 10% of the oil. The European fish species such as capelin, herring, sand eel, and sprat are intermediate in oil contents, ranging between 18% and 25%. The demersal fish such as cod and halibut have a lower oil content of 15% to 20% [115–117]. Oil from whole fish or their discards are traditionally recovered by the wet reduction process. It involves steaming of the whole fish or processing discards and pressing of the cooked material to separate the solid portion as press cake for use as fish meal. The oil and water released during the pressing stage are pumped through screens and decanters to remove suspended solids and then centrifuged to separate the oil, which is then filtered and stabilized with antioxidants for storage [118]. Extraction of oil from various fish such as cod, herring, salmon, and other fish has been discussed [4]. The traditional cooking process for oil extraction has been replaced by isoelectric precipitation of oil-bound proteins [119], enzymatic treatment [120], or supercritical extraction using CO_2 [121]. Principal fatty acids in some fish oils are shown in Table 4.

The liver of shark is 22 to 30% of body weight, and the oil content in the liver may be as high as 90% of its weight. Recovery of oil from shark consists of natural decomposition of the liver, acid ensilage in the presence of formic acid, alkali digestion, and steam rendering (90 °C for 30 min) [4]. Shark oils could be attractive sources of n-3 fatty acids, specifically DHA, with content between 13% and 18% [116]. The oil of *Echinorhinus brucus* (bramble shark) has DHA (18%), EPA (16%), palmitic acid (15%), oleic acid (12%), stearic acid (8%), and squalene (38.5%), besides fat-soluble vitamins such as vitamin A, 17 mg%; vitamin D, 15 mg%; and vitamin K, 11.5 mg%. The oil showed high in vitro cytotoxic effect against the human neuroblastoma cell line (SHSY-5Y) [123]. Oil from the liver of black shark (*Labeo chrysophekadion*), Mako shark (*Isurus oxyrinchus*), and hammerhead shark (*Sphyrna* spp.) is also rich in vitamins A and D [4]. Salmon oil is an excellent source of EPA (18%) and DHA (12%) and is commercially available [7]. Oil of Antarctic

Table 3 Bioactive peptides from some fishery sources and their hydrolyzates (FPHs)

Fish/Shellfish	Sequence and other characteristics	Functions/activities
Alaska pollock	Gly-Pro-Leu	ACE inhibitory
Wakame	Tyr-Asn-Lys-Leu	ACE inhibitory
Bigeye tuna frame	Gly-Asp-Leu-Gly-Lys-Thr-Thr-Thr-Val-Ser-Asn-Trp-Ser-Pro-Pro-Lys-Try-Lys-Asp-Thr-Pro	ACE inhibitory
Shrimp (protease)	Le-Phe-Val-Pro-Ala-Phe	ACE inhibitory
Shrimp	Peptide[a] (molecular size, <10, 10 to 30, >30 kDa)	Anticancer
Wakame (papain)	Tyr-Asn-Lys-Leu	–
Oyster	Cys, Leu, Glu, Asp, Phe, Tyr, Ile, Gly	Antimicrobial
American lobster	Gln-Tyr-Gly-Asn-Leu-Leu-Ser-Leu-Leu-Asn-Gly-Tyr-Arg	Antimicrobial
Jumbo squid	Gelatin peptide[a]	Antioxidant
Blue mussel (fermentation)	Glu-Ala-Asp-Ile-Asp-Gly-Asp-Gly-Gln-Val-Asn-Tyr-Glu-Glu-Phe-Val-Ala-Met-Met-Thr-Ser-Lys	ACE inhibitory, anticoagulant, antioxidant
Scallop	γ-glutamyl-valyl-glycine	Flavoring agent
Spider crab	Proline-arginine-rich peptide[a]	Antimicrobial
Snow crab (protamex)	Cationic peptide[a]	Anticancer
Oyster	Peptide[a]	Anticancer, immune-stimulant
Clam (thermolysin)	Peptide[a]	ACE inhibitory
Clam (protamex)	Various peptides[a]	Hypocholesterolemic effect
Oyster (thermolysin)	Peptide[a]	Antioxidant
Oyster (subtilisin)	Pro–Val-Met-Gly-Asp and Glu-His-Gly-Val peptides	Antioxidant
Squid skin collagen	Peptide[a]	ACE inhibitory
Krill	Various peptides[a]	ACE inhibitory
Naturally present peptides in raw muscle		
Crab, shrimp	Crustin or crustin-like, callinectin, tachyplesin	Antimicrobial
Crayfish	Astacidin[a]	Antimicrobial
Lobster	Crustin or crustin-like[a]	Antimicrobial
Mussel	Tyr-Pro-Pro-Ala-Lys	Antioxidant
Mussel	Mytilin, mytimycin, myticin, pernin[a]	Antimicrobial
Shrimp	Penaeidin, crustin-like peptide	Antimicrobial, antioxidant
Scallop	γ-glutamyl-valyl-glycine	Flavoring agent

Summarized from various sources
[a]Sequence not reported

Table 4 Principal fatty acids in some fish oils

Fatty acid	Capelin	Atlantic mackerel	Atlantic sardine	Anchovies
Myristic (14.0)	7	8	8	9
Palmitic (16:0)	10	14	18	19
Palmitoleic (16:1)	10	7	10	9
Oleic (18:1)	14	13	13	13
Eicosanoid (20:1)	17	12	4	5
Cetoleic	14	15	3	2
EPA (20:5)	8	7	18	17
DHA (22:6)	6	8	9	9

Values are % of total lipids
Source: Adapted from Ref. [122]

krill (*E. suberba*) contains omega-3 fatty acids, phospholipids and also natural pigments, and vitamins. However, since the oil content is only about 3% of the body weight, a large amount of krill needs to be processed for oil recovery [124]. The hydrolyzate of squid processing by-products had phospholipids fraction (45.6% of oil) which contained EPA and DHA at 16.9% and 29.2%, respectively. Peptides isolated from the soluble fraction exhibited angiotensin I-converting enzyme (ACE) inhibitory activity. The presence of both omega-3 fatty acids and ACE inhibitory peptides suggested the nutraceutical potential of the squid hydrolyzate [125].

Appreciable amounts of PUFA particularly EPA and DHA in fish oils denote significant therapeutic value of the oil. Moderate consumption of fish oil has shown to decrease the risk of major cardiovascular events including coronary heart disease (CHD) and atrial fibrillation [60, 126–128]. Shark oil has been an age-old remedy for various diseases as well as a source of strength and virility [116]. The favorable nutritional composition of bramble shark oil makes it a nutritional supplement [123]. While fish is the preferred source of omega-3 PUFAs, for those who do not consume fish, omega-3 PUFA supplementation is a feasible alternative [126]. This also holds good for consumers of Western-type diet, which is generally deficient in n-3 fatty acids [12]. It has been suggested that the daily intake of combined EPA and DHA should be at least 500 mg for individuals without underlying overt cardiovascular disease and at least 800 to 1000 mg for individuals with known coronary heart disease [128]. DHA is crucial for development of the brain and the central nervous system in infants and also to suppress neuro-inflammation and oxidative stress [70]. Studies indicate that long-chain n-3 PUFA can also have anticancer, anti-depressive, antiaging, and antiarthritic effects as well as neurodevelopment in children and can address a number of chronic diseases, including a spectrum of liver fat-related conditions [61, 62, 129–133]. Regular consumption of whole milk fortified with omega-3 along with oleic acid, minerals, and vitamins has been reported to reduce cell adhesion besides having anti-inflammatory effects in healthy children [131]. The mode of action of the PUFAs, particularly EPA and DHA, is attributed to their ability to give rise to a class of pharmacologically important groups of compounds, collectively called eicosanoids, as discussed in Sect. 3.3. In view of their therapeutic

benefits, many international and national health organizations recommend daily intakes of EPA and DHA in the range of 250 to 500 mg for general health and higher amounts for people diagnosed with CVD [126, 128]. Professional bodies such as the American Heart Association, Department of Health UK, and Food Safety Authority (FSA), among others, suggest daily total intake of EPA and DHA varying from 250 to 1000 mg/day [4, 35]. Microencapsulation technologies (spray-drying, spray-chilling, extrusion, co-crystallization, freeze-drying, and others) provide superior process to make odorless capsules containing the PUFA in gelatin or other capsules [4]. In view of the sensitivity of PUFA to oxidation, it is advisable that those who consume omega-3 may take adequate amounts of antioxidant nutrients, especially vitamin E, vitamin C, and selenium.

4.2.2 Squalene, Squalane, and Related Compounds

Squalene is a hydrocarbon ($C_{30}H_{50}$), having structures 2,6,10,15,19,23-Hexamethyltetracosa-2,6,10,14,18,22-hexaene. Livers of deep-sea shark species contain high contents of squalene and also other hydrocarbons like pristine, presumably for buoyancy, since they lack swim bladders. Liver oils of deep-sea sharks, mainly *Centrophorus* spp., found under depths in the Pacific, North Atlantic, and Indian Oceans contain about 85–90% unsaponifiable matter, which is essentially squalene [117]. The liver oil of shovelnose dogfish contains 60% hydrocarbons [4]. The liver oil of *Echinorhinus brucus* (bramble shark) has 39% squalene [123]. Squalene is a skin rejuvenating agent and possesses antilipidemic and membrane-stabilizing properties. Both squalene and its hydrogenated product, squalane, are considered to possess huge potential in nutraceutical, pharmaceutical, and cosmeceutical industries [134]. Pristane (C_{19} H_{40}) (2,6,10,14-tetramethylpentadecane), a natural saturated terpenoid alkane, and squalamine, an amino sterol antibiotic, are also found in shark liver oil. Squalamine has remarkable anti-angiogenic, antitubercular, and antiviral properties [4].

Other lipid-based bioactive compounds have been identified, particularly from mussels. A lipid extract of hard-shelled mussel (*Mytilus coruscus*) possesses strong anti-inflammatory activity and has the potential to treat rheumatoid arthritis [135]. The immune-strengthening properties of lipid extracts of the New Zealand green-lipped mussel (*Perna canaliculus*) have made the shellfish an alternative to conventional drugs in the treatment of rheumatic diseases like osteoarthritis, joint pain, and also atopic asthma [136, 137] .

4.2.3 Carotenoids

Shells of shrimp, prawn, krill, crab, and lobster contain astaxanthin ranging from 40 to 200 mg kg^{-1} dry weight, which is present as free or bound to proteins and/or chitin [63, 64]. Other shellfish carotenoids include canthaxanthin present in crayfish, mytiloxanthin in mussel, and mactraxanthin and fucoxanthin present in clams [2, 63, 64, 138]. The main pigment in the muscle tissues of the Yesso scallop, one of the important farmed scallops in China, was identified as pectenolone (3,3′-dihydroxy-β, β-caroten-4-one) [139]. The process of extraction of carotenoids from seafood discards involves initial digestion with proteolytic enzymes such as pepsin, trypsin,

or alcalase, followed by drying of the shell discard and recovery of the carotene pigments by organic solvents such as acetone, hexane, or isopropyl alcohol. If vegetable oil such as soybean oil is used for extraction, the isolate is pigmented oil. In recent years supercritical CO_2 has been successfully used for extraction of the pigments [64]. While the extracted carotenoids are used in aquaculture to impart color to the farmed fish and shellfish, in recent years there has been awareness on their bio-functions in human health. These include their antioxidant activities, their role as provitamins, and their anticancer activities, among others [63, 64, 66]. There is an immense scope to make use of these pigments for prevention of various diseases related to oxidative stress and resulting tissue damage, as discussed earlier (see Sect. 3.4).

4.3 Polysaccharide-Based Compounds

Polysaccharides are emerging ingredients against many chronic diseases. These macromolecules are biodegradable and characterized by water- and fat-binding capacities, gelation, viscosity, and other functional properties, which offer them various biomedical and food applications. Functions of polysaccharides in food and medicine encompass adhesive action, coating, emulsification, encapsulation, film formation, foam stabilization, and as swelling and thickening agents. Polysaccharides are amenable to chemical modifications, providing derivatives having enhanced and specific functions. While agricultural products are the traditional sources, marine polysaccharides are gaining importance because of recognition of their interesting therapeutic and other functions. These facilitate medicinal applications of marine polysaccharides and their derivatives in drug delivery, tissue regeneration, wound healing, dental implants, blood plasma expanders, vaccines, non-viral gene delivery, and many others [140, 141]. The major polysaccharide-based compounds from seafood and their various applications are briefly discussed below:

4.3.1 Chitin, Chitosan, and their Derivatives

Chitin is the second most abundant natural biopolymer derived from exoskeletons of crustaceans and also from cell walls of fungi and insects [142]. In lobster, crab, krill, shrimp, and prawn, chitin forms the outer protection coatings of the animal through a covalently bound network with proteins. The dry shell discards of crab, shrimp, and lobster may contain chitin up to 70% on dry weight basis, while its contents in dry squid skeleton pen and deproteinized shell of krill may be at a lower value of about 40%. Although not a nutraceutical, chitin offers various applications essentially through its deacetylated form, chitosan, as well as its numerous derivatives in medicine, food, and many other areas. The literature is voluminous on the topic and only a very brief discussion will be attempted here.

The process of isolation of chitin from crustacean discards consists essentially of three steps: demineralization of dried and pulverized shell discards usually by dilute hydrochloric acid, deproteinization by dilute alkali, and finally decoloration by sun

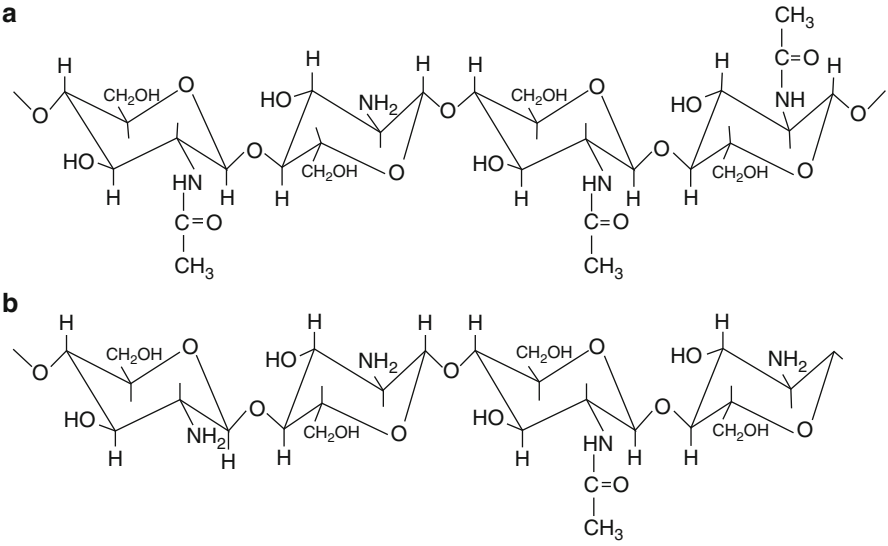

Fig. 1 Structure of chitin (**a**) and chitosan (partially deacetylated) (**b**)

drying, followed by washing and drying. Demineralization needs to be done under controlled conditions to prevent deacetylation of chitin. Proteins which exist as caroteno-protein complexes may be separated by trypsin treatment in the presence of ethylenediaminetetraacetic acid (EDTA). Decolorization can be performed by solvent extraction employing acetone or ethanol [142, 143]. An integrated process for isolating bioactive molecules including protein, chitin, carotenoids, and glycosaminoglycans from Pacific white shrimp (*Litopenaeus vannamei*) processing waste has been reported. Autolysis of 1 kg of the shrimp head followed by lyophilization of the autolyzate gave about 120 g of protein hydrolyzate. The recoveries of chitin and carotenoids were 25 ± 2 mg g^{-1} and 195 g^{-1} wet processing waste [144].

Chitin is a cationic polymer formed by units of N-acetyl-D-glucosamine, joined by ß-linkages. The structure of chitin is ß-(1–4)-N-acetyl-D-glucosamine, which is ß-(1–4)-N-acetyl-2-amino-2deoxy-D-glucose (Fig. 1a). It may be also regarded as a derivative of cellulose, in which, the C-2 hydroxyl group is substituted by an acetyl amino group. Chitin occurs in three polymorphic forms, the most common α-chitin and also β- and γ-chitins, which differ in their arrangement of the molecular chains. Chitin structure has an extensive intermolecular hydrogen bonding associated with exclusion of water, leading to its stability. Chitin is a very light, white or yellowish, powdery/flaky product. It is insoluble in water as well as almost all common organic solvents and acidic and basic aqueous solutions. Chitin swells in cold alkali when some deacetylation takes place. Chain lengths of chitin and degree of acetylation differ according to sources and recovery conditions. Chemical derivatives of chitin include carboxymethyl chitin, hydroxyethyl chitin, ethyl chitin, chitin sulfate, glycol chitin, and glucosylated chitin, which have varied chemical and functional properties [142].

Chitin upon deacetylation yields chitosan, which is a collective name representing chitin deacetylated to various degrees. Generally chitosan is produced by deacetylation of chitin using 30–60% (w/v) sodium or potassium hydroxide at 80–140 °C followed by drying to get chitosan flakes. Chitosan with a variable degree of deacetylation ranging from 60 to 80% was recovered at 17 ± 4 mg g^{-1} head discard (wet weight) of white shrimp (*L. vannamei*) [144]. Chitosan has also been extracted by various enzymes such as lysozyme, neutral protease, and chitin deacetylase. The average molecular weight of chitosan obtained using the enzymatic method is 268 kDa [145]. Higher extraction temperatures enhance deacetylation and also result in fragmentation of the chitosan. Chitosan polymers are thought to contain more than 5000 repeating acetylglucosamine and glucosamine units. The molecular weights of chitosan range from 300 to over 1000 kDa and its degree of deacetylation from 30% to 95%. Both molecular weight and degree of deacetylation have influence on the functionality of chitosan. A minimum deacetylation of 70% is required for chitosan to be acceptable for various purposes.

The structure of chitosan is β-(1–4)-linked-D-glucosamine, i.e., poly [β-(1–4)-linked-2-amino-2-deoxy-D-glucose] (Fig. 1b). Chitosan is a cationic polyelectrolyte white solid, insoluble in pure water, but unlike chitin, it is soluble in weakly acidic aqueous media. Chitosan derivatives in the form of acetate, ascorbate, lactate, and malate are water-soluble. Chitosan is soluble in aqueous acid and crystallizable from aqueous alkaline solution. The value of pKa for the positively charged ammonium group of chitosan is about 6.2. When the pH is raised to about 6.5, chitosan precipitates in a gel form. The net cationic charge as well as presence of multiple reactive functional groups in the molecule makes chitosan a valuable compound for practical uses.

Chitosan can be easily converted to various derivatives for diverse applications, as shown in Fig. 2. These derivatives, depending on their chemical nature, have interesting characteristics such as biocompatibility, biodegradability to harmless products, nontoxicity, physiological inertness, and antimicrobial and gel-forming properties, among others. Chitosan derivatives, depending on their chemical nature, can have bioactivities such as antioxidant, anti-inflammatory, anti-allergic, antitumor, anti-obesity, antidiabetic, anticoagulant, antiviral, immunomodulatory, cardioprotective, and others. These properties make chitosan and its derivatives valuable compounds in several fields including food, nutrition, medicine, agriculture, biotechnology, and material science [146–150]. Due to its cationic nature, chitosan binds dietary fat in the stomach, leading to decreased intestinal absorption of fat and cholesterol, thereby reducing low-density lipoproteins in the blood and liver. For dietary purpose, chitosan needs to be introduced through food and should be soluble at acidic pH. Chitosan can be a food preservative due to its antimicrobial activity against a wide variety of pathogenic and spoilage-causing microorganisms, including fungi and gram-positive and gram-negative bacteria. Chitosan films can be used as a packaging material for the preservation of foods [145]. Potential medicinal applications of chitosan and its derivatives include drug delivery, hemodialysis membranes, artificial skin, hemostatic agents, hemoperfusion columns, wound healing and blood

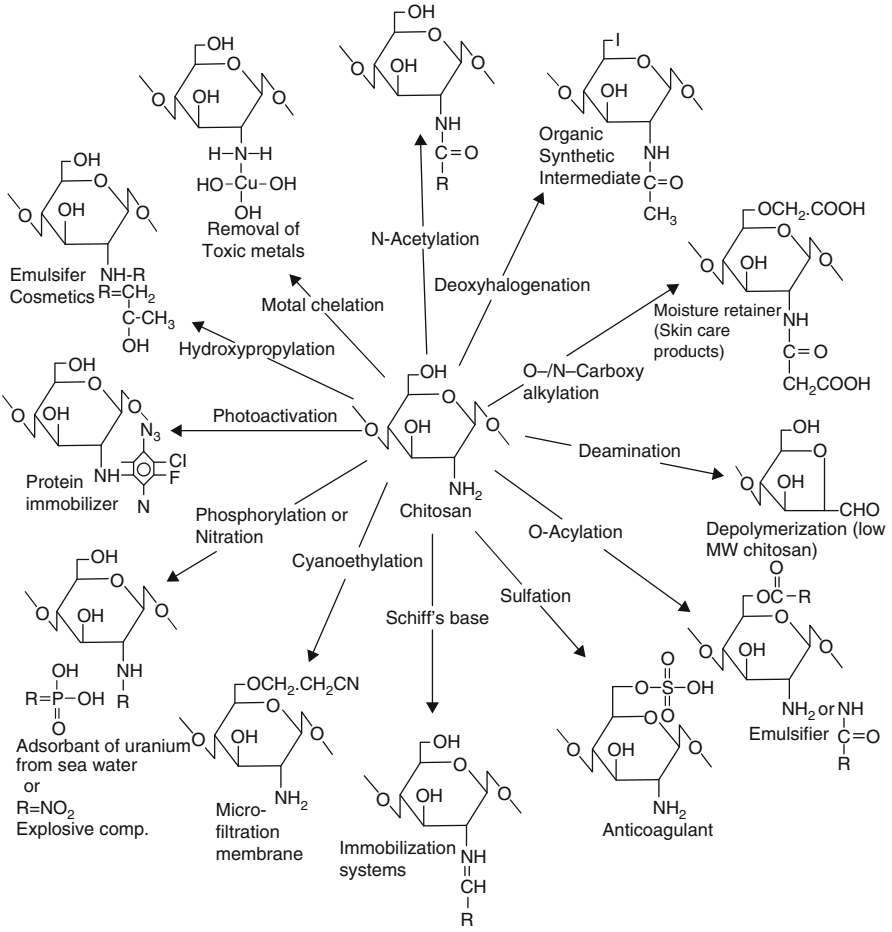

Fig. 2 Various chemical derivatives of chitosan and their uses (Source: Ref. 142 with permission from Taylor & Francis)

coagulation, and also gene therapy. The property of chitosan to form gel at slightly acid pH provides antacid and anti-ulcer activities [4, 140].

Chitosan and also other polysaccharides such as hyaluronic acid among others have received attention in the fields of regenerative medicine and tissue engineering, as ideal materials for artificial extracellular matrices [151]. Various physical forms of chitosan include nanoparticles, nanofibrils, microspheres, composite gels, fibers, films, and bandages. Chitosan-carrageenan composite nanoparticles have shown promise as carriers of therapeutic macromolecules. Nanocomposite films of chitosan and other marine hydrocolloids such as agar, alginate, and carrageenan can be a good carrier for nutraceuticals including omega-3 PUFA in the future [4]. Chitosan-based hydrogels and wound healing bandages have found commercial acceptance. Chitosan-based bone graft substitutes are biocompatible and biodegradable, with

structural similarity to the bone, having excellent mechanical strength. Derivatives of chitin and chitosan have applications as cosmetic ingredients. These include O-carboxymethyl chitin and O-hydroxypropyl chitin, carboxymethyl chitosan, chitosan acetate, adipate, glycolate, hydrolyzed chitosan, pyrrolidone carboxylic acid (PCA), hydroxyl methyl, hydroxyl propyl, formate, ascorbate, and salicylate of chitosan, among others [4, 103, 152]. Methods of manufacture of chitosan derivatives and biomedical applications have been recently discussed [153]. A number of these products are presently commercially available [91, 151, 153–155]. Salient biomedical applications of chitosan are pointed out in Table 5.

The biodegradation of chitosan by chitinases leads to formation of nontoxic oligosaccharides of variable length [149, 156]. While these oligosaccharides are not digested by gastrointestinal enzymes, they modify the viscosity and freezing point of foods, affect emulsification and gel formation, possess bacteriostatic properties, and act as humectants. Chitosan oligosaccharides are used as antioxidant, antitumor agent, and antimicrobial agents. They stimulate growth of lactobacilli and other probiotic organisms. Low molecular weight chitosans (25–50 kDa) suppress *H. pylori* and also have been recognized to protect normal cells from apoptosis [156].

4.3.2 Glucosamine

Glucosamine is the end product of hydrolysis of chitosan. It is an amino sugar that is naturally produced in humans and a key building block in the synthesis of glycosaminoglycans. Glucosamine is a recognized nutraceutical for joint pain relief. It promotes synthesis of cartilage proteoglycans and synovial production of hyaluronic

Table 5 Salient applications of chitosan in biomedical applications

Applications	Salient property
Wound healing, burn therapy	Forms tough, water-absorbent, biocompatible films that promote tissue growth
Hemodialysis membranes	Chitosan-cellulose blended membranes have improved dialysis properties in artificial kidney due to improved permeability
Drug delivery	Inexpensive carrier encapsulating nutraceuticals and drugs. It also helps transdermal delivery of drugs
Removal of toxins	Chitosan-encapsulated activated charcoal has potential to remove toxins
Hemoperfusion	Chitosan and its oligomers can satisfy the requirements of specificity and blood compatibility
Artificial scaffolds	Chitosan along with chondroitin sulfate supports proteoglycan production in cartilages
Anticholesterol drug	Reduces lipid absorption and hence reduces cholesterol
Dental bioadhesive biodegradable sutures	Collagen-chitosan membrane has potential for treatment of periodontal defects in dentistry
Composite films and nanoparticles with other polysaccharides	Various processes in tissue engineering for drug delivery, skin recovery, scaffolds, and others

Adapted from various references

acid (HA), which has anti-inflammatory and analgesic properties. Glucosamine along with chondroitin sulfate (see Sect. 4.3.3) is a highly effective treatment for arthritis and osteoporosis [148, 149].

4.3.3 Glycosaminoglycans

Glycosaminoglycans (GAGs) are heteropolysaccharides defined by a repeating disaccharide unit without branched chains, in which one of the two monosaccharides is an amino sugar (N-acetylgalactosamine or N-acetylglucosamine) and the other one is a uronic acid. GAGs are present on all animal cell surfaces and in the extracellular matrix where they exist as proteoglycans by covalently linking to proteins (such as growth factors, enzymes, and cytokines). Based on the disaccharide composition, linkage type, and presence of sulfate groups, GAGs may be chondroitin sulfate (CS), hyaluronic acid (HA), dermatan sulfate (DS), heparin, or keratan sulfate (KS). GAGs are significantly present in the cartilage, which serves as a cushion between bones and joints. The cushion structures are formed by a matrix of collagen and elastin associated with proteoglycans consisting of CS, KS, DS, and heparan sulfate. Hyaluronic acid (HA) is the only non-sulfated GAGs, which is not covalently bound to the protein in any tissue, although specific HA-protein interaction is shown. CS and HA are the most commercially valued GAGs because of their physiological functions and high activity. CS plays an important role in the elasticity and function of the articular cartilage and is mainly attached covalently to core proteins in the form of proteoglycans. CS is composed of an alternating sequence of sulfated and/or unsulfated D-glucuronic acid (GlcA) and N-acetyl-D-galactosamine (GalNAc) residues linked through alternating β (1–3) and β (1–4) glycosidic bonds and sulfated in different carbon positions, as shown in Fig. 3. Some GlcA residues are epimerized into iduronic acid, the resulting disaccharide being referred as dermatan sulfate. The classification and type of CS are dependent on sulfate group placing, namely, sulfate at carbon 4 (CS-A), at carbon 6 (CS-C, more common), both at carbon 4 and 6 (CS-E), at carbon positions 6 of GalNAc and 2 of GlcA (CS-D), and at carbon 4 of GalNAc/carbon 2 of GlcA (CS-B). Sulfation in different positions confers specific biological activities to chondroitin [157, 158].

CS from terrestrial and marine sources contains diverse chain lengths and sulfation. Examples are shark, CS-D; dogfish, CS-A and CS-D; squid and salmon, CS-E and CS-E; and ray, CS-A and CS-C [157]. The endoskeletons of shark are composed of cartilage, which contains up to 29% CS. Processes for isolation of CS from shark cartilage and also from the cartilages of ray, swordfish, dogfish, fins of shark and skate, and salmon nasal cartilage have been reported [158–160]. CS was extracted from fish head cartilage employing hydrolysis by alcalase (55.7 °C, pH 8.2) and chemical treatment of the hydrolyzates by alkaline-alcoholic saline solutions (0. 54 M NaOH, 1.17 V EtOH, and 2.5% NaCl) for selective dissolution followed by ultrafiltration [158, 159]. Optimization of skate (*Raja avirostris*) cartilage hydrolysis for the preparation of chondroitin sulfate has been reported [159]. A low-cost two-step process recovery of CS in non-denaturing conditions was reported. It consists of an enzymatic extraction followed by tangential membrane filtration [160]. Figure 4 provides an overview of chondroitin sulfate recovery and

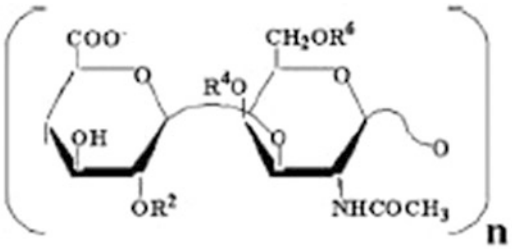

Fig. 3 Chondroitin sulfate derivatives

	R^2	R^4	R^6

purification processes from marine cartilage by-products. CS is quite stable to heating at temperatures as high as 121 °C for several min. Shark cartilage powder is traditionally used for wound healing and as anti-angiogenic, antiarthritic, and antitumor agent. CS is considered a nutritional supplement that provides support for strong, healthy cartilage and joints [161].

Hyaluronic acid (HA) is a linear, high molecular weight unbranched and non-sulfated GAG made by alternating disaccharide units of *N*-acetyl-D-glucosamine and D-glucuronic linked by β-(1 → 3) and β-(1 → 4) glycosidic bonds. It is used in ophthalmological surgeries and cosmetic regeneration of soft tissues. Marine discards have been also explored for HA [158].

The presence of heparin has been reported from different shrimp species. Sulfated glycosaminoglycans that exhibited electrophoretic migration pattern similar to mammalian heparin were recovered (79 ± 2 μg g^{-1} wet processing waste) from Pacific white shrimp (*L. vannamei*) shell discards. Their degradation products suggested the presence of C6-sulfated heparin sulfate [144].

Sea cucumbers are found in shallow water areas of the sea to deep ocean floors, where they live on decaying organic matter. The body wall of the sea cucumber contains high amounts of sulfated glycans, which differ in structure from glycosaminoglycans of animal tissues. The cucumber cell wall polysaccharide was comparable in backbone structure with the mammalian chondroitin sulfate, but some of the glucuronic acid residues displayed sulfated fucose branches. These sulfated glycans exhibit a wide range of biological activities, which include anticoagulant activity, venous antithrombic activity, and recombinant HIV reverse transcriptase activity [4].

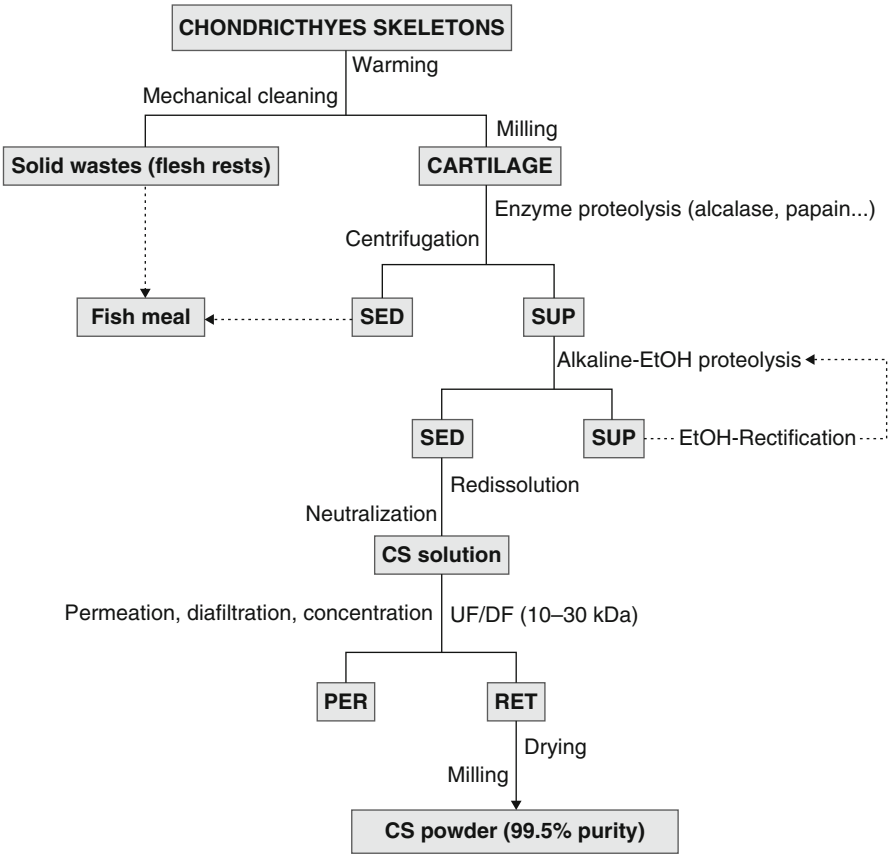

Fig. 4 Overview of chondroitin sulfate recovery and purification processes from marine cartilage by-products. SED, Sediment; SUP, supernatant; PER, permeate; and RET, retentate (Courtesy: Vázquez JA, Ref. 158)

4.3.4 Other Seafood Polysaccharides

Bioactivities and nutraceutical potentials of other polysaccharides from seafood have also been reported in recent times. Mollusks have a wide range of uses in pharmacology; several compounds from mollusks having pharmacological value have been described in the literature [4]. Mytilan, a mussel polysaccharide, possesses antibacterial, antioxidant, and immune-modulating activities. Another mussel polysaccharide, a (1–4)-D-glucan, is known to exhibit antioxidant activity and a protective effect on acute liver injury in mice [137]. The high radical scavenging capacity and total phenolics suggest the nutraceutical potential of the mussel *P. viridis* [83]. Abalone is a source of bioactive compounds having antithrombotic, anticoagulant, anti-inflammatory, antioxidant, and anticancer activities. Polysaccharides and also proteins and fatty acids of abalone provide health benefits beyond basic nutrition [162]. The glucan extract from China white jade snail

(*Achatina fulica*) has significant antioxidant activities, suggesting its potentials as dietary antioxidant [163].

4.4 Mineral-Based Compounds

4.4.1 Bone Powders

Fish bone is a potential source of calcium for use as a fortificant of the mineral. To prepare the product, fish is treated with hot water followed by hot aqueous acetic acid, which softens the bone and converts into an edible form. Superheated steam is preferred to reduce the loss of soluble components from fish tissue, which enables better recovery of the bone within a shorter period. The treated bones are subjected to saponification, degreasing, and degumming. The bone preparation is a good source of bioavailable calcium [164]. Tuna powder is a value-added product that contains a proper balance of calcium and phosphorus; it can be used as a food supplement and for treating osteoporosis [165]. The powder can also combat calcium deficiency in children [166]. The bone preparations of channel catfish have antibacterial activities, with pepsin hydrolyzate of the bone showing the greatest antibacterial activity [167]. A fish bone phosphopeptide (FBP) containing up to 24% of phosphorus has a molecular weight of 3.5 kDa and has high calcium-binding activity, which could be utilized as a nutraceutical [168].

4.5 Marine Biotechnology for the Isolation of Nutraceuticals

Marine biotechnology explores aquatic organisms for the recovery of nutraceuticals, pharmaceuticals, cosmeceuticals, and other products through a multitude of processes. Whereas the conventional processes include liquid–liquid or solid–liquid extraction and enzyme-assisted extraction, advanced biotechnological methods are pressurized liquid extraction, subcritical and supercritical extractions, and microwave- and ultrasound-assisted extractions, among others [93, 169–174]. Membrane separation is beneficial to extract, concentrate, separate, or fractionate bioactive compounds. Membrane bioreactors integrate reaction vessels with membrane separation units for producing materials such as peptides, chito-oligosaccharides, and PUFA from seafood discards [175]. Supercritical carbon dioxide (SC-CO_2) extraction at optimal conditions of 40 MPa and 65 °C was employed to concentrate PUFA from fish oil [176]. Vázquez et al. [158] suggested environment-friendly and sustainable processes combining various microbial, chemical, enzymatic, and also membrane technologies for the recovery of chitin/chitosan, chondroitin sulfate, and hyaluronic acid from marine discards. In this, the conventional process for chitin/chitosan was supplemented with protease treatment and/or lactic acid fermentation for protein removal and also use of fungal deacetylase for conversion of chitin to chitosan. The process appears to have scope for large-scale processing of seafood discards in eco-friendly conditions. The process is depicted in Fig. 5. The authors also reported a pilot plant scale processing of *Penaeus vannamei* by-products using a

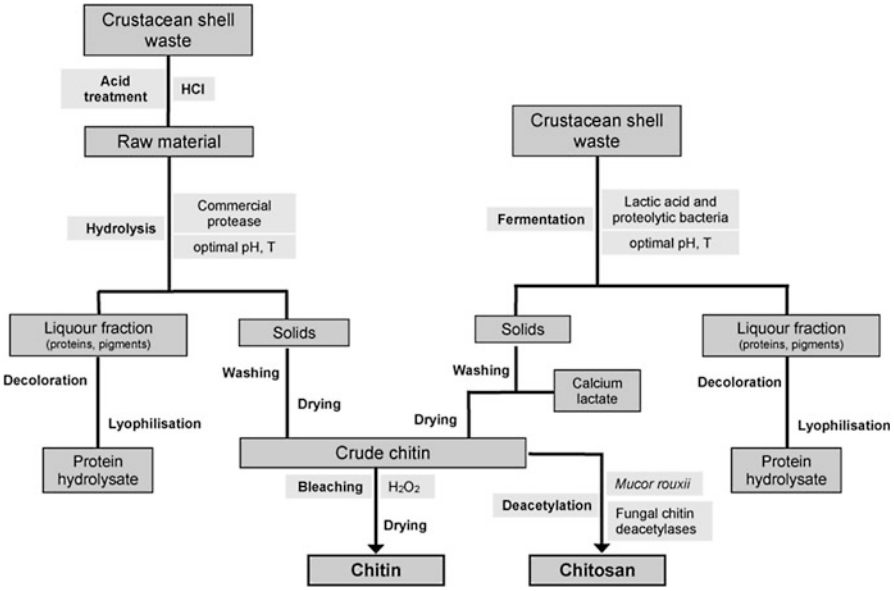

Fig. 5 Eco-friendly process for the preparations of chitin and chitosan from crustacean shell discard (Courtesy: Vázquez JA, Ref. 177)

combination of enzymatic and chemical technologies, which gave chitin with 30% yield. Deacetylation under optimal conditions yielded chitosan having a molecular weight of 82 kDa and 92% deacetylation [177].

4.6 Commercial Status

Interests in marine bioactive products are shown by the fact that in the past 8 years, annually, more than 1000 new compounds from marine organisms have been described [178]. A number of by-products from seafood have already entered commercial markets. Fish trypsin, chymotrypsin, and cold-active chlamysin (lysozyme) are available commercially. Some of the other commercial products include Neptune Aquatein, krill extract (http://ingredientsnetwork.com/neptune-technologies-bioressources-comp249137.html), heat-labile shrimp alkaline phosphatase, uracil-DNA glycosylase from Atlantic cod (http://arcticzymes.com), seafood protein extracts (http://novozymes.com), and protein blends from CIFT, Kochi, India (www.cift.res.in). Animal proteins can be used as a source of bioactive hydrolyzates and peptides with potential for use as functional food ingredients industry [179]. Fish gelatin is available commercially. Collagen or gelatin peptides with a molecular weight around 1–5 kDa containing tripeptides, dipeptides, and also free amino acids are marketed as nutraceuticals for the maintenance of normal bone and tendon integrity, improving joint health. Calcitonin is a hormone (32-amino acid peptide

containing a single disulfide bond), known to participate in calcium and phosphorus metabolism in mammals. The major source of calcitonin is from the parafollicular or C cells in the thyroid gland. Calcitonin produced from salmon is currently commercially available. Ziconotide is a 25-amino acid peptide derived from the ω-conotoxin of cone snail (*Conus magus)* found in tropical waters. Ziconotide has been approved by the US FDA for analgesic use. Other products from fish which are under clinical trials include fish gelatin and Gabolysat and Seacure® (a hydrolyzate of fish proteins) [103, 114].

Annually around 1 million tons of fish oil is produced, with a current global market valued at US$3.9 billion [180]. At present the main use of fish oil is for aquaculture. Current consumption level of fish oil for human nutrition is not adequate [181]. In order to increase the consumption, foods fortified with omega-3 are made available in the markets all over the world. Developments in fortification technology have encouraged more than 200 omega-3 PUFA-fortified foods, such as bread, dairy products, eggs, pasta, biscuits, margarines, and other spreads available commercially in Japan and other countries [182, 183]. Capsules such as Lovaza® which contains ethyl esters of EPA and DHA are available commercially (https://www.drugs.com/pro/lovaza.html). There is, however, concern that because of seafood production reaching a plateau in recent years, the commodity may not be able to fully satisfy future needs. Therefore, other sources such as algae may be required to produce EPA and DHA to meet the increasing demand [181].

Chitosan and its derivatives are finding several end users which, apart from healthcare, medical, food, and beverages, include water treatment, agriculture, biotechnology, and others, encompassing about 30 companies (www.strategyr.com/Chitin_and_Chitosan_Market_Report.asp) with a projection of a market worth of US $4.2 billion by 2020. Anti-inflammatory and antiarthritic dietary supplements such as “Seatone” and “Lyprinol” from mussel are commercially available [137]. Tetrodotoxin (TTX) and saxitoxin are neurotoxins found in many marine organisms including mussels and fish. TTX is currently under clinical trials due to its specific and reversible activity on voltage-dependent sodium channels [181]. CS, hyaluronic acid, and also chitosan have attracted increasing commercial attention in the formulation of cosmeceuticals, nutraceuticals, and food ingredients [103, 158]. Some fish-based cosmeceutical products include Penzim, a natural skin care product from Iceland, derived from natural marine enzymes from the Arctic Ocean from North Atlantic cod (http://www.andra.is/), extracts from male sturgeon gonads, zonase enzyme and gelatin from fish eggs for treatment of psoriasis and eczema, cod sperm as water binder in body lotions, shark cartilage containing chondroitin sulfate used in various creams, squalene from shark liver oil as moisturizer in body lotions, and guanine from fish such as herring and ribbon fish, used in nail polish [103]. A product depicted as “skin food from the sea” contains blend of marine-derived nutrients and is suggested for antiaging (www.nutreeplus.com/antiaging.html). A number of companies like Aquapreneur (www.aquapreneur.com), Sederma (http://www.sederma.fr), NutraIngredients (https://www.nutraingredients.com), SpecialChem (http://www.specialchem4cosmetics.com), Fortitech (fortitech-premixes.com), Copalis (http://www.copalis.fr/), and others have been active in

developing marine ingredients such as collagen, elastin, various peptides, GAGs, alkyl glycerols, fish oil, hydrolyzed proteins, calcium supplements, glucosamine, hyaluronic acid, and chondroitin sulfate for food, pharmaceutical, and other purposes.

5 Conclusions

Seafood items are rich in nutrients that can have positive influence on human health. Nutrient contents depend on the species, and thus consumption of individual species significantly determines the nutritional benefits derived by individual consumers. The health benefits derived from seafood items also depend on the frequencies of their consumption, as well as quantities consumed. Seafood items and also their processing discards are good sources of many nutraceuticals. In recent times, marine biotechnology has made rapid advancements, which could be used to recover nutraceuticals and other bioactive compounds from seafood discards. There is robust evidence that fish oil and its component fatty acids, especially EPA plus DHA, are beneficial in maintaining cardiovascular health in normal adults. Fish protein hydrolyzates contain peptides with significant antihypertensive and other bioactivities. Fish cartilage products such as shark cartilage and chondroitin sulfate, glucosamine, and other glycosaminoglycans are able to alleviate rheumatoid arthritis. Fish skin collagen and gelatin have a potential to replace bovine collagen and gelatin in food, pharmaceuticals, and cosmetics. Chitosan and its derivative offer immense applications in human health and cosmeceutical fields. There is large potential for development of functional foods fortified with nutraceuticals such as fish oils, bioactive peptides, and others. Gelatin, chitosan, and its derivatives can be carriers of nutraceuticals and drugs and food packaging materials. Uses of marine nutraceuticals are increasing in countries such as Japan and others. As Borresen [184] pointed out, there is a need for nutritionists and other scientists to evaluate the nutritional value of fishery items that can lead to total utilization of the commodity for human welfare.

Abstract

Starchy roots and tuber crops are important components in the human diet. There are number of roots and tubers belonging to several species and make an extensive biodiversity even within the same geographical location. From the ancient time of human evolution starchy roots and tubers have been a part of food choices and add variety to the modern diet in addition to offering numerous desirable nutritional and health benefits such as anti-obesity, antioxidative, hypoglycemic, hypocholesterolemic, antimicrobial, and immunomodulatory activities, among others. There are a number of bioactive constituents, namely, phenolic compounds, saponins, bioactive proteins, glycoalkaloids, phytic acids, and hydroxycoumarins, reported in tuber crops. Except the common potatoes, sweet potatoes, and cassava, other starchy tuber crops are yet to be explored for their nutritional and health benefits to use as functional foods. Some edible tubers are served for traditional and alternative medicinal sources. Tubers and roots are potential functional foods and nutraceutical ingredients to manage a number of ailments and to ensure general wellness.

Keywords

Antioxidative · Hypoglycemic · Hypocholesterolemic · Phenolic compounds · Saponins

List of Abbreviations

AMPK	Adenosine monophosphate-activated protein kinase
ACC	Acetyl coenzyme A carboxylase
DPPH	2,2, diphenyl-1-picrylhydrazyl
ERK	Extracellular signal-regulated protein kinase
FAO	Food and Agriculture Organization
GAE	Gallic acid equivalents
GGT	Glutamyltransferase
HCC	Hepatocellular carcinoma
LPS	Lipopolysaccharide
MTT	Microculture tetrazolium treatment assay
NCDs	Noncommunicable diseases
NASA	National Aeronautics and Space Administration
NO	Nitric oxide
IFN-γ	Interferon- γ
ORAC	Oxygen radical absorbance capacity
OGTT	Oral glucose tolerance test
SHBG	Sex hormone binding globulin
SOD	Superoxide dismutase
TPC	Total phenolic content
t-BHP	Tert-butylhydroperoxide
WSSP	White skinned sweet potatoes

1 Introduction

Roots and tuber crops are important cultivated staple carbohydrate sources, second to cereals, generally in tropical regions in the world. During fast few decades the roles of roots and tubers in the economy and food systems of developing countries have been changed. They are subsistence crops of pivotal importance in consumers and producers in low-income countries. In addition, they provide a substantial input for animal feeds and industrial products such as distilled spirits, starches, fermented foods, and other minor products. Economically important roots and tubers include potatoes, cassava, sweet potatoes, yams, and aroids.

An important agronomic advantage of root and tuber crops as staple foods is their favorable adaptation to diverse soil and environmental conditions and a variety of farming systems with minimum agricultural inputs. Further, the variation in the growth pattern and production requirements of root and tubers make their way into distinct production systems and varied consumption uses. However, roots and tuber crops are bulky in nature with high moisture content of 60–90% leading them to be associated with high transportation cost, short shelf life, and limited market margin in developing countries where they are produced.

The contribution of starchy roots and tubers to the energy supply in different populations varies with the region and the country. Their annual global production is approximately 845 million tons [1]. Asia is the main producer of starchy roots and tubers followed by Africa, Europe, and America. Asian and African regions produced 43% and 33%, respectively, in the global production of roots and tubers [1]. Cassava, potatoes, and sweet potatoes consist of 90% global production of root and tuber crops though a number of species and varieties are consumed [1]. Roots and tubers provide dietary energy in the form of carbohydrates, dietary fiber, vitamins, and minerals (Table 1; [2]). It is interesting to note that high yields of roots and tubers give more energy per land unit per day than those of cereal grains [3]. In general, roots and tubers provide low protein contents ranging from 1% to 2% on a dry weight basis [3]. However, potatoes and yams contain high amounts of proteins among other tubers. Sulfur-containing amino acids, namely, methionine and cystine, are the limiting ones in root crop proteins. Cassava, sweet potatoes, potatoes, and yam contain some vitamin C, and yellow varieties of sweet potatoes, yam, and cassava contain β-carotene. Roots and tubers are deficient in most other vitamins and minerals but contain significant amounts of dietary fiber [3]. Nutritional value of roots and tubers vary with variety, location, soil type, and agricultural practices, among others.

Noncommunicable diseases (NCDs) are in rise in developed as well as developing countries on concurrence with increasing aging population worldwide. Dietary and lifestyle factors play a prominent role in oxidative stress which contributes immensely to the etiology of NCDs as well as the aging process. Several epidemiological studies showed the association between plant food intake and reduced NCDs [4–7]. Furthermore, identification of specific plant

constituents which convey health benefits is of much interest. Foods of plant origin consist of a wide range of nonnutrient phytochemicals which are synthesized as secondary metabolites and serve a wide range of ecological roles in plants [8].

Tubers and root crops contain several bioactive compounds such as saponins, phenolic compounds, glycoalkaloids, phytic acids, carotenoids, and ascorbic acid among others. A number of bioactivities, namely antioxidant, immunomodulatory, antimicrobial, antidiabetic, antiobesity, and hypocholesterolemic activities are reported for tubers and root crops. This chapter discusses the distribution and bioactivities of several selected nutrient and nonnutrient phytochemicals in starchy roots and tuber crops.

Table 2 Common tuber crops worldwide

	Botanical name	Family	Common name
Potatoes	*Solanum tuberosum*	*Solanaceae*	
Country potato Hausa potato	*Solenostemon rotundifolius*	*Lamiaceae* (mint family)	Innala, ratala (Sri Lanka)
Cannas	Canna edulis	Cannaceae	Buthsarana (Sri Lanka)

Elephant foot yam	*Amorphophallus paeoniifolius*	*Araceae*	White pot giant arum; Stink lily

2 Starchy Roots and Tuber Crops

Roots and tubers are belonging to different botanical families but are grouped together as all types produce and store edible food in underground parts. Starchy roots and tubers store starch in subterranean stems, roots, rhizomes, corms, and tubers. Potatoes and yams are tubers whereas taro and cocoyams are derived from corms, underground stems, and swollen hypocotyls. Cassava and sweet potatoes are storage roots whereas canna and arrowroots are edible rhizomes. Vegetative propagation is a common characteristic of roots and tubers. These plant parts include tubers (potatoes and yams), stem cuttings (cassava), vine cuttings (sweet potatoes), and side shoots, stolons, or corm heads (taro and cocoyam). Table 2 presents commonly consumed starchy tuber and root crops worldwide.

2.1 Potato (*Solanum tuberosum*)

Potato is ranked currently at the fourth place of the highly consumed crops through the world followed by maize, wheat, and rice. The average annual potato production is about

381 million tones [1]. Potato has a highland origin and has been domesticated in the high Andes of South America. It is a popular food crop in the cool highland areas of South America, Asia, and Central and Eastern Africa [9]. China is the biggest potato producer followed by Russia and India. The average energy contribution from potato in the world ranged from 41 to 130 Kcal per day for developing and developed countries, respectively [10]. Potato is a high yielding cash crop with a short cropping cycle of 3–4 months. Further, potato is a significant source of carbohydrates and they can be processed into a variety of foods such as mashed potato, chips and fries, deep frozen and dehydrated products. Starch derived from potato has shown a great economic importance. The productivity of potato in terms of nutrients is higher compared to maize, wheat, and rice.

Potato produces high amount of calories, protein, and calcium from the same land than those of other major crops leading its significance as a food security crop. Potatoes have several secondary metabolites which demonstrated antioxidant as well as other bioactivities [11].

2.2 Sweet Potato (*Ipomea batatas* L.)

Sweet potato originated from the Central America and the cultivation has been spread through the tropical, subtropical, and warm temperate countries. In Asia it is predominate in lowland conditions. Sweet potato is known as the seventh largest food crop with an annual production of 106 million tones [1]. They are known as an insurance crop as the cultivation can be extended throughout the year under suitable climatic conditions and its greater capacity to withstand the adverse climatic changes. In addition, the crop can be harvested for an extended period of time giving advantages in the poor communities. Further, the short growing cycle of sweet potato is an advantage for the flexible planting and harvesting conditions in spite of the climatic changes. Rice and sweet potato can be grown with crop rotation. China is the largest producer of sweet potato [12]. National Aeronautics and Space Administration (NASA) has selected sweet potatoes as a potential crop to be grown and incorporated into the menus for astronauts on space missions due to its unique features and nutritional value [13]. It can be consumed in many ways such as boiled, baked, fried, boiled canned or frozen [14]. The biofortified sweet potatoes provide considerable amounts of beta-carotene, and it has been proved as a cost-effective strategy to provide vitamin A for the vulnerable communities including young children, pregnant and lactating mothers. Sweet potato is an important source of many vitamins, minerals, and dietary fiber. Further it is a good source of nonnutritive bioactive compounds such as phenolic acids and anthocyanins [15–19]. The different flesh colors such as cream, deep yellow, orange, and purple are attributed to the degree of anthocyanin and carotenoids content of sweet potatoes [15–18, 20].

2.3 Cassava (*Manihot esculenta*)

Cassava is a perennial shrub belonging to the family of *Euphorbiaceae*. Nigeria, Thailand, Indonesia, and Brazil are the leading cassava producers in the world. The

*Manihot g*enus comprises of 98 species and the most prominent species is *M. esculenta* [21]. The crop is originated in South America and has speared through tropical and subtropical regions of Africa and Asia [22]. Cassava is the sixth most important food crop in the world with about 268 million tones annual production [1]. It is the most widely cultivated root crop and contains nearly the maximum theoretical concentration of starch on a dry weight basis among food crops. The edible roots can store the foods underground for up to 3 years contributing for the food security consistently.

Different range of food products are derived from cassava such as traditional and novel food products, fermented products, ethanol, and livestock feeds. The starch extracted from cassava is used as the raw material for the production of bread, crackers, pasta, and tapioca. Cassava leaves are also a nutritious food addition. Through the west, steamed and boiled cassava roots are pounded in to sticky dough and consumed as *fufu*. The Philippines consume cassava pulp made into pellet as *landing* or cassava rice [23]. Cassava starches are popular in the industry due to its high availability (75–80% of the dry matter content of roots) and the easily extractable nature due to the lower content of protein and fat. Further, cassava is used for the manufacturing of paper, textiles, adhesives, and high fructose corn syrup [14].

Cassava is well known for the production of hydrogen cyanide (HCN) in toxic quantities. The presence of two types of cyanogenic glycosides such as linamarin (93% of the cyanide content) and lotaustralin has been reported [24]. High doses of HCN about 0.5–3.5 mg/Kg of body weight can exert lethal effects. Further, non-cyanogenic glycosides, hydroxycoumarins such as scopoletin, terpenoids, and flavonoids, have been investigated in cassava roots. Both roots and leaves contain the cyanogenic glycosides and the content is not significantly different from the roots. Despite that cassava leaves are a good source of calcium and protein [23].

2.4 Yams (*Dioscorea* sp.)

Yams are a group of many species of plants bearing rhizomes or carbohydrate rich underground tubers belonging to the genus *Dioscorea.* They are mainly distributed through the tropics and only a few numbers can be found in temperate regions of the world [25]. Yams are staple foods in West Africa, Southeast Asia, and the Caribbean regions in the world and help to ensure the food security and livelihood of at least 60 million people in West Africa [26]. They rank as the third important source of calorie and protein contributor for the livelihood of Benin and Ghana populations. The contribution for the protein intake is even higher than the widely grown and available cassava. They are classified into the genus *Dioscorea* of the family of *Dioscoreaceae*, which is one of the oldest members of the monocot group [27, 28]. Even though there are many varieties present, only few numbers of species are popular throughout regions in the world. About 603 species have been identified and from them 50 species are edible. *Dioscorea alata*, *Dioscorea esculenta Dioscorea rotundata*, *Dioscorea hispida*, *Dioscorea bulbifera*, *Dioscorea trifida*, *Dioscorea nummularia*, and *Dioscorea pentaphylla* are prominent yam species, among others.

A wide variation in morphological characteristics presents within the same species of yams and these include size of tuber, color of flesh, presence of roots, and thickness of peel (Fig. 1).

The yams are usually grown in intercropping systems with coconut palms. Further, yams can be easily grown due to their specific ability to thrive under low agricultural inputs, having tolerance to stress environmental conditions, ability to resist pest attacks, and high adaptability to mixed cropping systems. They are considered as seasonal crops which are generally planted in the end of March to April [29]. The harvesting season begins usually during the period of December to February. After harvesting, these yams would be on a dormancy period until the favorable conditions are met for the growth of new plant.

Dioscorea alata is called as winged yam, greater yam, or water yam and includes a wide array of tubers referred in several local names in different countries. It has been reported that *D. alata* are originated in Asia [30]. They are widely cultivated in India, Sri Lanka, South East Asia, and Pacific Islands and they prefer the low lands up to 800 m. The tubers are famous for the sweetness and the delicacy of the tubers. *Dioscorea alata* contains only a single large tuber per vine [30]. The shapes of the tubers have significant differences. They may be globular, long, and flattened or palmate. Sometimes they may be branched or lobed but usually large in size.

Yam tubers have various bioactive components, namely, mucin, dioscin, dioscorin, allantoin, choline, polyphenols, diosgenin, and vitamins such as carotenoids and tocopherols [31, 32]. Mucilage of yam tuber contains soluble glycoprotein and dietary fiber. There are evidences to show hypoglycemic, antimicrobial, and antioxidant activities of yam extracts [33, 34]. Yams may stimulate the proliferation of gastric epithelial cells and enhance digestive enzyme activities in the small intestine [35]. *Dioscorea esculenta* (Chinese yam, lesser yam, sweet yam) is one of the main yam species found in Sri Lanka [29]. They are native to Indo-China and at present they have widely been distributed through Madagascar and New Guinea. Usually the yams are cultivated in the lowland up to 700 m. Their stems contain a large number of tubers and they are generally ovoid and cylindrical in shape [29]. In addition, the tubers may be intermingled and covered with numerous spiny roots. The color of the tuber flesh varies from white to yellowish white. Leaves are broadly ovate with a chordate base. The raw tubers are known for a number of medicinal properties [30].

*Dioscorea pentaphyll*a is known as five-fingered yam and buck yam. These tubers are variable in shape such as finger shaped, cylindrical, or shapeless. The skin of the tuber is brown in color and the flesh ranges from white to yellow. Sometimes there may be violet spots in the flesh. The species is native to South East Asia and is grown in teak forests or forest borders with altitudes of 500–1000 m. Tubers are consumed as staple food especially as an alternative to maize in the dry areas. It is used as a raw material for the production of starch and alcohol. The origin of *Dioscorea bulbifera L*. is evidenced from Asia, Africa, and Oceania and are known as air potato, aerial yam, or potato yam. The characteristics of the vine are documented as stem round, twining to the left, without spines subterranean tuber small or absent, and spongy.

Fig. 1 Different accessions of *Dioscorea alata*

Leaves are alternate, broad, round, heart-shaped, and leaf blade embossed with well-marked veins. In addition, less known *Dioscorea* species have been reported and they include *Dioscorea rotundata Poir.; D. cayenensis* (African yam, white yam); *Dioscorea trifida L.* (*Cushcush*, Indian yam); and *Dioscorea nummularia Lam.* (Pacific yam, hard yam).

2.5 Aroids

Aroids are tuber or underground stem-bearing plants belonging to the family Araceae. Aroids can be grown in both rain-fed and irrigated climates. Taro is used as the generic name for the four related species belonging to *Araceae* including edible tubers such as taro (*Colocasia*), giant taro (*Alocasia*), tannia or yautia (*Xanthosoma*), elephant foot yam (*Amorphophallus*), and swamp taro (*Cyrtosperma*) [36]. They serve as a staple food for many islands of the South Pacific, such as Tonga and Western Samoa, and in Papua New Guinea. The cultivation has been extended to Asia, Africa, Pacific and Caribbean islands. Aroids originated from the Indo–Malayan region between Myanmar and Bangladesh. They are known to have thousands of different cultivars and most of them prefer the humid environments. The young leaves are eaten as vegetables. They are well cultivated in the low lands and highlands up to 2.7 m above the sea level. Aroids are considered as the staple in Irian Jaya, the Moluccas, and Mentawai Islands in West Sumatra. They can be consumed as chips as well as steamed forms among others.

3 Nutrients in Roots and Tubers

Starchy roots are major contributors to the supply of carbohydrates in the diet. The protein content of the tubers varies from 1% to 2% on fresh weight basis. The limiting amino acids of the tubers are identified as sulfur-containing amino acids, namely, methionine and cystine, whereas sweet potato contains lysine [3]. Vitamin C are available in cassava, sweet potato, and potato. Further, potato is a dietary source of micronutrients such as zinc and iron. Sweet potato cultivars are known for the dietary fiber, mineral, and vitamins including β-carotene and tocopherols. Especially the yellow-fleshed sweet potato varieties are known for their high β-carotene content. Taro and potato have appreciable level of potassium. All most all the tuber species are rich with dietary fiber (Table 2).

3.1 Proteins

Roots and tubers are not considered as appraisable sources of proteins and the contents are variable. In populations worldwide, global contribution of proteins from roots and tubers in the diet is less than 3%. However, this contribution varies from 5 to 15% depending on the quantity consumed as a staple in African

countries [9]. Cassava contains only 1–2% of protein on dry weight basis with low content of sulfur-containing amino acids [37].

Dioscorin is the main storage protein known to present in *Dioscorea* yams and is about 90% of water extractable soluble proteins in a majority of *Dioscorea* species. Among many activities reported dioscorin has shown carbonic anhydrase and trypsin inhibitor activities [38]. Further, dehydroascorbate reductase (DHA) and monodehydroascorbate reductase (MDA) and immunomodulatory activities of dioscorin in the presence of glutathione have been reported [39]. Dioscorin from fresh yam (*Dioscorea batatas*) showed 2,2, diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity [40]. Further, dioscorin demonstrated angiotensin converting enzyme (ACE) inhibitory and antihypertensive activities on spontaneously hypertensive rats [31, 41, 42].

Sporamin is a soluble protein and serves as the main storage protein of sweet potato tubers. It accounts for 60–80% of tubers total proteins [43]. The sporamin of sweet potatoes was initially known as ipomoein and is a nonglycoprotein without glycan. The sporamin is generally stored in vacuoles in the monomeric form. This protein is initially produced as preprosporamin, which is synthesized by the membrane-bound polysomes in the endoplasmic reticulum (ER) [44]. Sporamin is a trypsin inhibitor with a kunitz-type trypsin inhibitory activity which has potential application in the transgenic insect-resistant plants [45]. Furthermore, sporamin showed various antioxidant activities related to stress tolerance, such as DHA and MDA reductase activities [46].

Patatin is a storage protein in potato tubers and contributes to about 40% of soluble proteins [47]. It is a glycoprotein in the storage of parenchyma cells and exhibited a number of bioactivities [48].

3.2 Carotenoids

Carotenoids serve as the most extensively available natural pigments with yellow, orange, and red colors in plants. Carotenoids, either isolated from natural sources or chemically synthesized, have been widely utilized as natural nontoxic colorants in manufactured foods, drinks, and cosmetics due to the distinctive coloring properties. The majority of carotenoids are unsaturated tetraterpenes with the same basic C 40 isoprenoid skeleton resulting from the joining of eight isoprene units in a head-to-tail manner with the exception of the tail-to-tail connection at the center. They are hydrocarbons and are soluble in nonpolar solvents such as hexane and petroleum ether. However, the oxygenated derivatives of carotenes, such as xanthophyll, dissolve better in polar solvents such as alcohols. Carotenoids are important molecules in living organisms. They participate in a variety of photochemical reactions in photosynthetic systems of higher plants, algae, and phototrophic bacteria [49].

Carotenoids possess numerous bioactivities and are well known for provitamin A activity. In addition, they play important roles in human health and nutrition, namely antioxidant activity, regulation of gene expression, and induction of cell-to-cell communication [50]. It has been demonstrated that zeaxanthin and lutein are stable

throughout artificial digestion, whereas β-carotene and all-trans lycopene are degraded in the jejunal and ileal compartments. Among the isomers, the stability of 5-cis lycopene is superior to that of all-trans, and 9-cis lycopene [51]. Yellow to orange varieties of sweet potatoes and yams are good sources of carotenoids and lutein, zeaxanthin, violaxanthin and neoxanthin are major carotenoids in potatoes [52]. Further, digestive stability of lutein and zeaxanthin of yellow-fleshed potatoes were reported to be high ranging from 70% to 95% [53].

3.3 Ascorbic Acid

Ascorbic acid, also known as vitamin C, is a water-soluble vitamin. Ascorbic acid naturally occurs in plant tissues, commonly in fruits and vegetables but considerable quantities also present in several root crops. However, the level could be reduced during cooking of roots unless skins and cooking water are utilized [54]. Root crops, if carefully prepared, can make a significant contribution to the vitamin C content of the diet. Potatoes serve as a principal source of vitamin C in British diets, providing 19.4% of the total requirement [3]. In general, yams contain 6–10 mg of vitamin C/100 g and may vary up to 21 mg/100 g. Further, the vitamin C content of potatoes is very similar to those of sweet potatoes, and cassava. The concentration of ascorbic acid varies with the species, location, crop year, maturity at harvest, soil, nitrogen and phosphate fertilizers [3].

4 Nonnutrient Compounds in Roots and Tubers

Bioactive compounds in plants are secondary metabolites having pharmacological or toxicological effects in humans and animals. Secondary metabolites are produced within the plants besides the primary biosynthesis associated with growth and development. These compounds perform several essential functions in plants, including protection from undesirable effects, attraction of pollinators, or signaling of essential functions, among others. Roots and tubers are rich with nonnutritive phytochemicals. Yam tubers contain mucin, dioscin, dioscorin, allantoin, choline, polyphenols, diosgenin, and saponins [32]. Potatoes are rich with phenolic acids including chlorogenic acids and flavonoids and some varieties are rich sources of anthocyanins [55]. Cultivation location, climatic factors, soil type, agricultural practices, and environmental stress are the key important determinants of the nutritional and phytochemical profile of tubers.

4.1 Phenolic Compounds

Phenolic compounds are important molecules with an aromatic ring attached with one or more hydroxyl groups. They are derived from biosynthetic precursors such as pyruvate and acetate, amino acids such as phenyl alanine and tyrosine, and acetyl

CoA and malonyl CoA by following the pentose phosphate, shikimate, and phenylpropanoid metabolism pathways [8, 56]. Among groups of phenolic compounds abundantly found in plants simple phenolics, phenolic acids, flavonoids, coumarins, stilbenes, tannins, lignans, and lignins are reported to possess myriad of health benefits [8]. Cultivar, environmental conditions, cultural practices, post-harvest practices, processing and storage conditions affect the quantity of phenolic compounds present in a given species of plant material, among others [57]. Phenolic acids found in plants are categorized as hydroxybenzoic and hydroxycinnamic acids. Hydroxybenzoic acids include gallic, *p*-hydroxybenzoic, vanillic, syringic, and protocatechuic acids, among others. The hydroxycinnamic acids include *p*-coumaric, caffeic, ferulic, and sinapic acids. These latter compounds with a phenyl ring (C_6) and a C_3 side chain are known as phenylpropanoids and serve as precursors for the synthesis of other phenolic compounds. Flavonoids are common and known constituents synthesized by condensation of a phenylpropanoid compound with three molecules of malonyl coenzyme A. The subclasses such as flavones, flavonols, flavonones, flavononols, isoflavones, flavans (catechins and anthocyanidins), and flavanols are common molecules of flavonoids, among others. Flavones and flavonols are present as aglycones in foods [57]. The phenolics present in tubers render several health benefits, namely, antibacterial, anti-inflammatory, and antimutagenic activities.

4.2 Saponins and Sapogenins

Saponins are high molecular weight secondary metabolites and are glycosides consisting of a sugar moiety linked to a triterpene or steroid aglycone. The common biological feature of saponins include ability to lyse erythrocytes and foam [58]. The aglycone portion of the saponin molecule is called sapogenin which is hydrophobic. The hydrophilic sugar moiety present in saponins include one to three straight or branched sugar chains and they are composed of D-glucose, L-rhamnose, D-galactose, D-glucuronic acid, L-arabinose, D-xylose, and D-fucose [59]. Depending on the type of genin present, saponins are divided into three groups, namely, triterpenoid saponins, steroidal saponins, and steroidal alkaloid saponins. Steroidal saponins are precursors for the chemical synthesis of birth control pills (with progesterone and estrogen), similar hormones, and corticosteroids [60]. According to recent findings steroidal saponins could be a novel class of prebiotics to lactic acid bacteria and are effective candidates for treating fungal and yeast infections in humans and animals [61].

4.3 Steroidal Glycoalkaloids

Glycoalkaloids are belonging to phytochemicals found in species of the genus *Solanum* and *Veratrum* [62, 63]. Alkalioids are nitrogen-containing secondary metabolites and are found in several higher plants as well as microorganisms and

animals [64]. The skeleton of alkaloids is derived from amino acids and moieties from other pathways, such as those originating from terpenoids. The alkaloids in plants act as phytotoxins, antibactricides, insecticides, fungicides, and as feeding deterrents to insects, herbivorous mammals, and mollusks [65]. The two main glycoalkaloids present in commercially cultivated potatoes include α-chaconine and α-solanine which are glycosylated derivatives of the aglycone solonidine. Wild potatoes (*Solanum chacoense*) contain leptinine 1, leptinine 11, leptine 1, leptine 11, and dehydrocommersonine [66]. The major glycoalkaloid reported in tomatoes is α-tomatine which is a glycosylated derivative of aglycone tomatidine. Steroidal alkaloids and their glycosides present in several species of Solanum are known to possess a variety of biological activities such as antitumor, antifungal, teratogenic, antiviral, and antiestrogenic activities. Certain glycoalkaloids are used as anticancer agents [67, 68]. The steroidal alkaloid glycosides showed cytotoxic activity against various tumor cell lines [69].

5 Bioactivities of Phytochemicals in Roots and Tubers

5.1 Hormonal Activities

Some roots and tubers especially yams belonging to *Dioscorea* have demonstrated health effects due to the bioactivities affected on hormones. According to Wu et al. [70] yam diet has ability to reduce the risk of cancer and cardiovascular diseases in postmenopausal women. They showed that the levels of serum estrogen and sex hormone binding globulin (SHBG) increased significantly after subjects had been on a yam diet for 30 days. Further, serum hormone parameters such as estrogen, estradiol, and SHBG did not change in controls who had sweet potatoes compared to those who had yam diet. The risk of breast cancer increased by estrogens might be balanced by the elevated SHB and the ratio of estrogen plus estradiol to SHBG. The study further showed that increased SHBG levels had a protective effect against the occurrence of type 2 diabetes mellitus and coronary heart diseases in postmenopausal women [70].

Chen et al. [71] showed that chronic administration of *Dioscorea* may enhance the bone strength. Further it shed light on the role of *Dioscorea* in bone remodeling and osteoporosis during the menopause [71]. Administration of *Dioscorea* to ovariectomized rats decreased the porosity effect on bones and increased the ultimate force of bones. The changes in biochemical and physiological functions seen in these animals were similar to those in menopausal women [71].

5.2 Antioxidant Activity

Antioxidants play a pivotal role in attenuating several chronic diseases such as different types of cancer, cardiovascular diseases, arthritis, diabetes, autoimmune and neurodegenerative disorders, and aging in which oxidative stress plays a major

role in the development of the diseases. Several studies provide evidences for the antioxidant activities of roots and tuber crops.

Potato is a rich source of a number of phytochemicals and exhibit antioxidant activities to varying degrees. Methanolic extract of potatoes demonstrated high antioxidant activities as determined by DPPH radical scavenging activity [72]. Further, the total phenolic content (TPC) ranged from 16.6 to 32 mg gallic acid equivalents (GAE)/100 g dry matter, and EC_{50} of DPPH radical scavenging activity of potatoes extract was 94 mg/mL [72]. The major phenolic compound reported in potato was chlorogenic acid which constituted more than 90% of its phenolics [73]. Extracts of flavonoids and flavones of potatoes showed high scavenging activities of reactive oxygen species. Potatoes scavenged 94% of hydroxyl radicals [74]. In addition, a range of hydrophilic oxygen radical absorbance capacity (ORAC) of 200–1400 μmol trolox equivalents/100 g fresh weight (FW) and the lipophilic ORAC range of 5–30 nmol alpha-tocopherol equivalents/100 g FW were reported for potatoes [75]. Further the TPC of water soluble and insoluble extracts of 15 Andean potato cultivars ranged from 2.4 to 28 μmol GAE/g (dm) and TFC varied between 0.9 and 4.8 μmol CE/g (dm) [76]. Antioxidant activities varied between cultivars. In addition, five phenolic compounds, namely, gallic acid, protocatechuic acid, cholorogenic acid, syringaldehyde, and epicatechin, were identified as major compounds.

Han et al. [77] showed that ethanolic extracts of purple-fleshed potato flakes had effective free radical scavenging activity and inhibition of linoleic acid oxidation in a rat model. Further, potato extracts enhanced hepatic manganese superoxide dismutase (SOD), Cu/Zn-SOD, and glutathione peroxidase (GSH-Px) activities as well as mRNA expression, suggesting a reduced hepatic lipid peroxidation and an improved antioxidant potential [77]. Potatoes contain water-soluble antioxidant compounds such as glutathione and ascorbic acids [52].

Ji et al. [78] reported the contents of phenolic compounds and glycoalkaloids of 20 potato clones and their antioxidant, cholesterol uptake, and neuroprotective activities in vitro. Peels of purple and red pigmented potato clones showed higher phenolic content than those of yellow and un-pigmented clones [78]. Chlorogenic acid (50–70%) and anthocyanins, namely, pelargonidin and petunidin, were identified as major phenolic compounds present in potatoes. Major glycoalkaloids reported to present in potatoes included α-chacoine and α-solanin and their contents were reduced by granulation process. Peels of potato clones showed the highest DPPH radical scavenging activity followed by flesh and granules [78]. Thus, potato peels can be utilized as a potential source of nutraceuticals. In addition, carotenoids such as lutein, zeaxanthine, and violoxanthine present in potatoes contribute to the antioxidant activity. The contents of carotenoids range from 50 to 100 μg in white-fleshed varieties to 2000 μg per 100 g FW in orange-fleshed cultivars [79].

The peels of sweet potato possessed a potent wound-healing effect which appears to be related to the free radical scavenging activity of the bioactive constituents and their ability in lipid oxidation inhibition [80–82]. According to Suzuki et al. [80] sweet potato fiber was effective in healing of burns or decubital wounds in a rat model. They further observed the reduction of wound area and changes of the quality

of the wounds after treating with sweet potato fiber compared to those of the control. Later, Chimkode et al. [81] also showed that petroleum ether extract of sweet potato had a significant effect on the closure of scar area for the complete epithelialization compared to the control.

The methanolic extracts of the peels and peel bandage of sweet potato tubers were screened for wound-healing effect by excision and incision wound models on Wistar rats [82]. It was found that hydroxyproline content was significantly increased in the test group than that of wounded control. This may improve collagen synthesis which affects the increased wound healing. Further, the content of malondialdehyde decreased in the test groups compared to that of wounded control, indicating lipid oxidation inhibitory effect of sweet potato peels [82].

The flavonoid contents of different selected tuber crops such as sweet potato, potato, coco yam, dasheen (*Colocasia esculenta*), St Vincent yam, yellow yam (*Dioscorea cayenensis*), and water yam (*Dioscorea alata*) varied from 71.5 to 390.7 CE/100 mg. Water yam (*Dioscorea alata*) reported the highest DPPH radical scavenging activity of 96% among others [83].

Phenolic content and antioxidant activities of yam vary with the cultivar. Cornago et al. [84] showed that purple yam (*Dioscorea alata)* and lesser yam (*Dioscorea esculenta)* had a TPC ranging from 69.9 to 421.8 mg GAE/100 g dry weight. The purple yam variety *Daking* showed the highest TPC and antioxidant activities as measured by DPPH radical scavenging activity, reducing power and ferrous ion chelating capacity whereas varieties *Sampero* and *Kimabajo* showed the least.

Water and ethanolic extracts of yam peel showed the antioxidant activity on tert-butylhydroperoxide (t-BHP)-induced oxidative stress in mouse liver cells, namely Hepa 1–6 and FL83B [85]. Ethanolic extracts (EE) of yam peel exhibited a better protective effect on t-BHP-treated cells than that of water extracts (WE). Further, EE had increased catalase activity whereas WE decreased it.

Chen and Lin [86] showed that heating affected the TPC, antioxidant capacity, and the stability of dioscorin of various yam tubers. Cooked yams showed lower TPC than their raw counterparts. Further, the DPPH radical scavenging activities declined with increasing temperature. TPC and dioscorin content of yam cultivars (*Dioscorea alata* L. var. Tainung No. 2) and Keelung yam (*D. japonica* Thunb. var. pseudojaponica (Hay.) Yamam) correlated with DPPH radical scavenging activity and ferrous ion chelating activity [86]. Phytochemicals of yams seem to enhance the activities of endogenous antioxidant enzymes. The administration of yams decreased the levels of γ-glutamino transpeptidase (GGT), low-density lipoprotein, and triacylglycerol in serum of rats in which hepatic fibrosis was induced by carbon tetrachloride [87]. Treatment of rats with yams increased the antioxidant activities of hepatic enzymes, namely, glutathione peroxidase and superoxide dismutase [87].

Limited studies have reported the antioxidant activities of cassava roots. The antioxidant activities of organically grown cassava tubers were higher than those of mineral-base fertilized roots. They further found that TPC and flavonoid content (FC) were significantly higher for organic cassava compared to that of cassava grown with inorganic fertilizers [88].

5.3 Antiulcerative Activities

The antiulcerative activity of sweet potato tubers was studied in a rat model [89]. The extract of sweet potatoes did not show any toxic or deleterious effects by oral route up to 2000 mg/kg. Further, superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), and glutathione reductase (GR) activities were significantly elevated by administration of tuber extracts in treated rats, indicating the ability of restoring enzyme activities compared to the control. Kim et al. [16] showed that butanol fraction of sweet potato could be a better source for treating gastric ulcers induced by excessive alcohol intake.

5.4 Anticancer Activities

In the contemporary society cancer has been a leading cause of death mainly due to unhealthy food habits and lifestyle. Cancer is a multistage disease and tapping at any initial juncture could help to attenuate the disease condition. There are evidences to show that dietary components, specifically present in plant foods, are important to reduce and prevent the risk of cancers. A number of phytochemicals found in root and tubers have demonstrated anticancer effects in several types of carcinoma cell lines and animal models.

Extracts of sweet potatoes demonstrated antiproliferative activity in human lymphoma NB4 cells [90]. Further it has been shown that aqueous extract of sweet potatoes had higher antiproliferative activity than that of ethanol extracts. Cell proliferation was analyzed at 48 h after in human lymphoma NB4 cells which had been cultured with several concentrations of extracts 0, 25, 50, 100, 200, 400, 800, or 1000 μg dm/mL in the media using the microculture tetrazolium treatment assay (MTT).

Further it has been shown that the phytochemicals present in sweet potato roots may exert a significant effect on antioxidant as well as anticancer activities [90]. Antioxidant activity is directly related to the phenolics and flavonoid contents of the sweet potato extracts. There was an additive role of phytochemicals contributing significantly to the potent antioxidant activity and antiproliferative activity in vitro [90]. Two anthocyanin pigments, namely, 3-(6,6′-caffeylferulylsophoroside)-5-glucoside of cyanidin (YGM-3) and peonidin (YGM-6), purified from purple sweet potato inhibited the reverse mutation induced by mutagenic pyrolysates of tryptophan (Trp-P-1, Trp-P-2) and imidazoquinoline (IQ) in the presence of rat liver microsomal activation systems [91]. Red colored potatoes demonstrated higher inhibition of carcinogenesis compared to counterparts of white in breast cancer-induced rats [92]. In addition, the red cultivar of potatoes reported high levels of anthocyanins and chlorogenic acid derivatives which could be contributors for observed effects.

Further Madiwale et al. [93] demonstrated that purple-fleshed potato had higher potential in suppressing proliferation and elevated apoptosis of HT-29 human colon cancer cell lines compared to those of white-fleshed potato.

Storage of potatoes affected their antioxidant and anticancer activities and TPC. The extracts of fresh and stored potatoes inhibited cancer cell proliferation and elevated apoptosis. However, anticancer effects were higher in fresh potatoes than those of stored tubers. The investigators further demonstrated that storage duration of potatoes had a strong positive correlation with antioxidant activity and percentage of viable cancer cells but a negative correlation with apoptosis induction. These findings further elaborated that antioxidant activity and phenolic content of potatoes increased with storage, but antiproliferative and proapoptotic activities were decreased [93].

Apart from phenolics in roots and tubers, saponins play a pivotal role as anticancer/antitumor agents. A number of groups of saponins, namely, cycloartanes, ammaranes, oleananes, lupanes, and steroids, demonstrated antitumor effects on different types of cancers. Auyeung et al. [94] showed that cycloartanes possess antitumor properties in human colon cancer cells and tumor xenografts. They downregulated expression of the hepatocellular carcinoma (HCC) tumor marker α-fetoprotein and suppressed HepG2 cell growth by inducing apoptosis and modulating an extracellular signal-regulated protein kinase (ERK)-independent NF-κB signaling pathway [94]. Furthermore, oleananes exerted their antitumor effect through various pathways, such as anticancer, anti-metastasis, immunostimulation, and chemoprevention [94].

A number of studies reported that glycoalkaloids, namely, α-chaconine and α-solanine, present in some tubers are potential anticarcinogenic agents [95]. Glycoalkaloids showed antiproliferative activities against human colon (HT29) and liver (HepG2) cancer cells as assessed by the MTT assay [95].

The aqueous extract of *Dioscorea alata* inhibited the H_2O_2-$CuSO_4$-induced damage of calf thymus DNA, and protected human lymphoblastoid cells from $CuSO_4$-induced DNA damage [96]. Phenolic compounds saponins and polysaccharide mucilage present in yams are responsible for the observed bioactivities of yams extract. Water-soluble mucilage polysaccharides are the most important copper chelators in the extract of water yam. Thus *Dioscorea alata* aqueous extracts could serve as potential agents in the management of copper-mediated oxidative disorders [96].

5.5 Hypoglycemic Activities

Diabetes mellitus is among the NCDs marked by elevated levels of glucose in the blood leading to complications that can untimely cause death. Evidences are emerging that a number of phytochemicals in foods are effective agents in the prevention as well as management of type 2 diabetes. The extract of white-skinned sweet potatoes (WSSP) reduced hyperinsulinemia in Zucker fatty rats by 23, 26, 60, and 50%, after 3, 4, 6, and 8 weeks of oral administration, respectively, of WSSP similar to troglitazone (insulin sensitizer) [97]. Further lipid parameters such as blood triacylglycerol (TG) and free fatty acid (FFA) lactate levels were also lowered by the oral administration of WSSP. Further histological examinations of the pancreas

of Zucker fatty rats showed a remarkable regranulation of pancreatic islet of B-cells in the WSSP and troglitazone treated groups after 8 weeks. These evidences further reinforced that WSSP was likely to improve the abnormal glucose and lipid metabolism in insulin-resistant diabetes mellitus. In addition, supporting these observations extracts of sweet potato peels have shown reduced plasma glucose levels of diabetic patients [98]. Ingestion of 4 g of Caiapo, the extract of WSSP, per day for 6 weeks reduced fasting blood glucose and total as well as low density lipoprotein (LDL) cholesterol in male Caucasian type 2 diabetic patients who were previously treated by dietary management alone [98]. The improvement of insulin sensitivity, as determined by the frequently sampled intravenous glucose tolerance test (FSIGT), indicated that Caiapo extracts showed beneficial effects via reducing insulin resistance. Further Ludvik et al. [98] confirmed the beneficial effects of Caiapo on glucose and serum cholesterol levels in type 2 diabetic patients treated by diet alone for 3 months after recruitment for the study. Improved fasting blood glucose levels and glucose levels during an OGTT and in the postprandial state as well as improvement in long-term glucose control was also observed as expressed by the significant decrease in HbA1c [98].

The ethanolic extract of *Dioscorea alata* showed antidiabetic effects on alloxan-induced diabetic rats [99]. It was observed that diabetic rats who administered *yam* extract exhibited significantly lower creatinine levels which could be a result of improved renal function by reduced plasma glucose level and subsequent glycosylation of renal basement membranes. A number of bioactives, including phenolics, was identified in the ethanolic extract of *D. alata*. These include hydro-Q9 chromene, γ-tocopherol, α-tocopherol, -feruloyl glycerol, dioscorin, cyanidin-3-glucoside, catechin, procyanidin, cyanidin, peonidin 3-gentiobioside, and alatanins A, B, and C [99].

5.6 Hypocholesterolemic Activity

Diet plays an important role in the regulation of cholesterol homeostasis and CVDs are among the leading causes of death worldwide. External agents possessing anticholesteromic activities continuously show beneficial effects on risk reduction and management of CVDs.

Diosgenin, a steroidal saponin of yam (*Dioscorea*), demonstrated antioxidative and hypolipidemic effects in a rat model [100]. Rats fed with a high-cholesterol diet were supplemented with either 0.1 or 0.5% diosgenin for 6 weeks. The lipid profile of the plasma and liver, lipid peroxidation and antioxidant enzyme activities in the plasma, erythrocyte, and gene expression of antioxidative enzymes in the liver and the oxidative DNA damage in lymphocytes were measured. Diosgenin showed pancreatic lipase inhibitory activity, protective effect of liver under high cholesterol diet, reduced total cholesterol level, and protection against the oxidative damaging effects of polyunsaturated fatty acids [100].

Steroidal saponins of yams are used for industrial drug processing. Saponins, such as dioscin and gracilin, and prosapogenins of dioscin have long been identified

from yam. The content of the dioscin was about 2.7% (w/w). Diosgenin content was about 0.004 and 0.12–0.48% in cultivated yams and wild yams, respectively. The anti-hypercholesterolemic effect of yam saponin is related to its inhibitory activity against cholesterol absorption [101].

The hypocholesterolemic effect of yam diosgenin had been reported by an in vivo study. Rats fed with yam (*Dioscorea*) showed a decreased cholesterol absorption, increased hepatic cholesterol synthesis, and increased bilary cholesterol secretion without affecting serum cholesterol level [102]. In agreement with this finding, several studies showed that diosgenin, present in some *Dioscorea,* could enhance fecal bile acid secretion and decrease intestinal cholesterol absorption [103, 104]. The relative contribution of bilary secretion and intestinal absorption of cholesterol in diosgenin-stimulated fecal cholesterol excretion were studied in wild-type (WT) and Niemann-Pick C1 Like 1 (NPC1L1) knockout (LIKO) mice. NPCiL1 was recently identified as an essential protein for intestinal cholesterol absorption [105]. Diosgenin significantly increased bilary cholesterol and hepatic expression of cholesterol synthetic genes in both WT and LIKO mice. In addition, diosgenin stimulation of fecal cholesterol excretion was primarily attributable to its impact on hepatic cholesterol metabolism rather than NPC1L1-dependent intestinal cholesterol absorption [105].

Native protein of dioscorin purified from *D. alata* (cv. Tainung No. 1) (TN1-dioscorin) and its peptic hydrolysates showed ACE inhibitory activities in a dose-dependent manner [41]. The kinetic analysis of dioscorin showed a mixed noncompetitive inhibition against ACE. Their results suggested that dioscorin isolated from *Dioscorea* might be beneficial in controlling high blood pressure [105, 106].

Chen et al. [35] reported the effects of Taiwanese yam (*Dioscorea alata* Cv Tainung No.2) on mucosal hydrolase activities and lipid metabolism in male Balb/c mice. High level of Tainung No.2 yam in the diet (50% w/w) reduced plasma and hepatic cholesterol levels and increased fecal steroid excretions in the mice model. This could be due to the loss of bile acid in the enterohepatic cycle to fecal excretion [35]. They further suggested that the increased viscosity of the digest and the thickness of the unstirred layer in the small intestine caused by Tainung No.2 yam fiber (and/or mucilage) decreased the absorption of fat, cholesterol, and bile acid. Short-term (3 week) consumption of 25% Tainung No.2 yam in the diet could reduce the anthrogenic index, but not total cholesterol level in nonhypercholesteromic mice. However, additional dietary yam (50% yam diet) could consistently exert hypocholesterolemic effects in these mice [35]. However, diosgenin was not elucidated in Tainung No.2 used in this study [35]. Thus, authors suggested that diosgenin might not be involved in the cholesterol lowering effect of Tainung No.2 yam. Dietary fiber and viscous mucilage could be active components for the beneficial cholesterol lowering effects of yam. Further, short-term consumption (3 week) of 25% uncooked keelung yam effectively reduced total blood cholesterol levels and the atherogenic index in mice. Authors indicated that the active components for the lipid lowering effects may be attributed to dietary fiber, mucilage, plant sterols, or synergism of these active components [35].

5.7 Antiobesity

Obesity resulting from the chronic disruption of energy balance in the body has become an epidemic globally. Hypertrophy and hyperplasia of fat cells is clearly explained for their unique contribution in pathology of obesity. There are a number of behavioral, metabolic, and biological influences leading to obesity [107]. In addressing the management of obesity phytochemicals may be potential agents targeting increasing energy expenditure, fat oxidation or inhibiting adipose tissue proliferation.

Differentiation and proliferation inhibitory activities of sporamin of sweet potato tubers were reported in 3 T3-L1 preadipocytes [41]. It should be noteworthy that sporamin did not exhibit any cytotoxic activity toward the model cell line 3 T3-L1 preadipocytes which have frequently been used to study differentiation of adipocytes in vitro. Concentration range of 0.025–1 mg/ml sporamin showed antidifferentiation and antiproliferation effects on 3 T3-L1 cells similarly to 0.02 mg/ml berberine. Berberine is a traditional Chinese medicine used as an antimicrobial and antitumor agent [41]. Hwang et al. [108] demonstrated that purple sweet potato is a potential food, which can be used for the prevention of obesity. Anthocyanin fractions of purple sweet potato inhibited hepatic lipid accumulation through the induction of adenosine monophosphate activated protein kinase (AMPK) signaling pathways. AMPK plays an important role in the regulation of lipid synthesis in metabolic tissues [108]. Anthocyanin dose of 200 mg/kg of body weight per day reduced weight gain, hepatic triacylglycerol accumulation and improved serum lipid parameters in mice fed for 4 weeks with purple sweet potatoes. Furthermore, anthocyanin administration increased the phosphorylation of AMPK and acetyl coenzyme A carboxylase (ACC) in the liver and HepG2 hepatocytes. These authors further suggested that anthocyanin found in purple sweet potatoes may improve high fat diet induced fatty liver disease and regulate hepatic lipid metabolism [108].

5.8 Immunomodulatory Activities

Phytochemicals are reported to possess a number of bioactivities in management and risk reduction of NCDs and immunomodulatory and anti-inflammatory properties are reported among others. The mechanisms of action include effects on enzyme function involved in the generation of inflammatory mediators such as nitric oxide (NO), prostanoids and leukotrienes, regulation of gene, and protein expression [109].

The effects of purified dioscorin from yam tubers on native BALB/c mice spleen cell proliferation were assayed by MTT assay [26]. Dioscorin stimulated mouse macrophage-like cells RAW264.7 to produce nitric oxide (NO), in the absence of lipopolysaccharide (LPS) contaminations. Yam dioscorin exhibited immunomodulatory activities by the innate immunity which is a nonspecific immune system which comprises the cells and mechanisms that defend the host from infection by other

organisms in a nonspecific manner. Dioscorin was reported to stimulate cytokine production and to enhance phagocytosis. Furthermore, the released cytokines may act synergistically with phytohemagglutinin (PHA) which is a lectin found in plants that stimulate the proliferation of splenocytes [26].

Yam mucopolysaccharides (YMP) demonstrated the immune activity in several cell lines. In vitro cytotoxic activity of murine splenocyte against leukemia cells was increased in the presence of YMP of *Dioscorea batatas* at 10 μg/ml [110]. Furthermore, the production of interferon-γ (IFN-γ) was significantly increased in the YMP-treated splenocytes, suggesting their capability of inducing cell-mediated immune responses. In addition, YMP at a concentration of 50 μg/ml increased uptake capacity and lysosomal phosphatase activity of peritoneal macrophages [110].

Bioactive compounds from *Dioscorea* enhanced murine splenocyte proliferation ex vivo and improved regeneration of bone marrow cells in vivo [111]. Mice which were fed with a *Dioscorea* extract recovered damaged bone marrow progenitor cells that had been depleted by large doses of 5-flourouracil (5-FU). In addition, they found that the compound(s) responsible for these bioactivities had a high molecular weight ($\geq$100 kDa) and were most likely polysaccharides. The high molecular weight polysaccharides in *Dioscorea* crude extract–II (DsCE-II) may act on specific target cell types such as dendritic cells, intestinal epithelial cells, and T-cells in the GI tract to mediate a cascade of immune regulatory activities. This may lead to the recovery of damaged cell populations exposed to 5-FU or other chemical insults in the bone marrow, spleen, or other immune cell systems [111].

Oral administration of *Dioscorea* tuber mucilage from Taiwanese yams (*Dioscorea Japonica* Thunb var) showed significant effects on the innate immunity and adaptive immunity on BALB/c mice [112]. It was interesting to note that the specific antibodies rapidly responded against foreign proteins (or antigens) in the presence of yam mucilage. Mucilage from these yam varieties exhibited a stimulatory effect on phagocytic activity by granulocyte and monocyte (ex vivo), on peritoneal macrophages, and on the RAW 264.7 cells (in vivo) of mice [112].

Yams (*Dioscorea esculenta*) demonstrated anti-inflammatory activities on carrageenan-induced edema in the right hind paw of Wistar rats [113]. However, it was noted that the activity was short lived as it was quickly removed from the system after reaching the peak within 2 hours. Phytochemical screening of *D. esculenta* confirmed the presence of saponins, β-sitosterol, stigmasterol, cardiac glycosides, fats, starch, and diosgenin, which could be responsible for the observed activity [113]. Diosgenin contained in Chinese yam was an immunoactive steroidal saponin which also showed prebiotic effects. Diosgenin had also beneficial effects on the growth of enteric lactic acid bacteria [61].

In a human trial the impact of the consumption of pigmented potatoes on oxidative stress and inflammatory damages has been demonstrated [114]. In this study participants were administrated white-, yellow- (high concentrations in phenolic acids and carotenoids), or purple-fleshed (high content of anthocyanin and phenolic acids) potato once per day in a randomized 6-week trial which reported good compliance. The results showed that the consumption of pigmented potatoes

was responsible for elevated antioxidant status and reduced inflammation and DNA damage, which was observed through the reduction of inflammatory cytokines and C-reactive protein concentrations [114].

Methanolic extracts of *Amorphophallus campanulatus* (Suran) tuber also showed immunomodulatory activities in Wistar albino mouse model [115]. The mice were immunized with sheep red blood cells to assess delayed type hypersensitivity and charcoal clearance test. Active phagocytosis is the major defense mechanism against infection. They indicated that the presence of steroids and flavonoids in *Amorphophallus campanulatus* (Suran) tuber may be responsible for the observed immunomodulatory activity [115].

5.9 Antimicrobial Activity

Yam varieties with their phenolic compounds are potential agents with antimicrobial efficacy. Sonibare and Abegunde [116] reported that the methanolic extracts of *Dioscorea* yams (*Dioscorea dumetorum* and *Dioscorea hirtiflora*) showed antioxidant and antimicrobial activities. Antimicrobial activity was determined by the agar diffusion method (for bacteria) and pour plate method (for fungi). Nonedible *D. dumetorum* showed the highest in vitro antibacterial activity against *Proteus mirabilis*. The methanolic extracts from *D. hirtiflora* demonstrated antimicrobial activity against all tested organisms, namely *Staphylococcus aureus*, *E-Coli*, *Bacillus subtilis, Proteus mirabilis, Salmonella typhi, Candida albicans, Aspergillus niger,* and *Penicillium chrysogenum*. Saponin present in yams (*Dioscorea)* also has tendency to ward off microbes [117]. These compounds serve as natural antibiotics, helping the body to fight against infections and microbial invasion [117].

6 Conclusions

Foregoing evidences support the fact that roots and tubers are important components in the everyday diet for humans adding variety in the plate and a number of health implications to attenuate NCDs. They perform a pivotal role as an energy contributor while providing many desirable nutritional and health benefits, namely, antioxidative, hypoglycemic, hypocholesterolemic, antimicrobial, and immunomodulatory activities among others. There are a wide array of roots and tubers which can be utilized in preparation of numerous commercial foods though usage may vary with the country and region. Thus, tubers may serve as functional foods and nutraceutical ingredients to attenuate NCDs and to maintain wellness.

Betalains: Application in Functional Foods 49

Wee Sim Choo

Contents

Abstract

Betalains are plant derived natural pigments that are presently gaining popularity for use as natural colorants in the food industry. Although betalains from red beet are one of the most widely used food colorant, betalains are not as well studied as compared to other natural pigments such as anthocyanins, carotenoids, and chlorophylls. This chapter describes the chemical properties of betalains including their biosynthesis. Two main classes of betalains, betacyanins and betaxanthins, are described. Current reports on the biological and pharmacological properties of betalains from four main sources such as red beet, amaranth, prickly pear, and red pitahaya are also described. The biological and pharmacological properties of betalains that are covered in this chapter include antioxidant,

anticancer, anti-lipidemic, and antimicrobial activities. Lastly, this chapter describes the application of betalains as natural colorants and other potential application in functional foods.

1 Introduction

Betalains are one of the most common plant pigments found in nature besides carotenoids, chlorophylls, and anthocyanins. Unlike anthocyanins or chlorophylls which are ubiquitous in the plant kingdom, betalains are found in a much smaller group of plants. It has been established that in the plant kingdom there is mutual exclusivity with respect to betalains and anthocyanins whereby both pigments have never been reported in the same plant [1]. The occurrence of betalains are restricted to the order Caryophyllales and some higher fungi such as *Amanita muscaria* (fly agaric) [2]. Betalains can be found in the families of the Caryophyllales (Achatocarpaceae, Aizoaceae, Amaranthaceae, Basellaceae, Cactaceae, Chenopodiaceae, Didiereaceae, Halophytaceae, Hectorellaceae, Nyctaginaceae, Phytolaccaceae, Portulacaceae, and Stegnospermataceae). Only two families of the Caryophyllales, the Caryophyllaceae and Molluginaceae produce anthocyanins [3].

The most common and widely known source of betalains are those belonging to the Amaranthaceae (namely, *Beta vulgaris* L. and *Amaranthus* sp.) and Cactaceae families (namely, *Opuntia* sp. and *Hylocereus* sp.) [4, 5]. *Beta vulgaris* subsp. *vulgaris* or commonly known as red beet or beet root (Fig. 1a) is mostly cultivated in North America, Central America, and Europe. Red beet is the major commercially exploited betalain crop and a vegetable characteristic of the Eastern and Central European diet. Red beets are not only consumed as fresh vegetables but are also processed to obtain desiccated or frozen products, juices, and their concentrates as well as natural pigments used as food additives [6]. Amaranthus or collectively known as amaranth (Fig. 1b) is a cosmopolitan genus of annual or short-lived perennial plants made up of about 60 species. Some amaranthus are cultivated as leafy vegetables, grains, or ornamental plants, while others are weeds. Amaranthus are cultivated and consumed as a leafy vegetable in many parts of the world. Certain Amaranthus species are consumed as cooked or fresh [7, 8]. Several Amaranth species are raised as grains in Asia and America. *Opuntia* sp. fruits or commonly known as prickly pears or cactus pears (Fig. 1c) are widely distributed in Mexico, Central and Southern America, Australia, South Africa, and the Mediterranean. Prickly pears have edible cladodes, but its sweet and colored fruits are the most desirable and commercially valuable parts of this plant and present economic relevance throughout arid and semiarid areas of the world [9, 10]. *Hylocereus polyrhizus* or commonly known as red pitahaya or red dragon fruit (Fig. 1d) is well known for its aesthetically pleasing deep purple color pulp with numerous small

Fig. 1 Common sources of betalains (**a**) Red beet, (**b**) Amaranth (Source: iStock photos), (**c**) Prickly pear (Source: Peterson [11]), (**d**) Red pitahaya (Source: iStock photos)

soft seeds. This fruit has high appeal in the European and United States market and is cultivated in Asia and Australia.

Stenocereus sp. is an emerging common source of betalains belonging to the Cactaceae family. *S. pruinosus, S. stellatus,* and *S. queretaroensis* are endemic of Mexico. These species produce fruits named pitayas [12]. Fruits are spherical or ellipsoid, spiny, green or red peeled berries [13] with juicy flesh of different colors such as white, yellow, pink, orange, red, or purple [12]. In several references [14–17], the name pitaya has also been given to fruit of the species *Hylocereus* sp., but there are notable differences between the fruits from these two genera. The fruits of *Hylocereus* sp., named pitahayas, do not have spines, possess certain type of bracts, and their size is higher than that of the fruits of *Stenocereus* sp. [12].

Betalains are present in other plant families in interesting amount, such as Baselaceae, Asparagaceae, Nictaginaceae, Pandanaceae, Phytolaccaceae, and Portulacaceae. *Basella rubra* L. and *Ullucus tuberosus* are the most studied sources of betalains belonging to the from the Basellaceae family; *Cordyline fruticosa* belonging to the Asparagaceae family, *Mirabilis jalapa* L. from the Nyctaginaceae family, *Pandannus amaryllifolius* from the Pandanaceae family, *Rivina humilis* L. from the Phytolaccaceae family, and *Talinum triangulare* from the Portulacaceae family. In a plant, betalains can be present in seeds, leaves, flowers, sprouts, aerial parts, roots, and even in fruits [18]. The occurrence of betalains in different parts of plants has been discussed comprehensively in a recent review by Martin et al. [18]. Betalains play important roles in plant physiology and visual attraction for pollinators and seed dispersers [19]. In some plants they also have specific functions. Betalains were discussed to provide protection from the harmful effects of ultraviolet radiation in the ice plant *(Mesembryanthemum crystallinum* L.) [20]. In cactus thorns betalains provide insect-repelling signals whereas for underground plant like red beet, they can improve the resistance to soil pathogens [19]. In red beet, betalains act as reactive oxygen species scavengers, limiting damage caused by wounding and pathogen infiltration in the plant tissues [21]. In food, betalains serve two functions. Betalains improve the aesthetic value of foods and contribute to consumers' health and well-being [19].

In this chapter, the chemical properties of betalains including their biosynthesis are described. The biological and pharmacological properties of betalains from the four main common sources, namely, red beet, amaranthus, prickly pear, and red pitahaya and their application in functional foods or foods that potentially offer health benefits beyond basic nutrition are also covered in this chapter.

2 Chemical Properties of Betalains

Betalains are water-soluble nitrogen-containing pigments which can exist as the red-violet betacyanins or yellow betaxanthins. These two main classes of betalains can occur in the same plant part, despite the difference in coloration. However, betacyanins occur with greater frequency than betaxanthins. In early days, betacyanins were addressed erroneously as nitrogenous anthocyanins whereas betaxanthins were called flavonoids [22]. The term "betalains" was first introduced by Mabry and Dreiding in 1968 [23]. Betalains are immoniun derivatives of betalamic acid (Fig. 2) that is based on the protonated 1,2,4,7,7-pentasubstituted 1,7-diazaheptamethin system with a betalain color being attributable to the resonating double bonds (Fig. 2) [24].

When the basic structure is substituted with an aromatic nucleus, a change in the absorption maximum from 540 nm (red-violet betacyanins; Table 1) to 480 nm (yellow betaxanthins; Table 2) is observed [24]. To date, there are 51 and 23 different betacyanin and betaxanthin structures identified, respectively [18]. Common names of betacyanins or betaxanthins are assigned in relation to the plant from where they were first isolated. Examples are given in Tables 1 and 2 [22, 24, 25]. Betacyanin

structures show variations in their sugar or acyl groups whereas betaxanthins show conjugation with a wide range of amines or amino acids in their structures [26].

The aglycon betanidin (Fig. 3a) is the backbone of all betacyanins. The occurrence of different betacyanin structures is due to the glycosylation and acylation of the resulting 5-*O*- or 6-*O*-glucosides. The most common glycosyl moiety is glucose, although sophorose and rhamnose could also occur, but less frequently. The most common acyl groups are sulfuric, malonic, 3-hydroxy-3-methylglutaric, citric, p-coumaric, ferulic, caffeic, and sinapic acids [27]. Betanin (betanidin 5-*O*-ß-glucoside) from red beet was the most studied betacyanin pigment [22]. Betacyanins can be further classified into four groups: betanin, gomphrenin, amaranthin, and

bougainvillein (Table 3). These groups differ by the attachment of glucosyl groups to the oxygen atoms in the ortho position on the *cyclo*-DOPA (Fig. 3b) moiety. The betanin-type group has a hydroxyl group linked to the C6 carbon and a glucosyl group on the C5 one. Gomphrenin- type group is known as structural isomers of betanins with a hydroxyl group attached to the C5 carbon and a glucosyl linked to the C6 carbon [2]. Amaranthin-type group differs from the betanin-type group by having two contiguous glucosyl groups attached to the C5 carbon [28]. Bougainvillein-type group is known as carboxylated or decarboxylated betanins [22]. Betacyanins are known to display two absorption maxima, one in the UV-range between 270 and 280 nm due to the *cyclo*-DOPA structure and a second one in the visible range at about 540 nm [19].

In betaxanthins, the *cyclo*-DOPA unit of betacyanins is replaced by an amino acid or amine. Hence, betaxanthins can be classified into two groups: amino-acid-derived conjugate group and amine-derived conjugate group (Table 3). Indicaxanthin from cactus pear was the first yellow pigment structurally characterized, having proline as substituent. It is also the most commonly studied betaxanthins besides vulgaxanthin I with glutamine as substituent. Vulgaxanthin I is the most abundant betaxantin found in *Beta vulgaris* [22]. Condensation of betalamic acid with various amino acids or amines in betaxanthins produce hypso- and bathochromic shifts [19]. The maximum absorption of betaxanthins varies from 460 to 480 nm and is associated with the structure of the amino or amine conjugates. Amine conjugates display a lower absorption maximum than their respective amino acids [29]. The

highest absorption maximum was displayed by indicaxanthin and portulacaxanthin I with proline and hydroxyproline as a substituent, respectively [29, 30].

The biosynthesis of betalains was studied since the 1950s and their biosynthesis is summarized in a number of reviews [2, 31–36]. Betalains arise from arogenate of the shikimate pathway whereby arogenate is converted to L-tyrosine, an amino acid, via arogenate dehydrogenase [37, 38]. Betalains are therefore secondary metabolites derived from the amino acid L-tyrosine. The pathway involved in the biosynthesis of betalains begins with the hydroxylation of L-tyrosine to 3,4-dihydroxyphenylalanine or better known as L-DOPA [39] through the monophenolase activity of the enzyme tyrosinase (or polyphenoloxidase) [31, 40]. Betalamic acid is derived from L-DOPA by spontaneous intramolecular condensation through the activity of the enzyme 4,5-DOPA-extradiol-dioxygenase [31]. Condensation of betalamic acid with another DOPA derivative such as *cyclo*-DOPA produce red colored betacyanins whereas condensation of betalamic acid with an amino acid or amine produce yellow betaxanthins [1]. Figure 4 shows the biosynthetic pathway of betanidin, a betacyanin and indicaxanthin, a betaxanthin as examples of betalains [1].

3 Biological and Pharmacological Properties of Betalains

Betalains play an important role in human health because of their biological and pharmacological properties/activities such as antioxidant, anticancer, anti-lipidemic, antimicrobial, etc. [5]. Although various pharmacological activities of betalains have been observed in vivo, the use of extracts limits the conclusions drawn, the hypothesis on the mechanisms involved, and the therapeutic potential of the assays. To date, studies with purified pigments are scarce, but they provide exciting conclusions [41]. Also, the likely optimum concentration for daily intake may only be decided after systematically addressing stability and bioavailability issues of betalains [42]. There are lack of stability and bioavailability studies on different groups of betalains. Current knowledge on the stability or bioavailability of betalains has been discussed in a number of reviews [4, 18, 42–46]. Current reports on the antioxidant, anticancer, anti-lipidemic, and antimicrobial activities of betalains from red beet, prickly pear, amaranth, and red pitahaya are covered in this section.

3.1 Antioxidant Activity

A broad definition of antioxidant is “any substrate that, when present at low concentrations compared to those of an oxidizable substrate, significantly delays or prevents oxidation of the substrate” [47]. The term “oxidizable substrate” includes almost everything found in foods and in living tissues including proteins, lipids, carbohydrates, and DNA. The target chosen and the source of oxidative damage therefore play paramount importance in characterizing an antioxidant [47]. The bioavailability of betalains is at least as high as flavonoids, which are well-accepted natural antioxidants. Betalains, as natural antioxidants, may provide protection

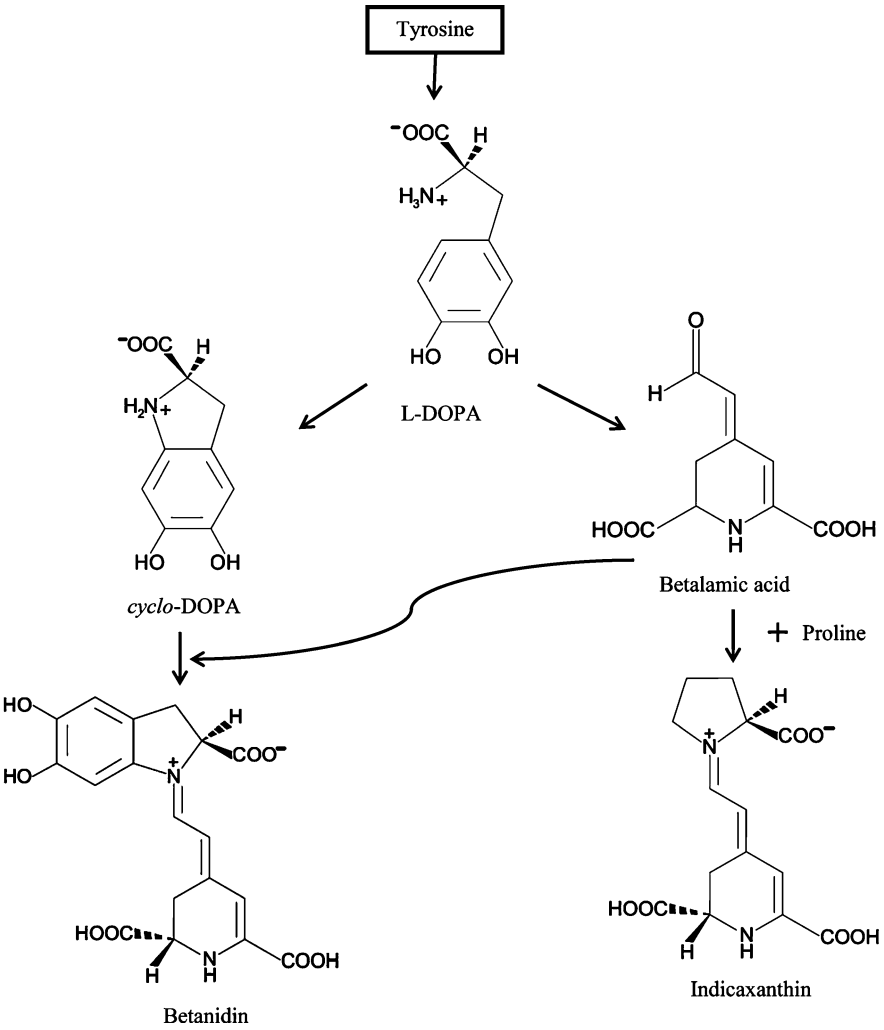

Fig. 4 Biosynthetic pathway of betanidin and indicaxanthin

against oxidative stress-related disorders [6, 48]. The antioxidant activity of betalains has been studied extensively and shown in several chemical and biological models [6, 22, 49–54] including the ex vivo oxidation of human low-density lipoproteins (LDL). However, ex vivo oxidation studies of human LDL or lipid inhibition studies are covered in a separate following section. The antioxidant activity of betalains in vitro was investigated using the DPPH (1,1-diphenyl-2-picrylhydrazyl) free radical scavenging assay, ABTS (2,2′-azinobis(3-ethylbenzothiozoline-6- sulfonic acid) diammonium salt) radical scavenging assay, electron spin resonance spectroscopy, etc. Some studies measured the TEAC (trolox equivalent antioxidant capacity) assay that is based on the ability of an antioxidant to

scavenge ABTS radical cation relative to that of the water-soluble vitamin E analogue, Trolox [55].

In vitro studies of betalains from red beets have demonstrated that they possess high antiradical and antioxidant activity. The free radical-scavenging activity of betanin from red beet measured in a TEAC assay at pH 7.4 and in a DPPH assay was about 7.5- and 3.0-fold higher, respectively, than that of vitamin C, which is commonly accepted as an effective natural water soluble antioxidant [50, 56]. Betalains from red beet in a TEAC assay were also found to have 1.5–2.0-fold greater free radical scavenging activity than some anthocyanins [56] such as cyanidin-3-*O*-glucoside and cyanidin, above pH 4 [57]. Purified betanin and indicaxanthin from prickly pear were more effective than Trolox at scavenging ABTS radical [49]. Similarly, EC_{50} values determined using the DPPH radical-scavenging activity method for pulp and peel extracts of red pitahaya containing betalains were 22.4 ± 0.29 and 118 ± 4.12 mol vitamin C equivalents/g, respectively [58]. However, betalain extracts of red pitahaya also have high content of ascorbic acid which acts as potential antioxidant. Isolated betacyanins such as betanin, phyllocactin, hylocerenin, and their isomers are therefore required to assess their antioxidant capacity separately [59]. Betalains from Amaranthaceae determined using DPPH method were found to have EC_{50} values ranging from 3.4 to 8.4 μM. Gomphrenin type betacyanins and betaxanthins assessed using the DPPH method demonstrated the strongest antioxidant activity which was three to four times stronger than ascorbic acid and also stronger than other potent antioxidants such as rutin and catechin [50]. In addition, betalain pigments from various plants of the family Amaranthaceae exhibited strong antioxidant activity presented as mean EC_{50} value (μM): amaranthine or isoamaranthine (8.37 or 8.35), iresinins (8.08), celosianins (7.13), betanin or isobetanin (4.88 or 4.89), 3-methoxy-tyramine-betaxanthin (4.21), (S)-tryptophan-betaxanthin, dopamine-betaxanthin (4.08), acylated gomphrenins (4.11), and simple gomphrenins (3.35) [50]. Although free radical scavenging activity investigated using the DPPH- or TEAC-assay can provide valuable insights on the mechanisms of action, it is important to note that in vitro chemical assays bear no similarity to biological systems including the absorption of antioxidant compounds by the human body [60]. The measurements of the in vitro antioxidant activity of betalains therefore needs to be carefully interpreted [5].

Betanin from red beet was reported to dose-dependently scavenge DPPH-, galvinoxyl-, superoxide-, and hydroxyl-radicals in electron spin resonance spectroscopy and spin trapping studies and prevented hydrogen peroxide induced cellular DNA damage in cultured HT-29 cells. Furthermore, betanin treatment induced the transcription factor Nrf2 and resulted in an increase of heme oxygenase 1 (HO-1) protein levels, PON1-transactivation and cellular glutathione (GSH). Nrf2 is a transcription factor regulating the expression of genes encoding proteins important in antioxidant defense. The antioxidant enzyme HO-1 is a Nrf2 target gene. The hepatic enzyme PON1 also exhibits antioxidant and antiatherogenic activity. GSH is an important cytosolic antioxidant centrally involved in redox signaling and stress response. These studies suggested that betanin is both a free radical scavenger and an inducer of antioxidant defense mechanism in cultured cells [61]. Red beet pomace containing betalains was evaluated on three different free radical species: DPPH·, ·OH and O_2^- using ESR

spectroscopy and was found to show better scavenging activity (EC_{50} OH = 0.0655 mg/mL, EC_{50}DPPH· = 0.0797 mg/mL, and $EC_{50}O_2^-$ = 1.0625 mg/mL) than those of butylated hydroxyanisole (BHA) (EC_{50}DPPH· = 0.180 mg/mL, EC_{50}·OH = 1.505 mg/mL, and $EC_{50}O_2^-$ = 2.680 mg/mL) [62].

The antioxidant capacity of betacyanins from red pitahaya was evaluated using the peroxyl radical generating system in the presence of AAPH and the peroxyl radical scavenging capacity was dose-dependent in the low concentration range (25–100 nM). The mol-Trolox equivalent activity/mol compound (mol-TEA/mol-compound) as an index of the antioxidant capacity indicated 3.31 and 2.83 mol-TEA/mol-compound for betanin and phyllocactin, respectively [54]. Betalains from red beets inhibited peroxynitrate-mediated tyrosin nitration and DNA strand cleavage [63]. It was also found that pre-treatment of HT-29 cells with betalains significantly reduced hydrogen peroxide induced DNA damage [61]. The nitrogen scavenging activity of betacyanins was examined using NOR3 as an NO donor, and it was found that the IC_{50} values of nitrogen radical scavenging activity were 24.48, 17.51, 6.81 for betanin, phyllocactin, and betanidin, respectively [54]. The reduction of the nitrite level when treated with betacyanins was high in comparison to flavonoids such as aromadendrin, quercitrin, and loliolide [64]. These studies demonstrated the potential DNA-protective effect of betalains against reactive oxygen and nitrogen radicals.

Sources of betalains such as cacti fruits and red beet exhibited strong antioxidant activities in biological environment [4] by inhibiting lipid peroxidation and heme decomposition at very low betalain concentrations. Betalains have been shown to protect vascular endothelium cells, which are direct targets of oxidative stress in inflammation from cytokine-induced redox state alteration [65]. Betalains also counteract lipoperoxidases which may damage gastrointestinal cells during food digestion [6, 50]. Human ingestion of a single dose of red beet juice resulted in an increase of antioxidants in the system with only 0.28% of betalains excreted in urine within the 24 h after consumption [66]. The oral administration of betalains from red beets (5, 20 or 80 mg/kg body weight) in mice exposed to gamma irradiation significantly enhanced the activity of antioxidant enzymes such as superoxide dismutase (SOD) and gluthathione peroxidase (GPx) in the liver, spleen, and kidney, in a dose-dependent manner [67]. *Opuntia ficus-indica* extracts containing betalains were also found to counteract the release of acetaldehyde in blood due to chronic alcohol intake by restoring the malondialdehyde (MDA) and GSH level in the erythrocytes [68]. The use of in vivo assays using mice models and human trials permit the detection of gross effects resulting from multiple mechanisms but they reveal little about the individual mechanisms of activity [69]. A combination of in vitro and in vivo studies may be able to provide an efficient and effective approach to screen the potential antioxidant activity of betalains [5].

3.2 Anticancer Properties

Cancer is a growing problem worldwide that had surpassed common infectious diseases as the second leading cause of death globally [70]. Different approaches

are being explored for the prevention and treatment of cancer [71]. Exploring natural compounds for their anticarcinogenic properties is one of the major approaches to prevent or treat cancer. In this context, the establishment of health benefits of edible fruits through in vitro anticancer assays would substantiate their potential as functional foods [72].

Betanin from red beet showed excellent growth inhibition of MCF-7 (breast), HCT-116 (colon), AGS (stomach), SF-268 (CNS), and NCI-H460 (lung) cancer cell lines with IC_{50} values of 162, 142, 158, 164, and 147 μg/mL, respectively [73]. Betanin/isobetanin concentrate from red beet was reported to significantly decrease cancer cell proliferation and viability of MCF-7-treated cells. The expressions of apoptosis-related proteins (Bad, TRAILR4, FAS, p53) were strongly increased and the mitochondrial membrane potential was altered, demonstrating the involvement of both intrinsic and extrinsic apoptotic pathways [74]. Betanin from red beet resulted in a 49% inhibition of HepG2 cell proliferation at 200 μg/mL, and betaine yielded a 25% inhibition at 800 μg/mL [75]. The in vitro inhibitory effect of red beet extract (betalains) on Epstein-Barr virus early antigen (EBV-EA) induced by the tumor promoter 12-*O*-tetradecanoylphorbol-I3-acetate revealed a high order of activity compared to paprika (capsanthin), cranberry (anthocyanins), red onion skin (anthocyanins), and short and long red bell peppers (carotenoids). An in vivo anti-tumor promoting activity evaluation against the mice skin and lung bioassays also revealed a significant tumor inhibitory effect [76]. Red beet extract containing betalains exhibited a lower cytotoxic profile compared to doxorubicin (a red colored anticancer antibiotic drug) in in vitro studies utilizing two cancer cell lines of human origin (prostate PC-3 and breast MCF-7). However, it had minimal effect on the growth of normal human skin (FC) and liver (HC) cells in contrast to doxorubicin. It was suggested that as a dietary supplement, the red beet extract may have the potential to lower the serious adverse effects associated with doxorubicin (adriamycin) therapy [77]. Red beet extracts containing betalains were also found to counteract the lethal effects of the chemical carcinogen 7,12-dimethylbenz[a] anthracene (DMBA) in the livers of Sprague- Dawley rats. This was achieved by a reduction in activity of EROD (CYP1A1 marker) and MROD (marker of CYP1A2) and an increase in the activities of hepatic phase II enzymes, gluthathione S- transferase (GST) and NAD(P)H:quinone oxidoreductase-1 (NQO1) [78]. Similarly, the effect of red beet extracts containing betalains on MCF-7 and MRC-5 (fetal lungs) cell lines determined by using the sulforhodamine B (SRB) assay resulted in inhibiting concentration (IC_{50}) values in the range of 362–504 and 383–588 μg/mL for MRC-5 and MCF-7, respectively [79]. Red beet pomace extract containing betalains exhibited cytotoxic properties against Ehrlich carcinoma (EAC) cells in vivo. The EAC cell numbers were decreased in all extract-treated groups compared with the untreated EAC control group. The largest decreases in EAC cell numbers were observed in the pretreated male (approximately 53%) and female (approximately 47%) mice, and also the EAC cell viability was decreased after administration of red beet pomace extract containing betalains [62]. In three different experimental tumor models in mice, a very low dose of betanin (0.0025%) from red beet acted as a potent chemopreventive agent [80]. Red beet extract containing

betalains consistently reduced multiorgan tumor formations in various animal models when administered in drinking water (25–78 μg/mL, equivalent to a daily intake of about 6–20 μg of beetroot betacyanins/kg body weight) [76, 81]. A long-term daily exposure to low doses of red beet extract through diet was postulated to be safe and sufficient to produce cancer chemopreventive effect in humans [82].

Immortalized ovarian and cervical epithelial cells as well as ovarian, cervical, and bladder cancer cells that were exposed to prickly pear (*Opuntia ficus-indica*) extracts containing betalains displayed a significant increase in apoptosis and growth inhibition in a dose- and time-dependent manner. The extracts containing betalains affected cell cycle of cancer cells by increasing G1 and decreasing G2 and S phases, significantly suppressed tumor growth in nude mice, increased annexin IV expression, and decreased VEGF by modulating the expression of tumor-related genes [83]. Betanin from *Opuntia ficus-indica* fruits were found to possess an antiproliferative activity in K562 cells with an IC_{50} of 40 μM. Betanin induced apoptosis in K562 cells through the intrinsic pathway and is mediated by the release of cytochrome c from mitochondria into the cytosol and poly (ADP) ribose polymerase (PARP) cleavage [84]. Another study showed that prickly pear extracts containing betalains exhibited a significant growth inhibitory effect on human ovarian cancer cells similar to a synthetic chemopreventive agent, 4- HPR, in nude mice [83]. Extracts containing betalains from prickly pears was found to be less effective in inhibiting colon cancer cell (HT29) growth compared to doxorubicin, an anticancer drug. Doxorubicin induced HT29 cycle arrest in G2/M phase [85] and thus combining the drug treatment with extracts from prickly pears that arrested cells on different cell cycle checkpoints (G1 and/or S phases) could be a promising strategy to improve the anticancer effect and diminished chemoresistance as an adjuvant of chemotherapy [86]. Screening of antiproliferative activity of extract containing betalains from the fruit of red pitahaya on AGS (a human gastric adenocarcinoma cell line), HeLa (a human cervical adenocarcinoma cell line), MCF-7 and B16F10 melanoma cell [87] was carried out but the results were not significant. To date, there are no reported studies on the anticancer or antiproliferative activity of extract containing betalains from Amaranthus. The use of cancer cell lines allowed the investigation of potential anticancer compounds in a simplified, controlled, and reproducible environment [88, 89]. However, the inability of cell cultures to behave like tumors and their interactions with the host [89] means that the efficacy of betalains as an anticancer agent in human clinical trials may not be the same. Further in vivo studies in a model that closely approximates the targeted human cancer are therefore needed [5].

3.3 Anti-Lipidemic and Lipid Oxidation Inhibition Effect

Betalains exhibited antioxidant effect to inhibit lipid oxidation. In a linoleate peroxidation assay by cytochrome c, linoleate peroxidation was inhibited by betanin, betanidin, catechin, and α-tocopherol with IC_{50} values of 0.4, 0.8, 1.2, and 5.0 mM, respectively. Betacyanins from red beet were therefore more potent

antioxidants than catechin or tocopherol in inhibiting linoleate peroxidation [6]. Betaxanthins from red beet were found to inhibit lipid peroxidation by cytochrome c at an IC_{50} of ~1.0 μM. In addition, betanin was almost twice as effective as catechin in preventing LDL oxidation by H_2O_2-activated metmyoglobin [6]. Betanin from red beet was found to inhibit lipid peroxidation in a model liposome oxidation assay using fluorescence spectroscopy [73]. Betalains from prickly pears inhibited the myeloperoxidase/nitrate-induced oxidation of human LDL by scavenging the initiator radical nitrogen dioxide and lipoperoxyl radical [90]. A short-term supplementation study on healthy volunteers with prickly pear fruit showed a significant decrease in 8-epiprostaglandin $F_{2\alpha}$ (8-epi-$PGF_{2\alpha}$) and malondialdehyde in plasma, the ratio of reduced to oxidized glutathione (GSH:GSSG) in erythrocytes, and lipid hydroperoxides in LDL (these are biomarkers of oxidative stress) whereas supplementation with 75 mg vitamin C did not significantly affect any marker of oxidative stress [91]. Betalains in prickly pear were suggested to be responsible in the protection of oxidative damage to lipid [6]. The lipid peroxidation inhibitory effects of prickly pear fruit extracts containing betalains on fish oil, fish oil-in-water emulsion, and linoleic acid were investigated using conjugated diene hydroperoxides, weight gaining, peroxide value, and thiobabituric acid reactive substances assays. Prickly pear extracts containing betalains were able to show multiple lipid peroxidation inhibitory effect on different stages of lipid oxidation products generation in oils and emulsion model systems [92]. In an ex vivo study in which pooled human plasma from 10 healthy volunteers was incubated with either 25–100 μM betanin or indicaxanthin isolated from prickly pear, incorporation of both compounds in LDL was observed, with a maximum binding of 0:52 and 0:51 nmoles of indicaxanthin and betanin, respectively, per mg LDL protein. Indicaxanthin-enriched and betanin-enriched LDL were also more resistant than homologous native LDL to copper-induced oxidation [93].

Lipid-lowering drugs are used for primary and secondary prevention of cardiovascular diseases. The use of plant extracts to treat or regulate the conditions of lipidemia are gaining interest as they are known to have no side effects or toxicity compared to common synthetic lipid lowering drugs [5]. Administration of an aqueous extract of *Amaranthus tricolor* containing betalains at 200 mg/kg and 400 mg/kg body weight to diabetic rats significantly reduced blood cholesterol, triglyceride, and LDL levels, and increased HDL level [94].

A study on hypercholesterolemic rats found that force feeding of 300 mg/kg (body weight) of betalain containing extracts from pulps of *Hylocereus polyrhizus* reduced their total cholesterol level by 43.5% [95], probably by increasing excretion of bile acids. Feeding of betalains enriched beet crisps in mice resulted in a significant decrease in serum glucose level, atherogenic index, isovaleric acid concentration in the caecal, and body weight in rats. Furthermore, oral administration of betalains suppressed production of short-chain fatty acids, prevented the rise in serum total cholesterol and triacylglycerol levels in dyslipidemic rat models [96]. Rats fed with a control diet containing mixture of powders containing red beet as a source of betalains showed a significant reduction in their plasma total lipids, total cholesterol, LDL, triglycerides, and the ratio of total cholesterol/HDL in different

degrees, while HDL increased significantly [97]. Betalains may therefore have potential application in the management of hyperglycemia and associated lipidemia [5].

3.4 Antimicrobial Activity

Betalains have been reported to exhibit antimalarial and antimicrobial effects, but their effects are dependent on the dose and type of betalains present. Betalain rich *Amaranthus spinosus* showed significant antimalarial activity in mice due to high levels of betanin and amaranthin. These compounds were able to chelate the indispensable inner cations (Ca^{2+}, Fe^{2+} and Mg^{2+}) in the parasite and block the parasites choline intracellular transport which is crucial for malarial parasite growth [98]. Beetroot pomace containing betalains induced zones of reduced growth in *Salmonella* Typhymurium, *Staphylococcus aureus,* and *Bacillus cereus* [99]. Beet root pomace containing betalains was also found to inhibit Gram-negative bacteria *(Escherichia coli, Pseudomonas aeruginosa, Citrobacter freundii, Citrobacter youngae, Enterobacter cloacae,* S. Typhimurium) with S. Typhimurium and *C. freundii* being most susceptible [100]. Red beet pomace extract containing betalains showed inhibitory activity against Gram-negative bacteria in which the most susceptible strains are S. Typhimurium and *C. freundii.* Among the Gram-positive bacteria, *S. aureus, Staphylococcus sciuri,* and *B. cereus* showed high susceptibility. However, the extract did not exert any activities towards wild strains Bacillus sp., *Enterococcus faecalis* and *Listeria monocytogenes* and did not inhibit the growth of microorganisms with eukaryotic type of cells such as *Saccharomyces cerevisiae*, *Candida albicans*, *Aspergillus niger,* and *Penicillium aurantiogriseum* [62]. Slight antibacterial activity of methanolic extracts of red beet was also obtained against *E. coli* and *S. aureus* and absence of antifungal activity against *A. niger* and *C. albicans* were also reported by Rauha et al. [101].

Extracts of xoconostle pear (*Opuntia matudae*) containing betalains had a significant inhibitory effect on the growth of *E. coli* O157:H7 with an increase in xoconostle pear extract concentration associated with a slower growth rate and reduction in bacterial populations [102]. Betalains-rich fraction extracted from the pulp of red pitahaya exerted a broad antimicrobial spectrum by inhibiting Gram-positive bacteria (*B. cereus, S. aureus, Escherichia faecalis, L. monocytogenes*) at 7.8 μg/mL, Gram-negative bacteria (E. *coli, Proteus mirabilis, Proteus vulgaris, P. aeruginosa, Salmonella typhi Ty2, Yersinia enterocolitica, Klebsiella pneumonia, Enterobacter cloacae, Enterobacter aerogenes)* at 15.6–62.5 μg/mL, yeasts (C. *albicans, Rhizoctonia solani)* at 125–250 μg/mL and molds *(Fusarium oxysporum, Cladosporium herbarum, Botrytis cinerea, Aspergillus flavus)* at 500 μg/mL [103]. Betacyanin rich extract from red spinach *(Amaranthus dubius)* (minimum inhibitory concentration [MIC] values: 0.78–3.13 mg/mL) demonstrated a better antimicrobial activity profile than that of red pitahaya (MIC values: 3.13–6.25 mg/mL) against nine Gram-positive bacterial strains (*S. aureus,* Enterococcus sp., Bacillus sp.). Similarly, betacyanin rich extract from red spinach (MIC values: 1.56–3.13 mg/mL) was more active than that of red pitahaya (MIC

values: 3.13–6.25 mg/mL) against five Gram-negative bacterial strains *(Shigella flexneri, S.* Typhimurium, *K. pneumoniae, E. coli, P. aeruginosa)* [104]. The antimicrobial activity of betalains may be due to their adverse effects on the structure, function, and permeability of the cellular membranes of the microbes which eventually leads to cell death [100]. Although betalains were found to inhibit a wide antimicrobial spectrum, very little is reported in the literature on the mechanism of microbial inhibition by betalains. The specific underlying cellular and molecular mechanism of antimicrobial activity of betalains should be investigated in future studies [5].

4 Application of Betalains

The main application of betalains to date is as natural colorants. Other potential application of betalains in functional foods is also covered in this section.

4.1 Natural Colorants

Colorants or color additives can be used to serve several purposes in food processing, including standardizing raw ingredient colors, providing color identities to otherwise colorless foods, and accounting for loss during processing or storage [105]. There is growing interest in the use of natural pigments for food coloring which are considered to be harmless or even healthy. Synthetic colorants are becoming more and more critically assessed by the consumer. There were numerous regulation changes worldwide in terms of permitted colorings throughout the years. Many advanced countries have their own regulations and a list of approved food colors that can be used, including maximum daily intake. For instance, the USA permitted list of synthetic colorants was reduced from 700 to only seven until the beginning of the twenty-first century [106]. The last synthetic food colorant to be approved by the Food and Drug Administration (FDA) was FD&C Red No. 40 (Allura Red) in 1971 and there are not likely to be any more in the near future [107]. Colored natural extracts are preferred over purified colors because declaration of the former allows clean labeling [108]. Betalains are less commonly used than anthocyanins in food processing despite being more pH stable than the anthocyanins [39]. Betalains are water-soluble pigments that are stable between pH 3 and 7 and well suited for coloring from sour (low acid) to neutral foods [4, 19] whereas the use of anthocyanins is not possible due to the instability at pH values over 3 [28]. Betalains can be effectively stabilized by ascorbic acid, which on the other hand is known to facilitate anthocyanin degradation [109]. Application of betalains instead of anthocyanins for coloring food with high vitamin C content or vitamin C-supplemented products may be of particular interest [44].

Betalains have been used as food colorants at least since the turn of the twentieth century [24]. The early application involved the use of pokeberry (*Phytolacca Americana*) juice to improve the color of red wine [24, 110]. The addition of pokeberry juice to wine was forbidden in France in 1892 because the juice also

contains a purgatory and emetic saponin called phytolaccatoxin [110, 111]. The red pigment from pokeberry was called phytolaccanin until research established that it was identical to betanin in red beets [111, 112]. Today, the food colorant known as "beetroot red," extracted from red beet is commercialized in European Union and USA as food colorant. This food colorant is also called betanin or known as E-162 in the European Union and as 73.40 in the 21 CFR section of the FDA in the USA [113]. Betanin from red beet is one of the successful natural colorants used in the food industry [114] and approved for use as colorants in dairy products, sauces, soups, cosmetics, and pharmaceuticals by the US FDA and European Union [115]. Red beet colorants can be effectively used to color dairy products such as yoghurt and ice cream, salad dressings, hard candies and fruit chews, frostings, cake mixes, gelatin desserts, starch-based puddings, meat substitutes, poultry meat sausages, gravy mixes, soft drink and powdered drink mixes [116, 117]. Commercial red beet colorants are available as either juice concentrates (produced by vacuum-concentration of red beet juice to 60–65% total solids) or powders (produced by freeze or spray drying), containing from 0.3% to 1% of pigment [24, 117, 118]. The concentration of pure pigment required to obtain the desired hue is relatively small, rarely exceeding 50 mg/kg, calculated as betanin [26] as betalains have good tinctorial strength [108]. Betanin from red beets are, however, afflicted with a narrow color spectrum [108]. The typical earthy flavor caused by geosmin [119] may also deter the commercial use of E-162 in food application. Furthermore, the risk of carry-over earth bound microorganism from the raw material red beetroot is an important consideration [120]. Red beets are notorious accumulators of nitrates and nitrites during growing, and there is a necessity to reduce these levels in red beets [110].

The use of *Opuntia* sp. as colorants has several advantages such as neutral smell and/or taste, low nitrate content [115, 121], a broad color range [19, 121], and represents a lower risk for microbiological carry-over [9]. In particular, the yellow orange prickly pear fruits are of promising potential because of the scarceness of yellow water-soluble pigments [121]. Moreover, the low levels of colorless phenolic compounds in prickly pear fruits make them very promising since potential interactions of betalains with these phenolics are avoided [9]. However, prickly pears contain high amounts of reducing sugars and amino acids and thereby may enhance Maillard product formation [9]. *Opuntia ficus-indica* is the most extensively studied Opuntia species. Recent research carried out with various Opuntia species has revealed *Opuntia stricta* to be a promising source of betacyanin pigments with high betanin levels (800 mg/kg) which are five times higher than those found in red fruits of *O. ficus-indica* and even higher than those shown by commercial red beets used for their purple color [115]. *Opuntia stricta* extracts lack the yellow betaxanthins, and betanin and isobetanin are the betacyanins present [122]. Concentrated betacyanin extracts from the fruits of *O. stricta* with its pleasant taste and flavor showed high potential to be used as a natural colorant [113, 122]. Red- purple powder from *O. stricta* fruit juice was successfully applied as a colorant in two food model systems: a yogurt and a soft-drink [123]. On the other hand, Amaranthus plants, which can grow in a wider range of environments are a potential source of

red-violet betacyanin pigments and an alternative to the use of red beet [124]. Some Amaranthus genotypes produce particularly high biomass and contain high levels of pigment [125]. Betacyanins from Amaranthus showed high potential to be used as natural colorants in jelly, ice cream, and beverage [126, 127]. Red pitahaya is high in betacyanins and devoid of betaxanthins (which are present in E-162) providing colorants with a better tinctorial strength. Therefore, the red pitahaya can be used as an alternative source of betacyanins in regions where it is grown [128]. Betacyanin from red pitahaya showed promising application as a natural colorant in dairy products such as milk [128] and yogurt [129] whereby sensory acceptability of panelists of using colorant preparations from red pitahaya were similar or higher than that of E-162 [128, 129].

4.2 Other Applications of Betalains

Commercially, fruits and cladodes of Opuntia species are made into products such as juices, jams, and dehydrated fruits [130]. Many research have been carried out to expand the use of betalains, particularly betalains from the four main sources, namely, red beet, prickly pear, amaranthus, and red pitahaya. Effort has been made to produce various types of red beet juice [131–138], prickly pear beverages or juices [121, 139–144], and red pitahaya juices [16, 145, 146]. In addition, spray drying or other drying and encapsulation techniques have been investigated to produce dried form (powder) of betalains or to further stabilize betalains [126, 138, 147–156]. Powdered or dried red beet containing betalains has been incorporated into edible or intelligent films [157, 158], emulsified pork sausage [159], and cheese [160]. Red beet juice containing betalains has been investigated to produce nutritious pasta [161] and added as part of a curing system to produce chicken frankfurters [162]. Red beet chips as healthy fried snack foods were also investigated [163]. Prickly pear containing betalains has been investigated to produce enriched cereal-based extrudates [164] whereas *Opuntia ficus-indica* cladodes as a functional ingredient was incorporated into bread [165]. The effect of betacyanin pigments from *Amaranthus tricolor* and *Amaranthus cruentus* on commercial wheat flours was investigated as a basis to expand the applications of betalains as natural quality enhancers of wheat-based foods [166].

5 Conclusions

The biological and pharmacological properties of betalains-rich foods such as red beetroot, amaranth, prickly pear, and red pitahaya show their great potential as functional foods. Betalains should be used regularly in the diet. Consumers are most likely to benefit from the regular consumption of products rich in betalains such as juice and other products made of foods colored with betalains. The lack of commercially available standards has limited betalain analysis. There is a need for more highly purified betalains and increasing of studies using purified compound

instead of betalain-rich extracts would help to establish the actual role played by betalains alone or in cooperation with other compounds. The underlying cellular and molecular mechanisms of betalains need to be addressed in more detail in future studies. Further research is also needed to determine the concentration, extractability, and stability of other source of betalains in order to expand the use of betalains. Plant sources of betalains other than red beet should be grown in sufficient quantities to ensure that betalains could be produced at a large scale for food industry use.

Abstract

Psidium guajava commonly known as guava is one of the economical fruit crops belonging to the Myrtaceae family and grows in tropical and subtropical region. Largely grown as wild crop or selection variants, disease-free quality planting materials for establishment of guava orchard is necessary. The fruit is also labeled as super-fruit, and because of its unique flavor, taste, and health-promoting qualities, it is regarded as functional food or potent nutraceutical. It is rich in antioxidant compounds and contains a high level of ascorbic acid content, carotenoids, and phenolic compounds. It is acclaimed as the "poor man's apple of the tropic." Traditionally guava leaves and fruits are used in folk medicine for the treatment of various ailments like diarrhea, flatulence, gastric pain, wounds, rheumatism, ulcers, etc. Guavas possess antioxidant, antimicrobial, anticancer, antidiabetic, and anti-inflammatory activities, supporting a great therapeutic potential and a wide range of clinical applications. The important active biochemical compounds in guava are essential oils, phenolics, flavonoids, carotenoids, triterpenoids, esters, aldehydes, etc. Guava fruit is highly perishable, so to increase its shelf life, it may be processed into various value-added products like guava juices, squash, nectar, leather, jam, jellies, powder, etc. This chapter describes in detail about the guava plant, ecological requirements for its growth, various methods of its propagations, current knowledge about its nutraceutical properties and its application in preparing guava-based value-added products.

Psidium guajava · Guava · Cultivation · Phytochemicals · Bioactive potential · Nutraceutical · Value-added products

1 Introduction

Guava (*Psidium guajava Linn.*) belonging to the family Myrtaceae, with about 133 genera and more than 3,800 species, is native to Mexico, Central America, the Caribbean, and the Northern part of South America [1]. It is also grown in all the tropical and subtropical areas of the world including India and adapts to different climatic conditions but prefers dry climates. It is widely grown in tropics with its fruit widely known for its exotic flavor and potent aroma. Guava is a traditionally used plant because of its immense food and nutrition value. World production of guava is estimated to be about 1.2 million tons; however India and Pakistan contributes to about 50 percent of the world production [2]. Guava is also known as poor man's fruit or apple of tropics. The common varieties of guava are the red

(*P. guajava* var. *pomifera*) and the white (*P. guajava* var. *pyrifera*) [3, 4]. Various parts of the guava plant, viz., root, bark, leaves, and fruits, are found to possess many pharmacological properties as it is used in the treatment of various disorders [5]. Guava is rich in minerals and functional components such as vitamins and phenolic compounds which makes beneficial contribution to the human diet and is well accepted by the consumers [6]. All parts of this tree, including fruits, leaves, seeds, bark, and roots, have been utilized traditionally in many countries for treatment of looseness of the bowels, menstrual disarranges, vertigo, anorexia, stomach-related issues, gastric deficiency, aroused mucous layer, laryngitis, skin issues, ulcers, vaginal discharge, cold, cough, cerebral ailments, nephritis, jaundice, diabetes, malaria, and rheumatism [7–9]. It additionally has anticancer properties. The leaves of the guava tree are full of antioxidants, anti-inflammatory agents, antibacterial, and even tannins that can have significant health benefits, from treating stomach troubles to chronic diseases like cancer [10]. The fruit is labeled as super-fruit, and because of its unique flavor, taste, and health-promoting qualities, it is regarded as functional food or potent nutraceutical [11]. The term nutraceutical was coined by Stephen DeFelice in 1989 from nutrition and pharmaceuticals. It is defined as a food that provides health benefits, including prevention and cure of a disease [12]. The term nutraceuticals as commonly used in marketing has no regulatory definition [13]. The concept of nutraceuticals, functional food, designer food, phytochemicals, bioactive compounds, etc. is misnomers and quite confusing and are often used interchangeably. The supplementary diets or dietary supplements however differ from nutraceutical in many ways. Nutraceuticals are not only supplementary food included in diets but also conventional food which is part of the daily diet having health benefitting potentials. Nutraceuticals are also referred to as natural functional food or bioactive phytochemicals that have health-promoting, disease-/disorder-preventing, or medicinal properties.

These nutraceutical contains the macro- and micronutrients like carbohydrates, proteins, fats, lipids, vitamins, minerals, antioxidants, etc.; however, bioactive compounds are minor components of food and are defined as having the following characteristics: they are present in low concentrations; they are not considered to be nutrients; and they have a proven health effect [14]. Interaction between functional food components such as prebiotics, probiotics, phytochemicals, and intestinal microflora has consequences on human health [2].

2 Ecological Requirements

Guava can be grown under a wide range of climatic conditions. Compared to other fruit crops, guava is highly resistant to drought. As compared to the tropical areas, those with distinct winter promote production of abundant crop with better quality. In the tropics and subtropics, guava is found from sea level to an altitude of 1500 m asl. Guava trees growing at lower elevation are generally vigorous with heavy fruit set. Sandy loamy soils with the pH range of 5.5–7.5 are highly suitable for growing guava. However, it can be grown with minimum care in marginal and soils affected

with salinity. A temperature range of 23–28 °C during flowering to fruiting is found to be optimum. Temperatures lower than 7–8 °C cease the plant growth, and the leaves turn to purple. Natural defoliation occurs during the low winter temperatures and the flowering induced with rise in temperature and increased soil moisture. A rainfall pattern with alternating dry and wet conditions is highly suitable for maximum fruit set and high yields.

3 Cultivation

3.1 Cultivars

Majority of the cultivars of guava have been evolved after selection from seedling variants. Several promising genotypes from other countries have also been introduced into India by researchers. Even though many varieties are available in India, Allahabad Safeda and Sardar (L-49) occupied maximum share owing to its yield and market acceptability. Recently ICAR-IIHR, Bengaluru, released a pink-fleshed variety named as Lalit that has attained a wide popularity across the guava-growing regions of the country. Apart from these prominent cultivars, some of the cultivars grown in India and their important varietal characters are described in below table.

S. no	Cultivar	Developed/ released by	Characters
1	Allahabad Safeda	CISH, Lucknow	The fruits are relatively soft and contain less number of seeds. Suitable for both table and processing purposes
2	Sardar	CISH, Lucknow	Fruits with white flesh and more number seeds. Skin is harder than Allahabad Safeda
3	Lalit	CISH, Lucknow	Suitable for high-density planting. Epicarp is in saffron yellow color, and the flesh is in red blush color. High yielder compared to the existing commercial varieties in India
4	Shweta	CISH, Lucknow	Fruits are very attractive with white creamy epicarp and red spots of blush; flesh is snow white in color
5	Allahabad Surkha	CISH, Lucknow	Large and uniform pink color fruits with deep pink color flesh. The fruit contains strong flavor with less number of seeds
6	Pant Prabhat	GBPUA&T, Pant Nagar	Fruits with smooth peel and light yellow in color. White color pulp with small seeds and high flavor
7	Arka Mridula	ICAR-IIHR, Bengaluru	Pulp is white in color with sweet taste. Keeping quality is good
8	Arka Amulya	ICAR-IIHR, Bengaluru	Medium-sized fruits with white and sweet pulp. Pulp contains round-shaped small number of seeds. Keeping quality is good
9	Arka Kiran	ICAR-IIHR, Bengaluru	Fruits with firm pulp and pink in color

(*continued*)

S. no	Cultivar	Developed/ released by	Characters
10	Arka Rashmi	ICAR-IIHR, Bengaluru	Medium-sized fruits with deep pink color pulp and soft seeds
11	Hisar Safeda	CCSHAU, Hisar	Medium-sized round-shaped fruits with smooth and yellowish green surface. Pulp is creamy white in color with few number of seeds
12	Hisar Surkha	CCSHAU, Hisar	Medium-sized round-shaped fruits with smooth and yellowish green surface. Pulp is pink in color with harder seeds

Apple color, Anakapalli, Banarasi Surkha, Chittidar, Dholka, Dharwar, Habsi, Karela, Punjab smooth, Sangam, Mizapuri seedling, Nasik smooth white, Thailand guava, Philippine guava, Florida seedling, etc. are some of the locally grown cultivars available in India.

3.2 Propagation

In spite of large number of private and public sector nurseries, still there is a shortage of disease-free quality planting materials for establishment of guava orchard. Mass multiplication through vegetative propagation results in uniform crop with relatively short pre-bearing period in guava compared to the seed propagation. Out of the several methods of vegetative propagation, air layering, wedge grafting, budding, and stooling are found better for raising the productive seedlings in guava [15]. Healthy, disease-free, and vigorous mother trees should be selected for raising the nursery stock.

3.2.1 Air Layering

In this method, the healthy branches of 1.2 cm or more diameter are selected and then girdled by removing a strip of bark with the width of about 2 cm. The girdled area is then covered with the sphagnum and wrapped with the polythene film. Within 3–4 weeks, the roots start developing from the layered portion. The rooted layers are detached from the mother plant and can be used for planting. Rainy season is the best season for air layering.

3.2.2 Wedge Grafting

The rootstock selected for grafting is split to about 4–4.5 cm with a knife, and wedge-shaped cut slanting from both the sides is made on the lower side of the scion material. The scion material is inserted in to the rootstock split and pressed properly to bring both the materials into contact with each other. The union is then tied with the polythene strip. The scion starts sprouting after 9–12 days and should be transferred for hardening after 1 month.

3.2.3 Budding

Patch budding is considered to be the efficient method of propagation in guava with high success rate. In this method, healthy seedlings of 1 year old are selected, and 1–1.5 cm long patch is removed from the rootstock. Unsprouted, dormant buds selected from the leaf axils of scion variety is fitted into the rootstock patch and tied with the polythene strip. After 2–3 weeks, the strips should be removed to examine the success of the budding.

3.2.4 Stooling

In this method, self-rooted plants are planted 0.5 m apart in the stooling bed and then allowed to grow for about 3 years. Then these are cut down to the ground level, and new shoots emerges on the stumps. All these shoots are mounted with the soil to a

height of 30 cm. On the onset of monsoon, the shoots are detached from the mother plant and can be used for direct planting.

3.3 Layout and Planting Systems

This refers to the planting of trees in an orderly manner to ensure the maximum number of trees per unit area and to facilitate the smooth operation of intercultural activities. Planting systems such as square, rectangular, triangular, hexagonal, and quincuncial systems can be adopted based on the availability of land. After completion of layout, the pits of 75 cm × 75 cm × 75 cm are dug and left open for 15 days. The grafts are to be placed in the center of the pits and pressed tightly all around. The graft/bud union should remain well above the soil surface. A planting distance of 5 m × 5 m is recommended for healthy and vigorous growth of the plants. With this spacing 400 trees can be planted in one ha of land. High-density planting with the spacing of 3.0 m × 3.0 m and 1.5 m × 3.0 m is also recommended for specific varieties. Rows should be planted in North-South direction to facilitate maximum sunlight exposure. Pits should be watered copiously immediately after planting. Mulching can be done at the basins to conserve the moisture during the initial stages of establishment.

3.4 Crop Regulation

Flowering and fruiting in guava follow specific pattern and occur in two major seasons, once during March to May and the later in July–August [16]. The fruits from March to May flowering are harvested in rainy season, and the fruits from second flowering are harvested during winter, i.e., late October to mid-February. The July flowering gives more number of flowers and good quality of the fruits compared to the summer flowering. Orchard losses can be avoided by adopting effective crop regulation practices to manage the flowering in guava and for harvesting the good quality fruits. Spraying urea at 10–15% twice during bloom (April–May) eliminates the rainy season fruiting [17].

3.5 Crop Management

3.5.1 Orchard Management

Guava, being a perennial crop, needs utmost care while selecting the varieties and the quality planting material. Any mistakes committed in the early stages of the orchard management cannot be rectified at a later stage.

3.5.2 Nutrient and Water Management

Amount of manures and fertilizers to be applied to guava tress depends upon the age of tree and the soil characteristics. At the time of planting, each pit should be filled

with well rotten farm yard manure at 15–20 kg and 1.5 kg of single superphosphate. A recommended dose of 260 g urea + 375 g SSP + 100 g of MOP per plant should be supplied in the first year. The dose increases with each passing year.

The fertilizers are applied in two split doses preferably in June and September. Guava is highly prone to micronutrient deficiency and remedial measures should be taken immediately with foliar sprays of micronutrients. Furrow and basin method of irrigation are most popular in guava orchards [18]. In the initial stages of plant growth, it is imperative to maintain the optimum soil moisture by watering every alternate day. After 2 years of age, watering may be done once in every 7 to 10 days interval during the summers, and irrigation should be avoided during the rainy season. During the dry season, the flowering and fruiting will be greatly influenced by the water availability [19]. Sprinkler and drip irrigations can be adopted for increasing the productivity and quality of fruits [20].

3.6 Harvesting and Handling

The quality of guava fruit depends on the stage of maturity. The fruits are usually ready to harvest 4–5 months after the flowering. Guava fruits are generally handpicked. Color change, specific gravity, total soluble solids, acidity, etc. are the useful criteria to judge the maturity levels in guava [21]. At the time of maturity, the specific gravity becomes <1.0, and it starts floating on the water surface. The fruits with the specific gravity of 1.00–1.02 have better shelf life and suitable for long-distance transport. It is desirable to pick the fruits along with 5–7 cm stalk and two to three leaves. Proper grading and sorting increase the postharvest shelf and fetch high prices to the growers. At room temperature, the shelf life is for a few days only. The fruits picked during the winter season can be stored for 7–8 days at ambient temperatures whereas rainy season picked fruits can be stored only for 2–3 days, depending on the variety. At low temperatures of 10–15 °C, the shelf life can be extended up to 3–4 weeks [22]. For low temperature storage, fruits must be picked at hard, green, and immature stage without color break.

4 Morphology

Guava trees are little shrubby evergreen trees with a considerable measure of wide-spreading branches and square fleece twigs. The branches are screwy bringing inverse clear out. The blooms are white borne independently, or in little gatherings in axils of leaves of late development, petals are incurved; they are fragrant with four to six petals. Each blossom bears various white needlelike stamens which oblige smooth anthers. Self-fertilization is conceivable, yet cross-pollination by creepy crawlies brings about higher yields [23]. The organic product is little, 3 to 6 cm long in different shapes going from ovoid, round, to pear-formed contingent on species. The external skin might be unpleasant having a severe taste or delicate and sweet.

The skin shading is typically green before development however winds up noticeably yellow, maroon, or green when ready with tissue running from white, yellow, and pink to red differing with species. Natural product might be thin-shelled with many seeds installed in a firm mash or might be thick-shelled with fewer seeds. Kind of natural product shifts from sweet to profoundly corrosive. The distinctive fragrance ranges from solid and penetrating to mild and pleasant [24].

5 Nutritional Attributes

Guava is reported to possess rich nutritional attributes ranging from carbohydrates, minerals, vitamins, to antioxidants. The nutritional composition of guava has been reported to vary with cultivars, season, and environment. The main carbohydrate in the form of simple sugars has been identified as glucose and xylose [25]. Every 100 gram of fresh guava fruit servings in general contributes to 75–85% of moisture, 3–7% of total dietary fiber, 1–6% of protein, and 0.7 to 0.11% of lipids. Among mineral contents, potassium content (352.7 mg/100gft) is reported to be highest in fresh guava, followed by phosphorus (17.8–30 mg/100gft), calcium (9.1–17 mg/100gft), and iron (0.4–0.7 mg/100gft) [2, 26, 27]. It is also reported to contain many of the vitamins required by human body of which the vitamin C content (50–300 mg/100gft) is reported to be highest in guava [28].

In a study [29], it was observed that with the advancement of fruit maturity at different stages, the total soluble solid (TSS), sugar (total, reducing, and non-reducing), and ascorbic acid contents increased significantly, while during fruit ripening stage both acidity and pectin decreased. Of all the guava cultivars studied, L-49 showed highest TSS (12.250B), total sugar (8.50%), and ascorbic acid (265.09%) followed by Allahabad Safeda, while L-49 showed minimum acidity (0.26%) and maximum pectin content (0.77%). Pectin methyl esterase (PME) activity increased progressively in all the cultivars up to half ripe stage (HRS) and subsequently decreased at full ripe stage (FRS). Maximum PME activity was found in L-49 (56.25 units/g.f.wt) at HRS, whereas it showed a decrease at FRS (52.25 units/g fresh weight (FW) followed by Allahabad Safeda and Lalit. Thus, it was concluded that L-49 was superior among all the commercial cultivars of guava grown under subtropical condition followed by Allahabad Safeda and Lalit.

5.1 Phytochemicals

Phytochemicals (phyto, plant) are biologically active chemical compounds found in plants offering health advantages for humans in addition to those attributed to macronutrients and micronutrients [30]. Phenolic compounds are secondary metabolites which are produced in the shikimic acid of plants and pentose phosphate through phenylpropanoid pathway [31]. They contain benzene rings with one or more hydroxyl substituent and range from simple phenolic molecules to highly polymerized compounds [32]. The phytochemical analysis of guava leaves revealed

the presence of flavonoids, glycosides, alkaloids, steroids, and many other metabolites and absence of tannins and saponins [33].

Guava is one of the promising fruits rich in lectins, saponins, tannins, phenols, triterpenes, and flavonoids. High levels of vitamins, dietary fiber, and carotenoids, altogether make guava therapeutically an important fruit [34]. The fruit pulp is rich in ascorbic acid and carotenoids (lycopene, β-carotene, and β-cryptoxanthin). The seeds, skin, and bark have glycosides, carotenoids, and phenolic compounds.

5.1.1 Polyphenols

Polyphenols are synthesized by numerous plants as secondary metabolites. Polyphenolic compounds serve as both functional components to the plant and the consumer. For instance, some polyphenols serve as pigment (anthocyanins) compounds to ward off insects and other herbivores such as astringent, tannins, and UV light protectants such as carotenoids [35].These compounds are also important in foods for their sensory attributes such as color, astringency, and bitterness, as well as their possible nutritional properties. Polyphenols are products of three major plant metabolic pathways. Phenolic compounds consist of a phenol and an aromatic ring with at least one hydroxyl group attached. Phenolic compounds can be classified into several categories based on their structures. Phenolic acids are secondary metabolites of the shikimate pathway; the phenylpropenoid pathway produces the cinnamic acid derivatives which are precursors of flavonoids and ligans, and the "flavonoid route" produces the numerous and diverse flavonoid compounds [36]. Polyphenols, which include flavonoids, have at least two phenol groups. The largest polyphenols are the tannins which can be classified into two subgroups, the hydrolyzable and the condensed tannins. Hydrolyzable tannins are those which are readily hydrolyzed by acids or enzymes into gallic or ellagic acid [37]. Hydrolyzable tannins are commonly found in foods such as guava, grapes, and wine. Both condensed and hydrolyzable tannins have been shown to have antioxidant, enzyme-inhibiting, and antimicrobial properties [36]. Condensed tannins, also called "vegetable tannins" or proanthocyanidins, are flavonoid polymers which can be degraded in the presence of acid and heat to form either cyanidin or delphinidin and are relatively stable as compared to the hydrolyzable tannins [37]. Common condensed tannins include polymers of catechin and epicatechin which can be found in guava, teas, and numerous fruits and vegetables. The third phenolic group is the phenolic acids that consist of a benzene ring and at least one carboxylic acid group. Examples of phenolic acids are caffeic, chlorogenic, p-coumaric, gallic, and ellagic acids (Table 1). Many phenolic acids are linked through ester, ether, and acetal bonds to either structural components of the plant such as cellulose, proteins, or lignin; to larger polyphenols (tannins); or to smaller organic molecules such as glucose [38]. This leads to considerable diversity among the various classes of polyphenolics and therefore inherent difficulty in analysis and identification. Limited information exists on the guava phenolics; however, previous studies have shown guava to contain a variety of polyphenolics including flavonols, phenolic acids, flavan-3-ols, and condensed tannins [39, 40].

Table 1 Phenolics in guava

6	Kaempferol		[41]
7	Ellagic acid		[42]
8	Naringenin		[43]
9	Quercetin		[42]

[a]Structure taken from ChemSpider structure draw online software

5.1.2 Ascorbic Acid

Fruits are the major source of ascorbic acid, a nutrient required for humans and one of the most abundant antioxidants consumed. L-ascorbic acid is an excellent reducing agent, and large quantities may help stabilize phenolics and other antioxidants during processing by the donation of hydrogen atoms. This reducing ability is due to its 2,3-enediol moiety. Ascorbic acid is often considered as an index of nutrient quality during processing and storage of foods because of its stabilizing nature [44, 45]. Guava contains approximately 230 mg of total ascorbic acid/100 g of edible portion of fruit, five times more than a serving of orange. Among all fruits, it is second to acerola cherry in vitamin C content [46].

5.1.3 Carotenoids

Carotenoids are abundant in red-, yellow-, orange-, and green-colored vegetables and fruits. After chlorophyll, they are the second most widely occurring plant pigment found in nature. Carotenoids are tetraterpenes that can be classified into two major groups including carotenes (hydrocarbons) and xanthophylls (oxygenated hydrocarbons). Carotenoids may be straight chained, such as lycopene, or contain a five or six carbon ring on one or both ends, such as β-carotene [47]. The high degree of hydration and long carbon chain length of these molecules make them hydrophobic and therefore fat-soluble molecules. The major purpose of carotenoids in the human diet is to serve as precursors to provitamin A. In order to serve this purpose, the carotenoid must contain a β-ionone ring [45]. Carotenoids containing this structure include β- and α-carotene and ß-cryptoxanthin. Carotenoids without this structure, such as lycopene, do not possess provitamin A activity yet serve as dietary antioxidants. As an antioxidant, carotenoids are known to quench singlet oxygen and protect against cellular oxidative damage [48]. A wide variety of carotenoids have been identified in guava including phytofluene, β-carotene, lycopene, cryptoflavin, cryptoxanthin, and lutein (Table 2) [28]. Lycopene is a fat-soluble carotenoid responsible for the red or pink pigment in several fruits and vegetables such as tomatoes, watermelon, pink grapefruit, and guava. Structurally, lycopene is a linear, 40 carbon hydrocarbon containing 11 conjugated and 2 non-conjugated double bonds [49]. Of all the dietary carotenoids, lycopene has the highest singlet oxygen quenching ability in the body. However, since lycopene lacks a β-ionone ring, it does not provide vitamin A activity.

5.2 Chemical Composition of Leaves

5.2.1 Leaf Phenolics

All parts of guava have been used for various purposes such as hepatoprotection, antioxidant, anti-inflammatory, antispasmodic, anticancer, antimicrobial, antihyperglycemic, analgesic, endothelial progenitor cells, anti-stomachache, and antidiarrhea. The primary constituents of guava leaves are phenolic, isoflavonoids, gallic acid, catechin, epicathechin, rutin, naringenin, and kaempferol having hepatoprotective, antioxidant, anti-inflammatory, antispasmodic, anticancer, antimicrobial, antihyperglycemic, and analgesic actions [51].

Table 2 Structure of major carotenoids reported in guava

S. no	Name	Structure	References
1	Beta-carotene		[28, 50]
2	Lycopene		[28, 50]
3	Lutein		[28]
4	Rubixanthin		[28]
5	Cryptoflavin		[28]

Gallic acid, catechin, and epicatechin have been found to inhibit pancreatic cholesterol esterase thereby decreasing cholesterol levels. Catechins are important as a preventive treatment for diabetes type 2 and obesity. Guava leaves contain two important flavonoids quercetin known for its spasmolytic, antioxidant, antimicrobial, anti-inflammatory actions and guaijaverin known for its antibacterial action [43, 52]. Quercetin has been associated with decreased mortality from heart disease and decreased incidence of stroke. Rutin is effective in the inhibition of triglyceride accumulation in adipocytes. Naringenin and kaempferol can promote moderate cytostatic activity against all cell lines, and kaempferol can be useful as anticancer [53, 54]. Leaf extract of guava has been reported for their antibacterial activity because of the presence of flavonoid glycosides, morin-3-O-alpha-L-lyxopyranoside, and morin-3-O-alpha-L-arabopyranoside [55]. Phenolic contents are key players of antimicrobial property of fruit leaves, certifying the importance of organic product of leaves as a solid nutritious items as well as multiresistant bacterial drug.

5.2.2 Leaf Oil

The leaves contain various constituents such as fixed oil (6%), volatile oil (0.36%), resin (3.15%), tannin (8.5%), fat, cellulose, chlorophyll, mineral salts, and a number of other substances [56]. In addition, the leaves contain an essential oil rich in cineol

and four triterpenic acids as well as three flavonoids, quercetin, its 3-L-4-4-arabinofuranoside (avicularin), and its 3-L-4-pyranoside with strong antibacterial action [52]. Guava leaves contain essential oil with the primary components being α-pinene, β-pinene, limonene, menthol, terpenyl acetate derivation, isopropyl liquor, longicyclene, caryophyllene, β-bisabolene, caryophyllene oxide, β-copanene, farnesene, humulene, selinene, cadinene, and curcumene [23].

Guava is known for its efficacy as a potent antimicrobial agent. The guava leaf crude extract showed minimum inhibitory concentration of 3.75 mg/ml for *Bacillus subtilis* and *Pseudomonas aeruginosa*. The phytochemical analysis of the extract revealed the presence of bioactive compounds such as saponins, alkaloids, flavonoids, terpenoids, carbohydrates, and tannins [57]. The methanolic extract has showed toxicity against clinically important gastrointestinal pathogens, viz., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Escherichia coli*, *Salmonella typhi*, and *Vibrio cholera* with *S. typhi* being highly susceptible with a zone of inhibition of 2 mm at 4 mg/ml [33].

5.3 Chemical Composition of Guava Fruit

5.3.1 Fruit Nutrients and Antioxidants

The main constituents of guava fruit are vitamins, tannins, phenolic compounds, flavonoids, essential oils, sesquiterpene alcohols, and triterpenoid acids. These and other compounds are related to many health effects of guava [4].

Guava is a rich source of dietary fibers; vitamins A, C, and folic acid; and various dietary minerals like potassium, copper, and manganese. Pulp contains ascorbic acid and carotenoids (lycopenes, β-carotene) possessing antioxidant, antihyperglycemic, and antineoplastic properties [56]. Reports indicate that a single guava (*Psidium guajava*) fruit contains about four times the amount of vitamin C as an orange. Ascorbic acid is recognized for its important antioxidant effects [51, 58]. It has been reported that strawberry guava (*P. littorale* var. *cattleianum*) notably containing 90 mg of vitamin C per serving has about 25% more of the amount found in more common varieties, with its total vitamin C content in one serving still providing 100% of the dietary intake [59]. Further, guava also contains both carotenoids and polyphenols like allocatechin, guaijaverin, leucocyanidin, and amritoside [5, 60] which are reported as major classes of antioxidant pigments giving them relatively high potential antioxidant value among plant foods [61]. Some authors have found high concentrations of carotenoids (beta-carotene, lycopene, and beta-cryptoxanthin), vitamin C, and polyphenols in guava pulp [50]. Lycopene has been correlated with the prevention of cardiovascular damage because of its positive effects on dyslipidemia. The pulp and peel of the guava are a remarkable source of antioxidants and antioxidant dietary fiber (AODF) [62].

Guava fruits contain carotenoids and polyphenol pigments responsible for production of fruit skin and flesh color. Therefore, guavas that are red-orange in color have more pigment content (polyphenol, carotenoid, and provitamin A) than yellow-green ones [63]. Ojezele et al. (2013) found the highest concentrations of

the bioactive principles in ethanolic extracts of the plants and reported the quantity of different bioactive components, i.e., tannin (11.5 mg/g), total polyphenol (1.67 mg/g), alkaloid (59.85%), and oxalate (6.66%) in guava [64]. In white and red guava, the ascorbic acid contents reported were 130 and 112 mg/100 g fw; total phenolic content, 145.52 and 163.36 mg gallic acid equivalents (GAE)/100 gfw; and total flavonoids contents, 19.06 and 35.85 mg catechin equivalents (CE)/100 gfw, respectively. The solid-phase microextraction (SPME)/gas chromatography (GC)/mass spectrometry (MS) analysis revealed the presence of cinnamyl alcohol, ethyl benzoate, ß-caryophyllene, (E)-3-hexenyl acetate, and α-bisabolene as the major constituents in white and red guavas [65].

5.4 Chemical Composition of Guava Seeds

The guava seeds have varying amounts of macronutrients and micronutrients with a high content of total dietary fiber, protein, iron, zinc, and reduced calorie content. The lipid profile of guava seeds has shown a predominance of unsaturated fatty acids (87.06%) particularly linoleic acid and oleic acid as well as significant amounts of bioactive compounds such as ascorbic acid (87.44 mg/100 g), total carotenoids (1.25 mg/100 g), and insoluble dietary fiber (63.55 g/100 g) [66].

The seeds also contain glycosides, carotenoids, and phenolic compounds having antimicrobial properties [56]. Pelegrini et al. (2008) isolated and purified the peptide Pg-AMP1 from guava seeds. Pg-AMP1 showed clear growth reduction in *Klebsiella* sp. and *Proteus* sp., the principal pathogens involved in urinary and gastrointestinal hospital infections. SDS-PAGE and mass spectrometry (MALDI-TOF) characterized Pg-AMP1, a monomer with a molecular mass of 6029.34 Da. Amino acid sequencing revealed clear identity to the plant glycine-rich protein family with Pg-AMP1, the first such protein with antimicrobial activity against gram-negative bacteria. Thus, Pg-AMP1 shows potential in the near future to contribute toward development of novel antibiotics from natural sources [67].

6 Bioactive Potential of Guava

6.1 Antioxidant Activity

Antioxidants play a crucial role in both enzymatic and nonenzymatic browning reactions and help to prevent lipid oxidation in foods as well. Dietary antioxidants include vitamins A, C, and E as well as numerous non-nutritive compounds such as polyphenolics, flavonoids, carotenoids, and thiol-containing compounds. Biologically antioxidants may be defined as compounds that prevent free radicals generated during various metabolic reactions occurring in living cells from destroying host cells. Free radicals result from reactive oxygen species (ROS) that contain an unpaired electron rather than the paired electrons present in stable functioning molecules. These free radicals can interfere in the body and cause destructive

damage that could lead to many chronic health issues including cardiovascular diseases, stroke, atherosclerosis, and cancer. Antioxidants that are chemically reducing agents donate electrons and cause a substance to be reduced and thus help to reduce the number of free radicals and in the process may reduce the risks of such diseases [68].

Almost all the parts of guava are reported to have antioxidant properties. *Psidium guajava* fruit peel aqueous extract has the ability to reduce the oxidative stress of the pancreas in streptozotocin-induced (45 mg/kg) diabetic rats by lowering malondialdehyde (MDA) and protein carbonyl level and the increased activity of superoxide dismutase (SOD) and glutathione (GSH) level [69]. Besides, the antihyperglycemic effect of guava is also associated with its antioxidative activity [70]. Pink guava puree supplementation can decrease lipid peroxidation and increase antioxidant enzyme activity such as catalase, superoxide dismutase, glutathione peroxidase, and glutathione reductase in spontaneous hypertensive rat's blood [71]. The antioxidant activity values of guava leaves determined by 2-diphenyl-1-picryhydrazyl (DPPH) free radical scavenging and ferric reducing antioxidant power (FRAP) assays were 10.28 μg fresh weight (fw)/μg and 78.56 μg Trolox equivalent (TE)/g fw for white guava and 7.82 μg/μg DPPH fw and 111.06 μg TE/g fw for red guava [65].

The comparative study of antioxidant activity and free radical-scavenging effects of extracts from guava leaves and dried fruit indicated that 94.4–96.2% of linoleic acid oxidation was inhibited by the addition of guava leaf and guava tea extracts at a concentration of 100 μg/ml. The guava dried fruit extracts exhibited weaker antioxidant effects than the leaf extracts. The results also demonstrated that the scavenging effects of guava leaf extracts on $ABTS^{+}$ radicals and superoxide anion increased with increasing concentrations. The guava leaf extracts displayed a significant scavenging ability on the peroxyl radicals. The extracts from leaves of various guava cultivars exhibited more scavenging effects on free radicals than did commercial guava tea extracts and dried fruit extracts. The chromatogram data indicated that guava extracts contained phenolic acids such as ferulic acid which appeared to be responsible for their antioxidant activity. The studies have shown that there exists a linear relationship between free radical-scavenging ability and the content of phenolic compounds of guava leaf extracts [72].

Mile et al. (2011) explored the possibility of obtaining phenolic extracts with antioxidant activity (AA) from Colombian guava seeds (*Psidium guajava* L.) using supercritical carbon dioxide adding ethanol as cosolvent (SC CO2/EtOH). The crude extracts were obtained by using block extraction designs step by step (four steps) as a function of pressure (10, 15, and 20 MPa) and temperature (313, 323, and 333 K). In each one of the extracts, the total phenolic content (TPC) and AA were determined through β-carotene bleaching and scavenging DPPH (2, 2-diphenyl-1-picrylhydrazyl) methods. Fraction IV showed a good performance in preventing the formation of peroxides, while the best crude extract inhibited the degradation of conjugated dienes suggesting that the guava seeds are a promising source of antioxidants which can be extracted using SC CO2/EtOH by special extraction step design and these compounds can thus be used as preservatives in foods such as edible oils [73].

6.2 Anti-Inflammatory Activity

Inflammation is a normal response to infection which involves the innate and adaptive immune systems. However, when allowed to continue unchecked, inflammation may result in autoimmune or autoinflammatory disorders, neurodegenerative disease, or even cancer [74]. A decoction of *P. guajava* leaves is used for the treatment of various inflammatory ailments including rheumatism. The presence of polyphenolic compounds and triterpenoids in the leaf of *P. guajava* contribute to its anti-inflammatory and analgesic effects. The aqueous extract of *P. guajava* at a dose of 50–800 mg/kg, i.p. (intraperitoneal), produced dose-dependent and significant inhibition of fresh egg albumin-induced acute inflammation (edema) in rats. Further, leaf extract (50–800 mg/kg, i.p.) also produced dose-dependent and significant analgesic effects against thermally and chemically induced nociceptive pain (pain caused by damage to body tissue) in mice [75].

Jang et al. 2014 investigated the in vitro and in vivo anti-inflammatory activity of ethanolic leaf extract of guava and demonstrated the significant inhibition of lipopolysaccharide (LPS)-induced production of nitric oxide and prostaglandin E2 by guava leaf extract (GLE) in a dose-dependent manner. GLE suppressed the expression and activity of both inducible nitric oxide synthase and cyclooxygenase-2 in part by the downregulation of ERK1/2 (extracellular signal-regulated kinase-1) activation in RAW 264.7 macrophages [76]. Studies on the anti-inflammatory activity of the aqueous extract of guava leaves (*P. guajava* L.) on white male rats through carrageenan-induced paw edema method have shown that the percentage of inflammation or edema (% E) is optimal at the 4th hour. Guava extract at 125, 250, and 500 mg/kg BW (body weight) reduced inhibitory percentage activities by 40.81, 55.45, and 43.61% ($p < 0.05$), respectively, suggesting that guava extract acts as anti-inflammatory properties by decreasing edema level [77].

6.3 Antidiabetic Activity

Guavas have high fiber content and low glycemic index thus playing an important role in preventing the development of diabetes. The fiber content ensures that the sugar levels are well regulated and the low glycemic index inhibits a sudden spike in sugar levels. The formation of advanced glycation end products (AGEs) are the major factors responsible for the complications associated with diabetes. In vitro studies support the anti-glycative potential of guava leaves. The investigation of the antihyperglycemic efficacy and mechanisms of action of *P. guajava* in streptozotocin (STZ)-induced diabetic rats revealed that oral administration of *P. guajava* leaf extract (300 mg/kg body weight/day) for 30 days to streptozotocin-induced diabetes rats significantly decreased the levels of blood glucose and glycosylated hemoglobin and improved the levels of plasma insulin and hemoglobin [78, 79]. The possible mechanism for the antihyperglycemic activity of *P. guajava* leaf involves the protection of pancreatic tissues as well as islet β-cells by guava leaf extracts against lipid peroxidation and the DNA strand breaks induced by STZ thus reducing the loss of insulin-positive β-cells and

insulin secretion, therefore strengthening the possibility of antihyperglycemic potential [70]. There are studies supporting that guava fruit could protect kidney against diabetic progression via its anti-oxidative, anti-inflammatory, and anti-glycative effects [80].

The tannins, polyphenolic compounds, flavonoids, pentacyclic triterpenoids, guiajaverin, quercetin, etc. were speculated to account for the hypoglycemic effects of the plant's leaf extract [81]. The aqueous guava leaf extract enhanced glucose uptake in rat clone 9 hepatocytes which revealed that phenolics are the principal component of the extract and high polarity fractions of the guava leaf extract are enhancers to glucose uptake in rat clone 9 hepatocytes and quercetin is the major active compound which promotes glucose uptake in liver cells.

Water-soluble solids showed higher superoxide dismutase-like activity and lipid peroxidation inhibition ability than ethanol-soluble solids in vitro, suggesting that anti-peroxidation of lipids is a possible mechanism for guava leaves to retard the progress of type 2 diabetes [82, 83]. In addition, normal, mild, and severely diabetic rat models had shown hypoglycemic as well as antidiabetic effect of the unripe guava fruit peel aqueous extract [84].

Long-term administration of guava leaf extracts increases the plasma insulin level and glucose utilization in diabetic rats. The activities of hepatic hexokinase, phosphofructokinase, and glucose-6-phosphate dehydrogenase in diabetic rats fed with aqueous extracts were higher than in the normal diabetic group, which provided evidence to support the antihyperglycemic effect of guava leaf extract and the health function of guava leaves against type 2 diabetes [85, 86]. The comparative study of the hydroalcoholic extracts of the fresh and dry leaves of guava plant for antihyperglycemic potential against alloxan-induced diabetes in rats revealed that the animals administered with doses of 500 mg/kg body weight of extract orally continuously for 30 days caused significant reduction in the fasting serum blood glucose levels. Among the two extracts, fresh leaf extract showed significant antihyperglycemic activity than the dry leaf extract which nearly produced equal reduction in serum blood glucose levels to that of standard glibenclamide 10 mg/kg body weight [87]. The evaluation of antidiabetic effect of *P. guajava* leaves on $Lepr^{db}/Lepr^{db}$ mice (*mice* that develop type 2 diabetes due to a recessive, autosomal mutation in the leptin receptor) showed significant blood glucose lowering effects after intraperitoneal injection of the extract at a dose of 10 mg/kg in both 1- and 3-month-old $Lepr^{db}/Lepr^{db}$ mice suggesting that the extract from *P. guajava* leaves possesses antidiabetic effect in type 2 diabetic mice model [85].

6.4 Antidiarrheal Activity

Diarrhea is one of the major problems in the world. The ripe fruit of guava has been reported as laxative which is used to treat constipation. The studies indicate that guava fruit is more effective antidiarrheal when it is used with the peel, but if taken unripe fruits in large quantity cause indigestion and vomiting [26, 88]. The leaf decoction of guava has been proved useful in case of gastroenteritis and chronic diarrhea, while the young leaves and shoots have been reported for dysentery and

diarrhea [89]. The binding of certain chemicals present in guava such as lectin to *E. coli* (a common diarrhea-causing organism) prevents its adhesion to the intestinal wall and thus preventing infection resulting diarrhea [90]. Guava leaf extract has also shown to have tranquilizing effect on intestinal smooth muscle, inhibits chemical processes found in diarrhea, and aids in the reabsorption of water in intestines. In another research, an alcoholic leaf extract was reported to have a morphine-like effect by inhibiting the gastrointestinal release of chemicals in acute diarrheal disease. This morphine-like effect was thought to be related to a chemical, quercetin.

In a study carried out with leaf extract of the plant, inhibition of gastrointestinal release of acetylcholine by quercetin present in extract was suggested as a possible mode of action in the treatment of acute diarrheal disease [91, 92, 93].

6.5 Antimicrobial Activity

Biswas et al. (2013) determined the antimicrobial potential of guava leaf extracts against foodborne and spoilage bacteria, viz., *E.coli* and *Salmonella enteritidis* (gram-negative) and *S. aureus* and *Bacillus cereus* (gram-positive). The findings suggested that the methanol and ethanol extracts of the guava leaves showed inhibitory activity against gram-positive bacteria, whereas the gram-negative bacteria were resistant to all the solvent extracts. The methanol extract had an antibacterial activity with mean zones of inhibition of 8.27 and 12.3 mm, and the ethanol extract had a mean zone of inhibition of 6.11 and 11.0 mm against *B. cereus* and *S. aureus*, respectively. This demonstrates that guava leaf extract might be a good candidate in the search for a natural antimicrobial agent. The mechanism by which they can inhibit the microorganisms can involve different modes of action. It has been reported that guava oils and extracts penetrate the lipid bilayer of the cell membrane, rendering it more permeable, leading to the leakage of vital cell contents [94, 95].

A study conducted to screen the antimicrobial effect of essential oils and methanol, hexane, and ethyl acetate extracts from guava leaves against bacterial strains isolated from seabob shrimp and laboratory culture strains revealed the inhibitory activity of essential oil and extract against *S. aureus* and *Salmonella* spp. The researchers concluded that guava leaf extracts and essential oil are very active against *S. aureus*, thus making up important potential sources of new antimicrobial compounds [96]. Choudhary et al. (2012) provided phytochemical and antimicrobial details of the methanolic leaf extract of *P. guajava* against clinically important gastrointestinal pathogens, viz., *S. aureus*, *P. aeruginosa*, *E. coli*, *S. typhi*, and *Vibrio cholerae*. The methanolic extract showed toxicity against all the bacteria, *S. typhi* being highly susceptible with a zone of inhibition of 2 mm at 4 mg/ml [33]. The aqueous and methanolic extracts of *P. guajava* leaves showed antimicrobial activity against bacterial elastase from *P. aeruginosa* and human neutrophil elastase (HNE), but the methanolic extract of the leaves showed more inhibitory capacity than that of the aqueous extract against both enzymes. The good inhibitory capacity of methanolic leaf extract as compared to water extract was due to the extraction of many active compounds present in leaves by methanol as a solvent stronger than that of water [97].

The comparative studies to investigate the antibacterial activity of extracts of the leaves, bark, and root of *P. guajava* as well as the leaves *of Moringa oleifera* against *Staphylococcus aureus*, *Streptococcus* spp., *Klebsiella* spp., *Proteus* spp., and *Pseudomonas* spp. revealed that the inhibitory effect of *P. guajava* bark at 280 mg/ml against *Klebsiella* spp. competed favorably with reflacine. Extracts of *P. guajava* leaves, root, and the synthetic drug reflacine gave equal antimicrobial effect against *Pseudomonas* spp. These results indicate that extracts of *P. guajava* can be used for the treatment of pathogenic infections caused by some bacteria [98].

6.6 Anticancer Activity

The dry extract of guava leaves has promising activity to be applied topically in the oral cavity or in the development of antitumor formulation or even be used as a functional food [99]. The antiproliferative capacities of guava peel, flesh, and seed on four cancer cell lines, A549 (human lung cancer cells), MCF-7 (human breast cancer cells), HepG2 (human hepatoma cells), and HT-29 (human colon cancer cells) evaluated by the MTT (3-(4,5-dimethylthiazol-2-Yl)-2,5-diphenyltetrazolium bromide) assay revealed that guava possesses strong antioxidant and anticancer actions. The active components of guava were identified as catechin, galangin, homogentisic acid, gallic acid, kaempferol, and cyanidin 3-glucoside, and the content of these in guava peel and seed were higher than that in guava flesh suggesting that guava could be developed to functional food for prevention of some diseases [41]. The acetone extracts of guava branch (GBA) is reported to have cytotoxic effects on HT-29 cells. The GBA showed high cytotoxic effects via the MTT reduction assay, LDH release assay (Lactate dehydrogenase), and colony formation assay. GBA of 250 μg/ml concentration showed 35.5% inhibition against HT-29 cells. As expected, GBA-induced characteristic apoptotic effects in HT-29 cells, including chromatin condensation and sharking that occurred 24 h after the cells, were treated [100].

Guava leaves have been reported to interfere with multiple signaling cascades linked with tumor genesis and provide a source of potential therapeutic compounds for both the prevention and treatment of cancer. The molecular mechanisms of guava leaf hexane (GHF) fraction in apoptotic potential are found to be correlated with the suppression of AKT (phosphatidylinositol 3-kinase) and *Akt* (protein kinase B)/mTOR (mammalian target of rapamycin)/S6 K1 (ribosomal protein S6 kinase beta-1) and MAPK(mitogen-activated protein kinase) signaling pathways in human prostate cancer cells. This effect of GHF is correlated with downregulation of various proteins that mediate cell proliferation, cell survival, metastasis, and angiogenesis [101]. The budding leaves of *Psidium guajava* contain huge amounts of soluble polyphenolics including gallic acid (348 mg/g), catechin (102 mg/g), epicatechin (60 mg/g), rutin (100 mg/g), quercetin (102 mg/g), and rutin (100 mg/g) and exhibit potent anticancer activity [61]. It has been reported that essential oil of *P. guajava* has the potent ant proliferative activity.

It could be used as an antitumor chemopreventive in view of anti-angiogenesis and anti-migration. The IC_{50} of *P. guajava oil* for DU145 cells was 0.57 mg ml^{-1} [102].

7 Value-Added Products and Nutraceuticals

Fruits are directly consumed by health conscious people but the changing era, lifestyle, and urbanization have drastically modified food habits of people like frequent use of ready-to-eat food, ready-to-serve fruit juices, jams, jelly, leather, powder, etc. Guavas also soften quickly during ripening being a climacteric fruit and therefore have a relatively short shelf life that limits the distribution of fresh guava fruit in market. Due to these fragile conditions, most guavas are processed into juice, puree, jam, jelly, syrup, nectar, fruit paste, or canned as halves [25]. The study conducted to determine the antioxidant activity, nutritional composition (sugar, protein, and fat,), and the bioactive phytochemicals (total phenolic compounds, flavonoid phenolic, condensed and hydrolyzable tannin, ascorbic acid, pigments such as anthocyanin, and carotenoids) as well as fiber content present in fresh fruits and flour cultivated in Argentina showed that the flour preserved flavor, aroma, and color of pulp from fresh fruits. The flour contained around 30% of sugar, 20% of total protein, and 0.5% of fat and high level of crude fiber. Carotenoids and ascorbic acid were the dominant phytochemicals in flour as well as in fresh fruits. The guava flour showed antioxidant activity with SC50 values similar to fresh fruits. The flour showed nutraceutical characteristics that are demanded by functional food and could be used as a dietary supplement [103].

Lanier (2005) studied phytochemical, antioxidant, and storage stability of thermally processed guava to assess the thermal stability and shelf life properties in guava nectar. He reported that possible degradation of the numerous phytochemicals in guava may occur during thermal processing and storage. This includes loss of ascorbic acid, isomerization of lycopene and other carotenoids, and decreases in overall polyphenolics and antioxidant activity [103, 104].

Verma et al. (2015) explored the antioxidant potential and functional value of guava (*Psidium guajava* L.) powder in muscle foods. They reported that guava powder which is rich in dietary fiber (43.21%) and phenolics (44.04 mg GAE/g) possesses good radical-scavenging activity which resulted in significant decrease ($p < 0.05$) in pH of emulsion and nuggets, emulsion stability, cooking yield, and moisture content of nuggets while ash and moisture content of emulsion were increased. Total phenolics, total dietary fiber (TDF), and ash content significantly increased ($p < 0.05$) in nuggets with added guava powder. Guava powder was found to retard lipid peroxidation of cooked sheep meat nuggets as measured by TBARS (2-thiobarbituric acid reactive substances) number during refrigerated storage which also did not affect sensory characteristics of the products and can be used as a source of antioxidant dietary fiber in meat foods [105].

Factors influencing the nutraceutical activity of guava fruits in fruit juices were reported, and it was observed that the levels of vitamin C and DPPH (2,2-diphenyl-1-picrylhydrazyl)-scavenging activity showed a sharp decrease with complete destruction after storage for 4 weeks at 5–10 °C. Levels of polyphenols and TEAC (trolox equivalent antioxidant capacity) showed a slower decrease in the levels [34].

Freeze-drying produced the best quality guava powder in terms of ascorbic acid, polyphenolic content, antioxidant activity, and flavor retention, though it was quite

hygroscopic in nature. It can thus be inferred that guava powder is a good source of natural antioxidants which can be an alternative to synthetic antioxidants. From the above study, it can be concluded that freeze-dried guava powder can be utilized as an ingredient for the development of value-added food product as it contains high total phenolic content with other nutrients. It was also found high in the mineral content and thus can be used in preparing a functional food [106].

In a study, guava powder (GP) was used as source of aroma and phenolic compounds to fortify wheat bread 10% (GB10) and 20% (GB20), as a substitute for wheat flour. Phenolic compounds, antioxidant capacity, volatile compounds profile, and sensory acceptability of control bread (CB; without GP) and guava breads (GB) were evaluated, and it was observed that incorporation of GP increased the phenolic compounds contents of bread two- to threefold. Ten phenolic compounds were identified in GB20, and quercetin-3-orutinoside was the major compound, while in CB, ferulic acid was the major among the six phenolic compounds in CB. Bread making seemed to promote the release of phenolic compounds from structural components. Breads incorporated with GP presented a richer volatile profile than CB, especially due to the presence of terpenes. GB improved aroma profile of bread. GP added aroma compounds and phenolic antioxidants and seemed to be an interesting approach to enhance bread bioactivity and acceptability [107].

8 Conclusion

Today, major concern of any individual is achieving better health and quality life either through use of synthetic chemical drugs like multivitamins or through the supplementary diets or dietary supplements. However the pharmaceutical industry is more focused toward development of new indigenous plant-based drugs through investigation of leads from traditional system of medicine and traditional uses of natural compounds. Thorough screening of literature available on *Psidium guajava* depicted various importance of guava leaf, fruit, and seed in treating large number of diseases and their use in making many value-added products. But these products are yet to be introduced in market as no branded products is available in market. The major drawback is the peculiar smell at ripening stage which needs biotechnological intervention to make this crop a superfood. Although guava possesses enormous health benefits, it can be an efficient nutraceutical in combating malnutrition and food in security.

Cereal-Based Fermented Foods of Africa as Functional Foods

51

Ome Kalu Achi and Naomi U. Asamudo

Contents

Abstract

The demand for consumption of health promoting foods is growing worldwide due to the increased awareness of consumers on the impact of food on health. Traditional fermented foods prepared from cereals such as maize, rice, millet, or sorghum are common in Africa. Fermentation of these cereal grains by traditional methods exploit mixed cultures of various beneficial microorganisms, referred to

as probiotics. The improved knowledge of functional aspects of these foods are related to the interactions of bioactive living cells with the host or indirectly as the result of the ingestion of bioactive molecules released during fermentation such as dietary fiber, minerals, vitamins, and antioxidants. Lactic acid bacteria (LAB), yeasts, and fungi are the major microorganisms often encountered together in the production of beverages and fermented foods. The beneficial effects of probiotic consumption include improvement of intestinal health by the regulation of microbiota, stimulation and development of the immune system, synthesizing and enhancing the bioavailability of nutrients, alleviation of lactose intolerance symptoms, and reducing the risk of certain other diseases. African cereal fermented foods could provide an abundant opportunity available for it to be made more functional by incorporating probiotic LAB strains with disease-specific functions and could also facilitate the understanding of when to use probiotics for specific pathological states.

1 Introduction

The health-beneficial concept of fermented foods has developed through rapid expansion of scientific investigations over the years thereby arousing consumer awareness of the functional basis for consuming such traditional foods in relation to health promotion and disease prevention [1, 2]. The realization that a healthy lifestyle, including nutrition, reduces the risk of disease and increases health and well-being has received a huge amount of publicity. Fermented foods are an important part of the diet in many cultures. Fermentation primarily has been used to preserve foods, enhance shelf life, and improve flavor. The beneficial effect of fermented foods on health is due to their excellent functional and nutritional properties assisted by fermenting microorganisms, and novel bioactive compounds released. The fermentation process and the resulting fermented products have recently attracted scientific interest as consumers are becoming aware of the possible positive role diet can play in disease risk management and perhaps because of their increasing interest in the relations between food and quality of life. In addition, microorganisms contributing to the fermentation process have recently been associated with many health benefits, and so these microorganisms have become another focus of attention. The most studied microorganisms in food fermentations are the lactic acid bacteria (LAB). During fermentation, these bacteria synthesize vitamins and minerals, produce biologically active components with enzymes such as proteinase and peptidase, and remove some non-nutrients [3, 4]. The bioactive compounds which are produced by the bacteria responsible for fermentation are also well known for their health benefits. Among these are conjugated linoleic acids (CLA), which have a blood pressure lowering effect; exopolysaccharides, which exhibit

prebiotic properties [5]; bacteriocins, which show antimicrobial effects; and bioactive peptides, which exhibit antioxidant, antimicrobial, antiallergenic, and blood pressure lowering effects [6]. As a result, fermented foods provide many health benefits such as antioxidant, antimicrobial, antifungal, anti-inflammatory, antidiabetic, and antiatherosclerotic activities [7].

Functional food development in the African context is associated with an increased interest in foods such as fruits, vegetables, and wholegrain products or in industrially manufactured products that offer additional health benefits. Most modern diets of the western world are very different than the traditional ones in the sense that they contain elevated amounts of processed foods and ready-to-eat products that contain numerous chemicals or refined additives that are used to increase shelf life, flavor, and physical properties. The westernization of urban African diets has contributed to some of the leading causes of death and increases in the risk of numerous diseases [4]. All of these unhealthy foods and bad eating habits, as it seems, are important causes of the increased incidence of obesity, high cholesterol levels in blood, high blood pressure, diabetes, and many other health problems including certain types of cancers [8]. According to Waters [9], this has led to an increase in demand for the nondairy-based functional beverage substitutes with high acceptance and functionality [10].

The traditional African fermented cereal-based foods have potential to fill this gap because they are potential sources of novel probiotics and may serve as a veritable delivery vehicle for functional food components [11–13].

Cereal-based beverages have been tested as functional and probiotic foods because of their nutritious and health-promoting properties [14]. They can be considered as belonging to the functional food category due to their beneficial effect on health [15]. In particular, the consumption of functional foods containing probiotics would be one avenue to reduce the risk of specific diseases such as diarrhea and malnutrition [16]. Normally, in the western dietary culture, the typical delivery vehicles for probiotics are predominantly associated with milk in yoghurt-type products. This would be impracticable in the African setting because of the unfamiliarity and relative high cost of such products [12]. Traditional fermented cereal products may be more easily accepted, as noted by Franz [12], by African rural populations with its high infant mortality. According to Corbo et al. [17], an attractive approach to improve the nutritional value of fermented functional foods relies upon the activity of functional bacteria [18]; for example, many LAB and *Bifidobacterium* spp. have been reported to produce vitamins such as folate, cobalamin, menaquinone (vitamin K), riboflavin, and thiamine [19]. The use of these cultures in food fermentation potentially provides routes not only to enhance the nutritional profile of the food but also to deliver microorganisms to the gut, where they can synthesize such vitamins *in vivo* [20]. Cereal fermentation leads to the decrease of the level of carbohydrates as well as some nondigestible poly- and oligosaccharides, while the availability of certain amino acids and B vitamins is improved [18]. Indeed, the selection of appropriate starter cultures for each variant of cereal beverage is an industrial need to drive, accelerate, and standardize the fermentation [21]. This chapter reviews the probiotic and functional attributes of African cereal fermented food products.

2 Major Factors Hampering the Development of Fermented Foods

The production of fermented foods, no doubt, is still largely a traditional family art carried out in homes in a crude manner. Consequently, production has not increased substantially to more than a cottage industry. Many of these foods gradually acquired the label of food for the poor population or were associated with low incomes. Among the various factors working against traditional fermented foods, the following appear valid [22]:

- Inadequate raw material, grading, and cleaning contributing to the presence of foreign matter (such as insects, stones) in the final product
- Crude handling and processing techniques employed
- Lack of durability (shelf life)
- Lack of homogeneity
- Unattractive presentation, which inhibits consumers from developing regular purchasing attitudes. However, plastic containers have replaced banana leaves as packaging material for food: a step in overcoming this hindrance [23]

Despite a long history of a large variety of fermented foods across Africa, these are not necessarily being passed down to the next generation or incorporated in the food-based dietary guidelines. The negative perceptions about fermented foods conveyed by especially among young urban people exist. A range of factors contributes to these perceptions. Traditional fermented foods are considered inferior because of their taste and quality (as a result of nonstandardized artisanal practices). According to Reid [16], the uneasiness with traditional fermented foods exhibited by young urban people is that their generation does not have time to wait for traditional fermented foods that take a while to prepare or cost too much. They opined that westernization/urbanization of African society, at least in cities, was seen as a barrier to embracing most fermented foods unless they could be made available as an affordable, easy, and tasty option. Many fermented cereals are multipurpose. A single product may be prepared in varying thicknesses and used as a fermented gruel for both adults and children, or it may be watered down and used as a fermented thirst-quenching beverage. As Wood [24] remarked, the latter type of product makes a meaningful contribution to nutrition. But, one among the factors that may work against fermented foods is the increasing popularity of junk foods introduced by western countries [25]. The potential of their replacement by cola-type beverages would result in a serious negative impact on the nutrition of people in developing countries.

Given the reported health benefits of fermented foods [26, 27], the general view is that consumption of these foods should be encouraged, especially since they are part of the traditional healthy diet. More importantly, the development of a traditional probiotic cereal fermented food in a locally sustainable way can reduce the adverse effect of malnutrition. Standardized starter cultures for consistent product development and innovation according to Reid [16], are seen as important for a new

approach to fermented foods The factors outlined here should continue to serve as a general guideline to some major goals in the exercise of improving the present status of fermented foods.

3 Cereal Fermentation

Fermentation of cereals is an ancient and inexpensive food preservation method and a cultural and traditional practice within indigenous communities in Africa and in most developing countries [28]. Examples of beneficial aspects of fermented foods [29–31], some of which are yet to be realized by industrialized settings, are listed in Fig. 1 emphasizing the broad nature and diversity of the benefits.

The microbiological and chemical compositions of cereal fermented beverages provide a complex probiotic effect owing to the presence of lactic acid bacteria and yeast. The metabolic substances produced during fermentation have proven

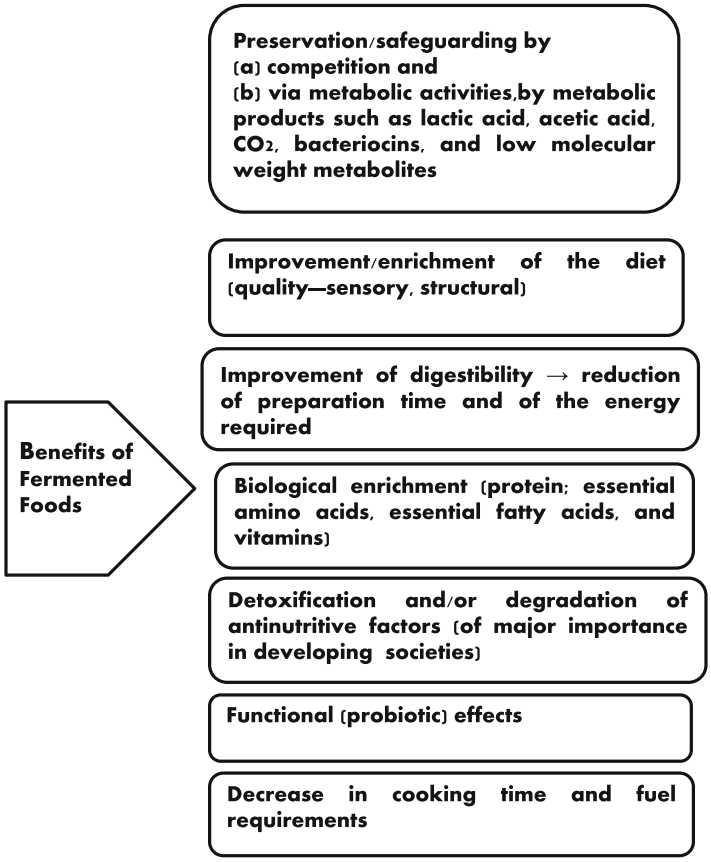

Fig. 1 Benefits of fermented foods

nutraceutical activities [32]. Probiotic microorganisms participate in the fermentation of various foods, generating bioactive components that enhance the functionality of food products [33]. These foods also serve as delivery vehicles of probiotic strains to the desired target sites in the human or animal body. To achieve health benefits, functional foods are expected to support the growth and maintain strains' viable count in the range of about 10^6–10^7 cfu/g of the product [34]. Naturally fermented cereals account for up to 80% of total calorie consumption in many African countries [14]. Owing to their potential for nutritional enhancement and the fact that their consumption substantially lowers the risk of significant diet-related diseases, cereals assume a basic role in the diet of industrialized countries [13]. Although cereals are deficient in certain basic nutritional components (e.g., essential amino acids such as lysine and group B vitamins) and also contain established antinutrients (phytic acid, tannins, and polyphenols), fermentation, also through probiotics, might be the most simple and economical way of improving their nutritional value, sensory properties, and functional qualities [35]. Fermentation of cereals leads to the decrease in the level of carbohydrates as well as some non-digestible poly- and oligosaccharides, while the availability of certain amino acids and B vitamins is improved.

Fermentation also provides optimum pH for enzymatic degradation of phytic acid which in turn increases the levels of soluble iron, zinc, and calcium [36]. According to Charalampopoulos et al. [37], multiple beneficial effects of cereals are exploited as:

(i) Fermentable substrates for growth of probiotic microorganisms, especially lactobacilli and bifidobacteria
(ii) Dietary fiber promoting several beneficial physiological effects
(iii) Prebiotics due to their content of specific nondigestible carbohydrates
(iv) Encapsulation materials for probiotic in order to enhance their stability

Cereals can be used as sources of nondigestible carbohydrates not only for promoting several beneficial physiological effects but also for selectively stimulating the growth of lactobacilli and bifidobacteria that are present in the colon and act as prebiotics [37, 38]. β-glucan and arabinoxylan, oligosaccharides such as galacto- and fructo-oligosaccharides, and resistant starch are the most important cereal-based water-soluble fibers, which have been utilized to fulfill the prebiotic concept during fermentation and product development.

Traditionally, many of the cereals are used in the production of gruels which are fermented into alcoholic beverages such as "*burukutu*" and "*pito*" or nonalcoholic beverage and meals such as "*kunu*" and "*ogi"* or "*agidi*" and represent a major dietary component in African countries [40–43]. These foods are used as weaning food for infants and children [44–46] and also for adults. The microorganisms may be indigenous to the food, or may be added as a starter culture after pretreating or cooking the product [35].

Lactic acid bacteria are a major contributor to fermentation process that takes place in the production of cereal-based fermented foods of Africa [47]. Fermenting

cereals with lactic acid bacteria provides a final product that contains lactic acid as a hallmark among other metabolites that may contribute to product characteristics [48, 49]. These organisms are generally regarded as safe (GRAS). Lactic acid bacteria can produce antimicrobial agents that exert strong antagonistic activity against many spoilage and pathogenic microorganisms. Metabolites such as organic acids (lactic and acetic acid), hydrogen peroxide, ethanol, diacetyl, acetaldehyde, acetoine, carbon dioxide, reuterin, reutericyclin, and bacteriocins [50] are examples of antimicrobial agents produced by LAB. The potential of antimicrobials from lactic acid bacteria is illustrated in Fig. 2. Organic acid produced by LAB leads to a reduction in pH levels and increases the production of hydrogen peroxide. These products exhibit antibacterial activity against various pathogenic microorganisms, including Gram-positive and Gram-negative bacteria [51, 52].

Fermentation can be applied to designing and manufacturing of functional foods. Since some of the major categories of cereal-based functional foods contain live microorganisms, they can serve as fermentable medium for the growth of probiotic

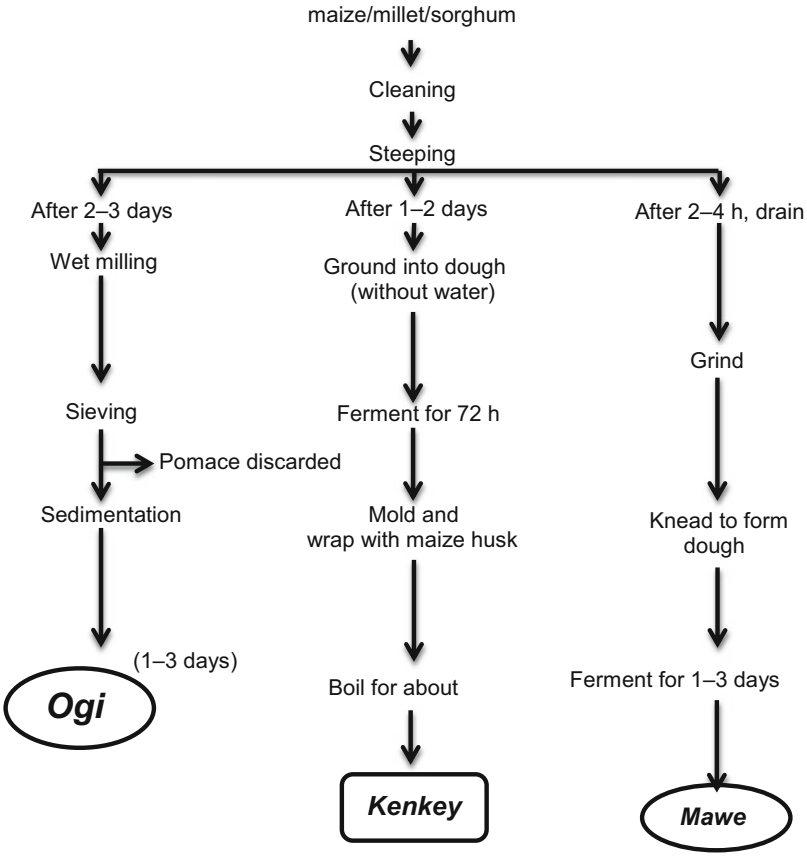

Fig. 2 Flowchart for the preparation of *ogi*, *kenkey*, and *mawe*

microorganisms and may be considered as vehicles for probiotic foods [22, 35, 52]. As noted by Kort et al. [53], the use of probiotic cultures for cereal fermentations can contribute to improving health and nutritional properties of the fermented foods by the delivery of beneficial bacteria, bioactive compounds such as vitamins, and sequestering toxic components.

3.1 Cereal Fermented Foods as Functional Foods

Cereal-based fermented food products are consumed in almost all parts of the world. Cereals contribute over half of the global food produced, and they are grown in over 73% of the world [54]. They are comprised of carbohydrates (60–70%), proteins (7–11%), fat (1.5–5%), crude fiber (2–7%), minerals, and vitamins [33, 55]. Proteins found in cereal are generally low quality compared to animal-based proteins, as a result of a lower amount of some essential amino acids, such as threonine, lysine, and tryptophan. The presence of antinutrients such as phytic acid, tannins, and polyphenols, can also bind to proteins, leading to a reduction in digestibility [42]. Fermentation by LAB has been shown to reduce phytic acids and tannins, therefore enhancing protein availability and digestion in various cereals such as maize, sorghum, and finger millet [54, 56]. Moreover, such fermented cereals have a higher composition of riboflavin, thiamine, niacin, and lysine [57]. Within the last decade, traditional fermented foods are increasingly considered healthy and wholesome, and as a result, public interest in their nutritional and health impact has increased, as has their demand. There is increasing scientific evidence to support the hypothesis that some foods and food components besides their provision of basic nutrition needs may modulate various physiological functions and may play detrimental or beneficial roles in some diseases [58]. These beneficial effects, which some food components exert beyond basic nutrition, have led to the concept of functional foods and nutraceuticals [59, 60]. "Let food be thy medicine and medicine be thy food," the age-old quote by Hippocrates, is certainly the opinion of today [61]. From a natural health perspective, functional food refers to nutritionally superior food products that have been enhanced through processing, fermentation, or growth technologies.

Due to lack of refrigeration facilities in less developed environments, many African traditional fermented foods rely heavily on lactic acid fermentation as a means of preservation and shelf-life extension. The low pH and high acidity encountered in cereal fermented beverages contribute to their bacteriostatic and antimicrobial properties. The need to develop cereal-based probiotic yoghurt-like beverages will go a long way in stimulating the concept of food as a health-promoting substance beyond basic nutrition [62].

3.1.1 Functional Foods

Functional foods are defined as the food or dietary components that may provide a health benefit beyond basic nutrition, do not contain synthetic compounds, and reduce illnesses with their bioactive nutrient. In this way, they help optimize physical and mental well-being [63].

The concept of functional foods is not new, but what does this term really mean? Functional foods, first introduced in Japan in the mid-1980s, contain bioactive food compounds or physiologically active nutrients and non-nutrients According to the definition, functional food is a part of an everyday diet and is demonstrated to offer health benefits and to reduce the risk of chronic disease beyond the widely accepted nutritional effects. This type of food is known in the Japanese market as "Foods for Specified Health Use" (FOSHU). The functional foods comprise: (i) conventional foods containing naturally occurring bioactive substances (e.g., dietary fiber), (ii) foods enriched with bioactive substances (e.g., probiotics, antioxidants), and (iii) synthesized food ingredients introduced to traditional foods (e.g., prebiotics).

Due to developments in ingredient technology, advances in scientific understanding of nutrients to promote well-being, and better management of health conditions, health and wellness trends are driving the commercialization of new ingredients for food and beverages. Functional components in functional foods include probiotic microorganisms, prebiotics, and bioactive compounds such as dietary fiber, polyunsaturated fatty acids, essential amino acids, antioxidants, vitamins, and minerals [64, 65].

Several methods are available for the production of functional foods which may rely on:

- Cereal compounds such as dietary fiber components, enrichment with an incorporated external ingredient, e.g., vitamin, minerals
- Modification of the functional compound enzymatically for release of bioactives, minerals or
- The synthesis of a functional compound by fermentation
- Addition of a probiotic strain such as *Lactobacillus* or *Bifidobacterium* [64]

In the light of this, a food can be made functional by applying any technological or biotechnological means to increase the concentration of, add, remove, or modify a particular component as well as to improve its bioavailability, provided that component has been demonstrated to have functional effect [66].

3.1.2 Fermented Probiotic Cereal Foods

Probiotics are living microorganisms which when ingested in certain numbers may exert health benefits beyond inherent general nutrition [67]. A probiotic food, on the other hand, is a live bacterial food supplement which, when ingested, may improve the well-being of the host in a variety of ways by influencing the balance of the host's intestinal flora. However, there is no general consensus as to whether probiotics should be viable in all cases to exert a beneficial effect, with some studies demonstrating that nonviable probiotic bacteria can have a beneficial effect on the host [68, 69].

Many traditional fermented cereal food products have been found to contain components with potential health benefits [45, 70]. Some may contain live microorganisms and are consumed in an active state of fermentation. Some African fermented products such as *Obiolor* [83] and *kunu zaki* are consumed unknowingly

as probiotic drinks, by local communities. The fermenting microorganisms might also indirectly impart health-promoting characteristics in food through the microbial production of bioactive metabolites (referred to as biogenics), such as certain vitamins, bioactive peptides, organic acids, or fatty acids during fermentation. Given that fermented food products can contain probiotics, prebiotics, or both, it is not surprising that their consumption has long been associated with good health [71]. While the potential benefit of probiotic bacteria has been generally accepted for decades, it is only recently that research has been able to document the beneficial health effect due to some specific strains [72]. The applications of probiotics have been well established throughout generations. The interest in the microorganisms in the recent years emanated from the discovery of their health effect in lowering plasma cholesterol. Probiotics are essentially nonexistent within poorer communities of Africa but some fermented probiotic cereal products are now been manufactured and may have an appeal for those communities. An initiative to introduce probiotic yogurt to Uganda, Tanzania, and Kenya has led to the creation of one gram sachets [25, 73] that contain dried starter culture of *Streptococcus thermophilus* and probiotic strains *Lactobacillus rhamnosus* GR-1 (Fiti), or a generic version of *L. rhamnosus* GG (Yoba) [26, 38, 53]. Each sachet can produce 100 L of probiotic yogurt, with a colony-forming unit (CFU)/mL of at least 1 billion, and is currently consumed by over 100,000 people per day in these countries [74]. Similarly, the effect of potentially human-derived probiotic bacteria on the physicochemical composition and acceptance of fermented cereal beverages showed good acceptance [75]. In a similar manner, an improved ogi *dogik*, which has been developed by Okagbue [70] using lactic acid starter with antimicrobial activities against diarrheagenic bacteria, were easily accepted.

The millet porridge *koko i*s a natural lactic fermented food product consumed daily by many people in Northern Ghana as lunch or an in-between meal. The fermented liquid top-layer called *koko sour water* (KSW) is also used fresh by the local population as a treatment for up-set stomachs or as a refreshing drink. As reported by Lei and Jakobsen, [45], the predominant LAB isolated from the fermentation of the cereal showed pronounced antimicrobial activity together with acid and bile tolerance. KSW with a low pH 3.6 and a content in the order of 10^8 live lactobacilli per milliliter is assumed to have a probiotic effect.

Regarding the functionality of probiotics, it is thought that in order to exert beneficial effects, they must be viable and available at a high concentration, typically at least 10^8–10^9 CFU per gram of product and should survive the human gastric juice in the stomach and reach the small intestine and the colon. It is generally agreed that best effect is achieved when the microorganisms colonize the intestinal epithelium since they can affect the intestinal immune system, displace enteric pathogens, and provide antimutagens and antioxidants, and possibly other effects by cell signaling.

3.1.3 Mechanism of Probiotic Action

The selection of a probiotic strain for human health and nutritional benefits requires that several aspects of functionality have to be considered: (1) acid tolerance and tolerance to human gastric juice; (2) bile tolerance (an important property for

survival in the small bowel); (3) adherence to epithelial surfaces and persistence in the human GI-tract; (4) immunostimulation, but no proinflammatory effect; (5) antagonistic activity against pathogens such as *Helicobacter pylori, Salmonella* sp., *Listeria monocytogenes*, and *Clostridium difficile*; and (6) antimutagenic and anticarcinogenic properties. The adhesion to mucosal surfaces by probiotic microorganisms is an important ability for the colonization of the human gastrointestinal tract, prevents their elimination by peristalsis, and provides a competitive advantage over pathogens.

Adhesion provides an interaction with the mucosal surface facilitating the contact with gut-associated lymphoid tissue mediating local and systemic immune effects. Thus, only adherent probiotics have been thought to effectively induce immune effects and to stabilize the intestinal mucosal barrier. Autoaggregation appeared to be necessary for the adhesion of probiotic strains to intestinal epithelial cells and coaggregation abilities may form a barrier that prevents colonization by pathogens [147].

The adhesion process can be divided into two steps: i.e., reversible adhesion due to long-range forces and subsequent interaction mediating a direct contact between microorganisms and support surfaces such as the hydrophobic interaction of microorganism and support. Biopsy sampling probably gives the most accurate information on the adhesion ability of probiotic strains. However, there are severe limitations in the technique: first and most importantly, ethical considerations limit the use of the technique. Secondly, the technique is very laborious and therefore only few individuals can be included in trials. Thirdly, the evacuation of the colon prior to colonoscopy probably leads to a loss of large number of adhering bacteria, leaving only the bacteria with the strongest adhering ability attached [148]. It could be argued that strong adhesion ability may increase the risk of infection in the host. Also, some probiotic strains are poorly adhering in vitro and/or in vivo and still they can show positive effects in the hosts.

The antimicrobial properties of probiotics can be attributed to both the competition for nutrients and the production of inhibitory compounds such as organic acids, hydrogen peroxide, and bacteriocins. The lowering of pH due to organic acids (especially lactic and acetic acids) produced by these bacteria in the gut has a bactericidal or bacteriostatic effect [49, 111].

The capacity to produce different antimicrobial compounds may be one of the critical characteristics for effective competitive exclusion of pathogen survival in the intestine and expression of a probiotic effect for the host. Although probiotic strains may produce bacteriocins, their role in the pathogen inhibition in vivo can only be limited, since traditional bacteriocins have an inhibitory effect only against closely related species such as other *Lactobacillus* or on spore-formers such as *Bacillus or Clostridium*. However, low-molecular-weight metabolites (such as hydrogen peroxide, lactic and acetic acids, and other aroma compounds) and secondary metabolites may be more important since they show wide inhibitory spectrum against many harmful organism like *Salmonella, Escherichia coli, Clostridium*, and *Helicobacter.* Lactic acid bacteria of the genera *Lactococcus*, *Pediococcus*, and *Lactobacillus* produce diacetyl which is rarely present in food fermentations at sufficient levels

to make a major contribution to antibacterial activity [111]. However, diacetyl production in sufficient amount inhibits the proliferation of food pathogens. The efficacy of bacteriocins particularly nisin to inhibit target organisms in food is determined by the chemical composition and physical conditions of the food system. The inhibition of such bacterial cells is caused by destabilization of the function of the cytoplasmic membrane.

Lactic acid fermentation not only inhibit pathogenic and spoilage organisms but also enhance flavor and texture by several mechanisms, such as the production of organic acids, hydrogen peroxide, and antimicrobial substances, as well as by lowering pH and oxidation/reduction potential [76, 77]. The development of functional fermented cereal food products has been the subject of several publications and reviews [11, 12, 35, 56, 61, 62, 78–80].

4 Production Methods for Fermented Cereal Foods and Beverages

Generally, African traditional cereal fermented foods are produced using various manufacturing techniques, raw materials, and microorganisms. On the basis of the use of microorganism(s), there are two types of food fermentation, namely, spontaneous fermentations and directed or controlled fermentations [44, 81].

4.1 Natural or Spontaneous Fermentations

Majority of the traditional cereal fermented foods and beverages from Africa are being produced spontaneously without inoculation or natural fermentations are carried out by the native microorganisms occurring on the raw material and in the environment of the production site [35, 82].

Spontaneous fermentation is a complex process carried out by the sequential action of different microorganisms. Contamination from the environment and equipment associated with the fermentation could be assumed to serve as natural inoculum of microorganisms in these foods [83, 84].

Most traditional African fermented food products are artisanal and are closely related to the local natural microbiota, which makes them a pertinent source of beneficial indigenous microorganisms [11]. As pointed out by Navarette-Bolanos [85], these native microorganisms, which have remained for a long time in the production areas, seemingly are the result of a natural selection associated to adaptation to the local environmental conditions. However, spontaneous fermentation is neither predictable nor controllable and occasionally presents low yield and poor quality outcomes.

The development of spontaneous food fermentation was primarily governed by climatic conditions, the availability of typical raw materials, the sociocultural ethos, and ethnic preferences. The growth and activity of microorganisms play an essential role in biochemical changes in the substrates during fermentation [32]. A large

number of fermented foods and beverages are made by this process, such as *ogi*, *uji*, *obiolor*, alcoholic beverages, etc. The quality of spontaneously fermented products is dependent on the microbial load and spectrum of the raw material, but it is always unpredictable because of the diverse microbiota initially present [86].

The spontaneous traditional fermentation is a complex microbial process operated by both cultivable and noncultivable microbial species, growing in succession or in combination throughout the fermentation process, exhibiting different metabolic patterns that can be either beneficial or detrimental to the product quality. In such conditions, the substrates and coexisting strains often interact through trophic or nutritional relations via multiple mechanisms [85].

4.2 Backslopping

Optimization of spontaneous fermentation processes has been made possible through inoculation of the raw material with a small quantity of a previously performed successful fermentation. After a few refreshments, repeated rebuilding or "backslopping" leads to a stable microbiota, giving rise to a selective enrichment of the best adapted strains [56, 87]. The dominant strain can be seen as a starter that shorten the fermentation process and reduce the risk of fermentation failure [31]. Based on spontaneous methods, the back-slopping technique is used in the preparation of several traditional fermented products [29, 88]. Back-slopping is also practiced in the production of *bushera*, but this has been considered to lead to fast production of acid and hence excessive sourness. Therefore, back-slopping is practiced in households where they prefer sour *bushera* over sweet one [89].

4.3 Controlled Fermentation

As the variation in the microbial community on such raw materials is considerable, such wild fermentations are difficult to reproduce and standardize. The need for consistent food quality culminated in the much better defined fermentation processes of today. In short, control is achieved through the pasteurization of the raw materials and the subsequent use of starter cultures. This results in the development and improvement of inoculants containing high concentrations of live microorganisms, and referred to as starter cultures. The development of pure cultures allowed the application of starter cultures for controlled food fermentation. A starter culture is a microbiological culture that actually performs fermentation or assists the beginning of the fermentation process in preparation of various foods and fermented beverages. Such cultures can consist of single strains or of (un)defined mixtures of strains and they are a major determinant for the organoleptic properties of the final product [90]. The modern large-scale production of fermented cereal-based foods is almost entirely dependent on the use of defined strains of these microorganisms, which could replace the undefined strain mixtures traditionally used for the manufacture of these products. A number of studies have been carried out to characterize yeast and

lactic acid bacteria diversity in cereal fermented foods and beverages in order to select suitable starter cultures or consortia for improving safety, quality, sensory and sometimes probiotic properties [91–93].

Many of the studies focus on the characterization of the microorganisms that are commonly associated with the processing of these products [42, 52, 94–99, 101, 103]. Salient information found in many African fermented cereal food products is shown in Table 1. The isolation of indigenous strains from the local production area and their selection and use as starter could ensure the adequate control of lactic fermentation and preserve some positive organoleptic contributions [14, 103].

4.4 Fermented Cereal-Based Products

Important class of fermented foods and beverages are made from cereals, which are popular in the continent of Africa. In particular, the natural microbial component is used to ferment grains including maize, millet, rice, or sorghum. The grains are often malted, heated, mashed, and sometimes filtered. Back-slopping is quite common, but

Table 1 Traditional lactic acid cereal-based fermented foods and beverages consumed in various countries in Africa

Product	Country	Cereal malt	Nature of fermented product	Product use
Banku	Ghana	Maize, cassava	Dough	Cooked dough
Ben-saalga, *koko*	Burkina Faso, Ghana	Pearl millet	Slurry	Gruel
Bushera	Uganda	Sorghum, millet + (S, Mi)	Slurry	Beverage
Gowé (*Sifanu*)	Benin	Sorghum + (S)	Cooked slurry	Beverage
Hussuwa	Sudan	Sorghum + (S)	Dough	Dough-like food
Injera	Ethiopia	Tef, sorghum, corn, finger millet barley	Batter	Flat bread
Kenkey	Ghana	Maize	Dough	Cooked/steamed dough
Kisra	Sudan, South Africa	Sorghum, pearl millet	Dough to thick batter	Flat bread
Mahewu	Zimbabwe	Maize + (S, Mi)	Slurry	Beverage
Mawè	Benin, Togo	Maize	Dough	Basis for ready-to-serve foods
Ogi	West Africa	Maize, millet, sorghum	Slurry	Basis for ready-to-serve foods
Togwa	East Africa	Maize + (Mi)	Cooked slurry	Beverage

the microbial populations responsible for the fermentation are now been characterized in an effort to source for starter cultures.

A wide range of cereal-based products is known, often with specific local differences in composition and method of preparation. A few principal categories of African cereal products could be distinguished. They include (semi) solid cooked doughs and porridges and liquid beverages, which may be nonalcoholic gruels [1, 76]. Table 1 presents these categories, showing the cereal-based food products that will be discussed in more detail in this paper. In this part of the chapter, these foods will be discussed with special reference to production methods, functional microbiota, and their impact on their nutritional contribution to the diet.

4.4.1 Ben-Saalga

Ben-saalga, a thin porridge, is prepared by cooking the fermented sediment of pearl millet (*Pennisetum glaucum*) in water, and is typical of Burkina Faso [76]. *L. fermentum*, *L. plantarum*, and *Ped. pentosaceus* typically dominate the natural fermentation. Some *L. plantarum* strains are able to degrade starch [96, 103] which can be beneficial as they can positively contribute to increase the energy density of cereal-based fermented gruels through starch hydrolysis [85, 96]. Although considerable losses of millet nutrients are suggested to occur as a result of discarding the coarse particles during preparation and by leaching into the water fraction, antinutritional components of pearl millet such as phytate are reported to be degraded by more than 50% in commercial *ben-saalga*, thereby facilitating the dietary uptake of proteins and minerals [76, 103].

4.4.2 Ogi

Fermented maize product, ogi, is a popular weaning and breakfast cereal in sub-Saharan Africa. *Ogi* is traditionally prepared by natural fermentation of maize grains to produce popular breakfast gruel and a complementary food for children. It is also made from sorghum or millet grains with the specific composition affecting the viscosity, fermentability, and content of the final product [104]. The stages of traditional *ogi* production include steeping (washing the grains, soaking in water for 24–72 h, wet milling, and wet sieving) and souring (sedimentation of the filtrate for 12–28 h) to obtain sour *ogi* [89, 105–107]. The periods of fermentation and souring determine the degree of sourness (measured by titratable acidity) and, to a large extent, the nutrient status of *ogi*.

The predominant microorganism in the fermentation responsible for the production of lactic acid is *L. plantarum.* A number of studies point to the ogi fermentative organisms as having probiotic qualities [91, 108]. *Ogi* is normally prepared as a water suspension and cooked before consumption. The cooked product is usually a gel of variable degree of stiffness. The fluid or semisolid cooked *ogi* is called by different names such as "*eko*," "*akamu*," or "*kafa*" in different localities, while the stiff gel is called "*agidi*" in Nigeria. *Agidi* is prepared by cooking, wrapping in leaves, and then allowed to set to form a stiff jelly. Ogi is usually consumed after heat treatment which destroys the lactic acid bacteria present, and therefore its probiotic effects. It must be pointed out that the functional aspects of these foods are related

not only to the interactions of bioactive living cells with the host but also indirectly as a result of the ingestion of bioactive molecules released during fermentation. Such bioactive components include dietary fiber, minerals, vitamins, and antioxidants. LAB fermentation directly affects nutrient availability by hydrolyzing carbohydrates and nondigestible oligosaccharides into functional compounds. On the other hand, the souring water obtained from ogi fermentation is normally used as a sweetened rich probiotic beverage and encouraged by nutritionists as a health-promoting drink and antidiarrheal tonic, thus further justifying their significance as functional foods [92, 108].

Fermented ogi liquor is considered as a preventative food in common diseases connected with diarrhea and abdominal discomfort. It is reported that many nursing mothers in many parts of Nigeria do give their babies *ogi* liquor (water from the fermented cereal pulp) and this causes the termination of such illness as diarrhea and abdominal discomfort [109]. Adebolu et al. [110] evaluated the antibacterial activities of ogi liquor from different grains against some common diarrheal bacteria in southwest Nigeria and discovered the inhibition of the pathogens by the ogi liquor which contains a variety of organisms including *Lactobacillus* species.

4.4.3 Obiolor

Obiolor is a nonalcoholic beverage produced from fermented sorghum and millet malts in Nigeria. *Obiolor* is consumed daily by the Igala tribe in Nigeria and highly associated with good health [83]. It is a thin gruel with sweet taste. The sweet taste is attributed to sorghum and millet malt. It is produced by steeping sorghum and millet grains in water overnight, after what, the grains are wrapped in fresh banana leaves and allowed to germinate for 3 days. The germinated grains (80% sorghum +20% millet) are wet-milled and prepared into slurry. The slurry is mixed with boiled water (ratio 1:4 v/v). The mash is cooled, filtered, and the residue discarded, while the filtrate is concentrated by boiling for 30 min with continuous stirring. The resulting gruel is cooled rapidly and allowed to spontaneously ferment for 24 h at ambient temperature, after which it is ready for consumption [83]. Chemical studies on the nutritional and antioxidant disposition of *obiolor* show it to contain 96% moisture, 7.8% crude protein, 8.9% available carbohydrate, 0.39% crude fat, 0.3% crude fiber, 2.4% ash, and 459.3 kJ/g energy value [112]. The beverage also was found to reduce ferric ion and Aflatoxin B_1-mediated increase in lipid peroxidation products (conjugated dienes, lipid hydroperoxides, and malondialdehydes) and protein carbonyl in animal models were reduced by the beverage. As evident from its antioxidant scavenging activity in addition to the gross energy content, the beverage can serve as functional food.

In another study, the effect of obiolor beverage on dyslipidemia, protein oxidation, lipid peroxidation, and DNA fragmentation in the liver of rats fed a high-fat diet was investigated. Results indicate that high-fat-diet-mediated alterations in liver and serum total cholesterol, triacylglycerol, high-density lipoprotein cholesterol, low-density cholesterol, and very low-density lipoprotein cholesterol were reportedly reversed by Obiolor [112]. The chemical study was able to show that

obiolor extenuated high-fat-diet-mediated dyslipidemia, protein oxidation, lipid peroxidation, and DNA fragmentation in rat [113].

4.4.4 Gowé

Gowé is an indigenous fermented sorghum-based sour beverage, which is widely consumed in urban areas of Benin Republic. It is made from a blend of malted and nonmalted sorghum flour that is produced by spontaneous fermentation involving mixed cultures of lactic acid bacteria (LAB) and yeasts. The fermentation process takes place in an environment with a moisture content varying between 52% and 87%. The sweet and sour dough obtained by decantation during fermentation needs to be cooked and further diluted in water to obtain the beverage. The dominant microorganisms of gowé fermentation were the lactic acid bacteria *Lactobacillus fermentum*, *Weissella confusa*, *Lactobacillus mucosae*, and *Pediococcus acidilactici*, and the yeasts *Kluyveromyces marxianus* and *Pichia anomala* [93]. Some of the lactic acid bacteria mentioned above have been proven to exhibit probiotic properties [114, 116].

Current efforts are geared toward the utilization of the sweet and sour dough without the hydrothermal treatment in order to preserve the probiotic qualities. A significant decrease in pH from 6.1 to 3.3, with a concomitant increase in titratable acidity (11–60 g/kg as lactic acid, dry weight), was observed after 24 h of fermentation when LAB was used either alone or in combination with yeasts in controlled conditions [93, 98, 99]. The LAB count increased significantly from 6.1 to 9.4 log CFU/ml, while the yeast count remained constant throughout fermentation.

4.4.5 Bushera

Bushera is the most common traditional fermented beverage produced in southwestern Uganda. It is mainly prepared from sorghum grains which may be germinated or nongerminated. *Bushera* is produced at household level by spontaneous fermentation. It is consumed by all age groups, and is used both as a weaning food and a thirst-quenching drink in the households and in B*ushera* bars [115]. The product is a common delight in both urban and rural areas of western Uganda. The sorghum or millet flour from the germinated sorghum and millet grains is mixed with the boiling water and left to cool to ambient temperature [116] Germinated millet or sorghum flour is then added and the mixture is left to ferment at ambient temperature for 1–6 days. The lactic acid bacteria isolated from Bushera comprised of five genera, *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Enterococcus*, and *Streptococcus*. *Lb. brevis* was more frequently isolated than other species [115]. Studies on the probiotic potentials of the fermentative organisms are still inconclusive, but evidence of antidiarrheal properties is established.

4.4.6 Borde

Borde is a cereal-based traditional fermented beverage and is widely consumed in the southern and western parts of Ethiopia. It is produced by spontaneous fermentation using rudimentary equipment [117]. Borde is an opaque, effervescent, whitish-gray to brown cultured beverage, with a dark consistency and a sweet-sour taste. It is

an important product because both adults and children often consume it as a low-cost meal replacement. Maize is more frequently used than other cereals (wheat, tef, sorghum, finger millet, and barley) for borde fermentation because of its low price [18] in rural Ethiopian villages. A combination of lactobacilli and yeasts are known to be involved in the traditional fermentation of a mixture of malted cereals (75%) and unmalted cereals (25%) for borde production. It usually takes about 4 days to produce a batch of borde. An average worker consumes about 1–2 liters of *borde* a day, which could sustain the individual without additional food for most of the day [117]. Consumers believe that borde enhances lactation and mothers are encouraged to drink substantial amounts of it after giving birth. Borde is also considered to alleviate malaria, diarrhea, constipation, and abscesses [107].

4.4.7 Mahewu

Mahewu, as reported by Gadaga et al. [118], is a sour beverage made from corn meal and sorghum/millet malt, and which is commonly fermented *by Lactococcus lactis* subsp. *lactis*. It is prepared from the maize porridge, which is mixed with the water. The sorghum, millet malt, or wheat flour is then added and left to ferment. The spontaneous fermentation process is carried out by the natural flora of the malt at the ambient temperature. *Lactobacillus bulgaricus* and *Lactobacillus brevis* have also been isolated from *mahewu*. *Mahewu*, inoculated with a *Lactobacillus* starter, is commercially produced in South Africa [119, 120].

4.4.8 Kwete

Kwete, on the other hand, is another Ugandan fermented cereal-based beverage mainly produced from a mixture of maize and malted millet flour. The millet grains are the only raw materials which are soaked (24–48 h), germinated (2–3 days), and sun-dried (1–2 days) during *kwete* production. The process of souring to produce sourdough is uncontrolled and carried out at ambient temperatures (24–30 °C) for 24 h. Kwete is ready for consumption within 24 h of fermentation and after being filtered using a cheese cloth or a bag woven from grass [121]. Filtering gives the kwete a smooth mouth feel as well as contributes to its uniform color distribution. Good quality *kwete* is creamish to light brown in color, with a thick consistency and a sweet-sour taste. The *Lactobacillus* and *Lactococcus* counts ranged from 5.40 to 7.36 log CFU/ml during fermentation. The greatest increase in lactic acid bacteria was noted between 24 and 48 h. Higher numbers of *Lactobacillus* than *Lactococcus* were observed, though by end of 72 h fermentation both species attained the same microbial population [123]. Fermentation of *kwete* is a spontaneous process initiated by the lactic acid bacteria and yeasts from both the malt and roasted sourdough. Malt also contributes the fermentable sugars and enzymes that initiate the fermentation process [123].

4.4.9 Kunun-Zaki

Kunun-zaki, an indigenous nonalcoholic beverage, is produced and widely consumed by adults and infants in the savannah region of Nigeria as a refreshing drink, an appetizer, a food complement, and to quench thirst. It is also used as a

substitute for or to complement soft drinks and wines at social gatherings. *Kunun-zaki* is prepared from either guinea corn (*Sorghum bicolor*), millet (*Pennisetum typhoides*), maize (*Zea mays*), or rice (*Oryza sativa*). Traditionally, the production involves steeping of whole millet or sorghum grains for 6–24 h, wet-milling with spices (ginger and pepper) and sweet potato, gelling of about 3/4 of the mixture in hot water pitching with about 1/4 fresh (ungelled) part of the mixture and allowing for overnight fermentation. The supernatant is ready for consumption after sieving.

The popularity of *Kunun-zaki* in Nigeria is due to its characteristic sweet-sour taste typical of other lactic acid bacterial fermented foods of African origin such as *mahewu* and *baganiya* [124]. The traditional processing of *kunun-zaki* involves the steeping of, wet-milling with spices, wet-sieving, and partial gelatinization of the slurry, followed by the addition of sugar and bottling. A brief fermentation usually occurs during *kunun-zaki* processing.

This short fermentation which usually takes place during steeping of the grains in water over a period of 8–48 h is known to involve both lactic acid bacteria and yeasts. Three species of lactic acid bacteria (*Lactobacillus plantarum*, *Lb. fermentum*, and *Lactococcus lacti*s) were isolated from fermenting kunun-zaki and characterized by [125].

4.4.10 Togwa

Another probiotic food togwa is a starch-saccharified beverage made from maize flour and finger millet malt [126] and usually consumed in the southern part of Tanzania. It is attractive to low-income groups due to its microbial stability, nutritional and organoleptic properties, as well as its probiotic potential [125]. *Togwa* is a sweet and sour nonalcoholic beverage and is one of the better studied African cereal beverages. It is produced from the flour of maize, sorghum, and finger millet and sometimes, cassava root; the chosen substrates are boiled, cooled, and fermented for approximately 12 h to form a porridge, which is then diluted to drink [127].

Its improvement in terms of flavor quality is essential for the development of the product for greater consumption. It is consumed by the working people and also used as refreshment as well as a weaning food. In the production of *togwa*, cereal flour is cooked in the water. After cooling at 35 °C, seed culture (old togwa) and cereal flour from the germinated grains are added. The fermentation process finishes at pH 4.0–3.2 [107, 128]. In a study on the microbiological and fermentation characteristics of *togwa*, Ref. [123] observed that the process was predominated by lactic acid bacteria (LAB) and yeasts. The isolated microorganisms were identified as *Lactobacillus plantarum*, *Lactobacillus brevis*, *Lactobacillus fermentum*, *Lactobacillus cellobiosus*, *Pediococcus pentosaceus*, *Weissella confusa*, *Issatchenkia orientalis*, *Saccharomyces cerevisiae*, *Candida pelliculosa*, and *Candida tropicalis*. The pH decreased from 5.24–5.52 to 3.10–3.34. Maltose increased initially and then decreased, fructose decreased, and glucose levels increased during the first 12 h of fermentation. The organic acids detected during fermentation included DL-lactic, succinic, formic, pyruvic, citric, pyroglutamic, and uric acid. Lactate was the predominant acid and increased significantly with time. The volatile organic compounds (VOC) detected included acetaldehyde, 2-methyl-propanal, 2-methyl-butanal,

3-methyl-butanal, ethanol, 2-methyl-1-propanol, 2-methyl-1-butanol, 3-methyl-1-butanol, diacetyl, and acetoin lactic-fermented cereal foods like togwa, used in Tanzania as a weaning food or as a beverage can serve as a vehicle for strains with probiotic properties. Since togwa is not heat-treated after fermentation, it contains live lactic acid bacteria such as *L. plantarum* [123]. Kingamkono [51] found that fermenting *togwa* inhibited the growth of some enterotoxin-producing bacteria and reported that a significant reduction in the enteropathogen occurrence in rectal swabs of children under 5 years old was achieved when they were fed togwa.

5 Functional Properties of Lactic Acid Bacteria in Fermented Foods

LAB has two main advantages; the health-promoting benefits induced by the interaction of ingested probiotics with the host (probiotic function properties) and enhancement of the nutritional value of raw materials by producing bioactive microbial metabolites during the lactic acid fermentation. These metabolites include certain vitamins, bioactive peptides, organic acids, or fatty acids [128]. In this part of the chapter, the functionalities of lactic acid bacteria in fermented cereal foods will be highlighted (Fig. 3).

5.1 Functionality for Improved Nutritional Quality of Foods

The microorganisms used as starter cultures in cereal fermentations have been shown to improve the nutritional quality of food products by increasing the nutritional value and digestibility, and by reducing the effect of antinutritional compounds [134]. Fermentation of cereal-based beverages, as well as other food substrates, by LAB has been shown to improve protein digestibility [29], increase nutritional bioavailability of minerals and other micronutrients [123], prolong shelf life, and finally enhance organoleptic qualities [14, 21].

As pointed out earlier, LAB fermentation directly affects nutrient availability by hydrolyzing carbohydrates and nondigestible oligosaccharides into functional compounds. In addition, fermentation with probiotic bacteria of cereal-based extracts produces fermented product which combine health-promoting properties of both probiotics as well as prebiotics included in cereals, such as dietary fibers β-glucans and arabinoxylans [129]. The LAB hydrolysis of the cereal substrates allow for fermented foods to have an improved nutritional value, since they are often more easily digestible than unfermented food [9].

LAB can also be an important source of vitamins in some fermented food products. Cereal grains include many bioactive functional ingredients such as antioxidants, vitamins, and dietary fibers. Dietary fibers are considered among functional food components associated with promoting human health. LAB have the capability to accumulate water-soluble vitamins such as those included in the B group (B2, B7, B9, and B12) during fermentation, a key processes for the production

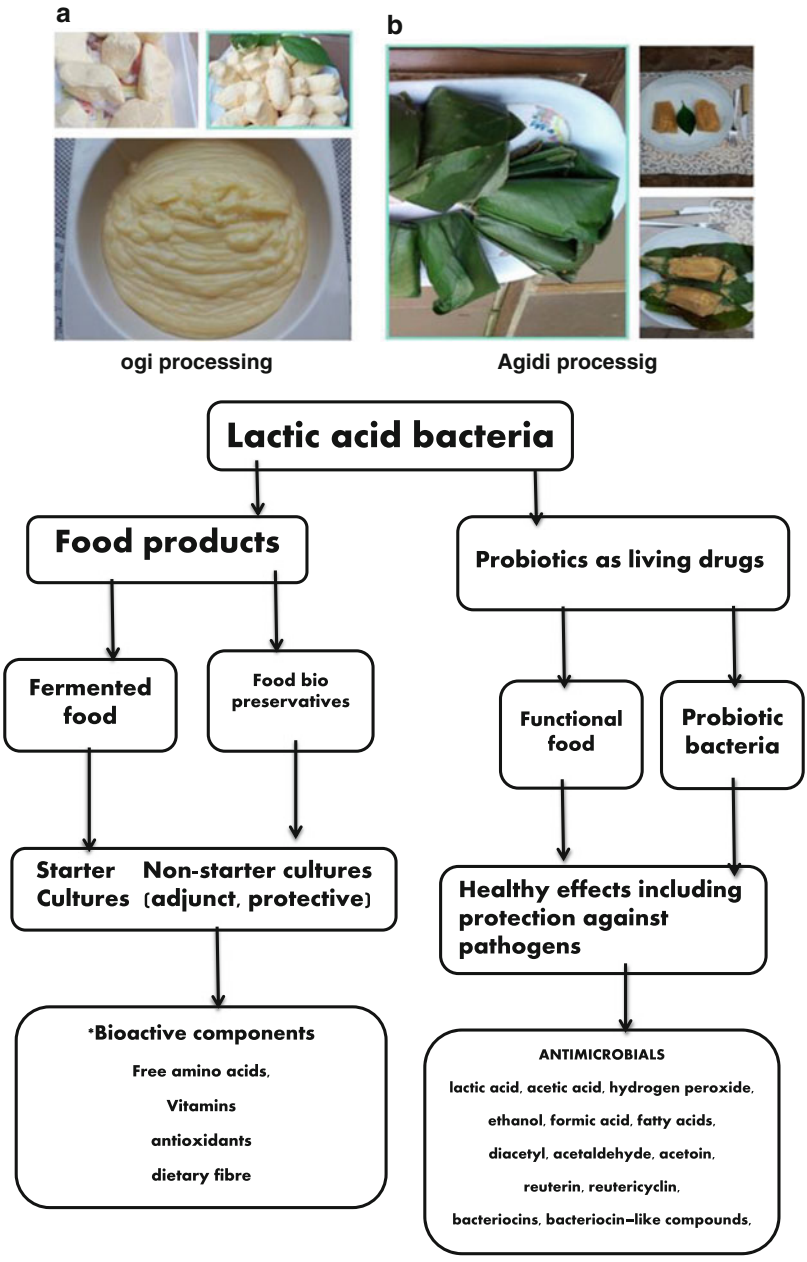

Fig. 3 Functional properties of lactic acid bacteria

of cereal-based beverages [130, 131]. The ability for lactobacilli to increase B-group vitamin production in cereal-based products offers novel opportunities for functional foods development. The possible strategies may lead to the elaboration of novel functional fermented foods [130, 149].

The nutritional quality of cereal grains and sensory properties of their products are inferior due to lower protein content, deficiency of certain essential amino acids, lower protein and starch availabilities, and the coarse nature of the grains, and is often counteracted by the presence of antinutrient components such as phytates, tannins, protease inhibitors, and polyphenols [33, 134]. In a sense, the antinutritive factors from cereals, including maize, sorghum, and millet, reduce the bioavailability of minerals such as calcium, iron, potassium, magnesium, manganese, and zinc, thus affecting the utilization of carbohydrates and proteins and causing deficiencies in the essential amino acids lysine, tryptophan, and methionine [9, 132]. LAB fermentation can overcome these problems by conferring to the final product, a higher protein quality and nutritional value, by inactivating protein inhibitors, or improving mineral solubility. In the case of cereal fermentation, the steps before fermentation, soaking, and germination causes increased activities of hydrolytic enzymes, improvement in the contents of certain essential amino acids, total sugars, and B-group vitamins, and a decrease in dry matter, starch, and antinutrients [129]. Phytic acid is present in cereals in the form of complexes with metal cations, viz. iron, zinc, calcium, and proteins. The enzymatic degradation of phytic acid requires an optimum pH which can be provided by natural fermentation. Such a degradation of phytic acid can increase the amount of soluble iron, zinc, and calcium a number of folds [36]. It has been reported that fermentation of millet grain for 12 and 24 h could reduce the food inhibitors, phytic acid and tannins [136].

5.2 Functionality to Improve the Health Benefits of the Host

Besides the quality improvements due to the prevention of spoilage and safety enhancement by the inhibition of pathogenic microorganisms, LAB fermented foods have numerous physiological effects on the host. The use of LAB as probiotics, living microorganisms that confer a beneficial effect on the host when administered in proper amounts, is the main health-related impact of this group of bacteria.

The dominance of *Lactobacillus* species during cereal fermentation and the presence of other bacteria with safety challenges were identified [99, 101, 146]. Therefore, harnessing many functional properties of these beneficial bacteria may significantly contribute to strategies that can improve nutritional quality and safety and promote health status of consumers of traditional fermented cereals, particularly in developing countries.

Starch is the major storage polysaccharide in cereal grains. Starch is composed of amylose and amylopectin. Amylase activity is an essential prerequisite during starchy food fermentation. Amylolytic bacterial strains are therefore desirable and could be readily applied as starter cultures during traditional cereal fermentation.

Amylase activity is an essential prerequisite during starchy food fermentation; it enhances hydrolysis of amylose and amylopectin to release fermentable maltose. Amylolytic bacterial strains are therefore desirable and could be readily applied as starter cultures during traditional cereal fermentation [137]. *L. plantarum* A6, an amylolytic strain, has previously been isolated from fermented cereals in Africa, and its α-amylase gene was cloned and sequenced [137], and the expression of this gene was also identified during in situ fermentation [101, 138]. Efforts have also been made to produce recombinant *L. plantarum* strains with amylolytic activity, but these clones are not particularly attractive to large-scale fermentation due to the requirement for the associated technologies that are not always available in developing countries.

5.3 Antimicrobial Activity of Probiotic Lactobacilli

Probiotic bacteria are able to change the population of the gut microbiota by influencing the metabolic and nutritional functions of commensal bacteria. They colonize the intestinal tract and exhibit protective properties by exerting antipathogenic effects based on competitive exclusion (for substrates and places of adhesion) and by inhibiting fermentation metabolites (organic acids and other antimicrobial compounds). They beneficially affect the host's physiology and health by improving microbial balance in the intestinal tract. Strong competitive exclusion of LAB toward pathogenic microbes has been observed in some studies. A *Lactobacillus* starter culture was used to produce an improved ogi called DogiK, which exhibited antimicrobial properties against some diarrheagenic bacteria [70, 139]. Application of probiotic starter cultures for control of infantile diarrhea showed promise, with some studies justifying their relevance in functional foods [140].

The antimicrobial properties of lactobacilli are also of special interest in developing strongly competitive starter cultures for food fermentation. Lactobacilli exert strong antagonistic activity against many microorganisms, including food spoilage organisms and pathogens. Production of the primary metabolite, lactic acid, and the resulting pH decrease is the main preserving factor in food fermentation. In addition, some strains may contribute to the preservation of fermented foods by producing other inhibitory substances, such as bacteriocins [141, 145]. Bacteriocins are antimicrobial proteinaceous compounds that are inhibitory toward sensitive strains and are produced by both Gram-positive and Gram-negative bacteria [142]. Research on bacteriocins from lactic acid bacteria has expanded during the last decades, to include the use of bacteriocins or the producer organisms as natural food preservatives.

Sanni et al. [141] reported the antimicrobial activity of partially purified bacteriocin produced during the natural lactic acid fermentation of *ogi* – a cereal fermented gruel by eight strains of lactic acid bacteria. The bacteriocin produced inhibited the growth of various target organisms with the inhibition strongly noticed using *Enterococcus faecalis* as indicator. While catalase treatment, pH changes and heat

treatment up to 80 °C had no effect on the activity of bacteriocin from these isolates, treatment with trypsin and proteinase K resulted in complete loss of inhibitory activity of the bacteriocins. A reduction in the inhibitory activity of the bacteriocins was also found to occur with increasing concentrations of glucose or peptone in the cultivation medium. There is no doubt that such microorganisms when used in cereal fermentations will provide a nutritious as well as a safe food product.

5.4 Fermented Food Functionality and Safety

The production of organic acids like lactic, acetic, and formic acids is the cornerstone of LAB's ability to impact on the growth of undesirable microflora from the early stages of fermentation, and therefore to preserve food. Carbon source, nitrogen source, and molecular oxygen play critical roles in supporting cell function and proliferation through providing of ATP reducing power and building blocks. Food preservation can also be achieved by LAB-triggered nutrient depletion, as well as by strain-specific production of inhibitors like ethanol, carbon dioxide, acetoin, diacetyl, acetaldehyde, or hydrogen peroxide (in aerobic growth). The balance between their presence and the potential negative changes in sensory properties of the products has, nevertheless, to be carefully considered. LAB has also the ability to produce different types of specific antimicrobial compounds to inhibit the activity of potential spoilage and pathogenic organisms. The selection of LAB capable of bacteriocin production, antimicrobial peptides, and proteins ribosomally synthesized has been the target of much research. Some of these bacteriocins, namely nisin, are already approved for use as food additive as they are very attractive alternatives to conventional antimicrobials.

Indigenous lactic acid fermented foods may have potential as probiotic treatment for diarrhea, due to high levels of lactic acid bacteria. Some fermented cereal-based foods available in West Africa may have probiotic potential.

Traditionally, uncooked Ogi is normally administered to diarrhea patients to reduce the frequency of stooling. Based on laboratory trials, Lei and Jacobsen [45] found that LAB isolated from *koko* can withstand the physiological challenges posed by the gastrointestinal tract (GIT) and may be able to colonize the GIT. In controlled human trials, Lei et al. [143] demonstrated that *koko sour water* (KSW) reduces diarrhea in children. Fecal enteric bacteria, such as *Salmonella*, *Shigella*, and *E. coli*, were found to be significantly less prevalent in children fed fermented maize gruel than in children who were not [144]. Similarly, lactobacilli strains isolated from uncooked ogi effectively inhibited the growth of *Salmonella* spp., either when inoculated after 8 and 24 h of growth of pathogen or when cultured overnight and then incubated with the pathogens [142–144]. Earlier, a *Lactobacillus* starter culture was used to produce an improved *ogi* called DogiK, which exhibited antimicrobial properties against some diarrheagenic bacteria [139]. Enhancement of lactation in nursing mothers is widely reported for the consumption of Kunun zaki, a fermented nonalcoholic cereal-based beverage in Northern Nigeria [124].

6 Conclusion

Fermentation is an age-old form of biopreservation in many parts of the world. Cereal fermentation provide an important source of energy and are represented by carbohydrates, proteins, and fats, but also fiber, vitamins, minerals, and other bioactive components essential to human health. Fermentation of cereals brings multiple improvements to nutritional composition, digestibility, shelf life, as well as flavor enhancement. Traditional cereal fermented food and beverages are widely consumed all over the continent of Africa. There is also a promising trend in the production of novel fermented cereal products aimed at the prevention of common diseases.

Naturally fermented foods may contain an abundant array of potential probiotic bacteria. Some of the cereal beverages are consumed while in an active state of fermentation. The number of live cultures in these foods may have enormous potential as candidates for the production of probiotic foods. Careful selection of these bacteria will provide an opportunity to develop foods that not only fulfill the commercial requirements, but also give the food functionality.

Abstract

Functional food concept is one of the hot topics in the food industry. In recent years, people want to consume food products having health beneficial effect as well as nutritive characteristics. Regarding functional food development, foods have also advantages and disadvantages in terms of delivering bioactive compounds due to formulation (interaction of the bioactive compound with other ingredients, calorie value provided) and production process (mechanical and thermal processes applied during production). When considering the factors restricting usage of the food products as a delivery system, chewing gum is one of the most up-and-coming products in many aspects: (i) simplicity of the formulation prevents the activity of bioactive compound by interaction, (ii) level of mechanical and thermal stresses applied during production, (iii) enabling the release of targeted molecule in a controlled and sustained manner, (iv) different consumption behavior abolishing calorie intake concern since it is only chewed without swallowing, and (v) holding time in mouth. Usage of encapsulated bioactive compounds can improve the release behavior of the functional ingredient. Mastication process and the formed matrix/structure of the chewing gum also influence the release of the bioactive compounds. The researches about improving functionality of chewing gum have indicated that chewing gum can be used as a delivery system for transportation of the desired bioactive compound to body/targeted site. However, during functional chewing gum development, formulation, production process, mastication process, and type/form of bioactive compounds should be considered to achieve the product with required functional properties.

Keywords

Chewing gum · Functionality · Bioavailability · Confectionery · Delivery system

NRT	Nicotine replacement therapy
ODF	Oral disintegrating film
PVAc	Polyvinyl acetates
Qt	Quercetin
TP	Tea polyphenols
UGTs	UDP-glucuronosyltransferases enzymes

1 Introduction

Bioactive compounds have begun to attract attention after people understood the relation between diet and health. Approximately 35 million people die every year because of noncommunicable chronic diseases such as obesity, cardiovascular diseases, cancer, and diabetes which are responsible for 60% and 70% of death ratio in the world and Europe, respectively [1]. Most of such noncommunicable diseases are related with diet/eating behavior of people. Therefore, especially in recent years, functional food term is a part of people's everyday experience, which has motived the producers in industry and researchers to manufacture functional foods and improve functionality of the food products. According to basic definition of functional foods, they must have a positive effect on health as well as nutritiousness, in other words, they have function in terms of sustaining the optimal health and decreasing the noncommunicable disease risk [2]. Functional food term was used firstly in Japan in 1984. The essential features of functional foods [3, 4] are summarized in Fig. 1. As functional foods have one of those features, they have also two or all of them. Widely used bioactive compounds in the food industry can be classified as the following [5]:

Antioxidants: Phytochemicals including polyphenols (curcumin), flavonoids (anthocyanins), isoflavones, resveratrol, carotenoids (lutein).
Antimicrobials: Enzymes (lactoperoxidase, lysozyme), polysaccharides (chitosan), bacteriocins (nisin), herbs, spices, essential oils (terpenes), phenols, acids, aldehydes, ketones, and esters.
Vitamins: Water-soluble (B_1, B_2, B_3, B_5, B_6, B_7, B_9, and B_{12} vitamins and Vitamin C) and fat-soluble (Vitamin A, D, E, and K) vitamins.
Probiotics: Lactobacillus (*Lactobacillus acidophilus*, *L. casei*, *L. plantarum*) and Bifidobacterium genera.

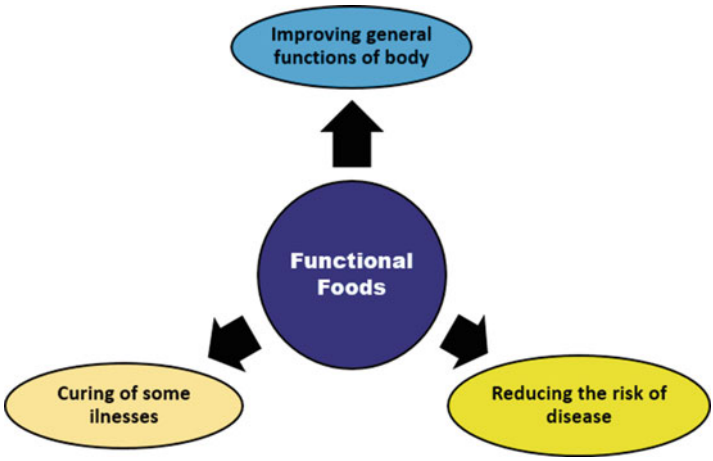

Fig. 1 General characteristics of functional foods

Prebiotics: Fructo-oligosaccharides, inulin, galacto-oligosaccharides, lactulose, polydextrose.
Other compounds: Natural flavorings (oregano, rosemary, β-pinene, sweet orange, lavender essential oils) and minerals.

Bioactive compounds (antioxidants, peptides, carbohydrates, lipids, and glucosinolates) are extra-nutritional agents that generally occur in low concentrations in foods. These constituents vary widely in chemical structure and function. Bioactive compounds actions can reduce the levels of circulating LDL, platelet aggregation, and tumor development. They also exhibit anti-inflammatory effect and estrogen-like activity, helping to maintain healthy bones, breast and increasing menopausal symptoms [6]. Phenolic compounds are present in plants especially in cereals, legumes, nuts, olive oil, vegetables, fruits, tea, and red wine. Most of the phenolic compounds have antioxidant properties, and they have desired effects on thrombosis and tumor-genesis and promotion. Antioxidants are applied in low concentrations to delay free radicals accumulation and hence inhibit oxidation of the food [7].

During functional product development, just adding the bioactive compounds mentioned above is not enough. Delivery system designed for bioactive compounds must provide: (i) maintenance of the activity and stability of bioactive compounds before their releasing, (ii) controlled and sustained release, and (iii) reaching and activating bioactive compounds in the target location [5]. Food matrix used for delivering and bioactive compounds should be taken into consideration with respect to these three factors. Otherwise, the targeted result cannot be achieved from functional food. In addition, as known, most of the bioactive compounds are sensitive to temperature, light, oxygen, and mechanical forces, which should be also considered during developing functional products. Therefore, in order to maintain them, encapsulated forms of the bioactive compounds are widely used in the food industry for preserving them against stresses applied during production and in the conditions of mouth, digestive, and gastric media.

Food matrix (structure of food influences release of the bioactive compound), production process of food products (heat level and duration, mechanical forces applied during production), and compositions of them (some bioactive compounds can interact with food components and lose their activity before reaching target side) directly affect effectiveness of delivery system. Considering all of the factors mentioned, chewing gum is one of the most suitable products for delivering of bioactive compounds in many aspects when compared to other food products:

(i) Production process of chewing gum: Level of applied heat and mechanical forces are not extreme and production process is quite easy in terms of both labor and equipment.
(ii) Formulation of chewing gum: Food products are compact products and they have many compounds such as fat/oil, protein, starch, simple or complex sugars, etc., at high amount. Some of these compounds can prevent activity or release of bioactive compounds.

(iii) Consumption style of chewing gum: Chewing gum differs from most of the foods in terms of consumption. Most of the foods are swallowed and stay at very short time in the mouth. However, regarding chewing gum, most parts of chewing gum (gum base) are discarded without swallowing. This distinctive feature of chewing gum can provide the following advantages: (i) providing less calories when compared with the other products, (ii) chewiness of the chewing gum in the mouth for a long time without being swallowed enable the controlled and sustained release of the bioactive compounds, (iii) only target compound can be released during chewing, and (iv) people of all age savorily consume chewing gums.

Chewing gum can be an attractive bioactive delivery system due to convenience for administration and controlled release of the corresponding bioactive compounds. Because of these favorable characteristics of chewing gums, they are widely used for medical purposes, medicated chewing gum. It was reported that chewing gum is the most convenient tool for delivering of encapsulated and un-encapsulated bioactive compounds due to its production processes where extreme heat and moisture conditions are not performed [8]. Fabrication and consumption characteristics of the chewing gum can provide an opportunity for manufacturing functional, nutritional, and dietetic chewing gums [9]. Concentration difference of the corresponding compound between saliva and chewing gum is a driving force for the transportation of the bioactive compounds from chewing gum to saliva. The nature of saliva in mouth gives rise to release of water-soluble compounds in short times, lower than 5 min, which can be accepted as negative aspects of usage of chewing gum for delivery of bioactive compounds. In order to eliminate the deficiency, chewing gum or bioactive compound/medicinal component can be designed to achieve controlled/sustained release [10]. Chewing gum formulation, encapsulation techniques used for encapsulation of bioactive compounds and encapsulating wall material should be organized in this respect. The interaction between gum base and bioactive compound specifies the release behavior of the functional ingredient. Therefore, selection of optimum gum base of the chewing gum is substantial for achieving targeted delivery system.

As all mentioned above indicates chewing gum is a suitable product for delivering of bioactive compounds and it has many advantages when compared with the other products; however, some attempts are required for enabling/improving achievement of delivery system of chewing gum. In this chapter, we describe formulation and production process of chewing gums and probable usages of chewing gums in delivering of bioactive compounds.

2 Chewing Gum

Chewing gums are defined as an elastic and extendable mass, which has two phases, containing sugar, polyols, gum base, aroma, acidulants, colors, and other ingredients and additives, according to the type of product [11–13]. Although chewing gum generally is classified as a subcategory of confectionery products, it is a food product

that can be expressed in terms of some of the consumption qualities it carries, even though there are different opinions about the definition as a food. The composition providing the winning character consumption or use by the gum mastication characteristics and properties of gum base portion is located mainly in the composition of elements and determines the applied processes [14]. The main feature that makes chewing gum as a special product in the food category is that it is long lasting in the mouth and undergoes the highest level of mechanical effect. Chewing gum is typically manufactured using an insoluble gum base blended with soluble sweeteners and flavorings.

In this part of the chapter, ingredients and types of the chewing gums will be introduced.

2.1 Chewing Gum Ingredients

Chewing gum consists of two phases: (i) water-insoluble continuous phase (gum base) and (ii) water-soluble discontinuous phase (sweeteners, color, flavor, etc.). These phases are generally formulated at a ratio of 1:3, respectively, depending on the chewing gum type [15]. The chewing gum contains a gum center (including a gum base, a bulk portion, and one or more flavoring agents) and an outer coating of layers which includes at least two sugar alcohols (preferably lactitol, erythritol, hydrogenated isomaltulose, or maltitol). Coating layers consist of 50–100% polyol. At this phase, more flavors, colors, and actives can be added. Sugar syrup, Arabic gum, starches, and other binders can be applied to the surface of gum. Optional components include vitamins, cooling and warming agents, menthol, plant extracts, etc. Gum base is the main composition of the chewing gum (20–30%) [11]. It is an inert, nonnutritive, and nondigestive product which is not dissolved while chewing; also it is used as a delivery system to carry sweeteners, flavors, and other substances in chewing gum. Gum base is made of a combination of food-grade hydrophilic and hydrophobic polymers, waxes, and softeners including elastomers, resins, plasticizers, fillers, and antioxidants. A generic chewing gum formulation is shown in Table 1.

2.1.1 Water Insoluble Chewable Gum Base Portion

Elastomer is a polymer and the key ingredient with high elongation properties that provides elasticity and cohesiveness and controls rubbery texture. When present in high quantities, the gums may have a hard texture, while low concentrations render the lack of elasticity of the product [16]. Latex or natural gums such as Jelutong, Lechi Caspi, Perillo, and Chicle are natural elastomers applied in chewing gum [17]. Butadiene-styrene copolymers, polyisobutylene, isobutylene isoprene copolymers are synthetic elastomers used in chewing gum formulations [18]. Also synthetic elastomers such as polyethylene mixtures and nontoxic vinyl polymer, such as polyvinyl alcohol, are widely used bases [19]. Types and quantity of elastomers determines the ability of formulation process.

Table 1 Typical chewing gum formulation

Ingredients	Examples	Functions
Gum base: Elastomer	Natural: Smoked or liquid latex, guayule, Jelutong, Lechi-caspi, Perillo, sorva, rosadinha, chicle, massaranduba balata, massaranduba chocolate, nispero Synthetic: Polyisobutylene, isobutylene, isoprene copolymer, styrene-butadiene copolymers, polyvinyl acetate	*Provides elasticity and cohesiveness*
Anticaking agent	Precipitated silicon dioxide, solid carbon dioxide	*Preventing agglomeration*
Plasticizer/ softener	Glycerin, lecithin, aqueous sweetener solutions, sorbitol, hydrogenated starch hydrolysate, corn syrup, tallow, cocoa butter, glycerol monostearate, glycerol triacetate, fatty acid (palmitic, stearic, oleic)	*Regulating the cohesiveness and modifying the texture*
Antioxidant	Ascorbic acid, tocopherol, butylhydroxytoluene	*Prevent oxidation of gum base*
Antitack agent	Slip-agent can be used as this purpose which may be comprised of α-cellulose and vegetable proteins Alkaline metal phosphate, maltodextrin	*Helps chewing gum not adhere to denture fillings and natural teeth*
Emulsifier	Mono-, di-, tri-stearyl acetate; lactylic esters	*Dispersing immiscible compounds*
Filler/ texturizer	Magnesium and calcium carbonate; ground limestone; silicate types; clay; alumina; talc; titanium oxide; mono, di-, tri-calcium phosphate; cellulose polymers	*Modifying the texture of gum base*
Elastomer solvents 15%	Ester gums: Glycerol esters, pentaerythritol esters of rosins (hydrogenated dimerized and polymerized rosins) Synthetic: Terpene resins	*Softening elastomeric material*
Colorants	Fruit and vegetable extracts, titanium oxide	*Improving color*
Sugar	Sucrose, dextrose, maltose, dextrin, dried invert sugar, fructose, levulose, galactose, corn syrup	*Bulk material, texture, and improving taste*
Polyols	Sorbitol, mannitol, xylitol, hydrogenated starch hydrolysate, maltitol	*Bulk material and texture*
Flavor	Essential oils, synthetic flavors, mixture (citrus oils, fruit essences, peppermint oil, spearmint oil, clove oil, oil of wintergreen and anise)	*Improving/providing flavor*
High-intensity sweeteners	Sucralose, aspartame, salts of acesulfame, alitame, saccharin	*Production of sugar-free product*

In addition, flavor release properties of the gum base are affected by the type of elastomer used. For instance, gum bases made with poly isobutylene showed higher affinity for flavor agents compared to polyvinyl acetate [20]. Resins are the conventional elastomer solvents aiding the softening of the elastomer base component.

They act as binders and softeners between elastomers and texturizers. Occurrence of solvents in low concentrations leads to unacceptable chewing properties [16]. Moreover, high quantities of solvent results in stickiness to dental surfaces. Terpinene resins such as polymers of alpha-pinene or beta-pinene, methyl, glycerol, or pentaerythritol esters of resins or modified resins and gums, such as hydrogenated, dimerized, or polymerized resins or mixtures, are applied.

Emulsifier is added in order to optimize the chewability and mouth-feel of the gum and also it allows two indissoluble phases to disperse in one another and can improve softness. Also it reduces gums adhesive nature. Emulsifier helps for ingredients to be mixed and hydrated while chewing. They include mono-, di-, tri-stearyl acetate, lactylic esters. Plasticizers or softeners such as lanolin, palmitic acid, oleic acid, stearic acid, sodium stearate, potassium stearate, glyceryl triacetate, glyceryl lecithin, glyceryl monostearate, propylene glycol monostearate, acetylated monoglyceride, glycerin, tallow, cocoa butter, natural and synthetic waxes, hydrogenated vegetable oils, polyurethane waxes, paraffin waxes, microcrystalline waxes, fatty waxes, sorbitan monostearate, propylene glycol are used to obtain desirable texture and adjust cohesiveness of chewing gum [19]. It reduces the brittleness and gives the elastomers softness.

Antioxidants such as propyl gallate, butylated hydroxy anisole, and butylated hydroxy toluene are applied in the product to prevent oxidation of gum base and also flavors during shelf-life. Fillers or textural agents provide overall texture and improve chewing ability. Texturizer's amount determines the cud size and stretching of the product. Commonly used fillers are magnesium and calcium carbonate, ground limestone, silicate types, clay, alumina, talc, titanium oxide, mono-, di-, tricalcium phosphate, and cellulose polymers [21]. Antitack agents such as slip-agent (comprised of α-cellulose and vegetable proteins), alkaline metal phosphate, and maltodextrin eliminate self-adhesiveness of resins because they have a tendency to stick together. It reduces fragmentation of the gum during mastication and terminates attaching to the teeth [22].

Natural elastomers such as latex or vegetable sources such as chicle, which is composed of cis- and trans-polyisoprene [23], were predominantly used in the past. However, synthetic elastomers are more commonly used today in their place [24]. When environmental safety and waste control are taken into consideration, it can be seen that natural and biodegradable elastomers in the gum composition have been re-emphasized instead of synthetic elastomers [25, 26]. There is a scarce study on the use of natural and biodegradable elastomers. When these studies are examined, it is seen that especially zein is used as an alternative natural elastomer [26–28]. The release amount of bioactive substance was determined to be 95%, as a result of the study conducted with medicated chewing gum produced using corn-originated zein. It is also a positive result that the textural properties are compatible with the control samples obtained using conventional synthetic gum base [27]. Plant-based polymers also show functional properties and have a potential in chewing gum production as a gum base. In a study, Kenger plant (*Gundelia tournefortii*) was used in the production of antimicrobial and antioxidant chewing gum. It was found that methanolic extract of gum exhibited 195.6 gallic acid equivalents (GAE) mg/100 g gum

antioxidant activity and 17.9 mm inhibition zone for *Escherichia coli* O157:H7 as an antimicrobial activity [29]. Production of functional chewing gum from such natural sources is very important for functional industry and such functional and natural products will attract attention and they will be the most preferred food products in the future.

2.1.2 Water Soluble Bulk Portion

Sweeteners provide the sweetness of chewing gum and also it improves the taste of the product. In addition, it masks the harshness of some flavor agents such as menthol and menthone. There are two types of sweeteners: aqueous and bulk. Aqueous sweeteners such as sorbitol, hydrogenated starch hydrolysates, and corn syrups are applied to blend components and keep the product fresh and flexible. Moreover, they act as a plasticizer or softening and binding agents [30]. Examples of bulking agents include sucrose, dextrose, maltose, dextrin, dried invert sugar, fructose, levulose, and galactose. Polyols such as sorbitol, mannitol, malitol, and xylitol are widely used as bulking agents; also a lower calorie gum is produced. High-intensity sweeteners (alitame, aspartame, acesulfame K, sucralose, saccharin, thaumatin, and neotame) are used when a lower calorie product is needed.

Coloring agents are added to the chewing gum in order to improve the color of the formulation. Colorants produce gentle and soft color in the product [31]. The coloring agents include fruit and vegetables extracts and also titanium oxide.

A variety of flavoring agents such as essential oils, synthetic flavors, and mixtures (citrus oils, fruit essences, peppermint oil, spearmint oil, clove oil, oil of wintergreen and anise) are suitable for providing an acceptable flavor and also they mask the bitter taste of some drugs incorporated in the product as an active ingredient [32]. Silicon dioxide and solid carbon dioxide are anticaking materials that are used to prevent agglomeration. These agents improve flowability and rehydration. They are added to the formulation to extend shelf life.

2.1.3 Sugar-Free Chewing Gums

There is a need to use alternative sweeteners to control sugar, carbohydrate, and calorie intakes. Low-calorie sweeteners aid in weight maintenance and also assist in the management of diabetes [33]. There are some reliable reviews and statements indicating that sucrose-free chewing gum can help reducing the risk of dental cavities, teeth demineralization, and other periodontal problems [34]. Bulking agents with a sweet taste are commonly used for the manufacture of sugar-free chewing gums. Polyols are soluble in water, thus they can quickly deplete from chewing gum during mastication.

The low sweetness of sugar alcohols can be enhanced by high intensity sweeteners. Acesulfame K-containing chewing gum has a pleasant sweet taste due to its fast onset of sweetness. Acesulfame K has good solubility; therefore it can be dissolved quickly by the saliva. Prolonged sweetness may be achieved by encapsulation of some of the sweeteners or usage of their combinations. Application of intense sweeteners like neotame and aspartame positively extends both sweetness

and flavor. Therefore, these sweeteners have flavor-enhancing property and may extend the flavor of chewing gum up to four times longer [35].

However, there is a challenge for formulation of sucrose-free chewing gums due to incongruity of some sweeteners with ingredients of the chewing gum matrix. High-intensity sweeteners are affected by factors such as pH, moisture, temperature, microbial growth, and chemical reactions. For example, heat, moisture, alkaline pH can destabilize aspartame. Also, the sweetening power of aspartame can be notably reduced in the presence of aldehyde-based flavors such as cinnamon. Likewise in the chewing gum formulations containing sodium pyrophosphate and aspartame can be degraded rapidly in the formulation. Aspartame can be stabilized by acid treatment prior to its incorporation into a cinnamon-flavored chewing gum [36] or it can be entrapped within a hydrophobic matrix consisting of lecithin, fatty acids, and synthetic waxes [37].

Haahr et al. [38] showed that the release of mint flavors from xylitol-containing chewing gums was higher than the gums made with sorbitol. This finding may be explained by the high water solubility of xylitol (2350 g/L) in comparison to sorbitol (182 g/L). According to the results obtained from Potineni and Peterson [15], release of flavors from a sugar-free phase did not follow the log P model. In a sugared chewing gum, the release of cinnamaldehyde was stable throughout the 8-min chewing time. In contrast, the cinnamaldehyde release from the sugar-free chewing gum was more rapid. Using tandem mass spectrometry, the researchers stated that hemiacetal products formed due to reaction of cinnamaldehyde with sorbitol. These components were more polar and unstable under slight alkaline conditions; therefore the more polarity of these products would result in a more rapid release rate of cinnamaldehyde.

Streptococcus mutans and *Streptococcus sobrinus* (mutans streptococci) combine water-insoluble glucans from sucrose and produce large amounts of acid, which is involved in tooth demineralization. The acid tolerance of these bacteria is extremely high, therefore allowing colonization and persistence under cariogenic conditions [39]. The chewing gum containing xylitol and sorbitol has been suggested to reduce caries rates. Xylitol is not fermented or used by *Streptococcus mutans* as a growth substrate; hence it can inhibit the microorganism growth in saliva [40]. In addition, the consumption of xylitol can decrease the metabolism of acidogenic flora and hence decrease the level of caries occurrence. Thaweboon et al. [41] investigated the effect of xylitol chewing gum on mutans streptococci (MS) in saliva and dental plaque. They observed that chewing 100% xylitol gum caused a considerable reduction in the salivary MS count. Chewing gum sweetened with 100% and 55% xylitol was well accepted by all the participants in the study. Adverse reactions like gastrointestinal discomfort or transient loose stools were not reported. The usage of sorbitol in chewing gum production was shown to be effective in reducing teeth remineralization due to maintaining interproximal plaque pH (>5.5). A clinical study conducted by Kleber et al. [42] showed the beneficial effect of baking soda on removing plaque and reducing gingivitis in a polyol-containing chewing.

Çaglar et al. [43] evaluated the effect of xylitol and probiotic (*Lactobacilli reuteri*) chewing gums on salivary mutans streptococci (MS). They examined the

oral effects of probiotic and xylitol together. The results demonstrated that a 3-week consumption of probiotic bacteria or xylitol in chewing gum significantly reduced ($P < 0.05$) the levels of salivary mutans streptococci; however, the combination of the two agents did not enhance the beneficial effect.

2.1.4 Medicated Chewing Gum, a Novel Drug Delivery System

Chewing gum can be applied as an oral drug delivery system because it can deliver pharmaceuticals and/or nutrients which are known as medicated chewing gum (MCG) and non-MCG. MCG adjusts a continuous release of medicine entrapped in the product [44]. Due to MCG's convenient administration, proven health, nutrition and cognitive benefits, it became acceptable all around the world [45]. The stability of the active substance incorporated in the chewing gum is good because it protects the drug from oxygen, light, and humidity. MCG has widespread application in medicinal and food industry because it has the ability to release active and functional components into oral cavity and also the release action is rapid and steady. Caffeine, nicotine, sodium fluoride, dimenhydrinate, chlorhexidine, acetyl salicylic acid, and vitamin C and are drug samples that were formulated in the form of chewing gum [46, 47]. The advantages and disadvantages of medicated chewing gums are briefly listed in Table 2.

Chewing gum as a drug delivery system can be used to cure and prevent the dental caries, pain, smoking cessation, obesity, motion sickness, acidity, and diabetes. To prevent tooth decay, several factors such as the amount of fluoride intake, good health, and decreasing the carbohydrates consumed by the bacteria is important.

Table 2 The advantages and disadvantages of medicated chewing gums [44]

Advantages	1. Increasing rate of effectiveness 2. Termination of drug delivery due to removal of gum any time 3. Reduced risk of overdosing 4. Requiring no water to drink 5. Protects the susceptible drugs from chemical or enzymatic attack in gastrointestinal tract 6. Suitable for both systemic and local drug delivery 7. Appropriate for rapid delivery 8. Fewer side effects 9. Reduced risk of intolerance to gastric mucosa 10. Great stability against light, oxygen, and moisture 11. Extirpation of xerostomia and help tasting and swallowing in people with dry mouth 12. Reducing hypoglycemic shocks in patients taking antidiabetic drugs 13. Help reduce food cravings
Disadvantages	1. disappearing of drug in oral cavity following salivary dilution 2. different release profiles because the chewing styles are different 3. short time of administration due to eating, speaking, and drinking 4. allergic reaction to artificial sweeteners 6. teeth decay through being coated by sugar 7. stomach irritations, aches, gastric ulcer through continuous swallowing of saliva and even flatulence because of presence of sorbitol in some formulations

Antimicrobial substances are used for treatment of gingivitis, periodontitis, plaque growth, and other oral and pharyngeal infections. For example, studies have proved that the use of chlorhexidine in chewing gum formulations was effective in reducing plaque and gingivitis and in masking its undesirable taste [48]. The roots, stems, and branches of evergreen shrub called *S. persica L.* have been used for oral hygiene for centuries. Extracts from *S. persica L.* roots and stems consists of powerful antimicrobial substances such as sulfur. Moreover, fluoride is also found in remarkable amounts, which is easily dissolved and released in water.

Large amounts of fluoride and antimicrobial agents in the plant lead to strong anticaries effects. The extract seems to have a slight bitter taste due to its volatile oils. The use of chewing gum leads to low and uniform contribution of fluoride in salvia. This is the most helpful way to prevent tooth decay [49]. In addition, there is no need to increase the drug release of fluoride salts because they are soluble in water.

Aslani et al. [50] formulated the medicinal gum by *Salvadora persica L.* in order to prevent tooth decay. Their results pointed out that 1 g of *S. persica L.* contained 0.04 μg of fluoride. The best sweetener and flavoring agent for persica gum were xylitol and peppermint, respectively. Also, the desired organoleptic characteristics were achieved by combination of xylitol and peppermint. The combination with the least elasticity and ductility increased the softness of chewing gum. It was concluded that the hard gum leads to lower drug release.

Nicotine is the basic active compound in cigarette that augments individual smoking behavior. Nicotine replacement therapy (NRT) can help smokers to quit smoking by replacing some of the nicotine attained from cigarettes [51]. One of the widely accessible NRT products is chewing gum. It can be used as smoking cessation aid and was confirmed by Food and Drug Administration (FDA) in 1984. Aslani and Rafiei [52] showed that the addition of 2 and 4 mg nicotine and aspartame as a sweetener and cherry and eucalyptus as flavoring agents had optimal chewing hardness and highest acceptability among smokers. The release of nicotine from 2 to 4 mg chewing gums at 45 min was reported 92% and 93%, respectively.

Aloe vera is a plant which has anti-inflammatory, antiseptic, anticancer, antiviral, antibacterial, antitumor, antioxidant, and antidiabetic effects. It contains several compounds such as vitamins, sugars, enzymes, minerals, lignin, saponins, salicylic acids, amino acids, and anthraquinone. One gram of *Aloe vera* powder contains 5.16 ± 0.25 mg/g of phenolic compounds and 104.63 ± 4.72 mg/g of carbohydrates [21]. Aslani et al. [21] designed the *Aloe vera* chewing gum. Results showed that the chewing gum containing maltitol, aspartame, and sugar sweeteners was selected as the optimal formulation according to its physicochemical and organoleptic properties. Also the peppermint flavor had the most acceptances between consumers.

3 Factors Affecting Release Rate and Amount

The composition, physicochemical properties of the chewing gum and active substances (solubility in saliva, crystallinity, polarity, and physical form like solid, liquid, emulsion, microcapsule), active ingredients amount, and duration of chewing

will determine the in vivo and in vitro release of active agents and flavors from a chewing gum matrix. The release and absorption of a drug through mucosa is dependent on several factors such as stability of gum base and its compounds to enzymes, molecular mass, and ionization. Lipid-soluble drugs are slowly released into oral cavity because they are bounded to lipophilic phase (gum base). Ingredients more soluble in water will be instantly released within few minutes of chewing; however, substances with hydrophobic characteristics are first released into gum base and then into salvia. Moreover, type and speed of chewing characteristics of different consumers will affect the release rate of active components. The difference mentioned all lead to variable results of drug release [44].

Although it was proved that chewing gum can be used as a delivery system for bioactive compounds, there are limited studies in the literature; therefore, aroma release and bioactive compounds release can be associated. Gum bases have tendency to absorb flavors with hydrophobic character, therefore complicates the flavor release from the chewing gum matrix [34]. The slow release of active ingredients can be achieved by coating them with appropriate materials (modifying their water solubility), or hydrophilic/hydrophobic balance of the chewing gum formulation could be manipulated through reducing the concentration of the gum base. Also, undesired interactions between different ingredients can be prevented by encapsulation of some ingredients by appropriate substances.

Encapsulation technique is used for coating food ingredients such as preservatives, oxidation-reduction agents, colors, sweeteners, enzymes, antioxidants, acids, buffers, flavors, nutrients, and cross-linking agents [53]. Microencapsulation can minimize the probability of interaction between ingredients in order to protect color, flavor, and texture of food [54]. It is evident that by inserting the microencapsulated bioactive compounds in chewing gum, the microcapsules contents will be released in a controlled/sustained manner by chewing (physical rubs) or mucus (chemical activity) [55].

Microencapsulation technique is carried out for acids or other components to produce long-lasting taste or to improve the releasing time of special tastes or flavors. Abbasi et al. [9] investigated the capability of microwave energy as a low-cost, rapid, and simple technique to microencapsulate citric acid powders coated using casein and inulin. Microcapsules were incorporated in chewing gum formulation. The results illustrated that citric acid powder without coating caused weakening and hollowing of the products texture. Probably citric acid can affect gum base negatively and therefore degenerates the gums structure and lattice. Chewing gum treated with inulin-coated citric acid gained the highest overall acceptance. Due to the prebiotic effect of inulin the findings are admirable. This functional nutritional and dietetic chewing gum contained 10%w/w of inulin.

Physical and chemical properties of a flavor ingredient determine their release from a food matrix. Two main factors including volatility and hydrophobicity of the flavor compounds affect their release in a chewing gum matrix [56].

The release profile of volatile compounds from chewing gum is determined by the hydrophilicity. Hydrophilic ingredients (mostly taste components) ($\log P < 1.8$) are released faster; however, compounds with $\log P > 1.8$ have an increasing release

rate over the whole chewing duration [57]. The release of flavors is a two-phase process; in the first 5 min of mastication period, the primary flavor release is dependent on the gum base to water partition coefficient of the compounds (water-soluble ingredients dissolve in the saliva). In this phase, combination of the water-soluble portion of the chewing gum compounds occurs and new surfaces are formed. During the second phase, the release of hydrophobic compounds and the extraction of non-polar ingredients occur [58].

The distribution of the flavor ingredients between the two phases is dependent on the compound affinity for each phase and mainly is related to the compound hydrophobicity. For example, components which are more hydrophobic would interact more with the gum base, therefore it results in a relatively low release rate during mastication. For various hydrophobic ingredients, a nonequilibrium partition model has been used for investigating flavor release mechanism [58]. According to this model, during the first 5 min of chewing, the flavor release is linearly dependent on gum base to water partition coefficient (Log cP). This phase is thermodynamic control. However, after the 5-min period, the air to water (saliva) partitioning coefficient controls the flavor release and is called diffusion control.

Harrison et al. [59] used the stagnant layer theory with the interfacial mass transfer from gum to saliva as a rate limiting step. Also the interaction of flavor compounds with the olfactory epithelium as a controlling factor was evaluated. Generally, the release rate was faster for flavor compounds with low chewing gum-to-saliva portioning coefficients, while flavor ingredients with a high chewing gum-to-salvia portioning coefficient were found to release slower. Both models indicate that the gum base acts as a determinative factor in release rate of diverse flavor ingredients.

Ferrazzano et al. [60] produced new chewing gums enriched with the polyphenol quercetin (Qt). The in vivo experiments were performed for Qt release in the saliva. The antibacterial effect of this bioactive compound against *S. mutans* was assessed after 14 days of consumption. The release analysis illustrated that due to the high solubility of Qt in the artificial saliva Qt released mainly in the first 10 min of chewing. Also adding Qt to the chewing gums did not change the saliva pH values, therefore the anticaries effect of Qt was not related to its buffering capacity. In addition, after 7 days of consumption, a significant reduction of the concentration of *S. mutans* strains in saliva was observed. The authors concluded that the biochemical mechanism of inhibition of quercetin against *S. mutans* growth is likely based on two different mechanisms of interaction with bacterial DNA or with the ATP binding site of bacterial gyrase.

Potineni and Peterson [12] reported that cinnamaldehyde release rate was correlated to the dissolution of the sugar alcohol. It did not follow the previous pattern predicted by the log *P* value. Because cinnamaldehyde forms transient hemiacetals within the sugar alcohol phase during chewing gum production. Upon mastication due to slight alkaline conditions in the mouth these hemiacetal products would degrade and again cinnamaldehyde and sugar alcohol forms. Also any alcoholic compound such as glycerine (4.0% of the chewing gum composition) can be involved in this proposed hemiacetal reaction mechanism. Glycerine release was

correlated to the polyol release phase. However, hemiacetals formed with polyols such as sorbitol seem to be more hydrophilic compared to hemiacetals formed with glycerin [15]. Over all cinnamaldehyde release in chewing gum is a two-phase process: (1) the release of hemiacetal bonded cinnamaldehyde compounds during the dissolution of sugar alcohol phase (dominate mechanism during the initial stage of mastication; 0–4 min) and (2) the release from the gum base as predicted by the log cP value (dominate after 6 min).

It is evident that the type of sweetener and its content will influence the release of flavor compounds from a chewing gum matrix; however, mechanism for this impact is still to some extent unclear. Hansson et al. [61] stated that mono- and di-saccharides affect the flavor release by salting out effect mechanism. Polysaccharides can interact with flavor in many ways due to their different structures. For examples starches and hydrocolloids such as carboxymethylcellulose and pectin may change viscosity of food systems by gel formation at a critical concentration, causing a reduced flavor perception [62]. Moreover, softer gels have been shown to release volatiles faster than harder gels, therefore resulting in increased intensity for flavor perception [63]. The formation of inclusion complexes, especially with starch and cyclodextrins, is the other way of interactions of carbohydrates with flavors. Hydrophobic interactions lead the flavor components to be trapped inside these complexes, and consequently retardation of flavor release or sometimes unavailable release occurs. Some authors have stated that lower affinity between the gum base and flavor agents leads to faster release or short lastingness during mastication and vice versa [20]. This theory is based on thermodynamic data. However, the release profile of flavor compounds from chewing gum during mastication would be correlated to the polyol release rate. These factors affecting flavor release can be taken into consideration to improve efficiency of the delivery of bioactive compounds with flavor of chewing gum.

4 The Effects of Chewing Gum Production Process and Mastication on Bioactive Compounds

Two different processes should be considered when targeting the quality characteristics and the use of the bioactive components in the chewing gum as a delivery system:

(a) Production process
(b) Mastication process

As in most food products, mechanical and thermal processes are applied in the production of chewing gum. Mechanical, chemical, and low-intensity heat treatment is also applied during different periods of consumption. Some consumers replace the chewing gum with new one after chewing for short times (<10 min) [64], although some continue to consume chewing gum for half a day or even longer [65]. The production process and consumption behavior of the chewing gum should be taken

into account as well as release characteristics mentioned in the previous part during use of the chewing gum as a delivery system.

The main characteristics to be considered when examining the stability of bioactive compounds present in the gum matrix can be listed as the following:

(a) Mechanical stability
(b) Thermal stability
(c) Oxidative stability
(d) Chemical stability
(e) Interactions with the other constituents

When considering the chewing gum system, there are two potential components for carrying bioactive agents. The first is the coating material used for the coating of chewing gum, while the other is the water-soluble base of chewing gum. However, considering the product range, it can be stated that the chewing gum is a more accurate carrier since coating part is more susceptible to environmental stresses such as light, oxygen, and temperature which can negatively influence the activity of the bioactive compounds. The presence of bioactive components in the gum base composition may be indicated as an up-and-coming approach with considerable strengths and disadvantages. In general, the gum base, main ingredient of chewing gum, is a raw material supplied directly by a limited number of producers/suppliers and its nonbiodegradable and artificial characteristics disturb the consumers. Furthermore, the processes applied in the production of chewing gum and the conditions of these processes may be mentioned as a disadvantage in terms of the stability of the bioactive components.

4.1 Production Process

The production processes of the chewing gum are presented in Fig. 2 [14]. The production of chewing gum can be carried out mainly by three different methods: (i) conventional/traditional method (fusion); (ii) freezing, grinding, and tabletting; and (iii) direct compression method [14]. However, the most common method is the conventional method named Fusion Method (FM). The method of freezing, grinding, and tabletting is stated to be disadvantageous in terms of oxidative stability, especially for bioactive compounds compared to other methods because of moisture content. The direct compression technique involves less severity heat treatment. Because, in conventional methods, the chewing gum is softened between 70–120 °C and mixed with the liquid plasticizer for 2–8 min with or without emulsifier(s). However, if the bioactive components are not involved in the process at this stage, the effects of the potential disadvantages of the FM on thermal stability will be reduced. In the FM, after gum base softening and mixing with the plasticizer, it is mixed for a further 1–4 min by adding 2/3 of the total sweetener and colorant. While the mass is slowly stirred, the remaining sweetener and flavor ingredients are added and then stirred for another 1–4 min. As a final step, fillers, moisturizers, and antioxidants are added and mixed for another 1–4 min [16].

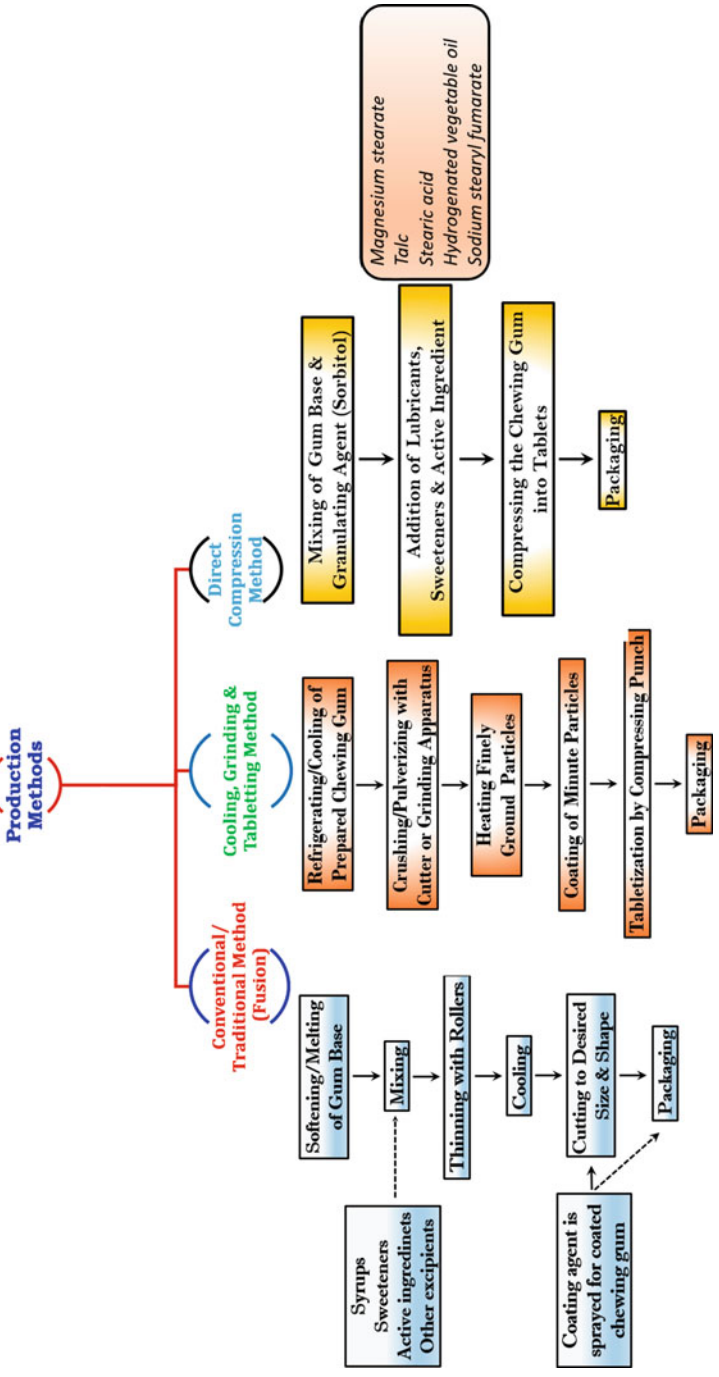

Fig. 2 Production processes of chewing gums

When considering the chewing gum process and the solubility and chemical properties of all the components, the water-soluble base part can be specified as a suitable carrier for bioactive components. Also considering the homogeneous distribution and dissolution properties of the bioactive components, they may also be advantageous, especially for thermal, oxidative, and mechanical process stability, to be incorporated at the same stage with the process colorants or aroma substances. The largest volumes of encapsulating matrices used in the industry are water-soluble and dissolve when in the presence of water [66]. The widespread use of encapsulation for the development of stability of bioactive components supports the fact that inclusion of the process as part of the water-soluble base in chewing gum is a more appropriate option.

The formed structure of the chewing gum presents good mechanical and thermal stability, and the encapsulation technologies used determine the extent of protection obtained and the stability of the functional compound during storage [67]. The number of studies for applying microencapsulated bioactive compounds in chewing gum matrixes is also very limited [8–10, 68]. However, flavor companies are nowadays interested in microscopically encapsulated aromas, which do not release directly but under precisely defined circumstances, for example, under mechanical stress such as chewing the chewing gum [69].

Among the existing stabilization methods, microencapsulation is a promising approach since it protects antioxidants from heat, light, and oxygen, allowing stability, bioavailability, flavor masking, and controlled release while maintaining their functional properties and increasing ease of handling [70]. Stability (process and storage), solubility characteristics, sensory and textural properties are the main factors that should be kept in mind in the encapsulation method. Also, the required features of the encapsulated products are dependent on the type of product. For example, sustained release of flavor compounds is desirable for chewing gum, while for powdered foods, flavors should be released by reconstitution (rehydration) [71]. Fast-release of the water-soluble bioactive compounds can also be arranged by encapsulation techniques/materials.

Oil-soluble bioactive components can also be present in the chewing gum as a water-soluble base component. For this purpose, for example, double or water-in-oil-water ($W_1/O/W_2$) emulsions can be used. However, the actual use of $W_1/O/W_2$ emulsions in food industry is still scarcely developed probably because they are highly susceptible to a variety of factors, generating destabilization mechanisms that are responsible for the system breakdown [72]. Also, during emulsification and encapsulation processes, solubility and interaction with saliva should be considered. The inconvenience of particle size after encapsulation may be caused by sandiness during consumption; therefore, it should be optimized during using chewing gum as a delivery vehicle.

One of the most characteristic features of the gum process is the nature and mechanism of the applied mixing/kneading process. Blade mixers are used with various deformable or plastic solids and high-consistency pastes to achieve a kneading and mixing action accompanied by heating or cooling. They are used for mixing the components of soft sugar confectioneries containing chewing gum [73].

The process involves compressing the fluid mass flat, folding it over on itself, and then compressing it again. The material is usually torn apart, and high shear is produced between the moving and stationary fluid elements. The mixing is usually performed by two Z-shaped heavy blades rotating in opposite directions at different speeds on parallel horizontal shafts [73]. When considering the fact that mechanical forces can damage the activity of bioactive compounds, the forces generated during mixing/kneading process should be considered during enrichment of chewing gums with bioactive compounds.

In manufacturing process, after kneading, extrusion process is applied; for this aim Z-blade type equipment are widely used. Extrusion cooking is a process of forcing a material to flow under a variety of conditions through a shaped hole (die) at a predetermined rate to achieve various products [73]. The principle of extrusion, developed for many nonfood products, has been applied successfully in the confectionery industry [74]. Three major types of extruders are used in the food industry: piston, roller-type, and screw extruders [73]. For some products, such as chewable candies and chewing gum, the roller extruder has modified to develop the multiple screw extruder [74]. Screw extruders utilize single, twin, or multiple screws rotating within a metal cabinet called the barrel. The screws convey the material forward and through a small orifice called a die, which can take many shapes and sizes. Several external parameters such as screw speed and configuration, the temperature of the barrel, the size and shape of the die, and the length of the barrel affect the properties of the final product [73]. The parameters of extrusion processes, temperature and shear stresses, can also affect the bioactive compound activity; therefore, the amount or form of bioactive compounds (encapsulated or not, heat stable or not) used in the chewing gum formulation should be selected attentively.

Shaping is carried out in the final stage of the chewing gum production. Products in the form of transaction, strips, pellets, or balls are gained. The most common is the strip form with different thicknesses and sizes. For this purpose, rolling and cutting operations are carried out after the extruder. In order to obtain chewing gum in the form of a ball, shaping is carried out after the extruder. Although strong mixing has disadvantagous for stability of bioactive compounds during chewing gum production, level and duration of thermal treatment in production cause advantages in terms of heat and oxidative stability of them. In functional product development studies, the selection of chewing gum for the delivery of a large number of active ingredients [65] and the positive results are indicative of the potential use of chewing gum as a bioactive component carrier and functional food [14].

During production of chewing gum or consumption, the potential influence of bioactive components on gum base should be considered and suitable gum base must be selected, accordingly. It is possible to obtain functional chewing gum with better bioactive component stability and bioavailability by studies carried out using different gum bases.

As can be seen, there are different parts of chewing gum process which include thermal and mechanical processes at different levels. Regarding high sensitivity of the most bioactive compounds to environmental and process conditions, there are

two main possible actions that can be done to achieve production of the functional product with desired bioactive compound content:

1. Optimizing the process conditions depending on the bioactive compounds used in the chewing gum.
2. Designing/selecting the suitable form/type of bioactive compounds.

In addition, in all circumstances, as optimization of processes or selecting the most bioactive compound type can be performed, an amount of bioactive compound is lost during production process; therefore, this deprivation should be tolerated by adding higher amount than targeted value.

4.2 Mastication Process

The mastication process is the first transformation to which food is subjected during eating/chewing [75]. Chewing gum can be defined as the product which remains in the mouth for a longer time and undergoes various speed, trajectory, and severe mastication process during this time, as mentioned above. During the mastication process, the substances contained in the composition are subjected to the mechanical effects of chewing. In addition, the temperature of the oral cavity ($<30°C$) and the presence and flow of saliva cause chemical and physical effects. These interactions may affect the bioavailability and stability of bioactive components in functional chewing gums, as well as on the product quality. Saliva plays an important early role in digestion where with the initial chewing of a portion of food, it contributes to the formation of a cohesive food bolus, covered by a mucin film, which facilitates the swallowing process [76, 77]. Mixing of saliva with food can have a diluting effect and play a role by initial breakdown of food, by affecting flavor release, transport of taste compounds to the taste buds, precipitation of proteins by tannins, e.g., resulting in a sensation of astringency, and acting as a buffering system, affecting the degree to which we perceive sourness [78]. Emulsifying agents such as lecithin or glyceryl monostearate, which are present in the chewing gum composition, play an important role in moisturizing the chewing gum with saliva.

Also, one factor that should be kept in mind is the need for saliva transfer for the transportation of bioactive compounds from gum matrix to the mouth. Otherwise, the active material will remain in the gum bolus and will be discarded at the end of consumption without any effect or bioavailability. This is not only in terms of bioavailability perspective, but also in terms of production costs. Minimizing the level of bioactive compounds to be thrown by the bolus will lead to optimum utilization in production. This will also optimize product costs. The bioavailability is a critical factor to determine the efficiency of bioactive compounds orally ingested, therefore it is necessary to develop different delivery systems to enhance the in vivo bioavailability of nutraceuticals orally administered [79].

Food characteristics are changing while the food is masticated, and they consequently influence the oral processes. It is therefore a dynamic process, where food

structure and perception change over time [75]. Chewing gum is not swallowed, it is consumed by chewing in the mouth [80], and various components are released during chewing. During chewing, the bioactive compound present in the chewing gum product is released from the matrix into the saliva and can be absorbed from the oral mucosa or metabolized by reaching the mast for gastrointestinal absorption [65]. For instance, parts of the encapsulated ingredients are released from the food structure due to the deformation observed in the product during chewing and digestion [71]. In vitro and in vivo studies need to be conducted in the field of functional gum development that determine the amount of bioactive ingredient passing to saliva. Factors that influence the amount and the stability of the bioactive components along the masticatory process are summarized as the following:

(a) Saliva temperature, amount, and flow rate
(b) Saliva composition, therefore, saliva viscosity
(c) Mastication time
(d) Mastication mechanism

In recent years, researchers reported that it is possible to improve the level of release of bioactive components in pretreatment and mastication processes. For example, oral disintegrating film (ODF) is a dosage form produced with water-soluble polymers and when placed in oral cavity, it is quickly hydrated by saliva, adhered to mucosa, and disintegrated in seconds releasing the active ingredient for mucosal absorption, which results in a rapid absorption and instant bioavailability due to high blood flow regions such as the sublingual [81]. Rapid and effective release of bioactive components can also be considered independent of the optimum size of chewing gum consumption. Taking bioactive compound from chewing gum matrix to mouth is related with the diffusibility of the saliva into chewing gum. Diffusibility of the saliva in the chewing gum affects amount and release rate of the bioactive compound; therefore, size of the product should be optimized. The important level of bioavailability is the release of the targeted level before the mastication process is complete. Since the duration of this process varies widely according to the consumption habits and product qualities, it is more advantageous to realize the release as soon as possible depending on the aim of the usage and behavior of active substance.

The total volume of saliva secreted per day has been estimated to be about 0.6 L [82]. Several studies have reported that the mean flow rate of unstimulated/resting whole saliva in healthy persons during the day is in the range of 0.3–0.4 mL/min but with a large standard deviation [73, 83]. The saliva flow rate in response to chewing gum consumption was 3.4 mL/min [84], and this ratio was used to stimulate the saliva flow [85]. The longer chewing gum period of each food bolus may result with the longer time for odor release and the greater incorporation of saliva, since the chewing gum process and gustatory stimulation both increase salivary flow rate while chewing flavored gum, as opposed to chewing gum base [76, 86]. Therefore, the fact that the use of bioactive components is not in the negative direction of the effect on flavor release in chewing gum may be asserted as a factor that can improve bioavailability.

The highest constituent in the salivary composition is water with 99% [76]. It is of great importance that the water-soluble bioactive component is preferred in the chewing gum production. Also, salivary fluid is composed of a variety of electrolytes (sodium, potassium, calcium, chloride, magnesium, bicarbonate, phosphate) and proteins, represented by enzymes, immunoglobulins and other antimicrobial factors, mucosal glycoproteins, traces of albumin, and some polypeptides and oligopeptides of importance to oral health. There are also glucose and nitrogenous products, such as urea and ammonia [87]. The main protein and also digestive enzyme in saliva is alfa-amylase (1,4-glucan 4-glucanohydrolase) [88]. The presence and level of this enzyme should also be taken into account for the stability and bioavailability of the bioactive components. Saliva has a strong potential to interact with all food macronutrients because of the diversity of its enzymatic composition. Its amylolytic activity is the most well-known, but proteolytic and lipolytic activities have also been reported in human saliva. The active role of these enzymatic activities at the early stages of the digestion may be limited in terms of food degradation because of the short duration of contact with food in the mouth [89].

In the process of mastication, the mechanism of the physical effects of chewing gum should be understood and taken into account in product development studies. The human chewing system is a complex system of upper and lower jaws with teeth on it [90]. It also includes the movement of tongue and cheek as well as saliva production. While chewing, the lower jaw (mandible) is moved with the muscles attached between the upper jaws [91]. The chewing movement starts with the opening of the mandible, so there is a gap between the teeth in the skull and the mandible. The tongue places the food particles that need chewing into the gaps in one side of the mouth. The mandibular then closes these food particles and separates the pieces and then falls into the tongue to reposite the particles during the next cycle. The opening of the mouth within chewing cycle is approximately vertical [92]. The opening phase of the mandible slows at the beginning and increases when the mouth is opened [93]. When the mouth begins to close, the mandibula moves laterally outward, and initially returns to the teeth, rapidly closing and slowing down for occlusion [90].

Texture is perhaps the most important sensory attribute linked to food structure [75]. The consistency of oral processing (chewing, swallowing) may be affected by the texture of the chewing gum thereby affecting the profile of flavor delivery in both the temporal and intensity dimensions [94]. The texture of the chewing gum affects the product quality and the mechanical effects that will be experienced during the mastication. Different food particles depending on their shape and texture are used to chew up. These differences create a different chewing mechanism for different food products. If a vertical chewing gesture is used, the teeth use their heads to break food particles [90]. If more lateral chewing is used, the teeth use sharp edges to function like blades and cut food particles [95]. Another important factor is the size of the bolus. According to the composition of chewing gum, the size of the bolus may vary during the mastication process. In this case, it is also possible that there may be differences in mechanical effects during mastication.

Simulations of chewing gum's mastication can be performed using different devices by in vitro studies [96]. One factor to be considered while designing the devices is the quality of the human mastication system, a perfect endowed art that cannot be completely imitated. Several studies have been conducted for this purpose [97–99]. It will also be useful to consider that panelists do not have the same severe mechanical effects during mastication and consumers perform slow and fast mastication over time [12]. For this purpose, the principles of sensory analysis studies carried out with the Time-Intensity technique can be taken into account. Also, chewing gum is an example of a product where the perceived intensity of flavor characteristics changes over time. Many sensory properties of the chewing gum can change, such as the flavor and texture. Flavor compounds differ in their rate of release as gum is chewed [26].

The material to be used as a natural gum base elastomer in functional and/or conventional chewing gums should be able to demonstrate the functions imparted to the product by synthetic elastomers. The main functions of these ingredients are elasticity, pliability, and stickiness. For example, if the chewing gum exhibits a high degree of adhesion to the teeth and/or palate due to the gum base to be obtained by the use of an alternative elastomer, the functional properties of this product will be acceptable to the consumer even if the functional properties are improved. It is also possible that there is a similar property, at the same time, that there are also adhesion problems in the packaging material. It is also important that, during consumption, the chewing gum cannot be cured, bent, and bended by elasticity and exhibit elastic behavior. Otherwise consumption will be difficult and consumption time will be shortened. Shortening of the consumption period will bring disadvantages in terms of completing the release of the bioactive components in the structure.

5 Buccal Delivery of Bioactive Compounds by Chewing Gum

Consumers are increasingly looking to nonnutrient therapeutic compounds for added benefits from their food which may pay the way for health promotion, disease prevention, and performance improvement. However, one barrier to obtaining high systemic levels of a bioactive in a delivery agent is that the body especially the digestive system or gut has a number of enzymes which rapidly changes molecules prior to their entry into the circulatory system. This presystemic metabolism is also known as the "first-pass" effect. Glucuronidation process occurred in the first-pass in the gut or liver and catalyzed by UDP-glucuronosyltransferases enzymes (UGTs) causes poor bioavailability of orally administered bioactive compounds and decreases their therapeutic effects [100]. Efficacy of bioactive compounds depends on the bioavailability; therefore, novel delivery systems should be developed to improve in vivo bioavailability of beneficial compounds orally administered [79]. Due to ease of usage and special physiological properties, buccal delivery of drugs has attracted particular attention. Moreover, it has been discovered that bioavailability of anthocyanins is enhanced in mouth by human saliva and oral microflora. It was found that deglycosylation of the parent anthocyanin to its respective aglycone

increases chemopreventive impact by removing the sugar groups which could cause steric hindrance and salivary β-glucosidase mostly produced by oral microflora hydrolyzed black raspberry anthocyanins which increased its chemopreventive effect against oral cancer [101].

Delivery of bioactive compounds can be conducted in two ways within the oral mucosal cavity: (i) topical delivery, which is delivery into local parts of oral cavity and (ii) intravenous delivery either via the buccal mucosa or sublingual mucosa. Since sublingual mucosa is thinner than the buccal mucosa and has a rich blood supply and surface area, it is more permeable. Although washing effect of saliva and tongue movement can decrease the durability of the bioactive compound, this route is preferred when a rapid onset is desired; in particular, for the treatment of acute disorders. On the other hand, buccal mucosa has an even surface therefore it is easier to place and remove controlled-release systems.

Buccal delivery of bioactive compounds is very advantageous for bioavailability due to avoidance of first pass effect. However, buccal delivery of bioactives exhibits the following disadvantages:

(a) Enzymes in saliva can modify chemical structure.
(b) Salivary secretion and swallowing can dilute and remove bioactive compounds from the absorption side.
(c) Limited surface area and the barrier feature of the buccal mucosa may cause ineffectiveness of this delivery route.

Total effective area for bioactive compound delivery on oral membrane is 31.5 cm^2 and thickness of oral mucosa varies between 100 and 800 μm. The amount of saliva in mouth is approximately 1.1 ml, 1% of which is organic and inorganic materials and depending on the secretion rate, salivary pH changes between 5.5 and 7.0. However, salivary secretion rate is between 0.5 and 2.0 L/day. Saliva can help transportation of bioactive compounds from bulk to absorption sites. However, dilution also occurs due to the presence of saliva which may reduce the amount of absorbed material.

5.1 Absorption Mechanism of Bioactive Compounds

Two different routes exist for the passage of bioactive compounds namely extracellular pathway through the intercellular space and intracellular pathway through passage into and across the cell. The former favors the absorption of hydrophilic substances due to its hydrophilic nature. However, the latter route includes the lipophilic cell membrane which can be favorable for the absorption of lipophilic compounds.

5.2 Obstacles for Oral Delivery

Oral route is convenient and maybe the most preferred to both clinicians and patient among wide range of routes for bioactive compounds delivery. Absorption of

bioactive compound generally depends on thickness and keratinization of oral mucosa and absorption increases by the decrease of these parameters. Therefore, it was found that permeability is the highest in sublingual mucosa and the lowest in the palatal mucosa [102]. However, membrane coating granules (MCGs) which are intercellular lipid substances cause the most important obstacle for bioactive compound permeability. By covering the apical surface of the cell, MCGs merge with the cell membrane and form stable barrier for absorption. Moreover, bioactive compound should be stable in first pass metabolism or encapsulated before incorporation into the delivery system to withstand enzymes included in saliva such as esterases, carbohydrases, and phosphatases.

5.3 Important Factors for Buccal Delivery

The crucial parameters for buccal delivery are sensorial and physicochemical properties, physiological conditions, and ingredients of dosage form. As diffusivity depends on molecular size and weight, small molecules lower than 75 Da is generally absorbed rapidly by oral mucosa. Hydrophilic materials also have better absorption characteristics. Another important factor is the dissociation constant (Ka or pKa) of the bioactive molecules that is dissociation of the molecules at the oral cavity pH which is around 6.8 and causes obstacle for the passage of the bioactive molecules.

The sensory properties of delivery agent can affect the consumer compliance or the acceptance of the product. Also it should be considered in the design of delivery agent that effective surface area of absorption site is about 2 cm^2; therefore, deliverable amount of bioactive compound in the delivery agent is limited. For this reason, buccal delivery route can be suitable for bioactive compounds, effective dose of which should be in the order of a few milligrams. Ingredients of delivery agent should not be irritant and toxic.

Concerning the physiological conditions, mucoadhesive polymers and absorption enhancers may be needed to improve bioactive compounds absorption by increasing residence time and absorption of bioactive compounds when dilution with saliva, swallowing, and the presence of MCGs severely limit the absorption of the compounds [103]. The important point for the mucoadhesive performance is the pH stability in the oral cavity. Resveratrol-loaded mucoadhesive tablets were found to prevent and/or cure inflammatory lesions of the oral cavity [104]. Another approach to increase the solubility and thus bioavailability of phenolics is developing a food-grade self-nanoemulsifying system. Wang et al. [105] achieved to improve the dissolution and absorption of ellagic acid by using self-nanoemulsifying delivery technique. This can be used in chewing gums to increase absorption of insoluble bioactive compounds.

5.4 Chewing Gum as a Modern Carrier

General factors affecting carrier capability of chewing gum is summarized in Fig. 3. Chewing gum is a novel and convenient carrier to deliver bioactive compounds via

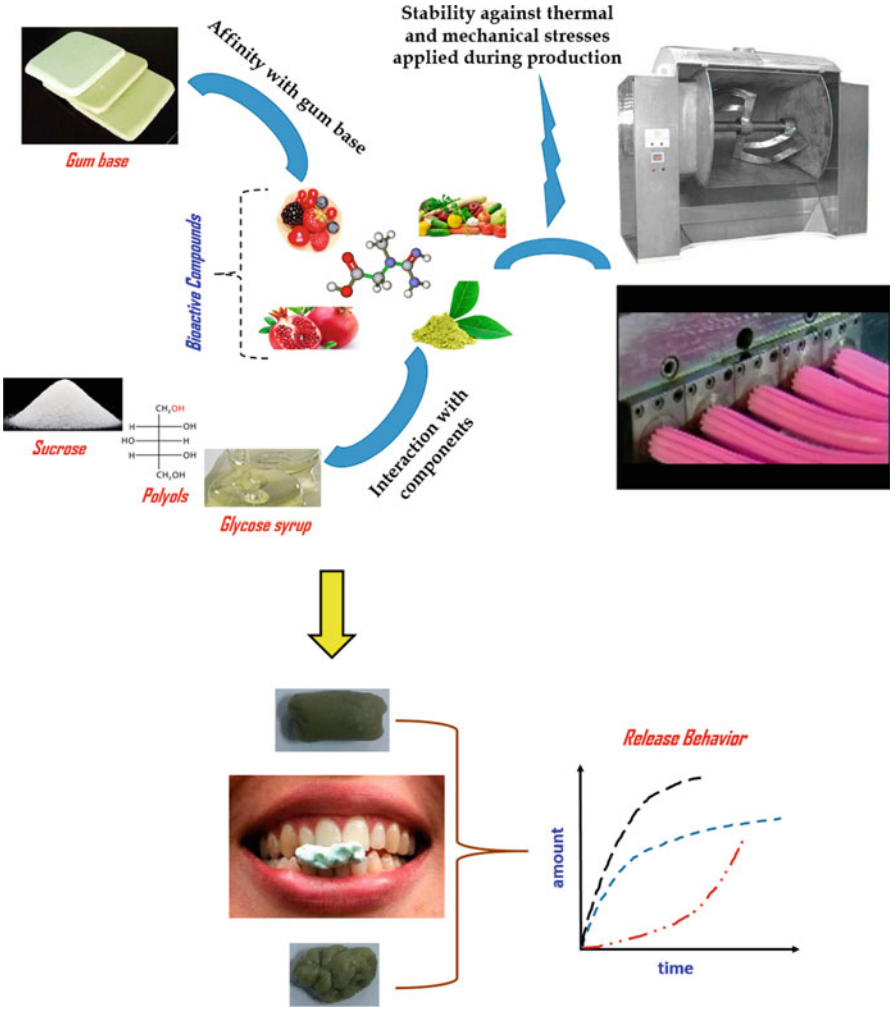

Fig. 3 General scheme for factors considered during functional chewing gum development

oral transmucosal route. Because chewing gum is generally kept in mouth much longer than capsules, rinses, and gels, this dosage form can increase bioavailability by delivering therapeutic agents for an extended period of time. Moreover, bioactive compounds can be released slowly and continuously depending on chewing gum formulation and production process. For this reason, some pharmaceutical companies invented special chewing gums to orally deliver drugs, in addition to the most common tablets and capsules [106]. It is also discovered that saliva increased the solubilization of lipophilic polyphenols present in fruits and plant beverages boosting their potent antioxidant effects and increased the stickiness of polyphenols to oral surfaces contributing to the enhancement of the redox status of the oral cavity

[107]. Therefore, chewing gum containing lipophilic polyphenol would have advantages by prolonged contact with saliva.

As mentioned before, the same factors can affect the absorption of bioactive compounds incorporated in chewing gum, namely, pKa of the compound, oral pH, saliva secretion rate and composition, enzyme content, permeability and thickness of the mucosa, keratinization and composition, cell renewal rate. Other factors related with chewing gum are bioactive compound solubility and interaction with other chewing gum ingredients, release rate of gum base, chewing rate, frequency, intensity, and duration.

5.5 Functional Chewing Gum Developing Studies

High amount of chewing gum products has been formulated and commercialized as vehicles for delivering health active agents. Progression in microencapsulation has allowed the design of carriers and systems which can exactly target a desired release site at a predesignate rate. Active substances ingested via the oral route can be schemed to be delivered using two paths: (i) local and (ii) systemic. Dental caries prevention, halitosis, angina relief, and xerostomia symptoms are examples of local effects delivery. Smoke cessation and pain relief are examples where confectionary products have demonstrated their effectiveness as systemic delivery carriers [34].

For the treatment of gingivitis and plaque build-up, Trivedi et al. [108] found that addition of rosemary extract to chewing gum prevented this kind of oral diseases by supplying antibacterial, antioxidant, and/or anti-inflammatory effect in the oral cavity. Rosemary extract includes ursolic acid and carnosic acid. Most of the cases, the extract is isolated from leaves of *Rosmarinus officinalis*. Rosemary oil, which is another product from *Rosmarinus officinalis*, is derived from steam extraction of flowering parts of the plant as well as the leaves. Although rosemary oil has been suggested for use in dentifrices along with other oils such as eucalyptol and menthol, it is found that the chemical composition of rosemary oil differs a great deal from rosemary extract and rosemary extract gave better results. Enhanced effects can also be possible by including triclosan or other phenolic antibacterial agents.

Quercetin (Qt)-containing chewing gum has been developed to inhibit the growth of oral *Streptococcus mutans* strains which are responsible for tooth decay [60]. In vivo release kinetics and antibacterial effects of Qt were studied. The release analysis in saliva of young volunteers demonstrated that the most of Qt release took place in the first minutes of chewing without changing saliva pH values. Moreover, in vivo antibacterial analysis showed after 14 days daily consumption that concentration of *S. mutans* strains in saliva decreased after 7 days of consumption. Therefore, Qt-included chewing gums can provide an effective anticaries concentration in saliva, without changing salivary pH values.

Bioactive compounds having low water solubility and high lipophilicity are released extremely slowly in chewing gums due to lipophilic nature of chewing gum base. Therefore, cyclodextrin can be used to enhance release rate of this kind of substances. Jacobsen et al. [109] studied chewing gums containing hydroxypropyl-

β-cyclodextrin inclusion complexes of imidazole antimycotics (miconazole, econazole, and clotrimazole) for local treatment of fungal infections in the oral cavity. In conclusion, antimycotic release from the chewing gum was increased by using both the econazole β-cyclodextrin inclusion complex and the miconazole hydroxypropyl-β-cyclodextrin kneaded product in the formulation of chewing gum.

Another approach which can be used in chewing gums to enable systematic release of therapeutic agents and increase their bioavailability is the utilization of oral disintegrating films. It is a dosage form produced with water-soluble polymers and when placed in oral cavity, it is quickly hydrated by saliva, adhered to mucosa, and disintegrated in seconds releasing the active ingredient for mucosal absorption, which results in a rapid absorption and instant bioavailability due to high blood flow regions. Tedesco et al. [81] investigated the release of peanut skin phenolic compounds from disintegrating films including gelatin and hydroxypropyl methylcellulose (HPMC). Higher gelatin containing films caused lower release due to cross-linking between gelatin and polyphenols. However, HPMC films showed better maintaining and release behavior. In vitro analysis demonstrated that 80% of phenolics were released in 5 min and 60% of phenolics remained stable according to accelerated stability tests.

Anthocyanins are suitable candidates to be used in chewing gum as a vehicle because they show chemoprotective activities in the oral cavity. Bioavailability of red grape and chokeberry juice anthocyanins were investigated in vivo [110]. Twelve volunteers kept red grape or chokeberry juice in the mouth for 5 min and anthocyanin stability, mucus binding, and uptake into epithelial cells were measured. Among the other anthocyanin-glucosides in red grape juice, major loss was found in the amount of delphinidin-3-glucoside in red grape juice exceeded that of other, and lesser mucus binding observed for delphinidin- and petunidin-glucosides, suggesting the degradation of this anthocyanin. Whereas in chokeberry juice, the most reduction occurred in the amount of cyanidin-3-xyloside and it was found that cyanidin-3-glucoside preferentially accumulated in epithelium cells. These results implied that chemical structure of anthocyanin influenced stability and buccal cell uptake and therefore the bioavailability of anthocyanin-rich products for the promotion of oral health.

For the treatment of supragingival plaque, chlorhexidine is usually used; however, it causes tooth staining. Smith et al. [111] investigated the effect of chewing gum incorporated with chlorhexidine on the plaque, gingivitis, and stain formation. Bleeding scores and plaque were less for volunteers who used chlorhexidine gum for 4 and 8 weeks. Moreover, stain intensity was significantly lower for the chlorhexidine gum than rinse at week 8. This result showed that controlled treatment of supragingival plaque can be done without causing tooth staining by using chewing gum formulation.

Apart from bioavailability of bioactive compounds, the typical human diet is no longer rich in sources of phytochemicals. Moreover, normal dietary sources of phytochemicals are likely not ideally suited for delivery of these substances to a subject in order to obtain maximum bioavailability. Moreover, normal dietary sources of phytochemicals do not contain ideal combinations of phytochemicals to

produce the maximum therapeutic or nutritional benefit. Therefore, chewing gum formulation with desirable combinations can be developed to deliver phytochemicals in a controlled manner for the treatment or prevention of diseases. For instance, a functional chewing gum was patented containing green tea polyphenol, black tea polyphenol, white tea polyphenols consisting of epigallocatechin-3-gallate, gallocatechin gallate, gallocatechin, catechin, catechin gallate, epicatechin, epicatechin gallate and epigallocatechin, ginger phenolics, chlorogenic acid, retinoids, carotenoids, narcotics, theaflavins, and garlic extract [112].

Tea polyphenols (TP) have been extensively used as an antioxidant in foods and cosmetics. EC (epicatechin), EGC (epigallocatechin), EGCG (epigallocatechin gallate), and ECG (epicatechin gallate) are the basic active components in TP. According to recent progress in clinical study, TP could be used as an oral drug for prevention and treatment of caries, plaque, and laryngopharyngitis and prevent the development of cancer [113]. Catechins are water-soluble active agents. It had been stated that water-soluble substances usually release easily and rapidly from chewing gum. Polyvinyl acetate (PVAc), an elastic component, could be used as a retarding release agent for active ingredients such as catechins [114]. Phenolic isomersmagnolol and honokiol from Magnolia bark extract was shown to permeate the oral mucosal barriers and reduce salivary bacterial count, biofilm growth, salivary mutans streptococci, and plaque [115]. Chewing gum prepared with tea extract, *Camellia sinesis* (rich in epigallocatechin gallate), was able to reduce gingivitis and oral microbial growth [116].

Lee et al. [117] explored the beneficial effects of green tea catechins. It was shown that chewing or holding tea leaves in the oral cavity is an effective method in distributing tea polyphenols to the oral cavity. Long chewing time and direct contact with buccal mucosa yielded great salivary levels of polyphenols. Therefore, chewing gum can be used as a delivery vehicle for bioactive compounds. Moreover, catechins found in green tea were aimed to the beneficial effects of reducing the risks of oral cancer, cardiovascular disease, and tooth decay.

Yang et al. [10] produced chewing gums containing catechins that were prepared by applying a novel solid dispersion and hot-melt fluid bed coating method. The active material was granulated with PVAc and the pellets were coated with acrylic insoluble polymer. Researchers observed that the releases of catechins from the product were well extended with the growing coating level of Eudragit to the granules. The results illustrated that the release rate of catchins could be controlled by altering the coating thickness of Eudragit. The kinetic parameters indicated that the release rate of the formulation tended to change inversely with the level of Eudragit coating. The mechanism of controlled release was found to be close to the Higuchi model. The chewing gum prepared with Eudragit and by particular coating methods retained the effective therapeutic concentrations of catechins over a possible chewing period (approximately 30–40 min) in vivo.

Starch inclusion complexes could be applied for controlled release of bioactive compounds, due to enhancing the stability, dispersibility, and quite possibly bioavailability of bioactive compounds encapsulated within a starch helix [118]. Blair [118] used the chewing gum as a delivery vehicle for bioactive polyphenols found in

green tea. They evaluated the release of the polyphenols from the chewing gum matrix to the saliva in free form and as a starch inclusion complex. The overall stability of catechins found in green tea can be increased when bounded to the complex because it is susceptible to oxidative reactions.

The consumption of plant foods like ginger, a well-known used plant, decreases the risk of obesity, diabetes, heart disease, and overall mortality. It consists of active phenolics agents such as gingerols and shogaols that improve gastrointestinal problems and motion sickness. Ginger has antioxidant and cancer-protective characteristics due to its free radical scavenging activity. Flavonoids and phenolic components of ginger contain gallic acid, tannic acid, catechin, epicatechin, rutin. Some other volatile oils constituents exist in ginger, e.g., cineole, linalool, citral, phellandrene [119]. It has phenolic content of 61.50 ± 5.27 mg/g and 76.75 ± 5.45 mg/g of concentrated extract as gallic acid and tannic acid equivalents, respectively. Chewing gum can be used as a pleasant food to deliver beneficial ginger active agents to the body due to the lack of hepatic first pass metabolism. Aslani et al. [119] found that the chewing gum formulations consisting ginger released almost 100% of their active agents after 60 min.

Chios Mastic Gum (CMG) is the dried exudate of the shrub-like tree *Pistacia lentiscus* L. var. *chia.* CMG contains triterpenes/triterpenoids, essential oil, phenolic compounds such as tyrosol and p-hydroxy-benzoic, p-hydroxy-phenylacetic, vanillic, gallic, and trans-cinnamic acids. The unique physicochemical properties of CMG and its composition combined with its health-promoting potential have encouraged the eastern Mediterranean and the Middle East residents to exploit the CMG for preparation of several traditional foods and beverages. The major ratio of the CMG could be used as a natural gum base in the manufacture of Chios chewing gum. Kehayoglou et al. [120] stated that the Mastiha particles act as a plasticizing agent when applied in chewing gum. The environment conditions, method of collection, and also the duration of product storage are effective factors on the polymeric fractions. For example, a steam process is applied for the recovery of essential oils. This procedure results in an increase in hardness due to elimination of the oil constituents because this polymeric fraction has plasticizing effect. However, incorporation of food additives such as wax and lecithin in mastic gum would reduce final hardness of the product.

There are some people who are keen to chew the natural Mastiha, due to its full advantage of flavor and health-promoting characteristics. But the natural Mastiha has poor textural characteristics and during chewing it sticks to the teeth. A wide variety of food additives such as sweeteners, stabilizers, gums, and plasticizers can be used for improving flavor and textural properties of the natural Mastiha [121].

One of the most important features of bioactive compounds delivery vehicles is organoleptic properties or consumer compliance. For instance, for the treatment of diabetes, prediabetes, polycystic ovary disease, and obesity, metformin and its pharmaceutically acceptable salts are utilized to reduce plasma glucose levels (particularly, postprandial glucose levels), hepatic glucose production, lipid levels, and intestinal absorption. Moreover, metformin influences without resulting in hypoglycemia. However, oral formulations of metformin may lead to a bitter

aftertaste, causing loss of appetite. Moreover, many people do not prefer it because of its side effects, including gastrointestinal disturbance and large pill size. The reason for the side effects such as vomiting, diarrhea, abdomen discomfort is due to abrupt release of active drug in gastrointestinal tract. These often give rise to the failure of consumers to comply with taking the therapeutic agents, i.e., "compliance issues." Compliance issues are prevalent in individuals of all ages, especially children, who typically do not want to take medicines that taste bad. Well-formulated chewing gum can mask bad tastes and prevent gastrointestinal disturbance. Therefore, metformin hydrochloride including chewing gum was developed as a drug carrier to increase organoleptic properties and solve compliance problem successfully [122]. Also, Mostafavi et al. [123] formulated metformin chewing gum having dosage content of 86.2%. After 5 min of chewing 70% of the metformin was released. Freeze-dried acesulfame-isomalt sweeteners were used to mask the bitter taste of drug. Therefore, metformin chewing gum prevented bitter taste with a suitable release rate.

Another medicinal material with having bitter taste is chokeberry. It includes large quantities of antioxidants, and shows a prophylactic effect against cancer, heart diseases, and Alzheimer's disease. However, chokeberry could not be used in food products and medicinal products for oral administration due to its sensorial properties. Therefore, chewing gum formulation can be developed to deliver chokeberry's therapeutic compounds with good acceptable taste. Porsgaard [124] developed a chewing gum containing chokeberry which masked its inherent bitterness. It is claimed that this effect was resulted from the slow release rate of chokeberry from gum base. Moreover it was believed that developed chewing gum can be used for removal of plaque and/or biofilm from the teeth by preventing colonization of streptococci in the initial phase of dental plaque formation.

Proanthocyanidins are natural antioxidants, free radical scavenging ability of which is 50 times of vitamin E and 20 times of vitamin C. By reaching maximum plasma concentration in 20 min, proanthocyanidins have a rapid oral absorption and half-life of up to 7 h. Moreover, proanthocyanidins have several positive health effects including skin protection, decreasing degenerative eye spots and the incidence of cataract, preventing cancer, and decreasing risk of diabetes. Grape seeds contain large amounts of oligomeric proanthocyanidins and seed extract is rich in anthocyanins. Therefore, chewing gum including grape seed extract was formulated [125].

Tree of heaven, *Ailanthus altissima* Mill. Swingle (Simaroubaceae), is rich in therapeutic compounds and used for the treatment of colds and gastric diseases in the Chinese traditional medicine as a bitter aromatic drug. Oil of its ripened form is rich in vitamin C, vitamin E, and other vitamins and minerals, sterols, saponins, seven kinds of essential amino acids, and unsaturated fatty acids including oleic acid, linoleic acid, alpha-linolenic acid. It helps to regulate blood pressure and gastrointestinal function, relieve diabetic complications, and sleep well. Samara oil including chewing gum was formulated to provide slow absorption through oral mucosa for maximum therapeutic effects [126].

6 Conclusions

Chewing gum, unlike other foods, is a product which is chewed without swallowing. Chewing gum is composed of water-soluble (flavor, polyols, sugar, glucose syrup, glycerin, sweeteners) and water-insoluble phases (gum base). There are different types of chewing gums: (i) sugar gum, (ii) sugar-free gum, and (iii) medicated chewing gum. Regarding medicated chewing gums, they can be used as a carrier of caffeine, nicotine, sodium fluoride, dimenhydrinate, chlorhexidine, acetyl salicylic acid, and vitamin C. Medicated chewing gums have been drawing attention in a pharmaceutical industry in terms of preventing and curing dental caries, pain, smoking cessation, obesity, motion sickness, acidity, and diabetes. Rosemary extracts, quercetin, anthocyanins, proanthocyanidins, tea polyphenols, cathechins, and ginger were added to chewing gum formulations for enrichment aim and the produced functional products have substantial health beneficial effects. All of the studies showed that production process of the chewing gum, consumption behavior of the chewing gum (chewed without swallowing in the mouth for a long time), and formulation of the product make it an important tool for delivering bioactive substances. However, organoleptic properties of the chewing gum should be considered during improving functionality since they directly specify the consumer acceptability of the products.

After production of the chewing gum with functional characteristics, it is important to observe release manner in the mouth. It is desired from the functional product that required amount of bioactive compounds release from the matrix and reach the targeted site of the body. During chewing, mass transfer occurs between chewing gum and saliva in the mouth. Regarding saliva composition, great part, higher than 99%, is made up of water; therefore, depending on the structure/strength of the matrix of the chewing gum, water-soluble bioactive compounds can be easily solved by saliva and transported to mouth. The research findings indicated that water-soluble compounds could release from chewing gum within lower than 10 min, which can enable advantages/disadvantages based on the bioactive compound characteristics and aim of chewing gum use. Controlled/sustained release might be desired in some cases where encapsulated bioactive compounds can be used or the structure of the chewing gum can be arranged by using suitable gum base. As known, all of the bioactive compounds are not water-soluble, and some of them are lipophilic nature, where types of compounds can be also encapsulated or emulsions can be formed to carry such compounds by chewing gum into mouth. Depending on the target site, encapsulation also benefits for transporting the compound without damaging further parts of the digestive system.

Mastication process performed during consumption is also important for releasing bioactive compounds. If the matrix is not degraded at desired level, the aimed release cannot be achieved. Therefore, chewing gum matrix should be optimized considering release behavior of the product or bioactive compound should be designed with respect to textural characteristics of the chewing gum. More studies should be conducted in detail to observe releasing different functional ingredients from chewing gum. Saliva viscosity is also another important factor affecting

release; therefore, ingredients affecting viscosity should be carefully used in the formulation of the product. In addition, chewing gum size and particle size of the compounds be used in the formulation should be considered since they directly affect the solubility of the compound in saliva. As can be seen, from formulation to production/quality parameters of the chewing gum (especially texture)/type or form of the bioactive compounds, there are many factors affecting release behavior; therefore, all of them should be optimized with respect to targeted outputs.

Consumer behavior against preference has tended to products prepared with natural ingredients instead of artificial ones. From this reason, usage possibilities of natural ingredients such as colorants, flavoring agents should be investigated. In addition, one of the most important concerns about chewing gums is associated with gum base, nonbiodegradable and artificial, used in the formulation. Therefore, researchers should expend energy to discover natural and bio-degradable gum base used in the chewing gum production. By eliminating disadvantages of using artificial ingredients and optimization of critical factors mentioned above relating both with chewing gum and bioactive compound delivered, chewing gum will be the most important delivery system among all food products.

Bioactive Molecules in Edible and Medicinal Mushrooms for Human Wellness

53

Chia-Wei Phan, Elson Yi-Yong Tan, and Vikineswary Sabaratnam

Contents

Abstract

Mushrooms are now gaining popularity not only as an ordinary culinary ingredient, but as a healthy and whole functional food. This chapter describes three major categories of bioactive molecules found in edible and medicinal mushrooms. First is the mushroom's polysaccharide which is widely accepted as a superior immune-modulatory agent. The mushroom β-glucans differ from the bacterial and plant glucans. Mushroom β-glucans consist of linear β-(1→3)-linked backbones with β-(1→6)-linked side chains of varying length and distribution. Several important β-glucans like lentinan, schizophyllan, grifolan, as well as polysaccharide krestin (PSK) and polysaccharopeptide, will be discussed. Next, the triterpenes family, which are highly conserved in *Ganoderma* species,

will be elaborated further in this chapter. Finally, the indole alkaloids, which are important in mushroom as pigmentation inducer and hallucinogens, will be briefly discussed with emphasis on the psilocin and its derivatives. Other pharmacologically important mushroom-derived alkaloids will also be included. Overall, the potential to develop mushrooms as nutraceutical foods for human wellness, and their bioactive molecules for drugs, is huge.

1 Introduction

Mushrooms are not only valued as a food source but also their long history of beliefs in curative abilities both from the western and oriental traditional medicine systems. What are mushrooms? Mushrooms are the macrofungi with distinctive fruiting bodies commonly occurring in fungi of the class Basidiomycetes and occasionally in the class Ascomycetes [1, 2]. Fruiting bodies are also used interchangeably with basidiocarps (the sexual fruiting body of Basidiomycetes) or ascocarps (the sexual fruiting body of Ascomycetes) [3]. Interestingly, even though the Basidiomycetes demonstrate a wide variety of fruiting body shape, the Ascomycete species still outnumbered the Basidiomycetes [4]. An overview of the mushroom species and the basic terminology used for a typical Basidiomycete mushroom is presented in Fig. 1.

In terms of food, mushroom consumption is considered popular in six countries known as the G-6 (USA, Germany, UK, France, Italy, and Canada) [5]. The six countries make up to 85% of the world consumption of mushroom. According to the Food and Agriculture Organization (FAO), the main exporters of fresh mushrooms in 2012 are Poland, Netherlands, China, Ireland, and Canada. The main importers of

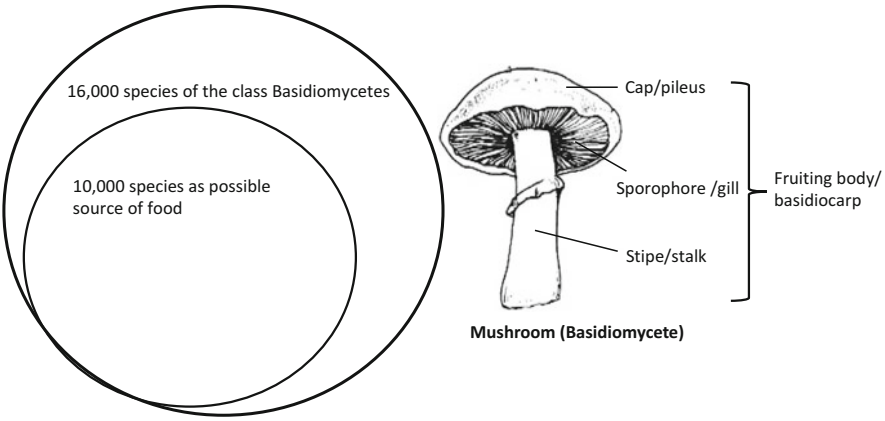

Fig. 1 A pie chart illustrates the number of species of the class Basiciomycetes (left) and the common term to describe the parts of a typical mushroom of Basidiomycete class (right)

fresh mushrooms in the world are the United Kingdom, Germany, Russia, France, and USA. To date, China is still the main producer of mushrooms in the world, producing 5.15 million tons of fresh and processed products yearly.

Indeed, there are many other important roles that mushrooms play in the world. Their expediency to man as food, as tonics and medicines, and also in the bioconversion of waste organic materials are all of great benefit to both man and nature [6]. Phan and Sabaratnam [7] have recently reviewed that the spent mushroom substrate can serve as a reservoir to recover important lignocellulosic enzymes like laccase, xylanase, lignin peroxidise, cellulose, and hemicellulase. In recent years, mushrooms are also known as "mycoremediation tools" because of their use in remediation of different types of pollutants [8, 9].

Mushrooms are now popular for their medicinal properties. There is also a fast mounting volume of in vitro and in vivo animal trials describing a range of medicinal and health promoting properties of mushrooms, including antitumor, anticancer, brain and cognitive function, immunomodulatory, and antiobesity [10]. However, as emphasized by Roupas et al. [11], there are still inadequate direct human intervention trials of the edible and medicinal mushrooms. Figure 2 shows the six most widely investigated edible and medicinal mushrooms [*Ganoderma lucidum* (Fr)

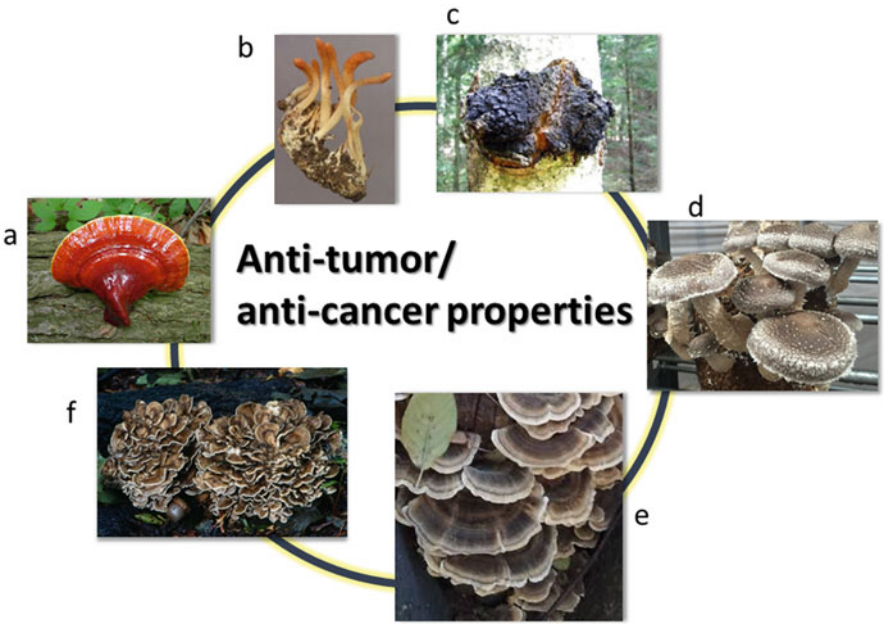

Fig. 2 The six most researched edible and medicinal mushrooms in the field of cancer therapy and oncology according to Scopus. a: *Ganoderma lucidum* (Fr) P. Karst, b: *Cordyceps militaris* (L.:Fr.) Link, c: *Inonotus obliquus* (Ach. ex Pers.) Pilát, d: *Lentinula edodes* (Berk.) Pegler, e: *Trametes versicolor* (L.) Lloyd, and f: *Grifola frondosa* (Dicks.: Fr.). All photos and names are retrieved from mycobank.com. All the mushrooms are of Basidiomycetes class, except for *C. militaris* (Ascomycete). Note the variety of shapes and colors of the basidiocarps

P. Karst, *Cordyceps militaris* (L.:Fr.) Link, *Inonotus obliquus* (Ach. ex Pers.) Pilát, *Lentinula edodes* (Berk.) Pegler, *Trametes versicolor* (L.) Lloyd, and f: *Grifola frondosa* (Dicks.: Fr.)] to fight cancer. The most recent research findings of the six mushrooms on antitumor and anticancer are stipulated in Table 1 [12–27].

In this chapter, we describe and emphasize on the highly sought after bioactive compounds (polysaccharides, triterpenes, and alkaloids) isolated from mushrooms. We also report on the recent advances in our understanding of these mushroom-derived compounds as well as their mode of actions.

2 Abundance of Nutraceuticals in Mushrooms

2.1 Polysaccharides

Bioactive polysaccharides are abundantly found in plants, yeast, bacteria, and fungi. In mushrooms, they exist in the form of α- and β-glucans [28]. Notably, each type of β-glucan comprises a different molecular backbone. They differ among bacterial, cereal, oat, yeast, and fungal glucans. The structural diversity of mushroom β-glucans has been reviewed recently [29]. Essentially, mushroom β-glucans consist of linear β-(1→3)-linked backbones with β-(1→6)-linked side chains of varying length and distribution [30, 31]. They can form tertiary structures stabilized by interchain hydrogen bonds. Some variations include 1→4 linkages, α-glucan moieties, protein complex, and alternate sugars [32]. Figure 3 shows the structure of a fungal (mushroom) β-glucan.

The involvement and importance of polysaccharides in tumor and cancer treatment were first recognized more than 100 years ago when it was found that certain polysaccharides could induce complete remission in patients with cancer. Ever since antitumor activity of macrofungal polysaccharides was first published by Chihara in the 1960s [33], researchers have isolated structural diversified polysaccharides with strong antitumor activity [34]. Unlike traditional antitumor drugs, these substances produce an antitumor effect by activating various immune responses in the host and cause no harm to the body [35].

Carrying out an extensive study in 1966, Gregory isolated the active substances from fruiting bodies of more than 200 Basidiomycetes mushroom species [36]. The polysaccharides isolated from 22 mushroom species and 50 culture media displayed an inhibitory effect on tumor cells, including Sarcoma S-180, adenocarcinoma 755, and leukemia L-1210 [36, 37]. Bioactive polysaccharides can be isolated from mycelium, the fruiting body, and sclerotium, which represent three different forms of a macrofungi in the life cycle [38, 39].

The most famous and most-talk-about polysaccharides isolated from mushrooms are the lentinan derived from *L. edodes*, tremellan from *Tremella fuciformis* Berk., polysaccharide krestin (PSK) and polysaccharopeptide from *T. versicolor*, ganoderan from *G. lucidum*, schizophyllan from *Schizophyllum commune* Fr.,

Table 1 The six mushroom species which are highly researched on their antitumor/anticancer activities. The most recent literature on the antitumor/anticancer properties of these mushrooms is included along with this table.

Mushrooms	Common name	Compound	Description	References
Ganoderma lucidum	Lingzhi, reishi	Ergosterol	Effectively inhibited tumor growth in Hepa1-6-bearing C57 BL/6 mice	[12]
		Genistein		
		Kaempferol		
		Ganoderic acid A		
		Ganoderic acid B		
		Ganoderic acid C2		
		Ganoderic acid D		
		Ganoderic acid H		
		Ganoderic acid Y		
		Ganoderenic acid A		
		Ganoderenic acid D		
		Ganoderenic acid G		
		Polysaccharides	The mushroom polysaccharides enhanced the radiosensitivity of hepatocellular carcinoma cell line HepG2 through Akt signaling pathway	[13]
		Triterpenes	Inhibited the proliferation of human prostate cancer cells and induced apoptosis	[14]
		Polysaccharides	Inhibited prostate cancer cell migration	[15]
Cordyceps militaris	Dongchongxiacao, caterpillar mushroom, winter caterpillar summer grass	Cordycepin	Inhibited malignant transformation, increased cell apoptosis, and decreased cell mitosis in a murine oral cancer model	[16]
		Cordycepin	Induced apoptotic cell death of human brain cancer	[17]
Inonotus obliquus	Chaga mushroom, black tree fungus	Polysaccharides	Inhibited NF-κB nuclear translocation in human nonsmall cell lung carcinoma (NSCLC)	[18]
		Lanostane-type triterpene (inonotusanes D)	Exhibited strong cytotoxicity against the 4T1 (mouse breast cancer) cell line	[19]

(*continued*)

Table 1 (continued)

Mushrooms	Common name	Compound	Description	References
Lentinula edodes	Shiitake	Polysaccharides	Exhibited inhibition of cell proliferation on HCT-116 and HeLa cells	[20]
		Acid heteropolysaccharides	Showed inhibition against A549 human lung cancer cells, SGC7901 gastric cancer cells, MCF-7 breast cancer cells, U937 histiocytic lymphoma cells, and MG-63 human osteosarcoma cells	[21]
		Selenium-containing polysaccharides	Cytotoxic against PC3 and HeLa cancer cells	[22]
Grifola frondosa	Yunzhi, maitake mushroom, hen of the woods	D-fraction polysaccharide	Showed synergistic effects with vitamin C against SMMC-7721 hepatocarcinoma cells	[23]
		D-fraction polysaccharide	Modulated mammary tumor progression	[24]
		Polysaccharide	Enhanced immunostimulatory activity	[25]
Trametes versicolor	Turkey tail	Extracts combined with metronomic zoledronic acid	Attenuated breast tumor propagation	[26]
		Glucan	Exhibited antitumor activity on Sarcoma-180 cells	[27]

grifolan from *G. frondosa*, and pleuran from *Pleurotus ostreatus* (Jacq.) P. Kumm [40] (Fig. 4).

Most recently, Ahn et al. [41] studied the effects of lentinan from *L. edodes* on mouse bone marrow-derived macrophages with and without inflammasome triggers. Lentinan was found to upregulate pro-inflammatory cytokines like interleukin (IL)-1β, IL-18, or caspase-1. However, lentinan was found to attenuate IL-1β secretion when the macrophages were treated with bacteria *Listeria monocytogenes* or lipopolysaccharide (LPS). This clearly shows that lentinan, a bioactive polysaccharide, can act as a "double edge sword." It increases the pro-inflammatory cytokines to initiate immune response when infection commences, and on the other hand, exerts anti-inflammation when an infection persists.

Interestingly, Zhang et al. [42] reported on the combinational effects of oral polysaccharides like lentinan and tremellan on mice which were immunized with inactivated H1N1 influenza vaccine. The results showed that mice in the

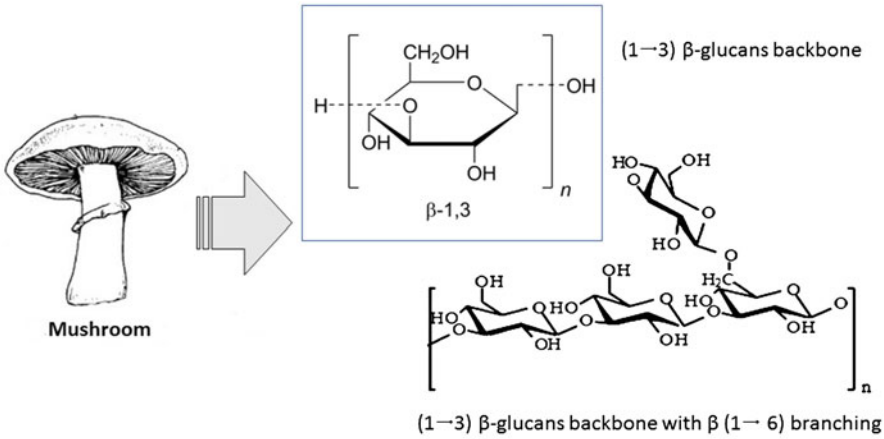

Fig. 3 Mushroom β-glucans consisting of linear β-(1→3)-linked backbones with β-(1→6)-linked side chains

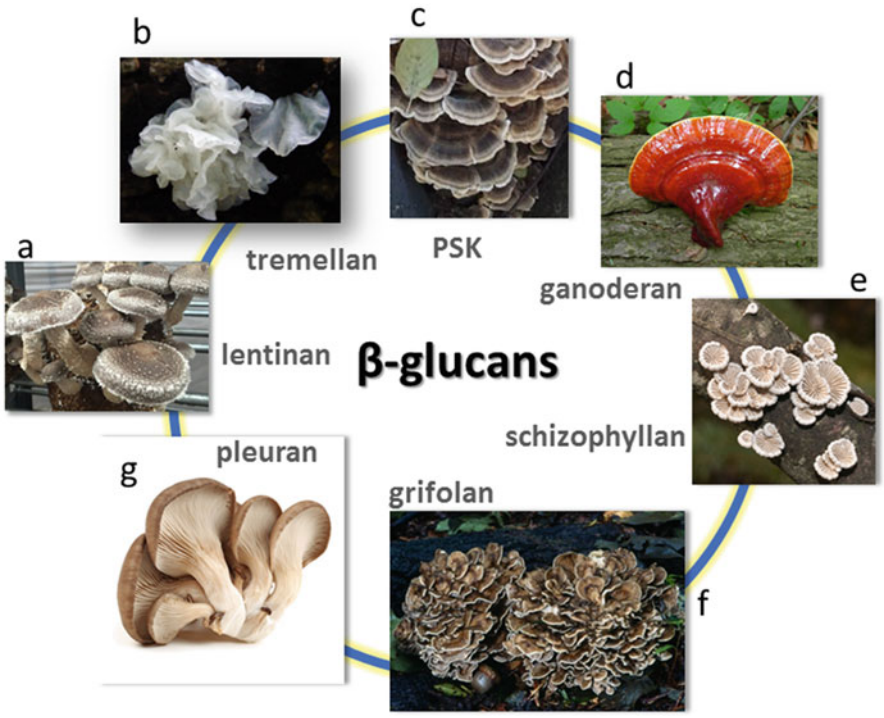

Fig. 4 The different names of bioactive β-glucan found in their respective mushroom origins. (**a**) *L. edodes*, (**b**) *T. fuciformis*, (**c**) *T. versicolor*, (**d**) *G. lucidum*, (**e**) *S. commune,* (**f**) *G. frondosa*, (**g**) *P. ostreatus. polysaccharides with vaccine groups had improved viral clearance. The immunized rat which were fed with lentinan and tremella recovered faster than the mice receiving only the vaccine after infection.

Some polysaccharides isolated from mushroom might possess an acidic or a neutral characteristic due to different types of glycosidic linkages. Some are bound to protein or peptide residues such as polysaccharide-protein/-peptide complexes. One example is the protein-bound polysaccharide K (PSK) from *T. versicolor*. PSK is very popular among the patients with gastrointestinal cancer (GIC) and they consume it with or without chemotherapy [43, 44]. Most recently, a network meta-analysis revealed that PSK combined with chemotherapy can increase the patient overall survival by 3–5 years [45]. Another meta-analysis and systematic review study also showed that PSK can extend survival in lung cancer patients [46]. As exemplified by PSK, in addition to the primary structure, a higher structure of polysaccharides, such as chain conformation, plays an important role in their antitumor activities.

Ganoderan represents an immunomodulatory polysaccharide from *G. lucidium*. It is an antioxidant polysaccharide that was shown to prevent and control cerebral arteriosclerosis by regulating the NADPH oxidizing enzyme expression [47]. It was also shown to exert protective effects in rats with chronic glomerulonephritis [48]. On the other hand, pleuran, which was extracted from *P. ostreatus*, was first reported to be formulated as a β-glucan-based cream. The pleuran-based cream was found to be effective in mild to severe atopic dermatitis [49]. In fact, β-glucan-rich *P. ostreatus* was found to be a functional food as it demonstrated hypoglycemic effect in diabetic mice, and it is capable of improving hyperlipidemia in obese mice [50, 51].

According to Zhang et al. [52], schizophyllan is a nonionic, water-soluble homoglucan which possesses a β-(1→3)-linked backbone with single β-(1→6)-linked glucose side chains at approximately every third residue. Schizophyllan is probably one of the oldest β-glucan discovered from mushroom. Since the mushroom *Schizophyllum commune* is an efficient wood-degrading fungus, it can directly utilize woody substances like corn fibers for the production of schizophyllan [53, 54]. Besides serving as a potential prebiotic with immunomodulating properties [55], schizophyllan is now being developed for bulk biomaterial applications, such as in enhanced oil recovery and as a component of bio-lubricants [56–58].

Grifolan is a branched β-(1→3) glucan extracted from *G. frondosa* [59]. The proposed mechanism by which grifolan exerts antitumor effect includes first the enhancement of immunity against the bearing tumors and secondly, a direct anti-tumor activity to induce the apoptosis of the tumor cells [60]. Grifolan also can be used for the prevention of the oncogenesis by oral administration (cancer-preventing activity). D-fraction, on the other hand, is a protein-bound β-1,6 and β-1,3 glucan (proteoglucan) extracted from *G. frondosa*. D-fraction was reported for the first time in 2017 with the ability to act directly on mammary tumor cells [24].

Overall, mushroom polysaccharides exert their bioactivity mainly via immunomodulation [61]. They help the host to adapt to various biological stresses

and exert a nonspecific action on the host, supporting some or all of the major systems. Most importantly, mushroom polysaccharides are nontoxic and place no additional stress on the body. Therefore, they are regarded as "biological response modifiers" with the potential as prebiotic to safeguard our gut microbiome [62].

2.2 Triterpenoids

Triterpenes are highly oxidized lanostanes. Triterpenes are widely reported in *Ganoderma* species. Zhou et al. [63] had reviewed that triterpene is one of the main components responsible for the claimed therapeutic efficacy of *Ganoderma*. In fact, the potential of *Ganoderma* triterpenoids against various cancer targets had been well documented [64].

Triterpenes reported in *Ganoderma lucidium* include but not limited to ganoderic acid A **(1)**, C **(2)**, F **(3)**, U **(4)**, V **(5)**, W **(6)**, X **(7)**, Y **(8)**, lucidimol A **(9)**, B **(10)**, ganoderiol F **(11)**, ganodermanondiol **(12)**, and ganodermanontriol **(13)** [65–68]. Ganoderiol F and ganodermanontriol were found to be active as anti-HIV-1 agents [69]. Ganoderic acid is a member of highly oxygenated C30 lanostane-type triterpenoids. Ganoderic acids and their derivatives are reported to modulate the signaling network in cancer signaling pathways, and they primarily target nuclear factor-kappa B (NF-κB), 3′,5′-cyclic adenosine monophosphate (cAMP), rapidly accelerated fibrosarcoma mitogen activated protein kinases (RAS-MAPK), phosphatidylinositol-3-kinase/protein kinase B/mammalian target of rapamycin (PI3K/Akt/mTOR), and cell cycle resulting in apoptosis [70]. Figure 5 shows the chemical structures of triterpenoids **(1–13)** from *G. lucidum*.

Although ganoderic acids are popular for their anticancer properties, their beneficial effects on the nervous system are widely pursued by researchers. The triterpenoids isolated from *G. lucidum*, namely, ganoderic acid A **(1)**, 7-oxo-ganoderic acid Z **(14)**, ganolucidic acid A **(15)**, methyl ganoderic acid A **(16)**, methyl ganoderic acid B **(17)**, ganoderic acid S1 **(18)**, ganodermic acid TQ **(19)**, and ganodermatriol **(20)**, have shown NGF- and BDNF-like neuronal survival-promoting effects [71], as well as neuroprotection activity [72]. Figure 6 shows the chemical structures of triterpenoids **(14–20)** from *G. lucidum*.

Besides *G. lucidium*, *G. tsugae* Murrill [73], *G. concinna* [74], and *G. pfeifferi* Bres. [75] were also reported to produce new lanostane-type triterpenoids. Tsugaric acid C **(21)**, tsugarioside B **(22)**, and tsugarioside C **(23)** from *G. tsugae* were found to be effective against human hepatoma cells [73]. Besides that, three new lanostanoids, i.e., 5α-lanosta-7,9(11),24-triene-3β-hydroxy-26-al **(24)**, 5α-lanosta-7,9(11),24-triene-15α-26-dihydroxy-3-one **(25)**, and 8α,9α-epoxy-4,4,14α-trimethyl-3,7,11,15,20-pentaoxo-5α-pregnane **(26)**, were isolated from *G. concinna* [76]. All the three compounds were found to induce apoptosis in human promyelocytic leukemia HL-60 cells. In 2003, Mothana et al. [75] discovered three new antiviral lanostanoid triterpenes from *G. pfeifferi*, namely ganodermadiol **(27)**, lucidadiol **(28)**, and applanoxidic acid G **(29)**, all of which showed antiviral activity against influenza virus type A and HSV type 1. Figure 7 shows the chemical

structures of different *Ganoderm*a-derived triterpenoids **(21**–**29)** from *G. tsugae*, *G. concinna*, and *G. pfeifferi*.

Ganoderma colossum (=*Tomophagus colossus* (Fr.) Murrill), found in Vietnam, was reported to possess anti-HIV-1 protease activity [76–78]. El Dine et al. [76] have reported the isolation of four new lanostane triterpenes, namely, colossolactone V

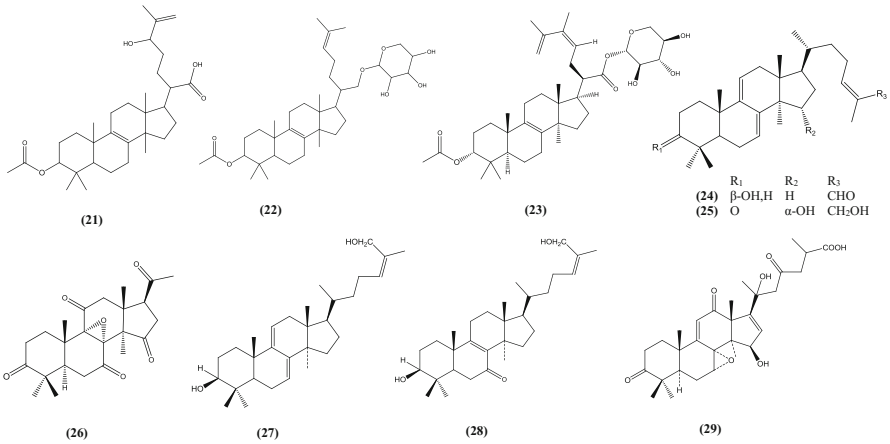

Fig. 7 Triterpenoids **(21–29)** from *G. tsugae*, *G. concinna*, and *G. pfeifferi*

(30), colossolactone VI **(31)**, colossolactone VII **(32)**, and colossolactone VIII **(33)** (Fig. 8), from the Vietnamese mushroom. Furthermore, nortriterpenoids, a derivation of lanostane-type triterpenoids due to degradation of side chains, have also been found in *G. resinaceum* Boud [79]. In the study of Chen et al. [79], six new nortriterpenoids **(34–39)** (Fig. 8) were separated and purified from the basidiocarps of *G. resinaceum*. The new compounds were identified as lucidone I **(34)**, lucidone J **(35)**, lucidone K **(36)**, lucidone I **(37)**, ganosineniol B **(38)**, and ganosineniol C **(39)**, based on high resolution mass spectrometry (HRMS), nuclear magnetic resonance (NMR), infrared (IR), and ultraviolet (UV). However, only compounds **34**, **35**, **38**, and **39** showed a significant α-glucosidase inhibitory activity.

There are several research groups that reported the presence of rare triterpenes in mushrooms such as *Piptoporus betulinus* (=*Fomitopsis betulina*) [80]. Annual white to brownish basidiocarps of the "Iceman" mushroom *F. betulina* can be found on trees in the northern hemisphere [81]. Several experiments had revealed that the extracts of *F. betulina* showed potential cytotoxic activities against several human cancer cell lines [82–84]. Lately, Tohtahon et al. [80] described the isolation and identification of five new lanostane triterpenoids, namely, piptolinic acids A-E **(40–44)** (Fig. 9). The authors also described their cytotoxicity effects against HL-60 and THP-1 human leukemia cell lines.

Astraeus odoratus Phosri, the earth-star mushroom, is popular as food in Thailand despite its strange looking star-shaped figure [85]. The mushroom is expensive due to the limitation of natural occurrence and the difficulty of artificial cultivation. Isaka et al. [86] reported the isolation of twelve new lanostane triterpenoids, astraeusins A–L (**45–56)** (Fig. 10) from the methanol extracts of *A. odoratus.* All the compounds, except for astraeusin F due to sample shortage, were subjected to antibacterial activities against *Bacillus cereus* and *Enterococcus faecium.* Astraodoric acid A **(57)** (Fig. 10) inhibited the proliferation of both *B. cereus* and *E. faecium* with minimum inhibitory concentration (MIC) of 6.25 μg/mL.

	R_1	R_2	R_3	R_4	R_5

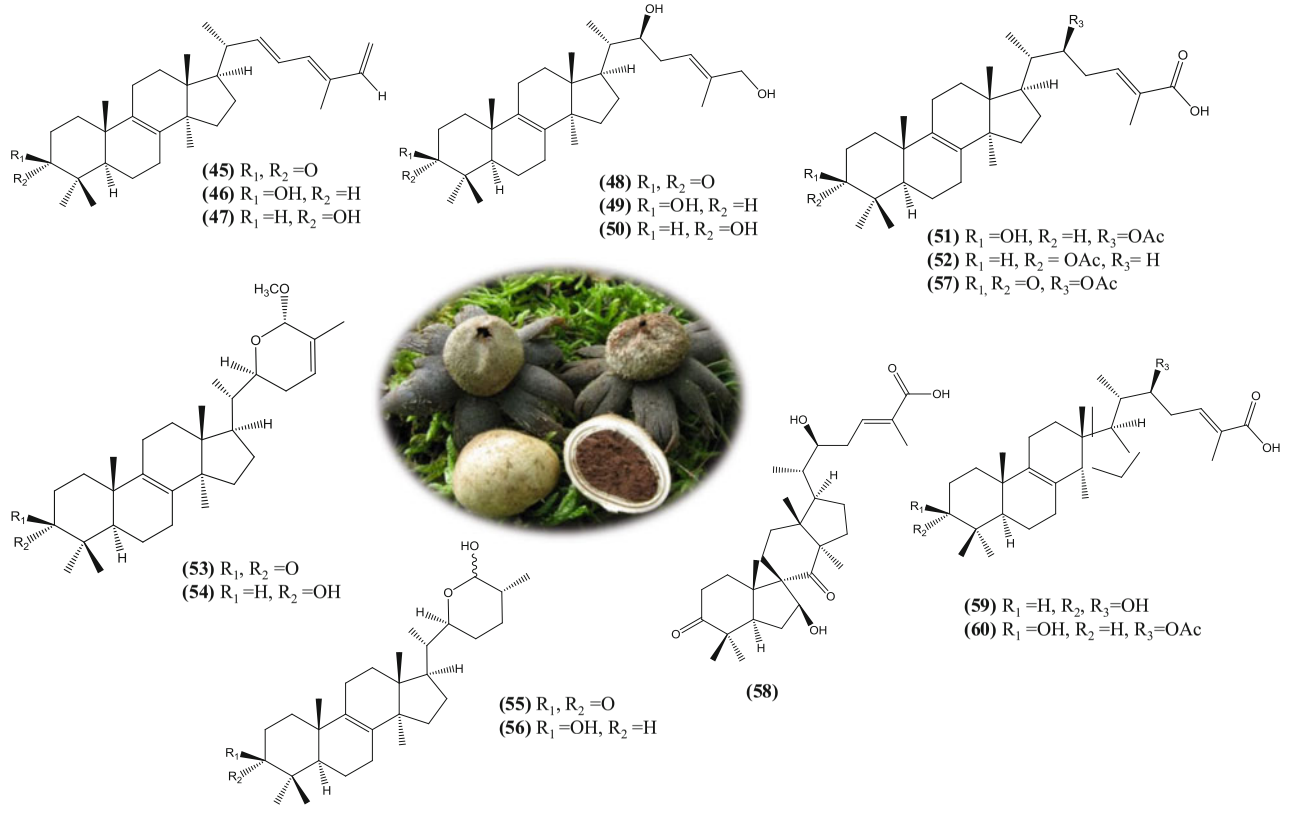

Fig. 10 Astraeusins A–L (**45**–**56**), **a**straodoric acids A, E, and F (**57**, **59**, **60**), and spiro-astraodoric acid (**58**) isolated from *Astraeus odoratus*. Mushroom picture retrieved from mushroomexpert.com

Srisurichan et al. [87] also reported three new lanostane-type triterpenoids which exhibited a varying degree of cytotoxicity against human cancer cells depending on the different side chains they contain. The triterpenoids were named as spiro-astraodoric acid **(58)** and astraodoric acids E **(59)** and F **(60)** (Fig. 10). Interestingly, compound **58** possesses a spirocyclic lanostane triterpenoid structure (Fig. 9). The authors suggested that the presence of an acetoxy group on a lanostane side chain increased the cytotoxicity of the lanostane triterpenoids.

2.3 Alkaloids

Alkaloids are nitrogen-containing heterocyclic compounds. Till now, fungal alkaloids are mostly known because of their toxicological relevance [88]. Perhaps the most widely known mushroom alkaloids are the hallucinogenic indole derivatives which encompass psilocin **(61)** and psilocybin **(62)**, found in "magic mushrooms." In fact, determination of psilocin and psilocybin (Fig. 11) is an important task of forensic analysis and researchers often used HPLC (high-performance liquid chromatography) for quantification.

Homer and Sperry [89] have recently reviewed on the isolation of mushroom-derived indole alkaloids, along with their associated biological activities. The alkaloid compounds can be found in different quantities based on mushroom species, their developmental stages, climatic conditions, and the availability of soluble nitrogen and phosphorous in the soil [90].

Psilocin **(61)**, an indole alkaloid found in the genus *Psilocybe*, is considered a natural monophenol which exhibit various properties including toxicity, and even antioxidant and therapeutic action [91]. It demonstrates bioactivity similar to other psychoactive tryptamines by inducing psychoactive effects like alternation of mood, ease of anxiety, and relief of depression [92]. Its mode of action is believed to occur through serotonin, a monoamine that regulates numerous physiological responses including those in the central nervous system [93, 94]. Most recently, Lenz et al. [95] reported the identification of ω-N-methyl-4-hydroxytryptamine (norpsilocin, **63**) (Fig. 11) from the carpophores of *Psilocybe cubensis* (Earle) Singer. Interestingly,

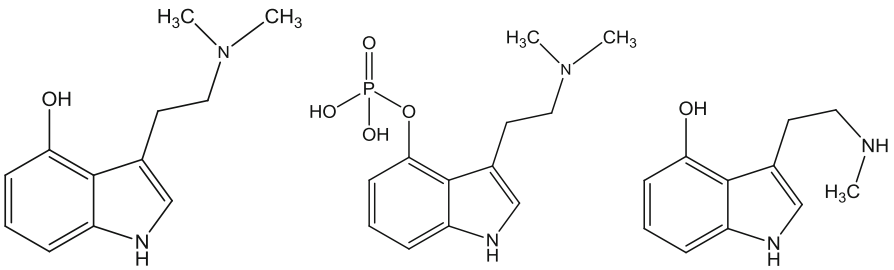

Fig. 11 The chemical structures of psilocin **(61)**, psilocybin **(62)**, and norpsilocin **(63)**

norpsilocin has not been previously reported as a natural product. According to the authors, it is probably liberated from its 4-phosphate ester derivative, which is a known natural product baeocystin. However, no bioactivity was reported for norpsilocin yet.

A recent clinical trial has shown that psilocybin exerts a pharmacological action against depression with no serious or unexpected adverse events in the patients on trial [96]. Subsequently, the authors reported on the possible mechanisms of the post-treatment brain effects of psilocybin and found out that decreased amygdala cerebral blood flow is likened with reduced depressive symptoms [97].

Overall, mushroom-derived indole alkaloids are generally screened from a variety of extracts, which are then found to exert some sort of beneficial bioactivity in vitro. Some of the examples include L-tryptophan **(64)**, which serves as a source of essential amino acid in human diet (Fig. 12). Other examples include corralocin B **(65)** and C **(66)** (Fig. 12), two indole alkaloids identified from the coral-alike lion's mane mushroom, *Hericium coralloides* (Scop.) Pers.[98]. The compounds were found to stimulate neurotrophin expression in human 1321N1 astrocytes. Corralocin B was reported to show antiproliferative activity against human umbilical vein endothelial cells (HUVEC) and human cancer cell lines MCF-7 and KB-3-1.

The basidiocarps of an nonedible but medicinal "bitter cap" mushroom, *Cortinarius infractus* (Pers.) Fr., also contained infractopicrin **(67)** and 10-hydroxyinfractopicrin **(68)** (Fig. 12) [99]. The acetylcholinesterase-inhibiting activity of these compounds was comparable to that of galantamine, a drug used for the treatment of mild to moderate Alzheimer's disease. Notably, the alkaloids present in *C. infractus* are responsible for the distinctive "bitterness" of this mushroom species [100, 101].

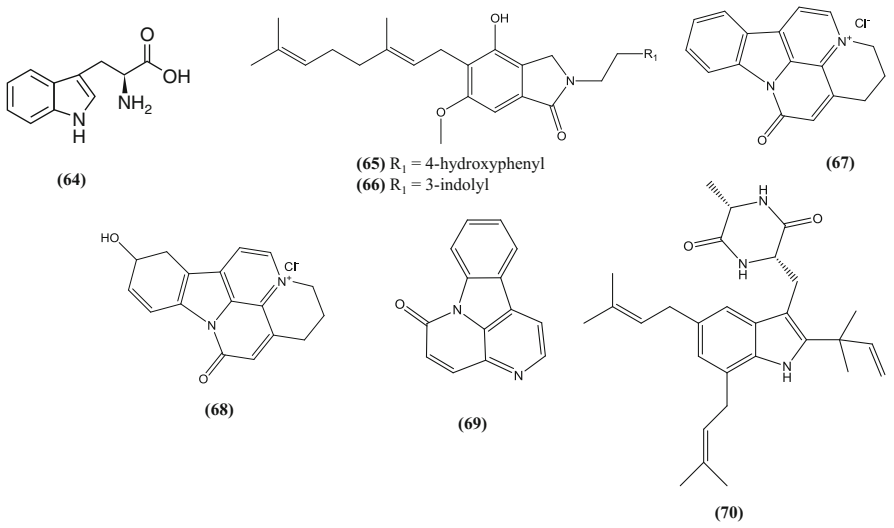

Fig. 12 The chemical structures of alkaloids **(64–70)** from mushrooms

Boletus curtisii Berk., an edible mushroom which is yellow when young and turns brown when old, produces an interesting collection of sulfur-containing β-carboline derivatives, one of which is canthin-6-one **(69)** (Fig. 12) [102]. This indole alkaloid which is responsible for the bright yellow pigmentation is also found in a variety of higher plants and possesses cytotoxic properties against leukemic cells [103]. Other alkaloids from edible mushroom also include echinulin (**70**), a triprenylated tryptophan-based diketopiperazine from an aromatic mushroom, *Lentinus strigellus* Berk [104, 105].

3 Conclusion

The study of mushrooms is growing in popularity because of their attributed health benefits. The aforementioned bioactive molecules found in mushrooms, i.e., polysaccharides, glucans, triterpenes, and alkaloids, contribute greatly to their curative properties like anticancer, anti-inflammatory, antivirus, and even anti-Alzheimer's disease. Indeed, edible and medicinal mushroom has huge demand as "whole functional food," as well as developed as a healthcare product. Overall, the mechanisms of action of the bioactive compounds, which were discussed in this chapter, still elude scientific inquiry and scientists are still working towards unraveling the biochemical pathways leading to the curative effects.

Abstract

Spirulina is a nature's gift as super food to mankind. It is a photosynthetic filamentous microalga which has emerged as a potent food supplement because of its rich micro- and macronutrient contents. The body of *Spirulina* is smooth and with weak cell wall that makes it easily digestible. It is a valuable source of proteins, vitamins, minerals, β-carotene, fatty acids, etc. which makes it perfect as food and fodder. NASA has stated that the nutritional value of 1000 kg of fruits and vegetables equals to 1 kg of *Spirulina.* In 1992 WHO has declared *Spirulina* as "Best food for future" to redress malnutrition especially in children. Apart from being a food supplement, *Spirulina* has gained considerable popularity and paramount importance due to the presence of certain pigments and secondary metabolites. It shows pharmacognosic properties like immuno-protective, anti-cancer, antidiabetic, antiviral, anti-obesity, etc. it is the most nutritionally concentrated compact whole food known which owe a potential to drastically lower the chances of developing cancer, heart disease, or stroke or of contracting a life-threatening virus such as HIV and prevent eyes from cataract formation. Many animal studies in vivo and in vitro and human trials have proved *Spirulina* to be commercialized and sold for therapeutic purposes. It appears to have a considerable potential for developing a key crop in coastal and alkaline regions where traditional agriculture struggles. Thus, looking at its global nutritional significance, more should be done in culture isolation, purification, and quality control of *Spirulina* and its products.

Keywords

Spirulina platensis · IIMSAM · C-phycocyanin · β-carotene · Nutraceutical · Hepatoprotective · Anticancer · Mass cultivation · Biofertilizer · Nephrotoxicity

Abbreviations

AIDS	acquired immunodeficiency syndrome
C-PC	C-phycocyanin
EFA	essential fatty acid
GLA	gamma linolenic acid
HIV	human immunodeficiency virus
IIMSAM	intergovernmental institution for the use of micro-algae *Spirulina* against malnutrition
NASA	National Aeronautics and Space Administration

NPU	net protein utilization
PER	protein efficiency ratio
PUFA	polyunsaturated fatty acids
WHO	World Health Organization

1 Introduction to *Spirulina*

1.1 Historical Background and Rediscovery as Food and Animal Feed

In sixteenth century a German algae scientist Dr. Darwin discovered the existence of spiral-shaped algae and called it *Spirulina.* Later Dr. Christopher Hills rediscovered these spiral blue-green algae in Lake Chad, Africa, and popularized it as a food supplement. He was called "The father of Spirulina." According to him, *Spirulina* contains billions of years of successful evolutionary wisdom coded in its DNA [1].

In Africa, *Spirulina* has served as sole of nutrition in certain communities in the times of famine, and the entire population has existed eating only *Spirulina* for over a month [2]. The National Aeronautics and Space Administration (NASA) used *Spirulina* predominantly as a food supplement for astronauts on space missions. NASA has stated that the nutritional value of 1000 kg of fruits and vegetables equals to 1 kg of *Spirulina* [3]. The United Nations World Health Organization (WHO) has accepted *Spirulina* as an interesting food for multiple reasons and can be administered to even children without any risk. WHO also confirmed it is effective in cancer prevention, hay fever, herpes, HIV, high cholesterol, liver protection, weight loss, etc.

A worldwide *Spirulina* campaign "Intergovernmental Institution for the Use of Micro-Algae *Spirulina* Against Malnutrition" (IIMSAM) was started in the United Nations by Sarah Obama for improvement of public health. IIMSAM works to promote the use of *Spirulina* as a humanitarian instrument in fighting against severe malnutrition worldwide. IIMSAM also maintains communication channels with entities around the world. *Spirulina* is also said to be highly nutritious potential feed resource for agriculturally important animal species, by improving growth, fertility, and nutritional product quality, and it is emerging as a cost-effective means of improving animal productivity for a sustainable and viable food security future [4].

1.2 Taxonomic Position and Characters

Spirulina is a 300 million years old Cyanophycean spiral-shaped filamentous microalgae (Oscillatoriaceae family) found naturally in alkaline, mineral-rich, pollution free waters with high pH. It thrives well in alkaline lakes where it is difficult or impossible for other microorganisms to survive [5]. Its name comes from a Latin word meaning tiny spiral.

It is microscopic but may attain a size of 0.5 mm in length, which makes some individuals visible to naked eyes. The helical shape of the filaments is characteristic of the genus and is maintained always. This helical shape of the filament and presence of gas-filled vacuoles in the cells result in floating mats. *Spirulina* has a prokaryotic organization, pluri-stratified cell wall, photosynthetic lamellar system, ribosomes and fibrils of DNA region, and numerous inclusions (Fig. 1).

Its main photosynthetic pigment is C-phycocyanin (C-PC). It is also rich in chlorophyll, carotenoids, and phycocyanin. *Spirulina* is an obligate photoautotroph, i.E., it cannot grow in the dark. It reduces carbon dioxide in the light and assimilates mainly nitrates. The main assimilation product is glycogen. It grows well in temperature ranging from 37 °C to 40 °C. Also the resistance of *Spirulina* toward ultraviolet radiations is high than any other algae [6]. The body surface of *Spirulina* is smooth and without covering so it is easily digestible by simple enzymatic systems. There are several species of *Spirulina*, but the most widely used species as food supplement are *S. platensis* and *S. maxima* [7] (Fig. 2).

2 Bioactive Molecules of *Spirulina*

By the past many decades, *Spirulina* has been of enormous interest by nutritional researchers because of its high micro- and macronutrient contents. Its concentrated nutrition makes it ideal for people of all ages and lifestyles. *Spirulina* is an incredible natural source of nutrients which has been used since ancient times. Its nutritional composition has been monitored and analyzed since 1970.

Fig. 1 Floating mats of *Spirulina*

Fig. 2 *Spirulina platensis**

It has been an excellent source of proteins, vitamins, fatty acids, minerals, photosynthetic pigments, and many secondary metabolites [8]. Its composition is discussed below (Fig. 3).

2.1 Proteins

Proteins are building blocks of life; they are essential for living a healthy life. The body uses proteins to build and repair muscles and other tissues. Proteins are broken down to amino acids which are necessary components in enzymes and hormones. Proteins are crucial component of every single cell in human body and that is why are vital to be included in one's diet.

Spirulina contains usually high amount of protein between 55 and 70% by dry weight [9]. *Spirulina* consists of essential amino acids mainly leucine, valine, isoleucine, tryptophan, methionine, phenylalanine, theanine, and lysine [10]. Aspartate and glutamate are the two nonessential amino acids present in *Spirulina* (Table 1). Unlike other plant-derived proteins, *Spirulina* is a perfect protein as it contains all the essential amino acids. Its status as a plant-based source of complete protein makes it an ideal dietary supplement choice for vegetarians.

Spirulina cells do not have cellulose walls but relatively fragile envelope of murein which is one of its kinds in plant kingdom. This explains the very high digestibility of its proteins [11]. The net protein utilization (NPU) is calculated by knowing the percentage of nitrogen retained when source of proteins under studying the only limiting nutritional factor. The NPU value of *Spirulina* is estimated between 55 and 92% more in comparison to casein [12]. While, the weight gained by the

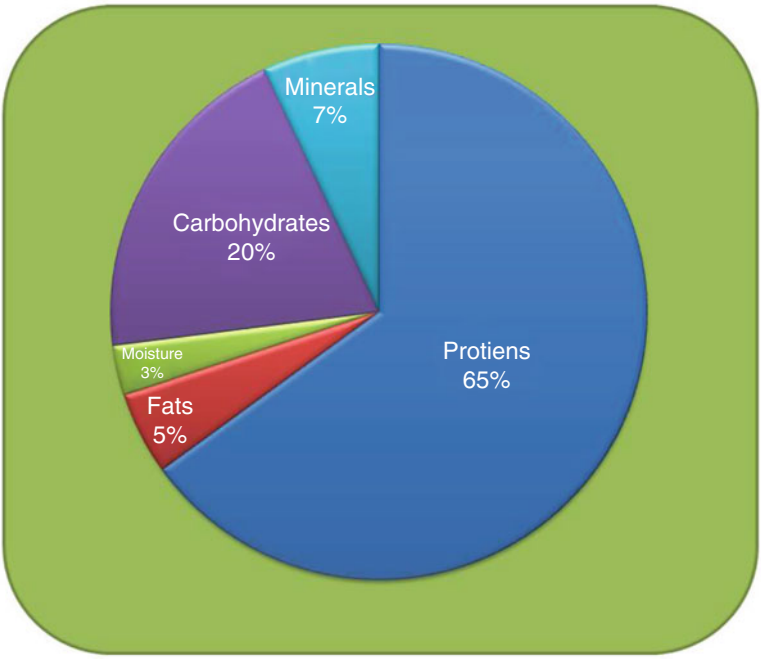

Fig. 3 Composition of biomolecules in *Spirulina*

Table 1 Protein composition of *Spirulina*

S.No	Amino acids	Concentration ($g100g^{-1}$)
1	Leucine	4.94
2	Isoleucine	3.20
3	Valine	3.51
4	Tryptophan	0.93
5	Theanine	2.97
6	Lysine	3.02
7	Methionine	1.15
8	Phenylalanine	2.78
9	Total	22.5

individual divided by the weight of protein ingested is called protein efficiency ratio (PER). The PER values for *Spirulina* was found out to be double than casein [13].

2.2 Vitamins and Minerals

Vitamins are organic compounds having diverse biochemical functions. These are essential nutrients that an organism needs in smaller amounts as it cannot make them by itself.

Table 2 Vitamin composition of *Spirulina*

S.No.	Vitamins	Concentration ($mg100g^{-1}$)
1	Vitamin B_1	3.5
2	Vitamin B_{12}	0.32
3	Vitamin K	2.2
4	Carotene	140
5	Riboflavin	4
6	Niacin	14
7	Folic acid	0.01
8	Biotin	0.005
9	Vitamin E	100
10	Total	264.035

Spirulina contains vitamin B_1 (thiamine), B_2 (riboflavin), B_3 (nicotinamide), B_6 (pyridoxine), B_9 (folic acid), B_{12} (cyanocobalamin), vitamin C, vitamin D and vitamin E (tocopherol), and most important provitamin a (β-carotene) (Table 2). *Spirulina* is the only vegetable source of vitamin B_{12} having two and half times more than meat. It contains the highest amount of beta-carotene much more than carrots, which is a precursor of vitamin a and is not dose dependent. It is also a very good source of vitamin E, similar to wheat germ.

Minerals are inorganic essential nutrients that the body needs to carry out various functions and processes for healthy living. *Spirulina* is an adequate source of many minerals like iron, zinc, sodium, potassium, phosphorous, manganese, magnesium, copper, and calcium (Table 3). Very high iron content makes *Spirulin*a economically important. The calcium, phosphorous, and magnesium occur in quantities comparable to those found in milk [14].

2.3 Carbohydrates and Essential Fatty Acids

Around 15–20% of dry weight of *Spirulina* is carbohydrate. It contains glucose, fructose, sucrose, glycerol, mannitol, and sorbitol. Mesoinositol is a carbohydrate which is an excellent source of organic phosphorous. *Spirulina* is eight times richer in mesoinositol than beef and very much more than vegetables. Recent studies indicate calcium spirulan (Ca-SP) is a novel sulfated polysaccharide found in *Spirulina* [14] (Table 4).

Seven percent of the total volume of *Spirulina* is lipids. It has a high amount of polyunsaturated fatty acids (PUFA). Vitamin-like substances which cannot be synthesized in the human body also called essential fatty acids (EFA) are essential for healthy living; they include linoleic, linolenic, and arachidonic acids. EFA help to reduce total cholesterol and triglyceride levels (associated with arteriosclerosis and heart disease). Their cell membranes are largely made up of lipids. When present with vitamins E and A, they protect the cell membranes against antioxidant and free radical attacks. Such attacks can alter the absorption of nutrients through the cell

Table 3 Minerals composition of *Spirulina*

S.No.	Minerals	Concentration ($mg100g^{-1}$)

membranes. Since membrane damage may alter antigens, this could cause the immune system to fail. *Spirulina* with a special fatty acid called gamma linolenic acid (GLA) has reportedly shown to be an effective immunoprotector. *Spirulina* is also nature's highest available source of GLA. It also contains stearidonic acid (SDA), eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and arachidonic acid (AA) (Table 5).

2.4 Photosynthetic Pigments or Phytonutrients

Spirulina is of special interest because of its color and presence of variety of pigments with specific functional properties. It contains mainly chlorophyll a, xanthophylls, beta (β)-carotene (both isomers), echinenone, myxoxanthophyll, zeaxanthin, canthaxanthin, beta cryptoxanthin, oscillaxanthin, phycobiliproteins, 3-hydroxyechinenone, c-phycocyanin (C-PC), and allophycocyanin [15] (Table 6).

It has predominance of phycocyanins and beta-carotenes which makes it an ideal nutraceutical worldwide. Different strains of *Spirulina* depicted variable influence on pigments with changed environmental parameters. Growth and pigment production was recorded to be most efficient under optimized conditions of light intensity (70 μmol m^{-2} s^{-1}), temperature (30 °C), CO_2 concentration (550 ppm and 750 ppm), pH (10.5), and NaCl level (2 g L^{-1}) [16].

3 *Spirulina* a Therapeutic and Nutraceutical Agent

Spirulina has emerged as a wonder drug because of its various medicinal properties for improvement of health in humans [17]. It boosts immunity and increases resistance power of individual. *Spirulina* is gaining more attention from medical science as "nutraceutical" and as source of potential medicine. Experimental data have suggested the following medicinal uses:

3.1 Used Against Cancer

Recent research findings show that the antioxidant and immune modulation characteristics of *Spirulina* have a possible mechanism of tumor destruction and hence play a role in cancer prevention especially stomach cancer [18]. It also contains pigment C-phycocyanin (C-PC) which inhibits liver cancer cells through an apoptotic mechanism [19]. According to a finding, combination of *Spirulina* and selenium inhibited breast cancer by growth arrest and apoptosis [20]. *Spirulina* is also chemoprotective and induced lesion regression in tobacco chewers with oral leukoplakia [21].

3.2 Used Against Diabetes

The presence of gamma linolenic acid (GLA), high fiber content, and peptides in *Spirulina* makes it a potent hypoglycemic agent; as a result the blood glucose levels are lowered [22]. Clinical studies on thousands of diabetes patients around the world

have shown a number of benefits and powerful effects to improve their condition. C-phycocyanin(C-PC) in *Spirulina* stimulates the body's insulin function; it also improves insulin resistance of patients and manages their lipid metabolism. These effects of *Spirulina* supplement in type 2 diabetes showed improvement in fasting blood sugar and lipid profiles [23].

3.3 Used Against AIDS and as Antiviral Drug

Calcium spirulan (Ca-SP) isolated from *Spirulina* has shown antiviral activities against different viruses such as (human immunodeficiency virus) HIV-I, herpes simplex virus type-I, and influenza virus. The antiviral activity is suggested to be due to the effect of chelation of calcium ion to sulfate groups [24]. A recent study on the antiviral activity of *Spirulina* has resulted in the isolation of cyanovirin-N (CV-N), a novel cynobacterial carbohydrate-binding protein that inhibits HIV-I and other enveloped viral particles [25].

3.4 Used Against Allergic Rhinitis and Asthma

The pigment present in *Spirulina* called C-phycocyanin (C-PC) can selectively inhibit release of histamine from mast cells and prevent increase in immunoglobulin E (IgE). IgE stimulated the immune system and causes the airways to become narrow and makes asthma symptoms worse. Thus reduction in IgE causes considerable improvement in allergic rhinitis and asthma. 1gm/day dose of *Spirulina* produced improvement in lung parameters [26].

3.5 Used Against Hypertension and Hyperlipidemia

Spirulina decreases lipoperoxidation products and show hepatoprotective activity. C-phycocyanin pigment present in *Spirulina* exhibits hypocholesterolemic action [27]. It is also suggested that the gamma linolenic acid (GMA) content also helps in the mechanism of action [28]. The high potassium and low sodium contents of *Spirulina also* have positive effects on blood pressure. It is thus shown that *Spirulina* reduced systolic and diastolic blood pressure when given by oral route [29]. In a study, volunteers given 4.5 g/day of *Spirulina* for 6 weeks lowered blood pressure and total cholesterol LDL and increased HDL [30].

3.6 Used Against Heart Strokes

The gamma linolenic acid (GLA) found in *Spirulina* works with the heart to improve a robust healthy system which helps to prevent heart diseases, cardiac arrest, and stroke. Another compound beta-carotene present in it also guards the cardiac system. According to a study, the degree of strokes and heart attack reduced to 50% in heart patients given

Spirulina supplement for more than 4 weeks. *Spirulina* is therefore beneficial in preventing atherosclerosis and reduced risk for cardiovascular diseases [31].

3.7 Used Against Anemia

Spirulina contains the pigment phycocyanin which is shown to stimulate the bone marrow to produce blood cells more effectively. It also modulates the production of cytokines by human blood mononuclear cells and increases flavonoids and sulfolipids [32]. *Spirulina* thus enhances red blood cell's production and function. Its intake has shown a steady increase in average values of mean corpuscular hemoglobin. Older women were benefitted more rapidly from *Spirulina* supplements [33]. Level of anemia was also decreased in children given *Spirulina* supplements for 12 weeks [34].

3.8 Used Against Eye Diseases

Spirulina contains ten times more beta-carotene than carrots. Beta-carotene gets converted to vitamin A which helps to protect the cornea, which is the outer surface of the eye. This is essential for having good vision. If it is not protected, then it may cause blurry vision, eye pain, eye redness, etc. it also protects the retina from clump deposits. Thus *Spirulina* provides the daily dietary dose of beta-carotenes which prevent blindness and eye diseases [35].

3.9 Used as Immunity Booster

Spirulina helps in building immunity and improving resistance to infections. Several experiments have shown that it has a favorable regulatory effect on the immune system [36]. It enhances the components of the mucosal and systemic immune system as it activates the cells of innate immune system. It also activates macrophages T and B cells [37]. *Spirulina* use leads to higher level of natural killer cells, interferon gamma, and more potent production of interleukins – The cytokines of low molecular weight that are produced by lymphocytes and macrophages and that function especially in regulation of the immune system [38].

3.10 Used as Antioxidant

Antioxidants are substances which neutralize the unstable free radicals generated due to oxidative stress. This beneficial antioxidant property of *Spirulina* is because of the presence of tocopherols, phenolic acids, and beta-carotene. This causes prevention of oxidative stress and inflammation and their associative damages [39].

Geriatric patients administered *Spirulina* for 16 weeks showed a remarkable improvement in antioxidant potential, as measured by increased levels of antioxidants in plasma of the individuals [40].

3.11 Used as Radioprotective Agent

The incredible radioprotective effect of *Spirulina* is due to its ability to bind to heavy metals and radioisotopes. Numerous studies have found that it protects the body against and even heals it from damaging harmful radiations. It was confirmed be a research in the early nineties that *Spirulina* effectively decreases the radioactive load received by the body when consuming radiation-contaminated food. After just 20 days, children fed 5gm doses of *Spirulina* every day for 2 weeks showed an average 50% reduction in urine radioactivity levels. *Spirulina* works so well at attenuating the damage caused by radiation that it was actually awarded a Russian patent in 1995 for improving the immunity of children affected by radiation from the Chernobyl disaster. Many exposed children became stricken with chronic radiation sickness and elevated immunoglobulin E (IgE) levels, and they also tested positive for high allergy sensitivity. On consuming *Spirulina* for 45 days, the children's IgE levels and allergic sensitivities were restored back to normal [41]. Later in 2001 a study showed *Spirulina* extracts effectively protect against both the damage caused by chemotherapy drugs and gamma radiation exposure. It was thus also prescribed to cancer patient undergoing chemotherapy [42]. S*pirulina* polysaccharides are believed to have a stimulating effect on DNA repair mechanisms which might explain the radioprotective effect mentioned several times in relation to *Spirulina*. Conclusively, *Spirulina* offers remarkable radioprotective benefits and offers a surefire way to mitigate the damaging effects of harmful radiation in addition to its many other health-promoting benefits.

3.12 Used as Trace Metal Supplement

Spirulina also contains selenium which is one of the important trace metals involved in immune function, reproduction, cardiovascular disease, cancer, viral infection control, and metal toxicity. Another essential trace element is iodine, whose deficiency affects thyroid function, cardiovascular function, and other brain disorders [43]. These trace elements help in preserving bone health since they reduce decalcification risk. *Spirulina* is an oxalate-free plant food; thus as with iron it provides calcium with high availability; thus it improves its absorption [44].

4 *Spirulina* a Food Supplement

4.1 *Spirulina* Value as Super Food and Feed

Spirulina is a miracle food that nourishes our body providing most of the proteins needed for healthy living; it helps to develop resistance against allergies, reinforce the immune system, help to control high blood pressure and cholesterol, and protect us from deadly diseases like cancer and AIDS. *Spirulina* is being developed as "food of the future" because of the presence of active biomolecules and their beneficial effects (Table 7).

Table 7 Beneficial effects of major bioactive molecules in *Spirulina*

Bioactive compounds in *Spirulina*	Functions in human body
β-Carotene, GLA	Protection and maintenance
Chlorophyll, lutein	Cleansing (removal of free radicals)
C-phycocyanin (C-PC), proteins	Repair
Zeaxanthin	Antioxidant damage repair
Arginine	Hormonal balance

Spirulina has three benefits – cleansing, restoring, and fortifying. It promotes the body natural cleansing processes, compensates for deficiencies in the diet, and stimulates metabolism. It boosts resistance and activates body's natural defense mechanisms. It was then adopted as a super food to overcome malnutrition.

It has gained considerable popularity in the human health food industry, and in many countries of Asia, it is used as protein supplement and as health food. *Spirulina* has also been used as a protein and vitamin-supplemented feed for fish, shrimp, and poultry. China is using this microalga as a partial substitute of imported forage to promote the growth, immunity, and viability of shrimp. In Japan, research on using Spirulina as aquaculture feed additives is accomplished [45].

4.2 Use as Supplement in Humanitarian Emergencies

As discussed in the chapter earlier, *Spirulina* can serve as a supplementary cure for many diseases and to cure malnutrition. The aftermath of malnutrition (lack of essential vitamins, iron, zinc, essential amino acids, etc.) leads to irreversible damages such as mental retardation, growth problems, blindness, and fatal infections. Malnutrition plays a role in more than half of children death over the world; its ravages get extended to the million survivors who will be disabled and chronically vulnerable to diseases. Malnutrition can only be overcome by allowing extremely poor populations to cover their essential nutritional needs. *Spirulina* local production system emerges as a micronutrient complement, responding to overcome malnutrition. This paved a way in the development of *Spirulina* producing industries.

A study on 28 children suffering from manifest protein-energy diseases was carried out from January to November 1989 in Zaire [46]. The parameters measured during this study show the generally positive effects of *spirulina* on patients' nutritional status, regardless of the inevitable hazards associated with studies in the field. Researchers in China analyzed the impact of a daily portion of 1.5 grams of *Spirulina* on the health status of the children and found it to be very beneficial [47].

4.3 Food Safety Aspects Related to Human Consumption

Before being adopted as super food and nutraceutical, it is very important to clarify the specific species of *Spirulina* used for human consumption is safe. It is known that

many of the existing blue-green algae species are known to produce toxin (microcystins, in particular MCYST-LR). It is particularly important in countries where no such regulation exists on this type of products.

The results of recent studies on risk management showed that only products from *Spirulina platensis* have so far been cleared for consumption (United States of America, Australia, Canada), under specific conditions, by public health authorities. In Canada, it was found that no microcystins was detected in blue-green algal products containing only *Spirulina* [48], while a study conducted for the Oregon Department of Agriculture (ODA) published in 2000 found MCYST-LR in all the 15 *Spirulina* samples (dietary supplements) analyzed [49]. *Spirulina* has been recognized as GRAS (generally recognized as safe) under the "indented conditions of use" implying that it is "for use as an ingredient in foods, at levels ranging from 0.5 to 3.0 grams per serving." This means in relatively small amounts. Special precautionary measures would be necessary on the consumption of spirulina products to some segments of the population at risk to include pregnant women, nursing mothers, and people in dialysis and immune-compromised.

5 *Spirulina* Industry and Products

Edible blue-green algae like *Nostoc, Chlorella*, and *Aphanizomenon* species have been used for food for thousands of years. Recently *Spirulina* has gained considerable popularity in the health food industry and increasingly as a protein and vitamin supplement to aquaculture diets. *Spirulina* grows well in alkaline waters, but its production for mass cultivation is to be done in areas with suitable climatic conditions. It is difficult to have an ideal growth due to different environmental factors like solar radiation, rain, wind, temperature fluctuation, etc.

5.1 Culturing *Spirulina*

Spirulina cultivation takes place either by natural production, laboratory cultivation small-scale commercial production, and commercial and mass cultivation.

5.1.1 Natural Production

Commercial production systems set for natural production of *Spirulina* are shallow ponds mixed by a paddle wheel. However, there are still some examples of *Spirulina* being harvested commercially from naturally occurring populations. In 1967 Mexico has the largest single plant for the production of *Spirulina* biomass at 2200 m at 18 °C. After filtration, the algal biomass is spray-dried after homogenization and pasteurization. The first pilot plant which produced 150 tons of dry *Spirulina* biomass per year started production in 1973; its production capacity was thereafter raised to 300 tons of medium-grade product per year from 12.0 hectares of natural ponds. The toxicological tests were performed before marketing the product [50]. Another seminatural lake in Myanmar has been reported to be used as a production

site for *Spirulina*. During the blooming season in the summer, when *Spirulina* forms thick mats on the lake, people in boats collect it. *Spirulina* is harvested on parallel-inclined filters, washed with fresh water, dewatered, and pressed again. This paste is extruded and dried in the sun on transparent plastic sheets. Dried chips are taken to a pharmaceutical factory, pasteurized, pressed into tablets, and marketed.

5.1.2 Laboratory Cultivation

For laboratory cultivation of *Spirulina*, the factors that should be taken care are luminosity (photoperiod 12/12, 4 luxes), temperature (30 °C), inoculation size, stirring speed, dissolved solids (10–60 g/liter), pH (8.5–10.5), water quality, and macro- and micronutrient presence (C, N, P, K, S, Mg, Na, Cl, Ca and Fe, Zn, Cu, Ni, Co, Se) [51].

Luminosity: In a culture of *Spirulina platensis* grown in a flat-plate photo bioreactor, cell concentration and productivity of biomass were obtained at the highest light intensity. It was concluded that the higher the light intensity, the higher optimal culture density, highest algal concentrations, and productivity of biomass will be obtained. But too high a rate of mixing resulted in cell damage and reduced output rate [52].

Nutritional media: *Spirulina* can be cultured on different media with inorganic and decomposed organic nutrients. Different types of *Spirulina* were cultured to evaluate growth and biochemistry under similar controlled conditions [53]. Out of the three species cultured, viz., *Spirulina platensis*, *S. laxissima*, and *S. lonar*, *S. platensis* showed highest growth rate, biomass, and pigment concentration. Thus *S. platensis* reached highest growth in shortest doubling time and could be the strain for large-scale cultivation. The most favorable growth rates of *S. platensis* occurred in the presence of 2.57 g/liter KNO3 with growth rate of 0.3 –0.4/day.

Spirulina can also be cultured in different agro-industrial wastes such as sugar mill waste effluent, poultry industry waste, fertilizer factory waste, and urban waste and organic matter. The growth parameters of *Spirulina platensis* were higher than other cultures on the supernatant of 2.0 and 6.0 g/liter digested poultry waste which might be due to appropriate nutrient content and other environment parameters [54]. Growth performance of *Spirulina platensis* was also studied in three different concentrations of banana leaf ash added with 0.4 g/liter jackfruit seed powder and 0.2 g/liter with urea in the laboratory which showed positive results [55].

5.1.3 Small-Scale Production

The small-scale production of *Spirulina* has emerged as a potential income-generating activity for village collectives. *Spirulina* produced could be used for local consumption by the poor farmers or for animal or aquatic feeds. *Spirulina* cultivation may be carried out in unlined ditches through which flow is low (e.g., 10 cm/s). Stirring may be provided by a simple device driven by wind energy or harnessed to humans. Harvesting may be readily performed using some suitable cloth, and the biomass dehydrates in the sun. The quality of the *Spirulina* product extracted by this process would not be as high as what is attained in "clean cultures," but product could serve well as animal feed. From early eighties, Bangladesh is

producing *Spirulina* through a pilot project using paddle wheel under transparent shade in the campus of BCSIR (Bangladesh Council of Scientific and Industrial Research). In India, the Murugappa Chettiar Research Centre in Chennai has developed the technology, and this has been successfully propagated on a large scale in the rural areas of Pudukkottai District of Tamil Nadu [56].

5.1.4 Mass Cultivation

The main commercial large-scale culture of *Spirulina* started in the early 1960s in Japan at Lake Texcoco, Mexico. *Spirulina* is produced in at least 22 countries: Benin, Brazil, Burkina Faso, Chad, Chile, China, Costa Rica, Côte d'Ivoire, Cuba, Ecuador, France, India, Madagascar, Mexico, Myanmar, Peru, Israel, Spain, Thailand, Togo, United States of America, and Vietnam. The total industrial production of *Spirulina* was about 3000 tons in 2004 [57]. Mass cultivation of *Spirulina* is usually carried out in shallow ponds, equipped with paddle wheels to mix the culture. Two types of open raceway ponds are typically used: the first is lined by concrete and is therefore expensive; the second is a shallow earthen tunnel lined with polyvinyl chloride (PVC) or some other durable plastic material. The surface of commercial raceways varies from 0.1 to 0.5 hectares, and culture depth is usually maintained at 15–18 cm. The paddle wheel, large (with a diameter up to 2.0 m and a speed of 10 rpm) or small (with a diameter of 0.7 m and a speed two to three times faster than 2.0 m diameter paddle wheel), is the most common stirring device [58]. The first successful culture of *Spirulina maxima* using untreated seawater in laboratory condition was reported in Italy in 1984 by Materassi et al. (1984). The culture technique developed in the laboratory has been successfully applied to outdoor mass culture of *S. maxima*. The United States of America has a number of the largest intensive farms in the world, mainly based in Hawaii and California (Fig. 4).

5.2 Extraction of Bioactive Molecules

Spirulina platensis is harvested directly from the cultivation area and is dried directly by using oven at temperature 40 °C for 10 h to get final water content below 10%. It is then extracted by using soxhletation (for dried *Spirulina*) and refluxion combined with sonication (for fresh *Spirulina*) and analyzed for the nutritional and bioactive compound of proximate analysis, flavonoid, phenolic, and antioxidant activity. 100 mL extract is added with ethanol with ratio of 2:1 and is used for further analysis [59].

5.3 *Spirulina* and Agriculture

Used as biofertilizer: In 1981 the FAO documented the possibilities of blue-green algae replacing chemical fertilizers and rebuilding the structure of depleted soils (FAO, 1981). *Spirulina* is used by rice farmers as this natural nitrogen source is only one-third the cost of chemical fertilizer, and it increases annual rice yield in India by

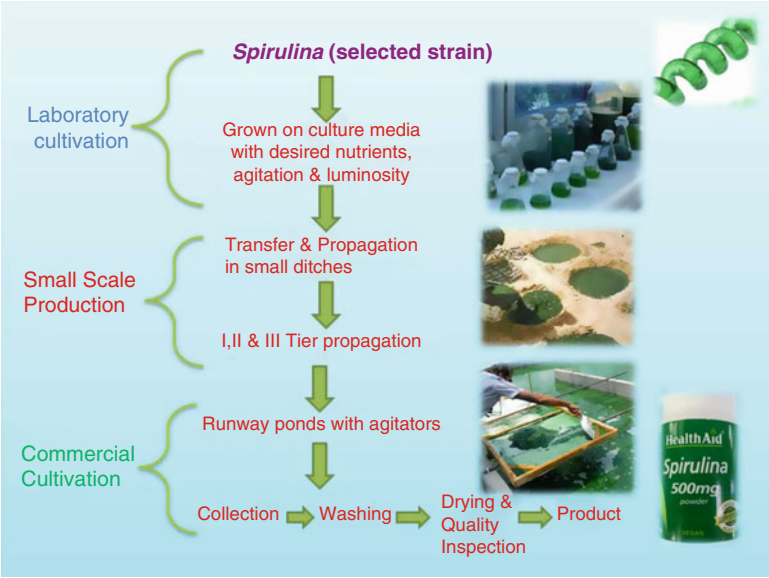

Fig. 4 Cultivation of *Spirulina*

an average of 22 percent. The use of *Spirulina*-based biofertilizers is impeded by the low cost, ready availability, and preferred use of inorganic fertilizers. Studies have proved Spirulina used in combination with other fertilizers also gave good yield of tomato [60]. *Spirulina* contains 10 percent N w/w (high percentage), and other macro- and micronutrients which are slowly released under normal soil conditions, and increases fertility.

Used as a protein supplement in poultry and livestock feeds: *Spirulina* can be used as an excellent feed for poultry. It has been studied and proved by researchers that the redness of muscles of broiler chickens reaches maximum when fed with 40 g *Spirulina* kg^{-1} diet [61].

Used as a natural colorant: *Spirulina* is rich in pigments; two of its pigments, viz., phycocyanin (blue) and chlorophyll (green), are combined with another group of pigments known as carotenoids (red, orange, and yellow) and used as food colorant. This phycocyanin extracted from *Spirulina* was first marketed in 1980 and was mainly used as a food colorant, as an edible dye in ice creams, and as a natural dye in the cosmetics industry. However, as the pigment is light sensitive, special care must be taken in protecting it from bleaching [62].

5.4 Recent Developments and Future Outlook

With the increasing demand of *Spirulina* as super food, transgenic manipulation is adopted to improve its quality in different countries of the world mainly China

[63]. But, s gene transfer system has not been established. Though conjugation has been widely used for gene manipulation in microalgae, very little lead was obtained in *Spirulina*. Electroporation was the method used transferring foreign genes in *S. platensis*. At present, *Spirulina* production is restricted to either countries with a high demand (i.e., the United States of America and China) or to a few countries that have specifically focused on small-scale production to supplement human diets or to integrate animal and fish production.

Spirulina has always been in the limelight as a nutraceutical, especially from the last few years. Recent studies have shown its development as a "super food for women," and it is used worldwide to improve women health. As discussed earlier, it has a novel compound GLA which reduces inflammation and eases the premenstrual syndrome (PMS). Studies done very recently have proved *Spirulina* diet when given to lactating mothers can protect against neuroinflammation and decreased antioxidant defense in the brain, possibly via decreased activation of p38 and high levels of the antioxidant miRNA-146a [64]. Nephrotoxicity is another disease which can be defeated by consuming *Spirulina* with camel milk [65].

6 Conclusions and Recommendations

Preventive healthcare says "let your food be your medicine." *Spirulina* truly comes in such category of food supplement. As discussed in the chapter, it has a range of bioactive molecules with extremely high amount of digestible protein, nine essential amino acids, high levels of β-carotene, vitamin B_{12}, iron and trace minerals, rare essential fatty acid γ-linolenic acid (GLA), and pigments like C-phycocyanin (C-PC) and phycobilin which makes it extremely desirable. In addition, it has no obvious negative cultural and religious issues associated with its consumption.

Spirulina also has considerable potential in industry, especially as small-scale crop in alkaline areas where other crops fail to grow. Its production occupies only a small environmental footprint, with considerable efficiency in terms of energy consumption. Its production can be done at different scales, from pot cultures to commercial bioreactors or natural large reservoirs. It also has potential for amalgamation with rural organic waste treatment process to ameliorate both environmental condition energy transfer efficiency in ecosystems.

With the developing need to move toward natural products, agriculture is also getting modernized, and the use of chemical fertilizers is minimized. As discussed earlier *Spirulina* is an excellent biofertilizer; recent studies have shown *Spirulina* increases rice growth and seed yield productivity [66]. This makes us to realize we need to pave a way toward new industries dealing with quality products. Thus, optimization of bioactive molecules of *Spirulina* can be a future prospect of research which may provide a direct link from laboratory to mass cultivation of this super food. One such study was conducted recently where the biomass and phycocyanin content of *Spirulina platensis* was enhanced [67].

But, despite of knowing the benefits of *Spirulina*, it has not received serious consideration it deserves to be a potential key crop in alkaline areas where traditional

agriculture struggles. An examination of the literature and research on S*pirulina* also suggests that interest in its development has dwindled over recent years. Much of the work was conducted over the 1980s and 1990s with relatively little over the last decade. Most modern articles available on the internet appear to highlight it as relatively little internationally recognized scientific material.

It is now the allegiance of both national governments and intergovernmental organization to re-evaluate the potential of *Spirulina* to fulfill both their own food security needs and a tool for their overseas development and emergency response efforts. International organizations working against famine victims and malnutrition should develop improved technical and economic solutions to *Spirulina* production as well as prepare tested production packages for rapid use in emergency situations where a sustainable supply of high protein and high vitamin food is required. An urgent need is there to develop clear guidelines on food safety aspects of *Spirulina* so that human health risk can be managed and all products in the market pass the toxicology test. And, the reputation loss which *Spirulina* is facing due to mixed cheap marketed products is prevented.

Abstract

Garcinias (Mangosteen, Brindle berry, and Kokum) are tropical fruits, and are rich source of nutrients, minerals, vitamins, and dietary fibers. They are also abundant with bioactive compounds namely xanthones, benzophenones, hydroxycitric acid, and anthocyanins. Many studies have detailed that these compounds possess antioxidant, anti-inflammatory, anticancer, antimicrobial, antiallergy, antiulcer, antiparasitic, and antihelminthic activities to aid in human health and also weight loss and appetite-reducing properties, making them good dietary supplements. Therefore, bioactive compounds extracted from Garcinia fruits could be used in the preparation of pharmaceuticals and nutraceuticals. This review presents an overview of the bioactive compounds derived from Garcinia fruits and their biological activities for promoting human health as food and drug.

Keywords

Brindle berry · *Garcinia* · Garcinol · Hydroxycitric acid · Kokum · Mangosteen

1 Introduction

Garcinias are important tropical fruits naturally occurring in Asia, Africa, South America, Australia, and Polynesia. Mangosteen (Botanical name; *Garcinia mangostana* L.), Brindle berry [Botanical name: *Garcinia gummigutta* (L.) N. Bobson. Syn. *G. cambogia* (Gaertn.) Desr.], and Kokum (Botanical name: *Garcinia indica* Choisy) are main fruit yielding trees cultivated in different regions of the world including Australia, Cuba, Dominica, Ecuador, Gabon, Ghana, Guatemala, Honduras, India, Jamaica, Liberia, Myanmar, Nepal, Philippines, Puerto Rico, Singapore, Sri Lanka, Thailand, Trinidad and Tobago, United States of America, Vietnam, and Zanzibar [1]. The fruits of Garcinias with medicinal and neutraceutical properties have been used since ancient times in traditional medicinal practices. The progress and promise in advanced technology for isolation of the bioactive compounds from plants was vital in preferring the synthetic products from the fruits of these plants for pharmacological treatment as it could help in structural modifications of the plant-derived compounds to produce potentially more active and safer drugs and also in improving the economy of pharmaceutical industries. The rind and fruit pulp of mangosteen, brindle berry, and kokum are the rich sources of compounds like xanthones, benzophenones, anthocyanins, and hydroxycitric acid which are proved to be the plant drugs demonstrating a large array of biological activities. Fruit pulp of these plants is rich in nutrients, minerals, vitamins, and dietary fibers. Hence, the Garcinia fruits serve as pools of nutrients as well as medicinal drugs to aid in human health.

2 Fruit Description and Traditional Medicinal Uses of *Garcinia* Fruits

Mangosteen, brindle berry, and kokum fruits are used in traditional medicine in Asian countries as folk medicine or herbal medicine to treat various ailments. Juice extracted from the entire fruit or extract obtained from the pericarp (rind) along with arils (pulp) or dried powdered rind (Fig. 1) is used in the preparation of drugs in Indian, Chinese, Thai, and Malaysian system of medicine.

2.1 Fruit Description and Traditional Uses of Mangosteen

Mangosteen fruits are round, red to purplish in color, soft, juicy with sweet flavor, and pleasant aroma, therefore, mangosteen fruits are popularly known as "Queen of fruits" (Fig. 2a) [2]. The pericarp or rind is rich in pigments especially anthocyanins (Fig. 2b). The arils (edible parts) are white, juicy, sweet, and acidic (Fig. 2c) [3]. Mangosteen fruit rinds are used in the treatment of dysentery, ulcers, skin infections, wound and as an astringent, antimicrobial, and antiparasitic agent in China, India, and Thailand [4–9]. The rind decoction is utilized to relieve diarrhea, cystitis, gonorrhea, and gleet [4, 7, 10].

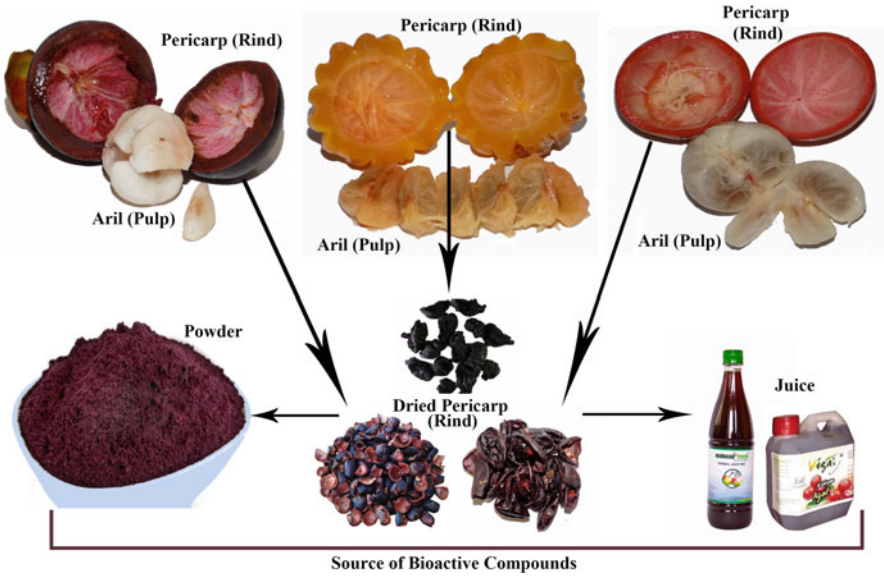

Fig. 1 Fruits, dried pricarp (rind), powdered pericarp and juice of mangosteen, bridle berry, and kokum used as a source of bioactive compounds

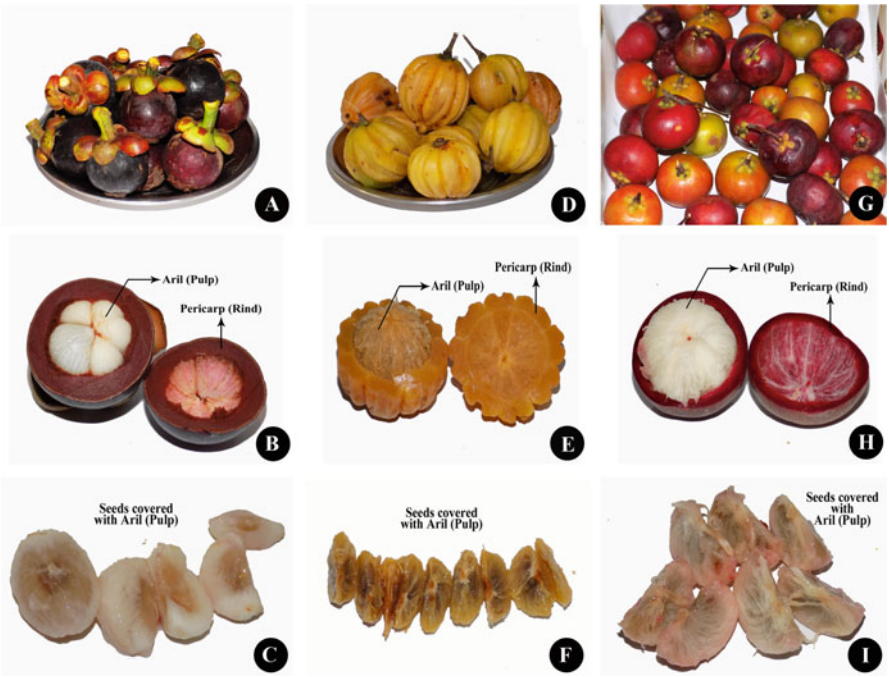

Fig. 2 Fruits of *Garcinia* species. (**a**) Fruits of mangosteen; (**b**) Cross section of mangosteen fruit showing aril and pericarp; (**c**) Arils of mangosteen; (**d**) Fruits of brindle berry; (**e**) Cross section of brindle berry fruit showing aril and pericarp; (**f**) Arils of brindle berry; (**g**) Fruits of kokum; (**h**) Cross section of kokum fruit showing aril and pericarp; (**i**) Arils of kokum

2.2 Fruit Description and Traditional Uses of Brindle Berry

Brindle berry fruits are small, about 5 cm in diameter with 6–8 grooves yellow or red in color (Fig. 2d, e). Arils are whitish to yellow (Fig. 2f). The fruits are edible, acidic and dried fruit rind is used as condiment. Fruits are also rich source of hydroxycitric acid which is an antiobesity drug [11]. Brindle berry fruits are edible; the rind is dried and used as condiment in India and Sri Lanka [1, 11]. The juice or powdered rind is used in traditional medicine to treat rheumatism and bowel problems. Rind preparations are used as purgative, hydragogue, antihelminthic and emetic [12].

2.3 Fruit Description and Traditional Uses of Kokum

Kokum fruits are round or oval, yellow to purple in color (Fig. 2g–i). The fruits are used in the preparation of juice which is used as a coolant and dried rinds are used as condiment (Fig. 1). Mangosteen, brindle berry, and kokum fruits are rich in nutrients, minerals, vitamins, and dietary fibers [13–15]. Kokum fruits are edible, delicious, and have a pleasant flavor and sour taste. Fruits are used in making health beverages

or squash and jellies. The dried rinds of Kokum are used as acidulant and preservative in Indian dishes [16]. The fruit juice is used as a coolant, and is beneficial to cure stomach and liver disorders. Kokum is also found to be effective in treatment of dysentery, tumors, and heart complaints [4, 17].

3 Bioactive Compounds Isolated from *Garcinia* Fruits

3.1 Bioactive Compounds Isolated from Mangosteen Fruits

The major bioactive compounds in mangosteen, brindle berry, and kokum fruits are xanthone derivatives [2, 18]; benzophenone derivatives [4, 19]; and anthocyanins [4]. Xanthones are secondary metabolites which belong to the polyphenolic group consisting of tricyclic aromatic ring. Xanthones are classified into five groups namely simple oxygenated xanthones, xanthone glycosides, prenylated xanthones, xanthonolignoids, and miscellaneous xanthones [20]. Mangosteen fruits consist of xanthones which have substituted isoprene, phenolic, and methoxy groups. α-mangostin was first isolated by Schmid [21] from mangosteen fruits and its chemical nature was elucidated by Dragendorff [22]. More than 54 xanthone derivatives have been isolated from mangosteen fruit till now (Table 1). Major benzophenones isolated are garcimangosone D, maclurin, kolanone [4]. Chrysanthemin, cyanidin-3-*O*-glucoside, cyanidin-3-*O*-sophoroside are the anthocyanins extracted from fruits of mangosteen (Table 1) [4].

3.2 Bioactive Compounds Isolated from Brindle Berry Fruits

The important phytochemicals reported from brindle berry fruits are organic acids, xanthones, and benzophenones (Table 2). Hydroxycitric acid (HCA) is the major organic acid isolated from the fruit of brindle berry and the concentration of HCA ranges from 10% to 13% [11, 48]. HCA lactone or Garcinia lactone was also obtained along with HCA from fruits [51]. Major xanthones isolated from fruits of brindle berry are polyisoprenylated xanthones, i.e., oxy-guttiferone I, oxy-guttiferone K, oxy-guttiferone K2, and oxy-guttiferone M (Table 2) [52]. Guttiferone I, guttiferone N, guttiferone J, guttiferone K, and guttiferone M were the polyisoprenylated benzophenones isolated from fruits of brindle berry [52].

3.3 Bioactive Compounds Isolated from Kokum Fruits

The principal phytochemicals isolated from kokum fruits with proven biological activity are hydroxycitric acid, benzophenone derivatives, and anthocyanins (Table 3). Kokum fruit contains polyisoprenylated benzophenone derivatives such as garcinol (camboginol/guttiferone E), isogarcinol (cambogin), xanthochymol,

4 Biological Activities of Compounds Obtained from *Garcinia* Fruits

4.1 Biological Activities of Xanthones

The most abundant xanthones in the mangosteen fruits are α-mangostin and γ-mangostin, and among these α-mangostin is reported to have antioxidant, anti-inflammatory, anticancer, and antimicrobial activities [62–65].

4.1.1 Antioxidant Activity

α-mangostin was reported to be a potent antioxidant and it was demonstrated to reduce copper/peroxyl radical induced oxidation of human low density lipoproteins [66, 67]. Jung et al. [2] showed optimal $ONOO^-$ scavenging activity of α-mangostin in mouse mammary organ cultures. Sampath and Vijayaraghavan [68] studied the impact of α-mangostin on the antioxidant defiance system and lipid peroxidation against isoproterenol-induced myocardial infarction in rats. Induction of rats with isoproterenol (150 mg kg^{-1}) for 2 days resulted in marked elevation of lipid peroxidation enzymes in the serum namely creatine phosphokinase (CPK), lactate dehydrogenase (LDH), glutamate pyruvate transaminase (GPT), and glutamate oxaloacetate transaminase (GOT) and remarkable decrease in various antioxidant enzymes such as glutathione-S-transferase (GST), glutathione peroxidase (GPX), catalase (CAT), superoxide dismutase (SOD), and glutathione (GSH). Pretreatment of α-mangostin (200 mg kg^{-1}) orally for 6 days prior to isoproterenol administration and 2 days along with isoproterenol administration substantially attenuated such changes.

The renoprotective effect of α-mangostin on cisplatin-induced nephrotoxicity in rats was reported by Perez-Rojas et al. [69]. For 10 days 12.5 mg kg^{-1} day^{-1} of α-

mangostin was administered to experimental rats and on the seventh day the rats were treated with a single dose of cisplatin (7.5 mg kg^{-1}). After 3 days, the rats were killed and studied for the impact of α-mangostin. The attenuation of renal dysfunction, oxidative/nitrosative stress, and structural damages was recorded. The preventive effect of α-mangostin on cisplatin-induced apoptic death is attributed to the inhibition of p53 expression and reactive oxygen species generation. Similarly, the protective effect of α-mangostin on cardiac reperfusion damage was investigated by Buelna-Chontal et al. [70]. Their findings show that α-mangostin could maintain the mechanical work of the heart, decrease the area of infarct, and even prevent the decrease in cardiac ATP and phosphocreatine levels in reperfused myocardium. The defensive effect of α-mangostin was related with reduction in oxidative stress. α-mangostin treatment was found to prevent reperfusion injury-induced protein oxidation, and reduction of glutathione content and lipid peroxidation.

4.1.2 Anti-Inflammatory and Antiallergic Activity

Alpha-mangostin was reported to have potent anti-inflammatory and antiallergic effects [23, 71–73]. Chen et al. [23] studied the effect of α-mangostin on the murine macrophage cell line RAW 264.7 and reported the inhibition of nitric oxide (NO) and prostaglandin E2 (PGE_2) production. At 3–25 μM α-mangostin, the amount of NO production was measured continuously and the IC_{50} value was 12.4. The production of PGE_2 in lipopolysaccharide-activated RAW 264.7 cell was also significantly reduced by α-mangostin (IC_{50} value of 11.08 μM). Chen et al. [23] also verified induction of nitric oxide synthase (iNOS) and expression of cyclooxygenase (COX) enzyme to investigate the effect of α-mangostin. α-mangostin concentration was found to reduce iNOS induction in a concentration-dependent manner. 1 μg ml^{-1} lipopolysaccharide was used to activate the RAW 264.7 cells for 12 h and nitric oxide synthase activity in the activated RAW 264.7 macrophages was inhibited following 24-h treatment of 5 μg ml^{-1} α-mangostin.

A study conducted by Chae et al. [73] to investigate the effect of α-mangostin and γ-mangostin on the bone marrow-derived mast cell (BMMC) mediated allergy mechanism induced by phorbol 12-myristate 13-acetate (PMA) plus calcimycin A23187. Both α-mangostin and γ-mangostin were shown to inhibit the production of interleukin-6 (IL-6), prostaglandin D2 (PGD2), and leukotriene C4 (LTC4) and degranulation of BMMC induced by PMA plus calcimycin A23187. In addition, both α-mangostin and γ-mangostin were found to repress cyclooxygenase (COX-2) expression as assessed by reverse transcription polymerase chain reaction (RT-PCR) analysis. These results advocate the usefulness of α-mangostin and γ-mangostin in reduction of allergic inflammatory responses.

4.1.3 Anticancer Activity

The α-mangostin (as well as β- and γ-mangostin) was reported to possess inhibition of cell proliferation of human cancer cells [74]. The antiproliferative effects of α-, β-, γ-mangostin were associated with cell-cycle arrest by affecting the expression of cyclins, cdc2, and p27. α- and γ-mangostin were found to induce apoptosis of cancer cells through G1 and S arrest by the activation of intrinsic pathway following the

downregulation of signaling pathways involving MAP kinases and serine/threonine kinase activities.

Matsumoto et al. [24] conducted a study on the inhibitory effects of α-mangostin, β-mangostin, γ-mangostin, mangostinone, garcinone E, and 2-isoprenly-1, 7-dihydroxy-3-methoxyxanthone on cell growth of the human leukemia cell line HL60, K562, NB4, and U937. α-mangostin was found to be potent at 10 μM concentration and exhibited the highest inhibitory activity compared to other xanthones. Matsumoto et al. [75] also studied antiproliferative effects of α-, β-, γ-mangostin and methoxy-β-mangostin on human cancer DLD-1 cells. Their results showed that α-mangostin strongly suppressed cell growth at 20 μM, and these effects were associated with cell-cycle arrest by affecting cyclins, cdc2, and p27 expression.

Sato et al. [10] examined the effect of α-mangostin on PC12 rat pheochromocytoma cells and the results showed apoptosis of cells through DNA fragmentation and caspase-3 cleavage. α-mangostin also exhibited features of the mitochondrial apoptotic pathway, including mitochondrial membrane depolarization. Besides, α-mangostin inhibited the endoplasmic reticulum Ca^{2+}-ATPase and activated c-Jun NH2 terminal kinase (JNK) which depicts endoplasmic reticulum stress. These results suggest that α-mangostin inhibits Ca^{2+}-ATPase to accomplish apoptosis of PC12 cells through the mitochondrial pathway.

Suksamrarn et al. [25] studied the effect of 19 xanthones on human breast cancer (BC-1), epidermoid carcinoma of the mouth (KB), and small cell lung cancer (NCI-H187) cell lines and reported that α-mangostin was found to be the most potent biochemical with an IC_{50} value (0.92 μg ml^{-1}) followed by gacinone E and γ-mangostin. Similarly, Kurose et al. [76] conducted a study on the effect of α-mangostin on the human breast cell line MDA-MB231 and described the apoptosis of these cell lines. They also reported significant cytochrome-c release with α-mangostin treated cell lines which suggested that MDA-MB231 cell line apoptosis occurred through the mitochondrial pathway. Their study also revealed that α-mangostin treatment induces cell cycle arrest though upregulation of the cyclin-dependent kinase (CDK) inhibitor $p21^{cip1}$ and cell cycle checkpoint regulator CHEK2 [76].

Hung et al. [77] evaluated the antimetastatic effect of α-mangostin against human prostrate carcinoma cell line PC-3 and reported the decreased expression of multiple matrix degrading proteinases including matrix metalloproteinase-2 (MMP-2), matrix metalloproteinase-9 (MMP-9), and urokinase-plasminogen activator (u-PA). α-mangostin also inhibited the phosphorylation of c-JUN N-terminal kinase 1 and 2 (JNK1/2) as well as activation of nuclear factor kappa B (NF-kB), oncogene c-Fos and c-Jun, which are associated with invasion and metastasis of cancer cells. Similar results were also recorded when human melanoma cell line SK-MEL-28 and squamous cell carcinoma cell line A-431 were treated with α-mangostin [78].

In a study, Aisha et al. [79] verified the effect of α-mangostin and γ-mangostin on colon cancer cell line HCT 116, and their study revealed that these xanthones showed strong cytotoxicity through induction of the mitochondrial apoptosis pathway. In addition, α-mangostin and γ-mangostin was found to inhibit cell

migration, invasion, and clonogenicity, which are the major steps in tumor metastasis.

4.1.4 Antimicrobial Activity

Xanthones isolated from fruits of *Garcinia* species especially α-mangostin and γ-mangostin have been shown to exhibit antimicrobial activity against a range of pathogens including bacteria, fungi, and viral species [26, 80–84]. Sundaram et al. [85] studied the effect of α-mangostin on majority of bacterial and fungal species including *Streptococcus aureus*, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Bacillus subtilis, Klebsiella* sp., *Proteus* sp., *Escherichia coli*, *Epidermophyton floccosum*, *Alternaria solani*, *Mucor* sp., *Rhizopus* sp., *Cunninghamella echinulata*, *Trichophyton mentagrophytes*, *Microsporum canis*, *Aspergillus niger*, *Aspergillus, flavus*, *Penicillium sp*., *Fusarium roseum*, and *Curvularia lunata*. The minimum inhibitory concentration of α-mangostin was between 1.25–50 μg ml^{-1} for bacteria and 1–5 μg ml^{-1} for fungi, respectively. Various scientists [62, 81] evaluated the effect of α-mangostin against Methicillin-resistant *Staphylococcus aureus* (MRSA) and results revealed that minimum inhibitory values ranging between 1.57–12.5 μg ml^{-1}. Gopalakrishnan et al. [27] demonstrated the potentiality of α-mangostin against phytopathogenic fungi, *Fusarium oxysporum vasinfectum*, *Alternaria tenuis*, and *Drechslera oryzae*.

HIV-1 protease activity of α-mangostin was demonstrated by Chen et al. [86] by using pepstatin-A as a positive control and α-mangostin exhibited an IC_{50} value of 5.12 μM. Kaomongkolgit et al. [87] discovered the inhibitory activity of α-mangostin against microorganism involved in oral-candidiasis, *Candida albicans*. They showed that α-mangostin was effective (at a minimum inhibitory concentration of 1000 μg ml^{-1}) when compared to clotrimazole and nystatin (antifungal medicines). Therefore, α-mangostin could be promising agent for the treatment of oral candidiasis. All the above investigations indicated the antimicrobial properties of α-mangostin.

4.1.5 Antiparasitic and Antihelminthic Activity

Various studies have shown that α-mangostin has insecticidal properties against dipteran, coleopteran, and hemipteran pests [88–90]. Ee et al. [88] discovered the inhibitory effect of α-mangostin on *Aedes aegypti* larval growth [lethal concentration (LC_{50}) was found to be 19.4 μg ml^{-1} for 24 h]. Kim and Lan [91] studied the larvicidal activities of α-mangostin using larvae and adults of the Colorado potato beetle, *Leptinotarsa decemlineata*. Their results reveal that α-mangostin had larvicidal activity at LC_{50} concentration of 63.33, 6.27, and 4.09 mM for 7-, 14-, and 23-day treatment, respectively. In addition, Bullangpoti et al. [92, 93] demonstrated the efficacy of α-mangostin against weevil (*Sitophilus oryzae*) and the brown plant hopper (*Nilaparvata lugens*), suggesting that α-mangostin inhibits esterase, acetyl cholinesterase, and glutathione *S*-transferase activities. Larson et al. [90] also demonstrated the larvicidal activities of α-mangostin in *Anopheles stephensi, Anopheles gambiae,* and *Culex pipiens, Anopheles aegypti* (Orlando strain), *Anopheles quadrimaculatus* Say, and *Culex quinquefasciatus* Say.

Keiser et al. [94] studied antihelmenthic effects of α-mangostin against trematodes *Schistosoma mansoni*, *Echinostoma caproni*, *Fasciola hepatica*, and the nematodes *Heligmosomoides polygyrus*, *Ancylostoma ceylanicum*, and *Trichuris muris*. Lack of activity of α-mangostin was recorded against *Heligmosomoides polygyrus* (third-stage larvae), *Ancylostoma ceylanicum* (third-stage larvae), and *Trichuris muris* (adults). A low activity was observed against *Ancylostoma ceylanicum* (adults; IC_{50} of 91 μg ml^{-1}), whereas promising activities were revealed against *Schistosoma mansoni*, *Echinostoma caproni*, *Fasciola hepatica* in vitro (IC_{50} value of 2.9–15.6 μg ml^{-1}). Worm burden reductions, ranging from 0% to 38% against *Schistosoma mansoni* and 11 to 54% against *Echinostoma caproni* were attained by single oral dose of the drug (400 mg kg^{-1} and 800 mg kg^{-1}) in vivo. The above investigations suggest that α-mangostin could be used as organic larvicidal and antihelminthic agent.

4.2 Biological Activity of Benzophenones

Natural benzophenones are a class of compounds having phenol-carbonyl-phenol skeleton. The A-ring is benzene ring which is derived from shikimic acid pathway, whereas B-ring is derived from acetate-malonate pathway, and undergoes prenylation and cylization producing a variety of compounds. Various numbers of –OH, OMe, prenyl, and geranyl groups are added as side chains [95]. Various polyisoprenylated benzophenones are reported from fruits of *Garcinia* species. Garcimangosone D, kolanone, and maclurin were isolated from fruits of mangosteen (Table 1) [4, 19]. Garcinol, guttiferone I, guttiferone J, guttiferone K, guttiferone M, guttiferone N were isolated from fruits of brindle berry (Table 2) [53–55]. Whereas fruits of kokum possessed garcinol, isogarcinol, xanthochymol, isoxanthochymol compounds (Table 3) [57, 58]. All the benzophenones isolated from the fruits of mangosteen, brindle berry, and kokum were reported to possess strong biological activities (Tables 2, 3, and 4) and garcinol is a well-known compound in terms of its pharmacological properties (Tables 5 and 6).

4.2.1 Antioxidant Activity

Garcinol exhibited a strong antioxidant activity against superoxide anion, hydroxyl radical, and methyl radicals. Yamaguchi et al. [96, 97] studied antioxidative, chelating, and free radical scavenging activities of garcinol and reported a moderate antioxidative activity in the micellar linoleic acid peroxidation system, while it exhibits nearly three times greater free radical scavenging activity against 2, 2, diphenyl-1-picrylhydrazyl (DPPH) radicals than the DL-α tocopherol (used standard chemical) by weight. These authors also recorded superoxide anion scavenging activity of garcinol and suppression of protein glycation in bovine serum/fructose system. Hong et al. [98] investigated a possible mechanism of antioxidant action of garcinol and its derivatives (cambogin, gracim-1, and gracim-2) on arachidonic acid metabolism and nitric oxide (NO) synthesis in lipoploysaccharide (LPS)-stimulated RAW264.7 cells. Results of this evaluation revealed that there was a significant

inhibition to the release of arachidonic acid and it metabolizes in macrophages with the treatment of 1 mM garcinol and its derivatives to cell cultures after 1 h of LPS stimulation. Similar inhibitory activity of garcinol was also recorded by Hong et al. [98] in intestinal cell lines (HT-29, HCT-116, and IEC-6). Garcinol remarkably decreased inducible nitric oxide synthase (iNOS) express and nitric oxide (NO) release from LPS-stimulated macrophages. In another study, Sang et al. [99, 100] assessed the mechanism of antioxidant reactions of garcinol with a stable radical DPPH and characterized the reaction products. Depending on the position of hydroxyl group (C-3 or C-5) which initiates the reaction, different reaction products were formed (GDPPH-1 and GDPPH-2). Their study revealed that garcinol reacts with peroxyl radicals by a single electron transfer followed by deprotonation of the hydroxyl group from the enolized 1,3-diketone to form a resonance pair. The above investigations suggested that garcinol has potentiality as a free radical scavenger. Similar to garcinol, other benzophenones like xanthochymol, isoxanthchymol, guttiferone K, and maclurin are reported to possess excellent antioxidant activities [95].

4.2.2 Anti-Inflammatory Activity

Aberrant arachidonic acid metabolism and generation of nitric oxide were reported in lipopolysaccharide (LPS)-induced/stimulated inflammation in rat neuron cultures [98]. Archidonic acid is released by phospholipase A2 (cPLA2) from membrane phospholipids and is further metabolized by cyclooxygenase (COX), lipooxygenase (LOX) enzymes, and cytochrome P450 pathways. Cell cultures treated with garcinol (5 μM) showed modulation of archidonic acid metabolism through suppression of cytosolic PLA2 (cPLA2) and inhibition of extracellular ERK1/2 kinase activation

and suppression of iNOS expression through modulation of the janus kinase (JAK) pathway [98], and the results suggested the potent anti-inflammatory effects of garcinol. Similarly, Hung et al. [101] demonstrated the inhibitory effect of garcinol against 12–0-tetradecanoylphorbol 13-acetate (TPA)-induced skin inflammation in mice. Topical pre-treatment of mouse skin with garcinol remarkably reduced TPA-induced expression of inducible nitric oxide synthase and cyclooxygenase-2. In addition, garcinol markedly reduced TPA-induced activation of extracellular signal-regulated kinases (ERK), c-Jun-N-terminal kinases (JNK), p38 mitogen-

activated protein kinase (MAPK), and phosphatidylinositol 3-kinase (PI3K)/Akt, which are upstream of NF-κB. In addition, Koeberle et al. [102] demonstrated the significant effect of garcinol and its interference with two enzymes that play crucial role in inflammation, namely, 5-lipoxygense and microsomal prostaglandin PGE2 synthase (mPGES)-1. Garcinol was found to suppress 5-lipoxygense product formations in intact human neutrophils and reduced PGE2 formation of interleukin-1β-stimulated A549 human lung carcinoma cells and in human whole blood stimulated by lipopolysaccharide. Garcinol also hindered with isolated COX-1 enzyme (IC_{50} of 12 μM) and with formation of COX-1-derived 12(S)-hydroxy-5-cis-8, 10-trans-heptadecatrienoic acid and thromoxane B2 in human platelets [102].

4.2.3 Anticancer Activity

Various studies have examined the potential of benzophenones, especially garcinol, against different cancer types including breast cancer, colon cancer, pancreatic cancer, prostate cancer, lung cancer, leukemia, hepatocellular carcinoma. Tanaka et al. [103] carried out studies on the effect of garcinol on the development of azoxymethane (AOM)-induced colinic aberrant crypt foci (ACF) in F344 rats. In addition, this group also studied the effect of garcinol on proliferating cell nuclear antigen (PCNA) index in ACF and activities of detoxifying enzymes namely glutathione S-transferase (GST) and quinone reductase (QR) in liver. It was noticed that garcinol administration significantly reduced PCNA index in ACF and considerably elevated liver GST and QR activities. Further, garcinol was also found to suppress superoxide anion (O_2^-) and nitric oxide (NO) generation and expression of inducible nitric oxide synthase and cyclooxygenase-2 proteins. Liao et al. [104] studied the effects of garcinol in human colorectal cancer cell line HT-29 and showed the beneficial effects of tumor prevention. The cell lines treated with 10 μM garcinol inhibited cell invasion and decreased the tyrosine phosphorylation of focal adhesion kinase (FAK). Western blot analysis revealed that garcinol inhibits activation of the Src, MAPK/ERK, and P13K/Akt signaling pathways. In addition, the study also indicated that decreased metalloproteinase-7 (MMP-7) protein levels in HT-29 cells result in sensitization to garcinol and that the compound significantly inhibits the expression of metalloproteinase-7 (MMP-7) in IL-beta-induced HT-29 cells. Hong et al. [105] conducted a study to examine the effects of garcinol and its derivatives, cambogin, gracim-1, gracim-2, on the growth of HT-29 and HCT-116 colon cancer cells, as well as IEC-6 and INT-407 which are the normal immortalized intestinal cells. Garcinol and its derivatives showed strong growth-inhibitory effects on all intestinal cells, with IC_{50} values in the range of 3.2–21.4 μM after 72-h treatment. Garcinol was found to be more effective in inhibiting growth of cancer cells than normal immortalized cells. These observations suggest the possible chemopreventive role of garcinol.

Garcinol reported to possess a strong growth inhibitory activity in human leukemia HL-60 cells (IC_{50} of 9.42 μM) through the induction caspase-3 activity in a dose- and time-dependent manner and including degradation of poly (ADP-ribose) polymerase (PARP) protein [106]. Matsumoto et al. [24] examined the effects of garcinol, isogarcinol, and xanthochymol on cell growth in human leukemia cell

lines, U937, K562, NB4, and HL60 and all the compounds exhibited strong growth suppression due to apoptosis mediated by the activation of capsase-3. Ahmad et al. [107, 108] has demonstrated beneficial effects of garcinol in suppression of breast, prostate, and pancreatic cancer cell growth by induction of apoptosis which was mediated by caspase-3 followed by downregulation of the NFkB pathway.

4.2.4 Antibacterial and Antiulcer Activity

Iinuma et al. [81] evaluated garcinol, isogarcinol, and xanthochymol for their antibacterial activity against methicillin-resistant *Staphylococcus aureus* (MRSA) and results revealed high efficacy of all the compounds with minimum inhibitory concentration values ranging between 3.1 and 12.5 μg ml^{-1}. Various physical and psychological stresses cause gastric ulceration in human and experimental animals [109]. Recently oxygen-derived free radicals have been shown to play a role in experimental gastric damage induced by ischemia and reperfusion [110]. Yamaguchi et al. [96] have reported a significant free radical scavenging activity against hydroxyl radicals and it was vigorous than that of α-tocopherol. Therefore, garcinol is expected to be useful for preventing gastric ulcers. Yamguchi et al. [97] demonstrated that garcinol suppressed the gastric injury in rats induced by indomethacin and water immersion stress. These investigations suggest that garcinol may have potential as an antiulcer drug.

4.3 Biological Activity of Hydroxycitric Acid

Hydroxycitric acid (HCA) is the major organic acid found in the fruits of brindle berry and kokum. HCA exist in free form as well as in the lactone form, and HCA in free form is reported to possess potent biological activities [111]. HCA is an antiobesity drug and its activity is through regulation of serotonin and food intake suppression, decreased de novo lipogenesis, and enhanced fat oxidation [112]. Various in vivo studies have been carried out to understand these effects of HCA. HCA has been shown to be a strong inhibitor of ATP citrate lyase (EC 4.1.3.8) which catalyzes the cleavage of citrate to oxaloacetate and acetyl-Co-A, results in limitation of acetyl-Co-A required for fatty acid biosynthesis [113, 114]. As a consequence of this, the consumed carbon source is diverted to glycogen synthesis in liver, which results in signaling brain cells and increased production of serotonin and concomitant with a reduced appetite. Preuss et al. [115] reported that HCA generated a significant reduction in appetite, weight loss, and plasma leptin level, accompanying with an increase in the serum serotonin level and a favorable lipid profile in human clinical trials. Asghar et al. [116] conducted experiments in obese Zucker rats which were fed with HCA and recorded decrease in body weight combined with increased serotonin levels. Another possible consequence of HCA effect is the depletion of the acetyl-Co-A which is the precursor of fatty acid and cholesterol biosynthesis. Various in vitro and in vivo studies conducted in rodent models by Sullivan et al. [113, 114, 117, 118] established the inhibition of lopogenesis by HCA. Several experimental evidences suggest that HCA intake is also responsible for increased fat

oxidation. Ishihara et al. [119] carried out a study on acute and chronic effects of HCA on energy metabolism. Acute administrations of HCA (10 mg μl^{-1}) per mice significantly increased serum free fatty acid levels and levels of glycogen in the muscle; however, respiratory exchange was normal. In contrast, chronic administration of HCA (10 mg μl^{-1} twice a day) significantly lowered the respiratory quotient during resting and exercised conditions in mice. Lim et al. [120, 121] also reported that short-term administration of HCA led to fat oxidation in human volunteers.

4.4 Biological Activity of Anthocyanins

Chrysanthemin, cynidin-3-*O*-glucoside, and cynidin-3-*O*-sophoroside are the major anthocyanins isolated from fruits of mangosteen (Table 1) [4], whereas, kokum fruits were rich in anthocyanins namely cynidin-3-*O*-glucoside and cynidin-3-sambubioside [15]. The anthocyanins from kokum has a high prospective as a natural colorant and they are used in the production of confectionery, jellies, jams, health beverages, and deserts [59, 122]. Anthocyanins are having become more important in the food industry because of their bright and attractive shades and water solubility, which allows their incorporation into aqueous food systems [59, 123]. Various studies have also proved that anthocyanins are having possible health benefits as antioxidant, anti-inflammatory, anticancer, antidiabetic, cardio-protective, and neuroprotective agents [124–126]. In a study Min et al. [127] demonstrated neuroprotective effects cynidin-3-*O*-glucoside in a mouse model of permanent middle cerebral artery occlusion (pMCAO) even when delivered 3 h after the onset of ischemia, which is a clinically relevant time point in stroke. Cynidin-3-*O*-glucoside decreased cerebral superoxide levels, inhibited apoptosis-inducing (AIF) release from mitochondria, but did not influence the cytochrome-c related cell death pathway. Wang et al. [128] conducted a study to examine the role of cynidin-3-*O*-glucoside in the prevention of triple-negative breast cancer (TNBC). It was discovered that cynidin-3-*O*-glucoside preferentially promotes the apoptosis of TNBC cells, which co-express the estrogen receptor alpha 36 (ERα36) and the epidermal growth factor receptor (EGFR). Cynidin-3-*O*-glucoside binds to the legend-binding receptor of ERα36, inhibited EGFR/AKT signaling, and promotes EGFR degradation. In summary, all of the above, results indicate that cynidin-3-*O*-glucoside is an important anthocyanin possessing potent biological activities, and mangosteen and kokum fruits are rich in cynidin-3-*O*-glucoside; therefore, these fruits could be used as a potential source of cynidin-3-*O*-glucoside and other anthocyanins.

5 Conclusion

Latterly, Garcinia fruits especially mangosteen, brindle berry, and kokum are used in the preparation of nutraceuticals, dietary supplements, and other health foods because of their nutrient richness and chemical compounds with potential health

promoting properties. All the three fruits are rich in bioactive phytochemicals such as xanthone derivatives and benzophenone derivatives. Brindle berry and kokum are abundant with hydroxycitric acid. While, mangosteen and kokum fruits are rich in anthocyanin derivatives. Various in vitro and in vivo studies have shown that xanthone derivatives, benzophenone derivatives, and anthocyanins obtained from mangosteen, brindle berry, and kokum fruits possess antioxidant, anti-inflammatory, anticancer, antimicrobial, antiallergy, antiobesity, antiulcer, antiparasitic, and anti-helminthic properties. At the same time, hydroxycitric acid has been recognized as a potential antiobesity drug. In addition, various studies have suggested the safety of these natural compounds for human consumption and utilization [65, 112, 129–132]. Nevertheless, further preclinical and post-clinical studies are warranted to prove the efficacy and safety of these natural phytochemicals.

Acknowledgments This work was partially supported by DST-PURSE-PHASE-II program.

Factors Influencing Sweet Taste in Apple

56

Mathilde Charles, Eugenio Aprea, and Flavia Gasperi

Contents

Abstract

Sweet taste is a major determinant of apple fruit as driving a large part of consumer preferences. As a consequence, increase in sweetness is very frequently one of the targets in breeding programs and is a key parameter for evaluating apple quality. Its perception can be modulated by several factors, and it is important to understand the individual impact of each of them and the processes involved in order to interpret it better.

This chapter reviews the studies of the past two decades dealing with apple and specifically its composition and the related sweet perception. It proposes an

1 Introduction: Preferences in Apples – The Prominent Role of Sweet Taste

Apples are one of the most frequently consumed fruits around the world. Its quality has traditionally been evaluated on the basis of external characteristics such as size, color, and the absence of surface defects. However, to improve quality evaluation, sensory attributes assessed by trained panels should also be considered.

More particularly, measuring sweet taste perception is a critical factor as sweetness is playing a significant role in food preferences. Different studies tried to investigate the apple consumer preferences in the last 20 years. For example, Daillant-Spinnler et al. [1] who studied 20 apple varieties from the southern hemisphere found that consumers could be split into two groups: those that had a preference for sweet and hard apples and on the contrary those that had a preference for juicy and acidic apples. Jaeger et al. [2] performed a study on fresh and aged apples to investigate consumer preferences. They showed that the first preference dimension was more strongly related to flavor differences (sweet taste and fruity/flowery flavors contrasting with acid taste and vegetal flavor) and the second dimension to texture differences (hard, juicy, crisp on the one side; floury and granulous on the other side). Other apple preference studies tended to take into account the full sensory variability of this fruit [3, 4]. The authors used 28 different

apple varieties in order to build more accurate preference models. They observed the segmentation of 224 consumers in three groups of which the first two, representing, respectively, 37% and 43% of the selected panel, appreciated sweet apples with high aroma intensity. These two groups were not in agreement according to the liking of acid taste and lemon aroma. The predominance of sweet taste in apple preferences was confirmed in a more recent study carried out with more than 4000 apple consumers across seven European countries [5]. Researchers used these data to develop a preference map for apple which was constructed with three main dimensions. The first one was described by the descriptors sweetness, fruitiness, and floweriness [6]. Symoneaux et al. [7] who used comment analysis of consumer's likes and dislikes as an alternative tool to preference mapping corroborated also previous results and identified sweetness along with crunchiness as main sensory preference key drivers for apple consumers.

All these studies underlined well the importance of sweetness in explaining apple preferences, but the complete understanding of it is more complex and is usually a question of equilibrium of several factors such as taste and texture as mentioned by Harker et al. [8]. It is often notable that consumers respond to a cluster of attributes, for example, sweetness and crunchiness, which reflect a particular subset of apple cultivars. From a biological perspective, these sensory attributes may be genetically associated with each other [8]. Thus, consumer preferences that link texture and acidity together may, in part, reflect the biological limitations imposed by co-location of genes on the apple chromosomes. If a consumer likes one attribute, then they are forced to also like the other. Over a period of years and of repeated experiences, consumer preferences have changed to match the biological constraints of the product.

Furthermore, food preferences are influenced by a wide range of factors such as age, gender, education, etc. [9]. For example, apple preferences associated with different age groups can be marked: children aged from 9 to 13 years tend to respond more positively to attributes of sweetness and flavor than adults who tend to respond to texture and sourness [10].

In addition, it must be considered that the acceptability of a product is the result of a combination of both intrinsic (sensory) and extrinsic attributes. Endrizzi et al. [11], for example, studied with a conjoint experiment performed on a large panel of Italian consumers how the intensity of intrinsic attributes (sweetness and crunchiness) and different information about fiber and antioxidant content (extrinsic attributes) provided immediately before tasting affect the acceptability of different apple varieties. The results confirm that high levels of sweetness and crunchiness positively influence overall liking, whereas information about nutritional components is less relevant in general but can be important for certain group of consumers which might be more aware of these aspects.

We have seen that sweetness is of great significance for apple consumers, but it is also important to consider that consumers of fresh apples take into account quality more than price [8]. Thus, postharvest research is increasingly being required to evaluate the flavor and other characteristics of fruit.

Preference for sweetness in apples and more generally in foodstuffs is depending on sugar composition of products and sweetness perception. In this chapter, we will

review the basic composition of apples, notably the different sweet taste components it contains, and how they can be measured analytically. Then, a focus will be made on the input of sensory analysis on sweet taste measurement. Sweetness perception is influenced by other sensory characteristics such as aroma and texture for which we will dedicate a part of this chapter.

2 Previous and Recent Researches Related to Sweet Taste Perception in Apple

Table 1 is an attempt to summarize research studies of the last 10 years which are related, with different degrees, to sweet taste perception in apple. The thirteen investigations reported in Table 1 dealt with various topics such as the characterization of different apple cultivars in terms of chemical/phytochemical composition, nutritional values and sensory description [12–16] and the assessment of apple quality [17–21]. Other works were more oriented on sensory science and investigated the modelization of sweet taste [22] and the impact of one sensory characteristic on the perception of another such as aroma on taste and texture perceptions [23] and mealiness on sweetness perception [24].

To achieve their goals, different investigators have used different techniques which were instrumental in some cases, sensory in others, or a combination of the two. Regarding instrumental measurements, the soluble solid content (SSC) is a frequently used index and was almost always measured. This was done by means of different kinds of refractometers. Other measurements were performed such as the quantification of single sugars (fructose, glucose, sucrose, xylose, galactose, maltose, and ribose), sugar alcohols (sorbitol, xylitol, and maltitol), and starch by means of high-pressure capillary ion chromatography [22], Luff-Schoorl technique [13], enzymatic kits [15, 20], high-performance liquid chromatography (HPLC) [14], and gas chromatography-mass spectrometry (GC-MS) [15]. See Table 1.

Concerning sensory measurements, the majority of the studies determined sweetness intensity, alone or in combination with other attributes describing apple such as sourness, crunchiness, juiciness, etc. [22, 23], with structured scales either continuous [21] or discrete [18]. Some were ranging from 0 to 9 [18], 1 to 7 [13], and 0 to 10 [19] and others from 0 to 100 [17, 22, 23] and 0 to 150 [24]. Evaluations were performed by a group of trained panelists from four [18] to nineteen panelists [22]. This variety of conditions illustrates well the fact that sweet taste measurement is complex and can be considered in different manners depending on the objective of the study. Another work that stands out from the others is the one of Charles and coauthors [23], who, in addition to conventional sensory profile to evaluate sweetness intensity, applied a dynamic method called temporal dominance of sensations (TDS) [25] to measure the evolution of perception in the time of an apple. With this method, panelists need to choose the dominant attribute at each moment of the tasting. A dominant attribute is defined as the attribute corresponding to the sensation that triggers the most your attention [25]. The attribute list was composed of

attributes describing the texture, the flavor and the taste, including sweetness, of apple [23].

As reviewed in this part, sweetness perception was investigated with different points of view using different techniques. It is a concept difficult to handle globally. Sweet taste perception in apple is very dependent on the composition of the fruit and of the presence of different types of sweet taste components such as sucrose, fructose, glucose, sorbitol, etc. It will be developed in the next part.

3 Basic and Sugar Composition of Apples

Chemical composition of apple fruit is very complex. It consists of numerous organic and inorganic compounds and macro-biogenic and micro-biogenic elements. Most represented are sugars, acids, pectin, tannins, starch, cellulose, and different biologically active compounds such as vitamin C and certain phenolic compounds which are known to act as natural antioxidants. Most represented chemical elements are nitrogen, phosphorus, potassium, calcium, sulfur, iron, and magnesium [12, 14, 16].

Sugars, organic acids, aromas, and phenolics determine the quality of apples and more particularly play important roles in sensory characteristics such as taste, flavor, and astringency [12, 27–30].

Different research teams investigated the composition of several apple cultivars and noted that the composition and more particularly the level of soluble solids (SSC) was varying considerably according to the cultivar [12, 14]. The cultivar harvested in summer, Delicious, showed relatively low levels of soluble solids, compared to the cultivars harvested in September and October such as Fuji and Ralls [14]. Aprea et al. [22] who collected and analyzed 40 apple batches corresponding to 17 different cultivars/accessions (harvested in North of Italy) noted a difference of soluble solid content of 6.3 Brix degrees between the extreme samples. The cultivar Pinova Roho presented the lowest value with 9.5° Brix and Fujion the highest with 15.8° Brix. They also calculated the total amount of sugars by summing the relative quantity of sucrose, fructose, glucose, and xylose and observed a range from 74.7 to 142.9 $g.kg^{-1}$, with an average concentration of 116.8 $g.kg^{-1}$. Moreover, other factors influence positively the level of sugars in fruit notably the maturity stage [28, 30] and the storage [31]. Different studies examined fruit sugars and showed increasing levels of fructose, glucose, and sucrose at advanced stages [28, 30].

Fructose and glucose were identified as the principal monosaccharides in the apple fruit [14, 22, 32, 33]. Fructose level was, with few exceptions, always higher than glucose level [14, 22, 34]. Sucrose is nevertheless the most abundant sugar (41.8%) followed by fructose (39.1%) and glucose (18.3%) [22]. Xylose, a major component of xyloglucans [35], was measured in several works and represents less than 1% of the total sugars [15, 22, 36]. A summary of apple sugar composition is presented in Table 2.

Table 2 Sugars in apple fruit: composition and relative sweetness index of individual sugars and sorbitol, soluble solid content, and total amount of sugars

	Concentration range[a]	Relative sweetness index compared to sucrose[b]
Sucrose	22–91.0 $g.kg^{-1}$	1
Fructose	27–61.0 $g.kg^{-1}$	1.08–1.33 [37–41]
Glucose	11–30.2 $g.kg^{-1}$	0.54–0.69 [37–39][41][d,e,f,h]
Xylose	n.d.–1.8 $g.kg^{-1}$	0.59 [41]
Sorbitol	1.3–13 $g.kg^{-1}$	0.54 [41]
Soluble solids	9.5–16°Brix	n.a.
Total sugars[c]	75–143 $g.kg^{-1}$	n.a.

Sorbitol is also an important compound in apple fruit as being a precursor of fructose and starch. It belongs to another class of compounds, the sugar alcohols, of which it is the most abundant in apples [36]. Sorbitol and glucose, formed from the products of photosynthesis in leaves, are the translocation sugars flowing through the phloem to reach fruit tissue, where they are converted, depending on the developmental stage, into fructose, glucose, malic acid, or starch [42]. Sorbitol is preferentially converted into fructose, while glucose is preferentially incorporated into starch [43]. In apples, only a small fraction of fructose is incorporated into starch; fructose instead accumulates in the vacuoles of apple cells [43]. As a consequence, fructose is always present in larger quantity than glucose in fruit tissue. Some researchers found that sorbitol content correlates with perceived sweetness better than any other single sugar or total sugar content [22] showing the appropriateness to take into account this compound when studying sweet perception in apples.

As just seen, apple contains a variety of sweet components that need to be measured to better understand sweet perception in apple but more generally apple quality. Different methods will be developed in the following part.

4 How to Measure Sugars by Analytical Measurements

With the goal to make the information from preference maps relevant to industrial players for use in grade or quality standards, it is necessary to translate sensory descriptors (e.g., sweet, crisp) into instrumental measurements that can be used in routine quality control protocols [8]. Currently, there exist standards defining eating apple quality in different production regions of the world including Italy, England, New Zealand, and the USA. These standards specify for the products lower and upper limits for several criteria notably for sugar content [44–46]. These specifications are strongly related to fruit ripeness.

Sugar measurements are crucial at several points of the production chain: before and at the harvest in order to pick the fruit on the right date at the desired maturity

and after harvest when fruit will be sold, transformed, or stored. The presence of sugars is an indicator of fruit ripeness which makes consequently its measurement in fruit a key point. During fruit formation, at a plant physiological level, sugar is produced in apple leaves and then transported to the fruits where it is chemically changed to starch and stored. The stored starch is slowly changed back to sugar during the period of fruit maturation [48].

In the past, several fruit ripening indexes, more or less based on empirical knowledge, were suggested such as flesh firmness, red or green color of the skin, flesh color, seed color, soluble solid content of the juice, taste, harvest drop, fruit internal ethylene concentration, and starch-iodine index [48]. They are still used by professionals in the orchards to predict harvest date and fruit maturity. In the next paragraphs, we will do a focus on the three types of measurements which are directly related to sugars, namely, the starch-iodine test evaluating the level of starch regression, the measurement of soluble solid content using a refractometer, and single sugar quantification by chromatographic methods.

4.1 Starch Regression

The starch-iodine test measures the level of starch regression and is based on the percentage of stained tissue using a fresh iodine solution [48]. The slow disappearance of starch in favor of simple sugars can be observed by periodically (once or twice each week) collecting apples and staining the starch. Briefly, the protocol consists in cutting the apple, picked up within 24 h, on the equatorial plan and applying the fresh iodine solution to one cut surface of one of the halves. One-minute delay must be observed in order for the starch pattern to be completed. Then the obtained pattern is compared to the pictures of patterns presented on the reference chart. They are associated with index number. The average starch-iodine index is then used to estimate the advancement in fruit maturity in the sampling area. It is worth noting that the pattern of starch disappearance is not the same in all apple cultivars [48]. An example of starch-iodine reference chart for Delicious is presented in Fig. 1.

4.2 Soluble Solid Content

The soluble solid content (SSC), used as an approximation of the global level of sugars, can be measured by means of a refractometer and a drop of juice [49]. Sugars are the major soluble solids in fruit juice, but other soluble materials are also present and include organic acids and amino acids, soluble pectins, etc. The result can be expressed as SSC (%) or as Brix degree (°Brix). The latter has been in common use for many years and is intended to represent the dry substance content of solutions containing mainly sucrose [50]. Refractometer optically measures the density of a liquid and is further calibrated in terms of refractive index which indicates how much a light beam is “bent” when it passes through the fruit juice. It also usually contains a scale in terms of degrees Brix. Temperature of the solutions is a very important factor

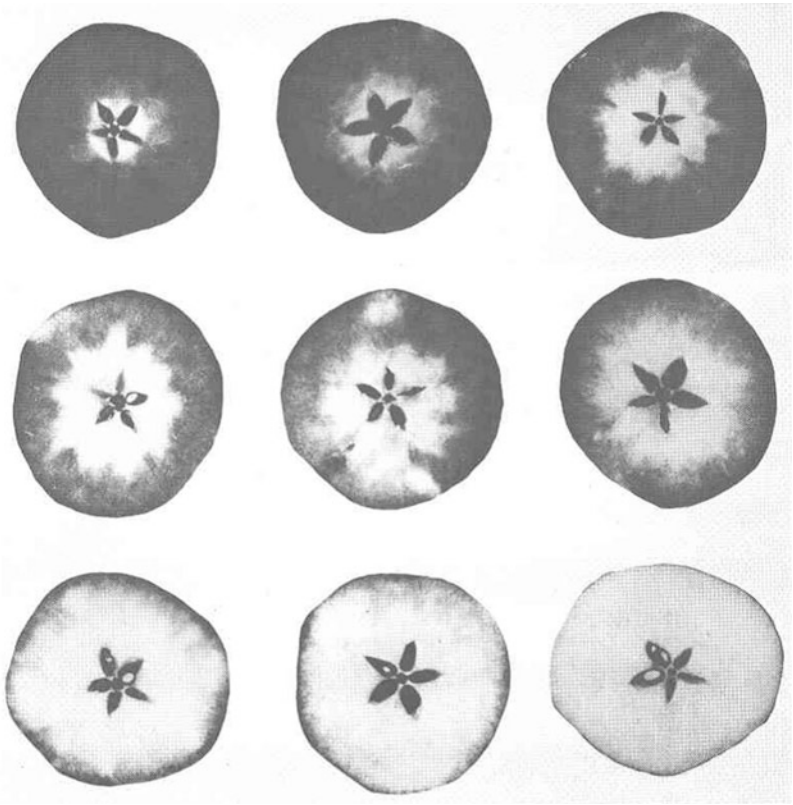

Fig. 1 Example of starch-iodine reference chart for Delicious apple cultivar. Least starch hydrolysis, top left, assigned value of 1 to the most starch hydrolysis, bottom right, assigned a value of 9 (Adapted from Smith et al. [47])

in the accuracy of reading. All materials expand when heated and become less dense. For a sugar solution, the change is about 0.5% sugar for every Celsius degree. Good-quality refractometers have a temperature compensation capability. Refractometers are often used for the measurements of concentration of solutions in the food industry [51]. The use of near-infrared ray technology as a non-destructive method is another way of predicting sugar level [44].

SSC is often included in assessments of both the preharvest ripeness and the postharvest quality of apples [52] and sometimes associated with sensory analysis tests [10, 18, 33, 44, 53–58].

4.3 Single Sugar Measurement by Chromatographic Methods

Different analytical methods, based on chromatographic separation, can be used to quantify single sugars. Chromatographic methods are rapid, sensitive, and suitable for routine analyses requiring dedicated instruments.

The method of choice in many laboratories for sugar analysis is the HPLC coupled to refractive index detectors. In the Official Methods of Analysis of AOAC International (Association of Official Analytical Chemists), the HPLC methods recommend the use of an analytical column containing a silica stationary phase with a propyl amine functionality that is very specific to the matrix. Besides the use of the stationary phase with a propyl amine functionality, there are many other separation mechanisms and chemistries for the HPLC determination of sugars. Anion exchange, cation exchange, liquid/liquid partition, and size exclusion represent a few useful chemistries. Other detectors coupled to liquid chromatography (LC) are pulsed amperometry (PA), evaporative light scattering (ELS), and mass spectrometry (MS). This allows the identification and quantification of individual carbohydrates [59].

Sugar can also be analyzed by gas chromatography after derivatization, necessary to make them volatile. Methyl ethers, acetates, trifluoroacetates (TFA), and trimethylsilyl (TMS) ethers are the most common derivatives used for carbohydrate determination. TMS ethers have a good volatility and the derivatives formed are well stable; furthermore the method is relatively simple making it one of the most popular [60].

5 Sensory Analysis: A Useful Tool to Measure Sweet Taste Perception in Apple

As seen in previous Sect. 4, the soluble solid content (SSC) expressed as °Brix is commonly used as an estimate of fruit sweetness and is included in assessments of the postharvest quality of apples [18, 61]. However, several studies showed that prediction of sweetness by °Brix in apples is inadequate [33, 62]. In general, sweetness prediction in apples is not an easy task [22, 24, 62]. Harker et al. [33] found that SSC and sweet taste are poorly correlated and recommended the use of trained sensory panels for the evaluation of sweetness in apple. Furthermore, 9 out of 13 studies, listed in Table 1, carried out sensory analysis tests to investigate questions related to fruit quality and sweetness perception.

Sensory analysis is defined as a set of methods and tools to evoke, measure, analyze, and interpret those responses to products that are perceived by the senses of sight, smell, touch, taste, and hearing [63]. There are several advantages in using these techniques both at industrial and research levels. Firstly, it reduces uncertainty and risks in decision making. Secondly, it ensures a cost-efficient delivery of new products with high consumer acceptability. Finally, human observers are good measuring instruments. People can sometimes detect odorants at levels lower than what can be detected by an instrument and instruments cannot measure liking [63]. Moreover, on the contrary to analytical tools which allow to measure only one type of compound or characteristic (e.g., sugars, volatile compounds, texture, etc.), sensory analysis is a more holistic approach considering all sensory properties at the same time or in a sequential manner but evaluated by the same unique "instrument," the human being.

Descriptive analysis is one of the major methods used to describe the sensory characteristics of products. There are a number of variants of descriptive analysis, depending on the procedures of training and testing and on the statistical treatment of collected data. Quantitative descriptive analysis (QDA®) [64, 65] is the reference method. Descriptive analysis (DA), described as a relevant method for evaluating fruit quality, consists in rating, in terms of intensity, a certain number of attributes defined beforehand [66]. Indeed, it allows detecting fine differences of quality [49].Nevertheless most of the fruit varies at a sensory level for several properties, within a given cultivar, which makes sensory characteristic measurement difficult [67, 68]. Sensory analysis has been used in the majority of the studies presented in Table 1 and is commonly used to support breeding programs [18, 69, 70].

Sensory analysis tends to be as objective as possible in measuring various characteristics of food products. Descriptive trained panels, which can be qualitative and/or quantitative, generate data that should be equivalent in terms of quality that the one expected for a machine – to know – repeatable, reproducible, and accurate [71]. Moreover, members of a panel need to demonstrate abilities to discriminate products and to be in agreement with each other [71]. In order to avoid any bias, some particular cares need to be taken before and all along the testing phase. Hence, different aspects must be controlled such as product preparation, panelists' screening and training, tasting conditions, and environment. More details are available in methodological manuals [63, 71]. We will review below some points regarding sweet taste perception in apples specifically.

As a machine, a sensory panel should be calibrated and its own sensitivity evaluated [71]. It has been demonstrated by several studies that taste sensitivity varies a lot among the population. It is thus necessary to organize a selection of the panelists before performing sensory tests. This screening step is usually a preliminary work to an experimentation [71]. Nevertheless, this step is rarely described in the literature in the case of apples and more particularly for sweet taste. Harker and colleagues [33], who studied sweet and acid tastes in apple fruit, screened 40 panelists for the taste sensitivity during a pre-screening session. They used artificial solutions containing mixtures of sucrose (7–14 °Brix) and malic acid (0.08–0.2% wt./v), as well as whole fruit. From this step, the authors selected the 20 most taste-sensitive panelists from the group.

Another point important to take into account when performing descriptive analysis method [63] is the definition of the terms belonging to the lexicon and the associated standard references. "Sweet taste" is defined by the ISO Standard 5492 [72] as "the basic taste caused by aqueous solutions of various substances such as sucrose." It is also generally associated in the literature with a very similar definition "the intensity of the taste sensation caused by sugars." Sweet taste is a very common trait evaluated when studying apples. Among the studies listed in Table 1, 9 out of 13 measured sweet taste intensity [13, 17–24]. Sweetness discrimination threshold in an apple matrix was also determined by Harker et al. [33] and is equivalent to 1° Brix for their trained panelists.

The choice of standard references is essential as panelists will use these references to calibrate themselves for scoring the attribute on a scale. Nevertheless, these references are not frequently indicated in research articles. Two studies used 20 $g.kg^{-1}$ and 80 $g.kg^{-1}$ fructose aqueous solutions for minimum and maximum sweet intensity in apples [22, 23]. Oraguzie and colleagues [18] proposed a different reference which consists of a 20-g sucrose/liter of fresh Fresh-Up Crisp Apple juice diluted 1:1 with distilled water for the point 4 of the scale (out of 9). Different types of sugars have been used for this purpose, either fructose [22, 23] or sucrose [3]. But it is important to underline that each type of sugar has its own sweetening power. For example, fructose has a relative sweetness index of 1.08 to 1.33 compared to sucrose in a 50 $g.kg^{-1}$ aqueous solution [37–41]. In Table 2 are reported the relative sweetness indexes of the most abundant sugars present in apple fruit. However, relative sweetness varies with concentration of the sugars, and the mixture of two or more of these sugars at the proper concentration can result in a solution possessing a sweetness greater than the simple addition of the two alone (synergism) [40]. Products and concentration used for standard references are selected and determined by panelists with control of the panel leader during the training phase. References are always compared with real products relatively similar to what will be tested at the end.

As stated above, sensory analysis is a holistic method, and it is difficult to distinguish and evaluate each sensory property individually and objectively. When someone put a piece of apple in his mouth and start chewing, he will perceive in few seconds different sensations such as hardness, crunchiness, juiciness, sweet, and acid taste. As a consequence, sweetness perception is obviously influenced by other sensory characteristics: other taste sensations, aroma, and texture.

To evaluate sensory quality of fruit, sugar/acid ratios are commonly determined [14] as good relationships were found along with consumer acceptability of fruit [73–75]. Besides, the calculation of this ratio illustrates the importance of taste interactions and the masking effect of sugar on acid taste: when sugar is present or added, the sweet taste perception overcomes and reduces the sourness perception [76, 77]. This phenomenon is also described as a contrast effect between sweetness and acidity [18] and can be observed in different conditions, both in water solutions and in complex matrices (see [78] for a review).

6 Importance of Aroma/Volatile Compounds

Sweet taste perception is modulated by other taste perceptions, but it is also influenced by the presence of certain molecules responsible for aroma perception.

Aroma perception is induced by volatile compounds released by the food in the mouth during eating or drinking. They reach the olfactory receptors located in the roof of the nose after swallowing through the exhaled breath. It is also called retronasal perception.

Fruit aroma is a complex combination of numerous volatile compounds that contribute to the overall sensory quality of fruit specific to species and varieties [79]. More particularly, apple aroma is made of more than 350 volatile compounds that have been identified [80, 81]. These compounds can be classified into two key categories: the vegetal/herbaceous category (reported with the sensory attributes of green/sharp, cut grass, green apple, cucumber, and pumpkin) and, the fruity category (banana, pear, pineapple, red apple, strawberry, and ripe) [82, 83].

Taste perception is closely linked to aroma perception as both of them enter in the combination of sensations which is called flavor. Flavor was first defined as the association of taste and aroma sensations [84, 85]. Since then, its definition has evolved thanks to various and numerous researches on this topic. Nowadays, under this term are brought together different stimuli: aroma, taste, somesthetic sensations, and texture but also sound and visual cues [86]. Furthermore, Keast and coauthors [87] described flavor perception of the food/beverage as a result of complex stimulus-response interactions between a food matrix and human sensory, perceptual, and cognitive processes.

Taste and smell (ortho- or retronasal), perceived through gustatory and olfactory receptors, respectively, can modulate the perception of each other, and this phenomenon is called interaction. The study on taste-smell interactions started about 40 years ago and was initiated by the works of Murphy et al. [88] and Murphy and Cain [89]. Different types of interactions between these sensory properties occur and have been demonstrated. Taste can be modified by an aroma in different ways, either by decreasing/masking or by increasing its intensity. This will depend on the congruency of the pair of the stimuli.

Sweet taste was the most studied basic taste. Several studies showed that fruity odor and aroma enhance sweet taste perception [23, 90, 91]. For example, strawberry flavor increased perceived intensity of sweet taste, but on the contrary, peanut butter aroma had no effect. This is due to the congruence phenomenon [92]. Aromas play also a role in the perception of other tastes. For example, in a sucrose solution, caramel aroma masked sourness and on the contrary leads to a rise in sweetness intensity [93] (see [94] for a review).

However, the majority of the studies dealing with sensory interaction have generally been performed using model matrices. It allowed the perfect control of the matrix in terms of composition but leads to conclusions based on something different from a real product and relatively distant from consumer perception [94]. To date, very few studies investigating the impact of smell on taste perceptions have used real products in general and more specifically fruit and vegetables. Studies on tomatoes and strawberries have highlighted the effect of volatile compounds on the perceived sweetness intensity of these fruits [95, 96].

One recent work investigated the effect of aroma on other sensory modalities in apple fruit [23]. They modified apple discs with different aromas either fruity or vegetal and/or sweet taste. Researchers showed that, thanks to TDS dynamic method, banana aroma increased logically fruity attribute dominance but also enhanced sweet taste dominance. More interestingly, it anticipated in the evaluation the period of dominance of sweet taste attribute (Fig. 2). They observed similar

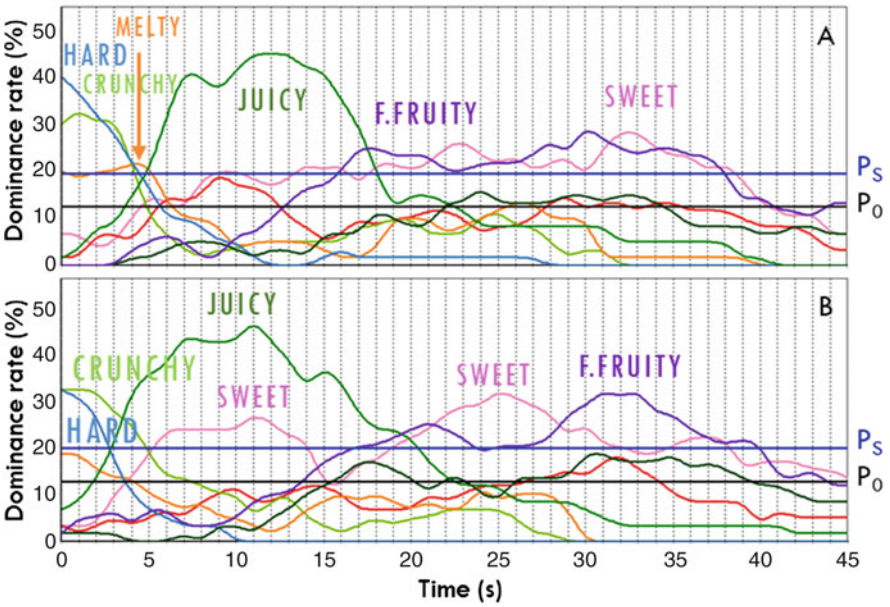

Fig. 2 **TDS curves of apples in "normal taste conditions"**. (**a**) sample without aroma addition, (**b**) sample with banana aroma. P_0 represents the chance level and P_s is the significance level (Adapted from Charles et al. [23])

results with green grass aroma. This study is the first attempt for investigating aroma-related interaction taking into account the time dimension and underlined the importance of aroma in sweetness perception in apples.

Furthermore, Aprea and co-workers [22] investigated the possible role of volatile compounds on the perception of sweetness using a statistic approach applied to a combination of instrumental and sensory data. They built different statistic models, based on OPLS regression, trying to predict sweetness perceived by sensory panel. The authors evidenced that the model including the volatile compounds (95 variables) together with single sugars (sucrose, glucose, fructose, and xylose), sorbitol, malic acid, and SSC explained 92.0% of sample sweetness variance with a good predictive ability (Q2 = 62.7%). More precisely, approximately 33% of perceived sweetness was accounted by volatile compounds. This shows once again that sensory perception is regulated by multisensory stimuli. Among the volatile compounds included in the model, some had a positive contribution of which three esters, three farnesene isomers, and benzothiazole. Furthermore, esters strongly contribute to sweet fruity descriptors in apple [97, 98] that may elicit odor-induced enhancement of sweetness perception [23, 90, 91]. On the contrary, other compounds associated with the attributes earthy fungal and green herbaceous contributed negatively to the sweetness model. A positive correlation between the intensities of sweetness with floral and fruity attributes and negative correlation with the green attributes in Fuji apples were also observed in another work [99].

7 Importance of Texture

Several authors have investigated the impact of texture properties on taste perception and specifically sweetness. These studies were mainly applied on model matrices such as solutions, juices, dairy products, and solid foods [100–105]. A common procedure consisted in adding thickening agents to modify the texture of the solutions or gels [100]. Generally, these compounds increase the viscosity of liquid systems or the hardness of gel-like systems and tend to reduce the intensity of flavor perception (taste and aroma). This is also true when using different types of sugar and with a slight different approach. Kokini [106] who studied the perceived sweetness intensity of sucrose and fructose in solutions changing the texture by varying the level of tomato solid content noted that the increase of tomato solids in solution decreased the sweetness intensity of sucrose and fructose.

The physical structure of the food matrix can impact individual physiological oral behavior (e.g., salivation, throat coating) and the strength, time, and speed of chewing. This could lead to diverse sensory interactions, which are linked to both mechanical and biochemical degradations [94]. More particularly, Gierczynski et al. [107] demonstrated that the oral behavior (i.e., chewing force, frequency and duration, as well as the opening and closing of the velum-tongue barrier) is influenced by the matrix structure. The researchers hypothesized that a firmer gel, perceived as granular and with a heterogeneous breakdown, required more attention to the texture by the subject than a softer gel did, which was perceived as smooth, spread, and thus more easily destroyed. As a consequence, for the firmer gel, less attention would be paid to other perceptions, such as taste, which would thus be perceived as less intense.

When talking about apple texture, several sensory attributes must be cited to grasp it as a whole. Juiciness, crunchiness, and hardness are usually considered as key drivers of liking, whereas mealiness is almost always rejected by consumers and seen as a defect [1–3]. Very few studies investigated the effects of specific aspects of texture on sweet taste in apples.

Harker et al. [34] studied the influence of juiciness and hardness on sweetness perception. By considering the biological understanding of apple fruit tissue, they hypothesized the existence of a relationship between perceived sweetness, hardness, and the amount of juice released during breakdown of apple flesh rather than measures of sugar and acid content. Indeed, they speculated that in mealy fruit, cell fluids are not released, and then less sugars and acids are expected to come in contact with the sensory receptors than in hard and juicy apples. Their results demonstrated that hardness had an influence on perceived juiciness; nevertheless, they did not clearly support a direct relationship between juiciness and sweetness. Thanks to the use of sensory temporal method, they showed that the sensation of sweetness persists after the sensation of juiciness has been lost. These researchers verified thus that perception of sweetness is not affected by the volume or rate of release of juice into the mouth during consumption. It seems that in this study, even if texture between samples was different (hard and crunchy vs. soft and mealy), the

viscosity of the solution (juice) was presumably unchanged. The apple system can be assimilated as a form of flavor encapsulation.

Other researchers investigated the relation between sweetness and mealiness [24]. They reported that apples displaying a high degree of mealiness are perceived as less sweet, while samples exhibiting a low degree of mealiness are perceived by the panelist as being sweeter. They also noted that this effect was not supported by a correlation between the two variables ($r = -0.15$), meaning that the effect of mealiness on the perception of sweetness is monotonous. This can be explained by the fact that in soft apples, tissue fracture occurs as a result of cell-to-cell de-bonding. Thus, when the sample is chewed, individual cells do not break and release their cellular juice avoiding sweetness perception of the dissolved sugars in the cellular fluids.

Sometimes, taste can, on the opposite, modulate texture perception. For example, a research group found that the acid taste of Boskoop apples was so strong that it tended to be more dominant than mealiness (a dry and often floury texture) in driving consumer preferences [2]. Mealiness is a negative attribute that generally causes most consumers to reject apples [108]. Furthermore, Henan et al. [109] showed interesting results about the influence of sugar composition on flavor release modulating texture in a strawberry-flavored cereal bar system by in vitro and in vivo analyses. The researchers demonstrated that the sugar composition of the cereal bars modified textural properties. More particularly, an easier structural breakdown during chewing significantly affected, as a consequence, the concentration of the flavor volatile compounds released.

8 Conclusions

Sweetness is essential in explaining preferences of apple consumers as demonstrated by various studies. However, this criterion is not the only one to be taken into account in breeding programs and when investigating apple liking. Sweet taste is always perceived in combination with the other sensory properties which thus influenced its evaluation.

Apple is composed of numerous elements of several sugars, notably sucrose, fructose, glucose, and sorbitol. Their measurements are necessary at different levels to assess fruit maturity, and quality and try to estimate its sweetness level. However, sweetness perception is a complex and multisensory process, and the consideration of gustatory stimuli solely is not sufficient to fully understand it and predict it. Other perceptions such as aroma and texture are essential. Indeed, fruity aroma tends to enhance sweetness perception contrarily to green or vegetal ones. Regarding texture, mealiness seems to decrease sweet taste intensity, but this does not mean that there is a link between juiciness degree and sweetness perception. Further researches need to be undertaken on the effects of aroma and texture on sweetness perception to better elucidate underlying mechanisms.

Ludmilla de Carvalho Oliveira

Contents

Abstract

Quinoa, amaranth, and buckwheat are the most important pseudocereals. Despite pseudocereals resemble in function and composition of those of the true cereals, the seeds overcome cereal properties in some aspects. Recently, the pseudocereals have attracted attention because of the proteins with high nutritive value, and their storage proteins are not toxic for celiac patients. Moreover, the seeds are an important source of dietary fiber and phenols, which are associated with health

benefits. Studies have shown the pseudocereal flour suitability as cereal flour replacer in diverse food products (functional and gluten-free). At present, the food application of pseudocereals in bakery products, fermented beverages, and extruded products, among others, has shown successful. Therefore, the pseudocereals have a great potential to popularize in several countries not yet achieved, by introducing crops in human's food diet and providing new products of high quality (technological, nutritional, and sensorial). For these reasons, this chapter describes some relevant and actual information about worldwide pseudocereal crop production, nutritional and functional composition, use of pseudocereal flours in food product development, and consumer perception.

1 Introduction

Pseudocereals (also referred to as Andean grains), which include amaranth, quinoa, and buckwheat, present an attractive nutritional profile and are gluten-free grains. Quinoa and amaranth are characterized by having excellent protein quality, while buckwheat has a high level of phytochemical. In this respect, pseudocereals have been used as ingredient to increase the nutritional status in several bakery products, beverages, and gluten-free products. The use of pseudocereals in bakery product manufacturing has advantage due to the starch content inside the seeds; starch is the predominant quantitative constituent [1–5].

The regular consumption of pseudocereals promotes health benefits as reduced risk of cardiovascular disease and diabetes, anticarcinogenic effect, anti-inflammatory, and antimicrobial. This effect is due the presence of isoflavonoids and phytosterols in the grain [6]. These grains have been increasingly researched as nutritious ingredients in gluten-free formulations and as source of bioactive compounds with health-promoting effects. The regular consumption of pseudocereals promotes health benefits as reduced risk of cardiovascular disease, diabetes, anticarcinogenic effect, anti-inflammatory and antimicrobial. Some of the most attractive features of these seeds include their high-quality protein and the presence of abundant quantities of fiber and minerals such as calcium and iron [7].

Currently, new food products have been obtained from pseudocereals, including for nutrient and mineral improvement purpose. Thus, it makes contribution for enhancing grain popularity between consumers. The use of pseudocereals as ingredient can be found in different food segments: snacks [8–10], traditional breads and gluten-free breads [7, 11–13], pasta [11], porridge [13], fermented beverages [14, 15], and probiotic foods [15, 16]. The potential use of such grains in food products has been ensured by good acceptance getting in sensorial tests.

This chapter focuses on pseudocereal grains and respective flour characterization (nutrients and bioactive compounds) and technological, functional, and sensory properties of pseudocereal-based food products. The interest by Andean grains has increased as researchers showed the potential of such grains on supplying proteins, fibers, minerals, and phytochemicals. Furthermore, the sensory profile, acceptance, and perceptions of consumer are important to consider in pseudocereal-based products. This chapter was split in three sections: (1) aspects about crop cultivation, (2) discussion on recent researches with respect to pseudocereal ingredient use in food development, (3) approach in sensory aspects and consumer perception.

2 Pseudocereal Crops

In recent years, the agricultural production has been increased compared to other times. In the years between 1960 and 2011, agricultural production has tripled due to the development and widespread use of new farming technologies. Thus, agricultural technology improvement provided higher yields of major crops as cereals, roots and tubers, pulses, sugar crops, and vegetables in some potential regions around the world [17].

Cereals are the most important crop category grown across the world. The major cereal crops include wheat, maize, barley, rice, and sorghum, as showed in Table 1.

Although wheat, maize, and rice cereals are the most important crops grown, pseudocereals (amaranth, quinoa, and buckwheat) have been recognized as a notable seed, potentially used for human nutrition, whose cultivation developed in various regions of the world [19].

2.1 Morphological Definition

Pseudocereals are defined as starchy food grains excluding those currently classified as cereals, legumes, oilseeds, and nuts [20]. They are dicotyledonous plants that resemble in function and composition those of the true cereals (monocotyledonous) but do not belong to Gramineae families. According to some phylogenetic

Table 1 Total production of major cereal crops

Crop name	Production in million tons (MT)
Maize	1037.8
Wheat	729.8
Rice	741.5
Barley	144.5
Sorghum	68.9
Oats	22.7
Rye	15.2

Reference [18]

classifications, the *Amaranthus* and *Chenopodium* genera belong together in the order Caryophyllales, whereas buckwheat (*Fagopyrum*) belongs in the Polygonales. Polygonales and Caryophyllales were closely related and are combined together in subclass Caryophyllidae, although later studies asserted that there is significant genetic distance between them [21].

The main grain amaranth species used today are *Amaranthus caudatus* L. (syn. edulis Spegazzini), *Amaranthus cruentus* L. (syn. *paniculatus* L.), and *Amaranthus hypochondriacus*. Among quinoa, sweet and bitter varieties exist, dependent on the content of saponins (saponin content <0.11% – sweet variety) [20]. Two varieties of buckwheat are commonly cultivated: common buckwheat (*Fagopyrum esculentum*) and tartary buckwheat (*Fagopyrum tataricum*) [22].

Amaranth seeds are lentil-shaped and measure about 1 mm in diameter. Quinoa seeds are slightly larger than amaranth seeds. In contrast to cereals, the embryo surrounds the starch-rich tissue (perisperm) in the form of a ring and makes about 25% of the total seed weight. The buckwheat seed is a three-angled achene, 6–9 mm long. The fruit of *F. tataricum* is smaller (4–5 mm) and more rounded at the edges. Structurally and chemically, the endosperm resembles that of a cereal grain consisting of a non-starchy aleurone layer and large cells packed with starch granules constituting the majority of the endosperm [22] (Fig. 1).

2.2 Pseudocereals: Cultivation Around the World

Among the pseudocereals, quinoa (*Chenopodium quinoa*) and amaranth (*Amaranthus*) were an important crop for the pre-Colombian culture in Latin America, while buckwheat (*Fagopyrum esculentum*) originated from Central Asia [1].

Quinoa is a food plant of the Chenopodiaceae family, *Chenopodium* genus, native to the Andean regions of Chile, Peru, Ecuador, and Bolivia, and its cultivation dates back thousands of years, making this food, which comes from the Andean cradle, the

oldest ever recorded. Quinoa plants stand out by the considerable resistance to weather climate and soil conditions. There is a great diversity in the properties and quality of quinoa products due to the wide geographic distribution and genetic resources. The most widespread varieties of quinoa are sweet and bitter seeds. The colors of quinoa seeds are rather various, including white, yellow, red, black, and so on [20]. The world production of quinoa is estimated at around 510 tons (102,745 ha). Today, the main producers and exporters of quinoa seeds in the world are Bolivia and Peru. Together, these countries are responsible by taking over the worldwide market [23].

Amaranth is a pseudocereal native from northern higher-altitude regions of Bolivia, Ecuador, and Peru, and its species have already been cultivated in Mexico since 400 years BC [24]. Furthermore, amaranth grains are grown in different tropical regions of Africa, Central and South America, and South Asia and warm region as North America [23]. The genus *Amaranthus* L. contains more than 60 species. The main amaranth species being cultivated for their seeds and most used for human nutrition are *A. caudatus* in Peru and other Andean countries, *A. cruentus* in Guatemala, and *A. hypochondriacus* in Mexico [25]. The crop has high potential of increasing its production and consumption, especially in tropical regions.

The origin of buckwheat started in Central Asia and Siberia. However, it was cultivated in Europe and Russia and so spread to North America. As a consequence of immigration, this crop was introduced to Brazil and Chile around 1866. In 2009, the world's buckwheat production reached 3,000,000 tons/year. The main countries responsible for buckwheat production are Russia, Ukraine, Poland, the United States, Canada, and Brazil [23, 26].

As previously reported, pseudocereal cultivation has been introduced in many countries because of the importance on population diet. As the dissemination of such information, the grains have gained the world market, thus reaching more consumers and consequently more countries [19].

2.3 Nutritional Composition

Amaranth, quinoa, and buckwheat are currently relevant theme with respect to nutritional composition. Quinoa is one of the most nutritious foods used in human food, chosen by the FAO as one of the crops destined to collaborate with food security in this century [27]. Pseudocereals are mainly dietary fiber and protein source (Table 2). Amaranth contains higher protein and lipid content (ash) than wheat and other cereals [28]. Quinoa also overcomes cereals in the level of lipids and vitamins B1, B2, B6, C, E. Otherwise, buckwheat composition is most similar to wheat.

Albumins and globulins are most of the storage proteins found in pseudocereals. On the other hand, prolamin- and glutelin-like proteins are less abundant. Exceptionally, amaranth, quinoa, and buckwheat are gluten-free seeds, which enable their use by celiac patients. The absence of gliadins (gluten-forming prolamins present in wheat) and protein fractions corresponding to gliadin (found in oats, barley, rye, and malt), which are considered toxic for celiac patients, makes

Table 2 Chemical composition of amaranth, quinoa, buckwheat, and wheat (g/100)

Chemical composition	Amaranth	Quinoa	Buckwheat	Wheat
Protein	16.5	14.5	12.5	12.0–14
Fat	5.7	5.2	2.1	2.5
Total starch	61.4	64.2	58.9	63.0
Dietary fiber	20.6	14.2	29.5	17.4
Ash	2.8	2.7	2.1	1.5

Reference [28]

pseudocereals appropriate for the preparation of food products popularly referred to as "gluten-free" [29].

Celiac disease is an autoimmune enteropathy associated to genetic factors (HLA-DQ2 and HLA-DQ8). The response to disease is triggered when blind gluten peptides link to HLA-DQ2 and HLA-DQ8 and present them to T cells, which are located in the lamina propria. The T cells found gluten-sensitive $CD4^+$ helper cells, and the mechanism of the disease (immune reaction) starts, and various symptoms occur [30]. The only currently available treatment for celiac disease consists in dietary exclusion of grains containing gluten and supportive nutritional care in case of iron, calcium, and vitamin deficiencies.

Besides having great amounts of protein, amaranth is an important source of some important essential amino acids: alanine, valine, leucine, arginine, phenylalanine, pralines, methionines, α-aminobutyric acid, tryptophan, and isoleucine [31]. Owing to the similar amino acid profile, amaranth can be considered a nutritive substitute for cereals [32]. Quinoa seed has attracted attention as a new food source, because of the quality and nutritional value of proteins. Quinoa contains more protein content and balanced distribution of essential amino acids than cereals, resembling the biological value of protein in milk (casein). Thus, quinoa is one of the few plant foods that provide all essential amino acids for human life with values close to those set by the Food and Agriculture Organization (FAO), being rich in sulfur amino acids and lysine, unlike the protein content of cereals, which are especially deficient in lysine [33–35]. Buckwheat contains higher levels of lysine, arginine, and aspartic acid compared to cereals [36]. Specially, the nutritional value and the techno-functional properties of proteins found in pseudocereals make them a promising alternative for food applications [24, 37].

Quinoa has been considered an alternative oilseed crop, due to the quality and quantity of its lipid fraction. Quinoa has a fat content between 2.0 and 9.5%, being rich in unsaturated essential fatty acids (66% of fat composition). The fatty acids of quinoa oil are polyunsaturated. The most abundant unsaturated fatty acids in amaranth and quinoa are linoleic and oleic acid, whereas palmitic acid is the major saturated fatty acid reported for all pseudocereals [2, 38].

Starch is the main quantitative carbohydrate and component of pseudocereals, like in cereals. The content of carbohydrates in quinoa seeds consists mainly of starch (53.5–69.2%, dry basis) and a small percentage of sugars (maltose, D-galactose, D-ribose, fructose, and glucose). Quinoa starch has excellent freeze-

thaw stability which makes it an ideal thickener for sauces, condiments, and soups due to its low gelation temperature and storage stability at low temperatures and in other applications where resistance to retrogradation is desired, and it may also be used to produce a creamy and smooth texture similar to fats. The gelatinization of quinoa starch occurs at a relatively low temperature, between 62.6 °C and 67 °C [39, 40]. The amylose content of quinoa starch ranges from 3% to 22%, which is lower than that present in wheat or maize. The starch of amaranth species grains has amylose content ranging from 2.0% to 65.2% [31]. Lastly, buckwheat starch amylose represents 20–28% content, similar to cereals [41]. The amylose content differs between botanical sources and has significant effect on physical-chemical properties and functional characteristics of starch. Generally, the content of starch in pseudocereals and their properties, such as viscosity, provide some opportunities in food applications as baked products.

Studies have shown that the pseudocereals amaranth, quinoa, and buckwheat represent good sources of dietary fiber. In particular, dietary fiber content is significantly higher in buckwheat seeds in comparison with amaranth and quinoa, which have fiber levels comparable to those found in common cereals (Table 2) [28]. Taking into account the inadequate intake of dietary fiber by celiacs, the experts have recommend a higher consumption of whole grain pseudocereals to alleviate, at least in part, the deficit in fiber intake in this sector of the population.

Pseudocereals contain high level of minerals compared to wheat (Table 3). Amaranth and quinoa contribute with 50% of Dietary Reference Intakes (DRIs) for copper, iron, manganese, magnesium, and phosphorus. These seeds are also a good calcium source, which are relevant for celiac, since some patients present osteopenia and osteoporosis [42]. However, potassium, magnesium, and phosphorus may dominate in some quinoa genotypes [43]. Buckwheat is considered a mineral source compared to cereal of levels of magnesium, zinc, potassium, phosphorus, copper, and manganese [26, 36].

Amaranth is a good source of vitamin C and riboflavin (B_2) [31], whereas quinoa has significant concentrations of pyridoxine (B6) and folic acid in quinoa. Furthermore, both amaranth and quinoa are important source of tocopherol (vitamin E) [44]. Buckwheat exhibits high levels of vitamins B and C and tocopherols [2, 36].

In short, the valuable nutritional composition of pseudocereals, similar or greater than cereals, makes the ancient grains adequate for food industry. Also,

Table 3 Mineral content in pseudocereals and wheat

Minerals	Amaranth	Quinoa	Buckwheat	Wheat
Ca	180.1 ± 6.1	32.9 ± 3.3	60.9 ± 3.3	34.8 ± 0.0
Mg	279.2 ± 1.1	206.8 ± 6.4	203.4 ± 8.8	96.4 ± 3.7
Zn	1.6 ± 0.0	1.8 ± 0.0	1.0 ± 0.0	1.2 ± 0.1
Fe	9.2 ± 0.2	5.5 ± 0.5	4.7 ± 0.1	3.3 ± 0.1

Reference [2]. Data presented as mg/100 g dry-weight basis ± standard deviation

pseudocereals seem a good solution for nutritional problems as celiac disease, especially in less developed countries.

2.4 Phenolic Compounds and Antioxidant Activity

Pseudocereals are good sources of phenolic compounds such as phenolic acids. Phenolics are relatively hydrophilic and may include phenolic acids, flavonoids, and tannins, and they make up the majority of the secondary metabolites of plants that contribute to diverse physiological effects. Such bioactive compounds have shown a positive correlation with antioxidant activity and total phenols in pseudocereals. Recently, much attention has been focused on natural antioxidants, which can play an important role in inhibiting free radicals and oxidation chain reactions within tissues, in particular for the protection of cell membranes, with proven success in neural functions, reducing the risk of several degenerative diseases associated with oxidative stress such as cancer, cardiovascular disease, and osteoporosis [45].

Among cereals and pseudocereals, buckwheat is one of the best sources of polyphenols, being quercetin, apigenin, and luteolin as the main flavonoid glycosides found. The polyphenol's content in the pericarp is significantly higher than in the grains [43]. Buckwheat bran and hulls have two to seven times higher antioxidant activity than barley, triticale, and oats.

Quinoa seeds are also an abundant source of flavonoids, which consist mainly of quercetin and kaempferol glycosides [46]. Quinoa grains contain other various phenolics such as rutin and their derivatives, vanillic acid, ferulic acid, and ferulic acid-4-glucoside [47]. Quinoa has higher antioxidative power than amaranth [48]. Recent findings have suggested that quinoa phenolics may have the potential to prevent hyperglycemia and its associated complications by means of their ability to slow both oxidation-related damage to various organs and intestinal digestion of carbohydrates [45].

Amaranth is a rich source of polyphenols (flavonoids) with relative high antioxidant activity. The major phenolics found in amaranth seeds are caffeic acid, p-hydroxybenzoic acid, and ferulic acid [46]. Ferulic acid was investigated in amaranth-insoluble fiber, and the results showed it is predominantly bound to pectic arabinans and galactans [49]. Other bioactive compounds are present in amaranth grain including flavonoids, phenolic acids, anthocyanins, tannins, and phytosterols [46].

Despite the high proportion of total phenols, other non-phenolic compounds, such as ascorbic acid, phytic acid, tocopherols, sterols, carotenoids, saponins, and ecdysteroids, among others, may be the most likely contributors to the antioxidant activity [50].

3 Food Application

The nutritional composition (protein, dietary fiber, and minerals) and antioxidant properties of pseudocereals have exerted great contribution to its popularity in human diet. In addition to presenting high nutritional quality, they are also characterized by being gluten-free, a characteristic that enables greater offer and variety of more nutritious and suitable food products for patients with celiac disease. Finally,

amaranth, quinoa, and buckwheat can be an alternative food in order to reduce malnutrition diseases.

Thereby, pseudocereals have been used to produce breakfast cereal, baked goods, crackers, infant foods, and gluten-free products, among others (Table 4) [51]. One of the most common uses of seeds and respective by-products is for gluten-free diets. Therefore, pseudocereals are increasingly used in gluten-free breads, cookies, and cakes [52]. Quinoa is usually used to enhance baking flours in the preparation of biscuits, noodles, and pastries and for the preparation of baked foods to maintain the moisture and give an agreeable flavor [50]. Recently, amaranth, quinoa, and buckwheat have also been used for brewing purpose. This versatility on beer production might become possible to produce gluten-free beer with high quality [53].

3.1 Bakery Products

3.1.1 Gluten-Free Breads

Currently, gluten-free breads are an emerging topic in the literature. The quality of the gluten-free products available on the market, and food choices, may represent

major determinants in the deficiencies in macronutrients and micronutrients of celiac patients [50]. Gluten-free cereal foods are frequently rich in carbohydrates and fats, and they are made using refined gluten-free flour or starch not enriched or fortified. In this way, studies are mainly focused on gluten-free ingredients or technologies aiming to produce breads with similar quality (physical-chemical and sensorial) to those wheat flour based [77–79].

Pseudocereal flours can be used for protein enrichment of gluten-free formulations. Besides prolamins' absence, pseudocereals are rich in nutrients and source of bioactive compounds with antioxidant properties [80], which have importance for recovering the nutritional status of celiac patients when used in gluten-free products [19]. In this section, the recent researches about this subject will be approached.

Different studies have revealed great results about pseudocereal use in gluten-free breadmaking. Breads containing amaranth, quinoa, or buckwheat flour have shown similar baking characteristics compared to rice-based bread. Incorporation of pseudocereal flours led to a considerable improvement in nutritional and texture properties of bread [60]. The use of 50% of amaranth and quinoa flours in gluten-free bread provided a final product of increased loaf volume and softer crumb. The effect on volume and crumb texture could be attributed to complexes formed between fat globules and starch especially in pseudocereal presence, which contributes to stabilize gas cells [81]. Reduced percent of amaranth and quinoa flour (20%) gluten-free bread formulations showed similar technological quality with reference to specific volume and firmness. The calories at these breads were similar to gluten-free bread produced with rice flour and starches (from cassava and potatoes). Notably, the breads produced with pseudocereals had greater amounts of proteins, lipids, and minerals [59].

An improved effect of sourdough fermentation on gluten-free bread quality of quinoa or buckwheat has been reported. Such breads have shown high quality and extend shelf life [74]. Other investigation showed that the presence of milk and buckwheat proteins, as well as hydrocolloids, was responsible for improving CO_2 retention in sourdough bread of buckwheat flour (37%) [82]. Hydrocolloids and guns have effect on dough rheology and bread quality parameters in gluten-free formulation and therefore are usually necessary in this case. However, results have shown that pseudocereals flours and linseed mucilage provided a water-binding capacity in gluten-free breads which combined with starch improved the final quality of bakery products [11].

Quinoa and amaranth have also attracted attention because of having hypoglycemic effect. Consequently, gluten-free breads elaborated with such pseudocereals can also contain low glycemic index compared to traditional formulations with starches and rice flour [7].

3.1.2 Biscuit, Cookie, and Cake

Cookies are widely consumed bakery products due to their long shelf life and strong consumer preference. Although the structure-forming ability of gluten influences the rheological properties of dough and affects overall appearance of bakery products, the development of a gluten network in biscuit and cookie dough is minimal and

undesirable [83]. Therefore, gluten-free cookie production is most easily to proceed rather than loaf bread. Generally, cookies are prepared from wheat flour, which are deficient in some essential amino acids like lysine and tryptophan. To increase its nutritive value, cookies are prepared with fortified or composite flour. Pseudocereal flours can be added to cookie formulation to achieve better nutritional profile without causing severe technological problems.

Light buckwheat flour was used in gluten-free rice and buckwheat cookies. The substitution of rice flour in gluten-free cookie formulation by 10–30% light buckwheat flour increased mineral content, total phenolic content and rutin content, and antioxidant activity [83]. The shelf life study of gluten-free cookies based on a mixture (80:20) of rice flour and light buckwheat flour (chosen as optimal) suggested sensory properties as relevant parameters for predicting the endpoint of cookie shelf life rather than total aldehyde content.

Cookies were prepared from the composite flour containing various proportions of the whole amaranth flour. The physical properties of the amaranth-enriched cookies were affected in a positive way by demonstrating a decrease in bake loss, an increase in diameter, a higher spread ratio, and lesser hardness, leading to softer eating characteristics which are required in cookies. The composite cookies were darker in color at higher levels of substitution. So, the use of amaranth flour in cookie was effective for technological advantages of cookies [84].

Roasting of seeds is often done to enhance flavor and reduce antinutrients such as phytic acid and saponins. However, the effect of roasting on food quality has not yet been reported for quinoa. Such assumption led to gluten-free and allergen-free cake formulation maked up by different roasting times of quinoa. From the results, application of the resulting flours in an allergen-free, gluten-free cake formulation in particular may benefit from a blend of roasted and nonroasted quinoa flours when gelatinization is needed, but retrogradation must be limited for functionality and shelf life purposes [85].

3.2 Pasta

Pasta has a primary role in human nutrition, thanks to its complex carbohydrate profile, the large global distribution, and the extended shelf life. The World Health Organization (WHO) and Food and Drug Administration (FDA) consider pasta a good vehicle for the addition of different nutrients to diet [86]. Otherwise, there is an increasing interest of producers, consumers, and the scientific community toward the addition of high-protein vegetable ingredients deriving from pseudocereals and others to pasta formulations [87], even though on nutritional improvement, the replacement of semolina is still a challenge for the food industry, since the addition of alternative ingredients markedly affects technological and sensory properties [13].

In a recent study, fermented quinoa flour (with lactic and acid bacteria) was used for pasta fortification with the aim of enhancing its nutritional features. Addition of 20 g/100 g of quinoa flour to semolina was successful in improving the nutritional characteristics of pasta without compromising the technological and sensory quality.

Pasta containing fermented quinoa flour presented a higher nutritional profile compared to the other pasta, characterized by improved protein digestibility and quality, high nutritional scores, low predicted glycemic index, and high antioxidant potential. Fermentation as well other available technologies may be a successful way to produce pasta from quinoa (and other pseudocereals) with high nutritional potential.

Interest in amaranth flour has grown since studies have shown that it can contribute to the improvement of the structure and the cooking quality of pasta as well as enrichment of the essential mineral content in the case of gluten-free products [88, 89]. In line with that, amaranth leaves (DAL) and seed flour (AF) were used as ingredients for pasta production. Generally, amaranth pastas had lower cooking time than control pasta. Pasta with AF and DAL exhibited significantly higher content of protein, crude fiber, iron, zinc, magnesium, and potassium compared with the control pasta. Even though antioxidant capacity decreased due to the cooking process, AF and DAL have improved the pasta antioxidant capacity [90].

3.3 Extruded Products

Extrusion is a food process used to obtain a variety of foods from fundamental ingredients. This technology uses the extruder to produce foods as snacks, ready-to-eat breakfast cereals, and flours. Extrusion can be advantageous compared to other food processing techniques due to the short processing time [91].

Studies have shown that extrusion may have a definitive positive nutritional effect on food, if it is done appropriately. Specially, extruding of amaranth and quinoa has increased their nutritional value. Interestingly, extruded products from the pure grains of quinoa and amaranth (no cereal source), i.e., gluten-free, were produced in single-screw extruder [45].

A comprehensive study on impacts of extrusion processing conditions on quinoa flour showed moderate expansion characteristics as compared to widely used cereal grains, suggesting that this variety of quinoa is not well suited for making direct expanded products. However, this variety may be more useful in the products where direct expansion is not an important textural quality [91].

4 Sensory Aspects and Perceptions of Consumers

The food industries need to innovate their products constantly in order to satisfy consumer demand and maintain a leadership position in the market. The main factors impelling the preferences for food are appearance, taste, aroma, texture, cultural factors, cost, and the benefits that it promotes [92–94]. In this context, the sensorial analysis is a science used to analyze consumption products through human's sense as sight, smell, taste, touch, and hearing. The results obtained with the sensorial tests can help new food developer to evaluate the quality and consumers' satisfaction and give direction of a successful production in the market [95]. In addition, it is possible

to obtain information about different formulations, preferences of the products, or relationship between the variables, purchase intention, and consumers' perception [96]. An example of food innovation concerns to pseudocereals' use as ingredient in order to provide an attractive and functional food. Interestingly, in design of new food product, quinoa (20%) showed an acceptable sensory profile, so being an option for industries specialized on functional food development [97].

Currently, an expressive number of reports in the literature have indicated the benefits of ancient grains. Moreover, consumers are most concerned and consequently interested to buy products with health benefits. The pseudocereals present an acceptable flavor that consumers can easily adapt [51]. Therefore, quinoa, amaranth, and buckwheat present an increase sensory acceptability as the products are developed. However, the critical point is the difficulty of replacing 100% of wheat flour by pseudocereals [44, 98].

The use of quinoa and amaranth to develop extrudates (20, 30, 40% of pseudocereal flour) promotes a positive sensory perception characterized by crispness. However, when studying the temporal dominance profile of this snack cereals (sensorial technique used to study the profile of two or more sensations), during the mastication, crunchiness is the dominance sensation [99]. An acceptance test showed 70–78% of the preference of snacks being those produced with quinoa flour in the quantity 92–86% [8].

Also, the use of pseudocereals for gluten-free bread has been studied. The incorporation of 20% of quinoa or amaranth flour in gluten-free breads did not influence the texture perceptions of consumers and had a moderate acceptance. Additionally, the adhesiveness, amaranth aroma, and taste contributed positively for sensory acceptability. In contrast, quinoa showed negative drivers of linking as brown color of the crust and strong quinoa taste. In this context, amaranth flour seems to have better sensorial response than quinoa in substitution to starch in gluten-free bakery products [100].

Sensory evaluation of fresh spaghetti produced with amaranth flour showed a great sensory acceptance and purchase intention. Once again, the results indicate amaranth promising to gluten-free product [58]. In a recent finding, amaranth was used in porridge formulation, and from the consumers viewpoint, porridge showed a similar acceptability for maize-based porridge [101]. Thus, amaranth can be recognized as a potential ingredient to replace cereals or to be used in gluten-free products with sensorial acceptance of consumers.

Quinoa and buckwheat have been tested in a brewing process for the development of beverages. Fermented quinoa-based beverage was considered a potential drink, having good acceptability, since it is produced with bilberries (*Vaccinium myrtillus*) and has an added chocolate flavor [62]. Beer is another fermented beverage that has been investigated. Beer developed with quinoa had an interesting sensory profile characterized as black color, nutty aroma, grayish foam, and astringent. On the other hand, beer produced with buckwheat presented a quality characterized by bitterness and sparking aspect. Concluding, buckwheat beer is quite similar to traditional barley one.

Although pseudocereals are unpopular in some countries, the application of this grains in researches with focus in sensorial analyses should be become amaranth, quinoa and buckwheat, popular, and more applicable in the human food habits.

5 Conclusion

Despite all the issues discussed, pseudocereals are not widely used. High cost (imported grain as quinoa), little knowledge of their benefits by most consumers. Furthermore, pseudocereals present functional properties as excellent nutritional profile and bioactive compounds and are gluten-free. In this scenario, the Food Science and Technology has a crucial role to explore and disseminate knowledge about these grains. The pseudocereals present high commercial value and special functional and nutritional benefits next to popularize among people.

Abstract

Fruits and vegetables play an important role in human nutrition and health; they constitute an important part of our daily diet. They are important sources of carbohydrates, vitamins, trace minerals, and antioxidants. Therefore, they can be contaminated by pesticides used for the protection of their culture. The use of pesticides to control pests in fruits and vegetables can lead to the presence of pesticide residues. The level of these residues can be below the maximum residue limit (MRL) if good agricultural practices (GAP) were used. The presence of residues with level exceeding MRLs should be interpreted as violation of GAP. In many reports, pesticide residues are present in the majority of fruits and vegetables; they are more detected in fruits than in vegetables. The percentage of exceeding MRLs is less than 20% in most monitoring programs. The risk assessment for long-term and short-term exposure must be done for all pesticides detected to ensure consumer's health protection.

Keywords

Fruit · Vegetable · Pesticide residues · Risk assessment · MRL

1 Introduction

Pesticides are a subject of debate in today's society. In the past, these products were synonymous with the control of agricultural production, the guarantee of food resources, and the eradication of diseases transmitted by insects, but now, they became associated with a real public health problem. In few years, pesticides have gone from revolutionary products and benefactors to harmful products that must be eliminated [1].

In fact, the excessive and unreasonable use of pesticides since the middle of the twentieth century has led to a widespread contamination of the environment. Since the 1970s, these products and their metabolites have been detected in all compartments of the environment, including air, river water, and groundwater, and food [2, 3].

Pesticides, by their toxic properties, represent a real danger to man when they are not used under appropriate conditions. On the other hand, it seems complicated to remove their uses in the near future because our society depends on them (whether agricultural or nonagricultural use). The current global trend is to gradually decrease their use through the improvement of agricultural practices and the strengthening of the legislative measures related to their registration and use. To this end, the maximum residue limits (MRLs) in fruits and vegetables imposed by international legislation have become lower.

Fig. 1 Some vegetables and fruits

Fruit and vegetables are rich in vitamins and minerals. They also contain antioxidants, such as beta-carotene and vitamin C; they also contain fiber. This can help to control cholesterol levels and keep blood sugar levels steady. Many studies encourage eating at least five portions of fruit and vegetables each day (Fig. 1). Regular monitoring of residue levels in fruits and vegetables is so required to keep these products safe.

2 Definitions

According to FAO, the term "pesticide" means "any substance or combination of substances, or micro-organisms including viruses, intended to repel, destroy or control pests, including vectors of human or animal diseases, harmful pests, undesirable species of plants or animals causing damage or otherwise causing harm during the production, processing, storage, transport or marketing of food, agricultural products, timber and wood products, or food for animals, or that can be administered to animals to combat insects, arachnids and other endo- or ectoparasites. The term includes substances intended to be used as a growth regulator of insects or plants, as a defoliant, as a drying agent, as a fruit thinning agent or for preventing the premature fall of fruit, as well as substances applied to crops, before or after harvest, to protect products from deterioration during storage and transportation. This term also includes the synergistic and detoxifying products of pesticides when they are essential for the satisfactory performance of the pesticide" [4].

In this chapter, the word pesticide is synonymous with an active ingredient to differentiate it from the commercial pesticide. Indeed, pesticides are rarely used in the form of an active ingredient alone; they are sold in mixtures of one or more active ingredients and adjuvants and give rise to different formulations. Different types of adjuvants are used [5]:

- Emulsifiers stabilize an organic phase in water. They ensure the easy dilution in water of a concentrated liquid product. Once mixed, the pesticide is evenly dispersed in water in tiny droplets.
- Wetting agents or spreaders are added when the liquid to be sprayed remains in the form of a drop instead of spreading on the surface of the plant leaf. Wetting agents are surfactants; they allow the droplet of slurry to expand to wet a larger leaf area.
- Solvents are used for liquid formulations; they allow dilution of active ingredient. There are only a few active substances that can be dissolved in water; the most used solvents are organic solvents such as hydrocarbons, alcohols, and oil.
- The carrier substances are neutral and harmless substances that carry and dilute the active ingredient in dry formulations (powders or granules); the most used carriers are silica, aluminum or magnesium silicate, and talc.
- Dispersants are used to obtain stable and homogeneous suspensions of solid active substances; the dispersing agent plays the same role as the emulsifier in liquid formulations: it stabilizes the suspension of the powder in water. The dispersing agent makes it possible to distribute the powder uniformly in the water in small particles; a homogeneous liquid is thus obtained, ready for application.
- Agglutinating agents or adhesives are added to help the pesticide to attach to the leaf surface, thus decreasing the risk of leaching of the active ingredient during rain.
- Coloring agents are added to reduce the risk of accidents, for example, by clearly showing the difference between treated (and therefore toxic and nonedible) seeds and untreated seeds.
- Synergists are adjuvant that improves the treating action of active ingredient.

Pesticides can be classified according to the target pests in herbicides, fungicides, insecticides, and acaricides.

3 Herbicides

These are substances intended to destroy or limit the growth of plants that are herbaceous or woody. Desiccant herbicides are pesticides that destroy the above-ground parts of plants to facilitate harvesting.

Herbicides can be active preemergent, that is, on seed, or postemergent, when the plant is emerged from the soil. Their action is systemic if they cross the cuticle of the undesirable plant and are transported throughout the plant or local if they act only at the level of the organ on which they are applied [6].

3.1 Herbicides Acting on Plant Growth

3.1.1 Synthetic Phytohormones

Phenoxyalkanoic acids, or aryloxyacids, include 2,4-D (2,4-dichlorophenoxyacetic acid), MCPA (4-chloro-2-methylphenoxyacetic acid), mecoprop, and dichlorprop; they are associated with derivatives of benzoic acids (dicamba, tricamba) and pyridine derivatives (picolinic acid), of the same mechanism of action. These compounds indeed have auxinic activity; they are called synthetic phytohormones [6]. Used at low doses to increase the size of the fruits and prevent their fall, they have at high dose an herbicide activity. They cause an abnormal development of the undesirable plant. They are systemic herbicides, widely used in agriculture, for the maintenance of forests, and in products for domestic use.

3.1.2 Nonhormonal Compounds

Amides (especially dichloroacetanilides), dinitroanilines (pendimethalin, trifluralin), certain carbamates (phenmedipham, chlorpropham, asulam), and thiocarbamates (molinate, triallate) block the growth of the plant by a nonhormonal mechanism [6]. Amides act by inhibiting protein synthesis of the plant and root elongation. Alachlor and metolachlor, which are dichloroacetanilides, are the two main representatives of this family, the most widely used in the world, pre- and postemergence [7].

Dinitroanilines are derivatives of 2,6-dinitro-4-benzene-amine. They are also widely used worldwide, preplanted and preemergent on cereal crops and for many nonagricultural and ornamental uses. The mode of action of dinitroanilines is the inhibition of mitosis, therefore of cell growth, by blocking the polymerization of microtubules.

3.2 Photosynthesis Disruptors

3.2.1 Triazines

These substances block the transfer of electrons in the photosynthesis reactions. They are photosynthetic inhibitors at photosystem II, site A. The products of this family are used pre- and postemergence on crops and all sites requiring weeding; the penetration is both root and foliar, but migration is important by root [7]. Other chemical families act in the same way as benzothiadiazoles (bentazone), nitriles (bromoxynil), and pyridazinones (chloridazone or pyrazon).

3.2.2 Substituted Ureas

The substituted ureas (diuron, linuron, monuron) are photosynthetic inhibitors in photosystem II, site B. These herbicides migrate only in the xylem (upward only). The lesions appear after the exit of the cotyledons and the first true leaves.

3.2.3 Bipyridines

Bipyridines or quaternary ammoniums (paraquat, diquat) cause the formation of superoxides leading to lipoperoxidation and disturbances in oxidation-reduction

reactions [8, 9]. They act by contact; their effect is very fast. They are very toxic, very soluble in water, nonselective, and strongly fixed on the clay-humic complex so that their persistence of action is null.

3.3 Inhibitors of Protein Synthesis

3.3.1 Inhibitors of Glutamine Synthesis

This is glufosinate-ammonium, which has a leaf penetration and acts primarily by contact (little scattering in the phloem/xylem). It acts by inhibiting glutamine synthetase [8]; it is nonselective and broad spectrum.

3.3.2 Inhibitors of Aromatic Amino Acid Synthesis

These glycines (glyphosate) have a leaf penetration and a systemic action. It acts by inhibiting the enolpyruvylshikimate phosphate (EPSP) synthase. This is the group of herbicides that spread the most in the plant. Widely used worldwide in agriculture as for amateur gardens, they are totally nonselective and broad spectrum and can be very toxic to crops also. Glyphosate is quickly and firmly adsorbed on soil particles. It therefore has no action in the soil, which allows a culture to be implanted in a short time after treatment [9].

3.3.3 Inhibitors of Branched Amino Acid Synthesis

These are mainly imidazolinones (imazamox, etc.), sulfonylureas (amidosulfuron, chlorsulfuron, sulfosulfuron, tribenuron-methyl, etc.), and triazolopyrimidines (florasulam, metosulam, etc.). They act by inhibition of acetolactate synthase [9]. These compounds all have both foliar and root penetration and significant migration in weeds. They can cause atrophy of grasses and yellowing (chlorosis) or purple discoloration of inter-nerval regions.

3.4 Inhibitors of Lipid Synthesis

Most lipid synthesis inhibitors are inhibitors of the enzyme acetyl-coenzyme A carboxylase, also called “vegetative point destructors of grasses.” They act by blocking the level of the meristems of the initial stage of the synthesis of fatty acids; the chemical families concerned are aryloxyphenoxy propionates “fops” and cyclohexanediones “dimes.” They are widely used in combination with other herbicides for the weeding of cereal crops. Another type of lipid synthesis inhibitors that uses a mechanism other than the inhibition of the enzyme acetyl-coenzyme A carboxylase is the case of thiocarbamates.

Aryloxyphenoxypropionates act only against grasses. They all have a systemic mode of action, but diclofop and fenoxaprop spread little and do not control perennial grasses.

Cyclohexanedione “dimes” such as clethodim and cycloxydim are also systemic anti-grass compounds with a systemic mode of action.

4 Fungicides

Agricultural fungicides can be used to control phytopathogenic fungi that can cause damage to crop plants and crops. Potential losses caused by fungal diseases range from 10% to 30% depending on the crop [10]. Fungicides are used on seeds, soil, and crops, as well as on stored commodities, in feeds. The treatments are preventive most often, or applied at the first symptoms of infestation, more rarely curative; some, anti-sporulating, prevent the spread of the fungus.

The products are either systemic or penetrating, if they penetrate the cuticle but act only at the level of the organ treated or surface [6].

4.1 Fungicides Acting on Mitosis and Cell Division

The methyl benzimidazole carbamates act by blocking mitosis by interaction with tubulin [6]. Benzimidazoles were the first systemic polyvalent fungicides with healing properties, but resistance has developed in a very large number of pathogens, for example, benomyl, carbendazim, thiophanate-methyl, and thiabendazole. Benzamides also act with the same mode of action, for example, fluopicolide and zoxamide.

Iprovalicarb, cymoxanil, and dimetomorph belong to different chemical families but have a similar mode of action.

4.2 Fungicides Acting on Respiration

Strobilurins (azoxystrobin, kresoxim-methyl, pyraclostrobin, etc.) show a broad spectrum of activity, excellent preventive and curative action, long persistence of action, and low doses of use but were soon confronted with the development of resistance.

Other active substances of different chemical nature act with a similar mode of action of famoxadone, fenamidone, dinocap, meptyldinocap, fluazinam, and cyazofamid.

4.3 Fungicides Acting on the Sterol Biosynthesis in the Membrane

Triazoles are part of a group of fungicidal molecules called IDM (demethylation inhibitors). They act by disrupting the biosynthesis of the cell membranes of the fungus. They act on an enzyme called 14 alpha-demethylase or CYP51; thus, they prevent the synthesis of ergosterol, one of the main constituents of fungi cell membranes resulting in the increase of membrane permeability and cell disintegration, causing premature death of the pathogen [11]. Several active ingredients exist: bitertanol, bromuconazole, difenoconazole, epoxiconazole, flutriafol, hexaconazole,

myclobutanil, penconazole, propiconazole, prothioconazole, tebuconazole, tetraconazole, triadimenol, triticonazole, flusilazole, and cyproconazole.

Other fungicides belonging to other chemical families also act on the synthesis of sterols; these are triforine, prochloraz, fenhexamid, spiroxamine, and fenarimol.

4.4 Fungicides Affecting the Biosynthesis of Amino Acids or Proteins

It is essentially the family of anilinopyrimidines (cyprodinil, mepanipyrim, and pyrimethanil) whose primary target is not known.

4.5 Fungicides Acting by Contact: Multi-sites

Inorganic active substances: They account for a large part, in tonnage, of the fungicides used. They are active especially at the stage of germination, in prevention. These are sulfur, polysulfides, and copper derivatives (copper sulfate, copper oxychloride).

Dithiocarbamates: They are active mainly in prevention, by inhibiting the germination of the spores of many fungi, and are used in the treatment of aerial parts, seeds, or soils. They must be applied often because they are rapidly hydrolyzed and not systemic [12]. Examples are mancozeb, maneb, ziram, zineb, thiram, propineb, and metiram.

Phthalimides: They are not volatile or water-soluble. They act preventively by inhibiting the germination of fungal spores; they are systemic fungicides that appeared in the early 1950s. Their characteristic group S-CCl3 on nitrogen is responsible for their interaction with cell thiols. Their spectrum of action is quite broad; they are not persistent in the environment, for example, captan and folpel.

Chloronitriles: Chlorothalonil is a broad-spectrum anti-fungal, inhibiting enzymatic reactions in fungal spores. Non-water-soluble and nonvolatile, its persistence in soils is quite important (up to 3 months) and is very toxic to fish. It is used on the aerial parts of many crops and in some xyloprotective products [13].

5 Insecticides

The major chemical families of compounds with insecticide activity, sometimes also acaricide, anti-arachnid, and nematicide, are organochlorines, organophosphorus, carbamates, and pyrethroids. Other compounds are also widely used, such as rotenone, fipronil of the phenylpyrazole family, imidacloprid of the neonicotinoid family, and abamectin of the avermectin family. The products are active on the insect either by ingestion and digestive absorption or by contact and absorption at the cuticle or by inhalation.

At the level of the organism to be protected (plant or animal), there are the so-called "contact" products, which are present only at the level of the organ on which they are applied, and the "systemic" or endotherapeutic products, which migrate into the body and protect it completely. Insecticide targets are, depending on the compounds, the nervous system, the biosynthesis of chitin, the production of energy, or the hydration of insects. Hormones that control molts and chemical mediators that allow communication between insects or between insects and plants can also be used [6].

5.1 Insecticides Acting on the Nervous System

Some neurotoxic compounds are axon poisons: organochlorines such as DDT and pyrethroids block the closure of voltage-gated sodium channels, and endosulfan, phenylpyrazoles, and avermectins block the GABA-coupled chlorine channel. Others are synaptic poisons, such as acetylcholine esterase inhibitors (organophosphorus and carbamate), and neonicotinoids, which are irreversible cholinergic receptor agonists. These neurotoxins all cause neuronal hyper-excitation, and their specificity for insects compared to mammals or other animals is more or less strong, so organophosphorus and carbamate can be very neurotoxic for mammals, while avermectins and pyrethroids are less neurotoxic.

5.1.1 Organochlorines

Organochlorines were the first organic insecticides used, with DDT (dichlorodiphenyltrichloroethane), marketed in 1942. It played a very important role in the fight against the vectors of typhus, malaria, and cholera. Characterized by a very low toxicity for mammals, these compounds, very persistent, accumulate in fats and along the food chain (bioaccumulation). Compounds such as lindane (gamma-hexachlorocyclohexane) and methoxychlor, slightly less lipophilic, were then synthesized [6]. Most organochlorines act as modulators of sodium channel (DDT, aldrin, lindane, methoxychlor, etc.). The use of this type of organochlorines in agriculture has been banned in the world since the years 1960–1970.

5.1.2 Organophosphorus

Organophosphorus insecticides, obtained from the search for chemical weapons in the 1930s, were marketed from 1942 with the very toxic and quickly abandoned TEPP (tetraethyl pyrophosphate) and then the parathion in 1944 [13]. They have gradually replaced organochlorines, which are too persistent.

The toxic action of insecticides or acaricides of organophosphorus is due to the selective inhibition of acetylcholinesterase. The mites have developed a resistance to most organophosphorus compounds causing the withdrawal of their use.

They can be classified into three groups: aliphatics (e.g., malathion), aromatics (e.g., parathion), and heterocyclics (e.g., phosalone), or according to the presence of sulfur atoms into: organophosphorus compounds (e.g., dichlorvos), thio-organophosphorus compounds (e.g., diazinon), and dithio-organophosphorus compounds

(e.g., malathion) [13]. Aromatic and sulfurous derivatives are the most persistent; most compounds are however not persistent in the environment (they are hydrolyzed quickly). They do not accumulate in living organisms either. They are generally not very volatile, except chlorpyrifos, dichlorvos, and fenthion, and very lipophilic. They act by contact and by ingestion, sometimes also by inhalation, on a large variety of insects and worms. Some have a systemic spread in the plant or animal.

5.1.3 Carbamates

Carbamates, and more particularly *N*-methyl aryl carbamates, are potent insecticides; the first molecule, dimetan, was synthesized by Ciba-Geigy in 1945, and then carbaryl, still widely used, by Union Carbide in 1957 [13]. *N*-methyl carbamates of oxime, such as aldicarb, are also nematicides and miticides. Most are less volatile and fat-soluble (except pirimicarb, which is highly water-soluble). These products have a broad spectrum of action; some are systemic. They act by contact and by ingestion, sometimes also by inhalation, on a large variety of insects and worms. Carbofuran and aldicarb, used to treat soil, are among the most dangerous pesticides for mammals, while carbaryl and propoxur are very well tolerated and incorporated into many household products.

5.1.4 Pyrethroids

Pyrethroids, synthesized later, have the advantage of being nonpersistent and not very toxic for mammals; they are chemically similar to pyrethrum, derived from plants of the family Asteraceae. The latter is a mixture of esters of pyrethric and chrysanthemic acids, two derivatives of cyclopropane carboxylic acid. It is a diverse group, which includes allethrins, tetramethrin and resmethrins which are relatively photolabile compounds, and also more stable and persistent halogenated compounds: permethrin, deltamethrin, fenvalerate and cypermethrin. They are generally classified into two groups, type I (not containing cyano radical CN: permethrin, tetramethrin) and type II pyrethroids (comprising a cyano radical CN: deltamethrin, fenvalerate). Most of the compounds used are esters of 3-phenoxyphenyl alcohol. Very little volatile and very lipophilic, they are almost insoluble in water. They act by contact and ingestion and lead to immediate stupefaction (knockdown effect) and then the death of the unwanted insect; synergists, such as piperonyl butoxide, increase their insecticidal activity. Pyrethroids are widely used in all types of crops and nonagricultural uses but are toxic to bees and aquatic life [14].

5.1.5 Neonicotinoids

Neonicotinoids have become the best-selling insecticide class in the world, used to control biting-sucking insects, some beetles, and Lepidoptera [15]. The first neonicotinoid on the market, imidacloprid, has the distinction of being more selective for insects than for mammals [16]. Neonicotinoids are the only insecticides with three modes of application: treatment of the aerial parts of the plant, soil treatment, and coating of the seed. However, their uses are subject to controversy because of the harmful effects they generate on nontarget organisms such as bees and pollinating insects [17, 18].

5.2 Other Insecticides

The insecticides presented below have the advantage of being specific to insects and are very toxic to mammals. We will only present them very quickly.

5.2.1 Insecticides Inhibiting Molting

Benzoyl phenyl ureas, among the recent insecticides, were synthesized from the 1970s; they are contact insecticides and active after ingestion by the insect. Hexaflumuron, lufenuron, and diflubenzuron act by inhibiting chitin biosynthesis, the main component of the insect cuticle which disrupts molting. They also have ovicide action.

Juvenoids are compounds that mimic the action of juvenile hormones of insects: when the cerebral secretion of these hormones ceases, the larvae can be transformed into adults. Under the action of juvenoids, the insect remains immature and cannot reproduce. This group includes hydroprene, methoprene, pyriproxyfen, and fenoxycarb; they are also called growth regulators.

5.2.2 Insecticides and Acaricides Acting on Respiration

This group of pesticides contains mainly stannic derivatives which are specific acaricides; they act by contact and ingestion by inhibiting the oxidative phosphorylation at the level of the mitochondria; the most well-known acaricides in this group are azocyclotin, cyhexatin, and fenbutatin oxide.

6 Fungicides and Insecticides Authorized on Fruits and Vegetables

The production of fruits and vegetables is often confronted with biotic stresses exerted by different bio-aggressors (insect pests, fungal and bacterial diseases, weeds, etc.). These bio-aggressors cause considerable losses: yield decreases and deterioration of the quality of fruit or vegetables at harvest and storage. Crop losses may be quantitative or qualitative [19]. Quantitative losses result from reduced productivity, leading to a smaller yield. Qualitative losses from pests may result from reduced nutritional content, reduced market quality, reduced storage characteristics, or contamination of the harvested product with pests, parts of pests, or the toxic products of pests (e.g., mycotoxins from plant-parasitic fungi) [20].

In order to ensure sufficient production of fruits and vegetables for a growing population, agriculture often uses pest control through the use of pesticides; these products remain in most cases the most effective means and the most easy to handle and allow better optimization of yields.

6.1 Fungicides and Insecticides Most Authorized on Fruits

Fruit production can be attacked by several fungal and bacterial diseases, among which we can mention late blight, powdery mildew, peach leaf curl, scab, fire blight

(*Erwinia amylovora*), and monilia. Several fungicidal molecules are authorized all over the world to prevent or treat these diseases; these fungicides can be of the same chemical families with the same mode of action or of different chemical families with the same or different modes of action. The existence of several pesticides to treat the same disease or the same insect is very important in order to avoid the problems of resistance.

The most common fruit pests are aphids, psyllids, mites, cochineal, thrips, and leafhoppers.

The following table (Table 1) summarizes the list of fungicides and insecticides most authorized for each type of fruit [21, 22].

6.2 Fungicides and Insecticides Most Authorized on Vegetables

The most common diseases found on vegetables are mildew, seedling blight, *Alternaria*, *Rhizoctonia*, and fusarium wilt, while the most harmful pests are mites, codling moth, leaf miner, aphids, moths, and Colorado potato beetle. Table 2 gives the most common diseases and pests of vegetables as well as the fungicides and insecticides authorized to control them.

7 Toxicological Risks of Pesticides

The presence of pesticides in the various compartments of the environment results mainly from the intentional application of these products on crops and forests (spreading or spraying) as part of the fight against bio-aggressors or for other uses (domestic, public health, fight against vector-borne diseases, etc.) but also unintentionally following accidents related to manufacturing, transport, and storage. Pesticides in the environment cause different types of pollution that can have negative effects on living organisms.

For humans, apart from occupational exposure, exposure to pesticides is indirect from their environment and due to the presence of these toxic substances in the natural environment, food, and drinking water [3].

Multiple routes of exposure to pesticides can be encountered in humans; occupational exposure is mainly for people handling the products. Farmers are a particularly exposed population; in agriculture, the exposure is mainly cutaneous and rarely oral; the absorption of pesticides by the skin is revealed as the most significant route [23]. One study showed that wearing a protective suit did not completely prevent operator skin contamination with dithiocarbamate fungicides [24]. In several epidemiological studies, there has been a significant association of pesticide use among farmers and the occurrence of certain types of cancer such as cancers of the lips, prostate, stomach, kidneys, brain, but also most cancers of the hematopoietic system (leukemia, multiple myeloma and especially non-Hodgkin's lymphoma), cutaneous melanoma and soft tissue sarcomas [25–34].

Table 1 Fungicides and insecticides most authorized on fruits

Crop	Authorized pesticides	Diseases or pests
Grapes	**Acaricide insecticides**: cypermethrin, acrinathrin, bifenthrin, clofentezine, cyhexatin, fenbutatin oxide, diclofop, dimethoate, fenpyroximate, hexythiazox, propargite, pyridaben, lambda-cyhalothrin, pirimicarb, chlorpyrifos, acephate, beta-cypermethrin, diafenthiuron, esfenvalerate, fenvalerate, fenitrothion, imidacloprid, malathion, methomyl, spirodiclofen, bromopropylate, flufenoxuron, fenoxycarb, lufenuron, indoxacarb, diazinon, phosalone, trichlorfon, spinosad, tetradifon, tau-fluvalinate	Leafhopper, mite, flea beetle; borer, budworm, cochineal
	Fungicides dimethomorph, pyriproxyfen, captan, famoxadone, cymoxanil, metalaxyl, tebuconazole, copper, chlorothalonil, metiram zinc, mancozeb, maneb, azoxystrobin, difenoconazole, cyprodinil, procymidone, benomyl, thiophanate-methyl, iprodione, carbendazim, fludioxonil, thiram, fenhexamid, ziram, sulfur, zoxamide, tolylfluanid, fosetyl-aluminum, folpel, propineb, zineb, benalaxyl, iprovalicarb, fluopicolide, fenamidone, hexaconazole, penconazole, triadimenol, boscalid, pyraclostrobin, tetraconazole, trifloxystrobin, myclobutanil, spiroxamine, kresoxim-methyl, dinocap, difenoconazole, bromuconazole, pyrimethanil, triflumizole, mefenoxam, fenbuconazole, pyrimethanil, flusilazole, ofurace, fenarimol	Late blight, black rot, excoriose, powdery mildew, gray rot
Apples	**Acaricide insecticides**: azocyclotin, abamectin, amitraze, fenpyroximate, pyridaben, tebufenpyrad, endosulfan, alphamethrin, cypermethrin, acrinathrin, bifenthrin, clofentezine, cyhexatin, fenbutatin oxide, diclofop, dimethoate, hexythiazox, propargite, azinphos-methyl, carbaryl, chlorpyrifos, dimethoate, lambda-cyhalothrin, pirimicarb, deltamethrin, diflubenzuron, acephate, beta-cypermethrin, diafenthiuron, esfenvalerate, fenvalerate, fenitrothion,	Mites, codling moth, leaf miner, aphids, leaf roller

(*continued*)

Table 1 (continued)

Crop	Authorized pesticides	Diseases or pests

	fenazaquin, fenbutatin oxide, hexythiazox, pyriproxyfen, endosulfan, lambda-cyhalothrin, carbofuran, pirimicarb, rotenone, diclofop, formetanate	
	Fungicides: iprodione, mancozeb, maneb, thiophanate-methyl, myclobutanil, thiram, cuivre, fosetyl-aluminum, azoxystrobin, bupirimate, hexaconazole, dinocap, penconazole, mefenoxam, carbendazim, cyprodinil, fludioxonil, diethofencarb, fenhexamid, mepanipyrim, procymidone, pyrimethanil, vinclozolin, metalaxyl	*Alternaria*, anthracnose, late blight, powdery mildew, gray mold, verticillium wilt, *Zythia*
Melon	**Acaricide insecticides**: bifenthrin, abamectin, acrinathrin, clofentezine, cyhexatin, diclofop, fenazaquin, hexythiazox, buprofezin, deltamethrin, methomyl, pymetrozine, cyromazine, carbofuran, alphamethrin, esfenvalerate, lambda-cyhalothrin, pirimicarb, rotenone, tau-fluvalinate, acrinathrin, formetanate	Whitefly, leaf miner, aphids, borer, thrips
	Fungicides: chlorothalonil, mancozeb, maneb, thiophanate-methyl, myclobutanil, cuivre, carbendazim, azoxystrobin, benalaxyl, fosetyl-aluminum, mefenoxam, propamocarb HCl, bupirimate, dinocap, fenarimol, fenbuconazole, penconazole, sulfur, triadimefon, triadimenol, diethofencarb, procymidone, vinclozolin	Anthracnose, cladosporiosis, late blight, powdery mildew

Several studies have shown neurological damage; thus, an increased risk of Parkinson's disease associated with the exposure of insecticides or herbicides has been shown, and this risk would be higher if exposed to organochlorines, organophosphorus, or carbamates [35]. Baldi et al. [36] showed in a study in France that occupational exposure to a pesticide was associated with twice the risk of developing Alzheimer's disease. It has also been associated with mild cognitive dysfunction and risk of dementia in Parkinson's [37].

In the event of acute exposure, pesticides are responsible for nearly three million serious poisonings and 220,000 deaths each year worldwide [38].

The entire population may be exposed to pesticides for domestic use but especially to residues of these pesticides through its environment (water, air, suspended particles, dust) and its diet. WHO experts say pesticide contamination of food is by

Table 2 Fungicides and insecticides most authorized on vegetables

Crop	Authorized pesticides	Diseases or pests
Beets	**Acaricide insecticides**: bifenthrin, cyfluthrin, deltamethrin, lambda-cyhalothrin, diazinon, carbofuran, imidacloprid, aldicarb	Mites, flea beetle, leafhoppers, aphids, atomaria
	Fungicides: bitertanol, cyproconazole, tetraconazole, difenoconazole, flusilazole, flutriafol, mancozeb, maneb, sulfur, iprodione	*Cercospora*, powdery mildew, phoma, pythium, ramulariosis, rust
Potatoes	**Acaricide insecticides**: alphamethrin, carbosulfan, ethoprophos, beta-cyfluthrin, chlorpyrifos, cypermethrin, deltamethrin, endosulfan, esfenvalerate, lambda-cyhalothrin, phosalone, pyrimicab, azinphos-methyl, tefluthrin, malathion	Wireworms, Colorado potato beetle, aphids, moths
	Fungicides: mancozeb, imazalil, benalaxyl, chlorothalonil, copper, cymoxanil, probineb, fluazinam, folpel, thiophanate-methyl, iprodione, thiabendazole, flutolanil, maneb, captan, mandipropamid, famoxadone, fenamidone, propamocarb HCl, zoxamide, benalaxyl, metalaxyl, dimethomorph, difenoconazole, iprovalicarb, azoxystrobin, ofurace, mefenoxam, fentin hydroxide, fluopicolide	*Alternaria*, fusariosis, silvery scab, mildew, phoma, rhizoctonia
Olive	**Acaricide insecticides**: carbaryl, methidathion, fenoxycarb, deltamethrin, dimethoate, fenthion, diazinon, lambda-cyhalothrin, malathion, trichlorfon, phosmet, chlorpyrifos	Cochineal, olive fly, psyllid, ringworm
	Fungicides: copper, mancozeb, difenoconazole, dodine, probineb	Peacock's eye, bacteriosis
Carrot	**Acaricide insecticides**: benfuracarb, carbofuran, chlorfenvinphos, diazinon, diethion, endosulfan, lambda-cyhalothrin, pirimicarb, rotenone, taufluvalinat	Fly, aphids
	Fungicides: azoxystrobin, chlorothalonil, difenoconazole, hexaconazole, iprodione, carbendazim, mancozeb, myclobutanil, pyrimethanil, mefenoxam, copper, dinocap, sulfur	*Alternaria*, mildew, powdery mildew, sclerotinia
Celery	**Acaricide insecticides**: lambda-cyhalothrin, cyromazine, chlorfenvinphos, diazinon, diethion	Leaf miner, aphids, flies

far the most important route of exposure. Risk assessments attribute 90% of exposure to food versus 10% to water [3].

The chronic exposure of the population to pesticides is related to various neurobehavioral [39] and neurodegenerative disorders [36] (such as Parkinson's disease and Alzheimer's disease) but also disorders of the peripheral nervous system (neuromotor and neurosensory disorders) [40]. Other studies have shown a link between environmental exposure to pesticides and the risk of hormone-dependent cancers such as breast cancer [41].

Some pesticides are identified as endocrine disruptors. They act by interfering with natural hormones because of their high binding potential with estrogenic and androgenic receptors [42]. They can also interfere in the synthesis, metabolism, and elimination of these hormones causing a decrease in their concentration; this is the case of cyhalothrin and fipronil that can inhibit the production of thyroid hormones [43]. They can also affect spermatogenesis reducing male fertility [44].

The exposure of the child to pesticides can take place very early, in utero via the placenta following the exposure of the mother [45], but also after birth, either directly by exposure to domestic contaminations (pesticides used in the home or garden or living in an agricultural area) or via breast milk and food [46] or indirectly for children of parents professionally exposed (e.g., farmers). It should be noted that diet has been shown to be a major source of exposure of children to organophosphorus pesticides [47].

In children, endocrine-disrupting pesticides are likely to cause developmental abnormalities: low birth weight, fetal death, childhood cancer, cryptorchidism, and hypospadias [48]. Another study by Merhi [3] showed that pesticide exposure is linked to a 10% increase in the risk of developing childhood cancers. The results show a very significant increase in leukemias, non-Hodgkin's lymphomas, and Ewing's sarcomas. For all cancers, the "prenatal" exposure period would appear to be the most critical in that it showed a 36% increase in all cancers [3].

8 Exposure to Pesticide Residues Through Food and Risk Assessment

Pesticide residues have become the permanent concern of the scientific community and public health organizations around the world. In order to guarantee consumer safety, very strict international, community, and national legislation has been put in

place. Monitoring of pesticide residues is a key tool to ensure compliance with regulations and to monitor compliance with good agricultural practices [49]. Toxic residue obviously means any residue that may be of toxicological significance in the margin of residual doses; there is no toxic compound but rather toxic doses. For this, many highly sophisticated methods have been developed for detecting, identifying, and measuring multi-residues contaminating matrices of different natures [50, 51].

8.1 Pesticide Residues

According to the Codex Alimentarius [52], a pesticide residue is any substance (derivative, metabolite, impurity, etc.) present in food, agricultural products, or animal feed as a result of the use of pesticides.

Indeed, after application, phytosanitary products evolve quantitatively and qualitatively over time. The amount of active substance or its transformation products present in the plant at harvest constitutes the residue. Its importance depends first and foremost on the nature of the product used but also on a number of external conditions such as climate, conditions of use, dose, and, in particular, the time to harvest [1].

8.2 Maximum Residue Limit (MRL)

The MRL is the maximum level of residues found in a crop product following the application of a pesticide in accordance with good agricultural practice (GAP) and therefore the maximum concentration of pesticide residue that is legally permitted or recognized as acceptable on food, agricultural commodity, or animal feed; it is expressed in milligrams of residues per kilogram of foodstuff [53].

Good agricultural practices for an active substance and a given crop correspond to the practice that leads to a residue concentration below the MRL. It usually reflects:

- The respect of the time before harvest
- Compliance with the dose per hectare indicated by the manufacturer
- Compliance with the number of application per season

As a result, the MRL appears as an agronomic standard, which reflects a use of the active substance in line with good agricultural practice and not a toxicological standard. An exceedance of the MRL must be interpreted as a non-compliance with an agricultural practice (generally no respect of the preharvest period).

Codex MRLs are used as national standards by many countries; however, some countries continue to establish their own MRLs or tolerances and impose zero tolerance to residues of pesticides on imported crops which do not have nationally/regionally agreed-upon MRLs. An example of the variation in MRLs for some pesticides in grapes is shown in Table 3 [54].

Table 3 Comparison of Codex and national/regional MRLs ($mgkg^{-1}$) for grapes

Pesticide	Codex	EU	Japan	USA
Captan	None	3	5	50
Chlorpyrifos	0.5	0.5	1	0.5
Dimethoate	1	0.02	1	2
Endosulfan	1	0.5	1	2
Myclobutanil	1	1	2	1
Spinosad	0.5	None	0.5	0.5

8.3 Acceptable Daily Intake (ADI)

It is the amount of a chemical present in the diet, which can be ingested daily by the consumer throughout his life without adverse effects on his health. It is calculated on the basis of toxicological studies from NOAEL (no-observed-adverse-effect level) observed in animals, divided by a safety factor taking into account intraindividual variability, interspecies variability, uncertainty associated with experimental protocols, and, if necessary, the nature of the effects of the substance. If available, data from epidemiological studies in humans can also be used [55]. ADIs are set by scientific assessment organizations at the international (JMPR: joint meeting of pesticide residues FAO/WHO Expert Committee), community (EFSA: European Food Safety Authority), or even national level. The ADI is used for the evaluation of food additives, pesticide residues, and veterinary antiparasitics. It is expressed in milligrams of substance per kilogram of body weight and per day (mg kg^{-1} bw day^{-1}).

8.4 Acute Reference Dose (ARfD)

It refers to the maximum amount of active substance (expressed as mg of active substance per kg of body weight) that can be ingested by the consumer for a day or less, in food or drinking water, with no adverse health effects. It is calculated from a no-observed-adverse-effect level (NOAEL) and a safety factor. The NOAEL chosen for the calculation comes from the most appropriate study on a sensitive and representative animal species. The safety factor takes into account intra- and interspecies variability and the nature of the effects of the substance.

9 Analytical Methods Applied to the Research of Pesticide Residues

Pesticide residues in foods have received a great deal of attention as an important element in food safety, and as a result, national and international laws have become stricter in respecting MRLs. Monitoring residue levels in foods requires reliable methods of analysis.

Nevertheless, pesticides are generally present at very low concentrations in the environment and in food. Their number is high, and they are of different physicochemical natures. Research and quantification of their residues are a permanent challenge and require the implementation of highly sensitive and reliable multiresidue analysis methods [56]. Several methods of analysis exist, and their choice depends on the nature of the pesticides studied and the targeted matrices.

9.1 Sample Preparation

The analysis of pesticide residues in fruits and vegetables consists of sample preparation and instrumental determination. Although analytical instruments have long been developed, detector background noise, detection limits, and final quantification are often influenced by matrix interference [57]. Thus sample preparation is the critical step for an efficient and accurate analysis of traces of pesticide residues [58]. The purpose of sample preparation is to isolate minute quantities of the analyte from a large quantity of complex matrices and to eliminate interference from the food matrix as much as possible.

The process of sample preparation typically includes sampling/homogenization, extraction, and purification. Traditional extraction methods, especially liquid extraction, have been widely used in the analysis of pesticide residues; however, these methods are laborious and consume a lot of time and solvents and are subject to analyte losses. Thus, new extraction and purification methods are introduced in the field of analyses of pesticide residues in foods [59]. These are supercritical fluid extraction (SFE), pressurized liquid extraction (PLE), microwave-assisted extraction (MAE), ultrasound-assisted extraction (UAE), solid-phase extraction (SPE), solid-phase microextraction (SPME), liquid-phase microextraction (LPME), QuEChERS, etc.

The QuEChERS method (acronym: quick, easy, cheap, effective, rugged, and safe) has become the most widely used technique in pesticide residue extraction in vegetables and fruits. Table 4 illustrates some examples of the use of this method for residue analysis in fruits and vegetables. This method was developed in 2003 by Anastassiades et al. [60], and its simple implementation is done in two short stages of extraction and purification. Its main advantages are to significantly simplify the work of sample preparation in the laboratory and to reduce the use of solvents and glassware. Its cost is low, and it generates small amounts of waste unlike other conventional techniques. This method has a few steps:

– Solid/liquid extraction using acetonitrile (ACN) and manual stirring for 1 min. Acetonitrile can extract a wide range of pesticides and is miscible with water (the moisture content of most fruits is in the range of 80–95%) which gives good penetration into the aqueous fraction samples, also allowing for relatively easy separation in subsequent steps.

Table 4 Examples of application of the QuEChERS method to the analysis of pesticide residues in fruits and vegetables

Pesticides	Matrices	Extraction	Purification	Pesticide determination	Recovery	References
229 pesticides	Lettuce and orange	15 mL ACN	1.8 g $MgSO_4$, 300 mg PSA	HPLC-MS/MS	70–120	[62]
		6 g $MgSO_4$, 1.5 g NaCl		GC-MS		
43 pesticides	Apple, lemon, and lettuce	10 mL ACN 5%	150 mg $MgSO_4$, 50 mg PSA, 50 mg C18,	LPGC-MS/MS	90–110	[63]
		HOAc (v/v)	7.5 mg GCB			
		7.5 g ammonium formate

Table 4 (continued)

Pesticides	Matrices	Extraction	Purification	Pesticide determination	Recovery	References
		+ 1 gNaCl + 4 g $MgSO_4$				
215 pesticides	Vegetables	10 mL MeCN, 4 g $MgSO_4$ + 1 g NaCl	$MgSO_4$:150 mg	LC-MS/MS	70–120%	[71]
			PSA:50 mg	GC-MS/MS		
			C18: 50 mg			

- Addition of salts to promote the separation of phases and the transfer of pesticides to the organic phase; the salts used in the original version of QuEChERS method are NaCl and anhydrous MgSO4. Other salts are used in the modified versions; it is mainly trisodium citrate dihydrate and disodium hydrogen citrate sesquihydrate in the buffered citrate version and sodium acetate in the buffered acetate version.
- Purification on dispersed solid phase. In the case of pesticides in plants, it is composed of a mixture of several phases: grafted silica support octadecyl (C18) and a mixture of primary and secondary amines (PSA).

It should be noted that the QuEChERS method was first developed for pesticide residue research in fruits and vegetables [60] where water content is high; however, several authors have used this method on another matrix with a low water content such as cereals [61].

10 Determination of Pesticides

Once the extraction process is complete, the next step is the analysis of separating, identifying, and assaying isolated substances. Depending on the nature of the pesticides studied, two analytical separation techniques are generally used for their identification and quantification: gas chromatography (GC) and liquid chromatography. These techniques can be coupled to specific or universal detectors.

Mass spectrometry (MS) was coupled with GC in commercial instruments during the 1980s, and they were initially used for qualitative confirmation purposes in pesticide analyzes. In the 1990s, the performance characteristics of the instruments improved to the point that the detection limits were low enough that GC-MS could be used to replace the GC selective detectors for quantitative and qualitative analysis and reduce the need of multiple injections in the GC. By the end of the 1990s, GC-MS had become commonplace in surveillance laboratories, particularly in developed countries [72].

The operating principle of the mass spectrometer is based on the action of an electromagnetic field on the molecules leaving the GC column; the mass spectrometer breaks each molecule into ionized fragments and separates them according to their specific mass to charge (m/z).

11 Monitoring Pesticide Residues in Fruits and Vegetables

Descriptive data on pesticide contamination of fruit and vegetables are derived mainly from official country monitoring programs or from published research.

The majority of the fruits and vegetables samples were positive for at least one pesticide (Table 5). In Poland, a total of 144 samples (of black currants, red currants, raspberries, cherries, strawberries, blackberries, cauliflowers, and broccoli) were analyzed for the determination of 60 pesticides. Residues of 15 fungicides and insecticides were detected in 32% of samples. The percentage of samples with residues above the maximum residue limits (MRL) was 15%. Samples with multi-residues represented 9%. In the report on pesticide residue monitoring elaborated in the UK, residues were found in 79% of sample of fruits and vegetables; the most found residues are fungicides: boscalid and azoxystrobin.

In the USA, no residues were detected in 48% of 3905 samples of fruit and vegetable and 87.3% of samples had violative residues. In Algeria and Kuwait, samples with pesticide residues represent more than 57%. Exceeding of LMRs was observed in 12.5% of samples from Algeria and 21% of samples from Kuwait. In Turkey, detectable residues were found in 62.2% of 1432 samples of fresh fruits and vegetables collected from 2010 to 2012 [73].

Table 6 shows the result of pesticide residue analysis for some crop. A higher number of pesticide residues were found in apple (from 5 to 15) and strawberry (from 6 to 19). In tomatoes, two to nine pesticide residues were found. The number and the nature of residues detected in the same crop vary considerably and depend on the pesticide regulations of each country and also on the method of analysis (the number of pesticides sought).

The percentage of fruit with pesticide residues is higher than that of vegetables in the majority of monitoring programs carried out by the different countries (Fig. 2). Brazilian monitoring programs for pesticide residues in fruits and vegetables showed that 59% of fruit samples contained residues and only 36% of vegetable samples contained those [79]. Similar found was reported in US and EU monitoring programs [77, 80].

12 Risk Assessment Method for Dietary Exposure

The consumer is exposed to pesticides through residues that are found in fruit and vegetable; these residues constitute the liabilities of crop production treatments by pesticides. Alimentation is the bulk of consumer exposure; non-food exposure represents only a small part of total exposure.

The risks for the consumer are very difficult to evaluate because they are – except accidents – very small doses ingested almost daily for a very long time and the disorders they could cause are sometimes minimal and not taken in count, so it is very difficult if not impossible to make the link of cause and effect; it is essentially for this reason and for others already mentioned about the exposure of operators that epidemiological surveys are very difficult to implement and are therefore extremely rare.

Table 5 Results of monitoring residues in fruits and vegetables found in published works

Country	Sample number	Sample identity	Number of analyzed pesticides	Samples with residues (%)	Samples with multi-residues (%)	Sample with residues above LMR (%)	Number of detected residues (most found)	References
Poland	144	Black currants, red currants, raspberries, cherries, strawberries, blackberries, cauliflowers, and broccoli	60	32	9	15	15 (carbendazim, acetamiprid)	[74]
UK	62	Apple, banana, carrot,, raisin, strawberry, sugar snap pea, sweet pepper, and tomato	More than 300	79	66	0	42 (boscalid, azoxystrobin)	[75]
Kuwait	150	Tomato, bell pepper, eggplant, cucumber, zucchini, cabbage, carrot, potato, strawberry, watermelon, apple, and grapes	34	58	42	21	16 (imidacloprid, deltamethrin)	[76]
USA	3905	Fruits and vegetables	≈400	52.11	/	8.73	207 (imidacloprid, chlorpyrifos)	[77]
Algeria	160	Apples, pears, plums, peaches, nectarines, grapes, figs, apricots, strawberries, tomatoes, lettuce, potatoes, zucchini	10	57.5	32.5	12.5	08 (lambda-cyhalothrin, metalaxyl, and chlorpyrifos)	[78]

Table 6 Result of pesticide residues in some kind of fruits and vegetables found in published works

Country [reference]	Crop	Pesticides analyzed	Sample with residues	Sample with multi-residues	Residues detected	Sample with residue above LMR
UK [75]	Apples (11)	360	11	11	Boscalid, captan, chlorantraniliprole, cyprodinil, dodine, dithiocarbamates, dithianon, flonicamid, fludioxonil, indoxacarb, methoxyfenozide, myclobutanil, pyraclostrobin, thiacloprid, trifloxystrobin	0
	Strawberries (06)	358	6	6	Boscalid, bupirimate, cyprodinil, dimethomorph, ethirimol, fludioxonil, fenamidone, fenhexamid, fenpyrazamine, fluopyram, mepanipyrim, myclobutanil, penconazole, pyraclostrobin, pyrimethanil, quinoxyfen, tebufenpyrad, thiacloprid, trifloxystrobin	0

12.1 Evaluation of Long-Term Exposure to Residues (Chronic Risk)

For an active substance, it is important to verify that the quantities of residues that an individual is likely to find daily in his diet do not exceed the toxicological reference standards of the acceptable daily intake (ADI) and the dose of acute reference (ARfD).

The theoretical long-term exposure of a consumer to a pesticide is evaluated by calculating theoretical maximum daily intake (TMDI) which makes it possible to verify that the quantity potentially ingested each day by a consumer is lower than the ADI.

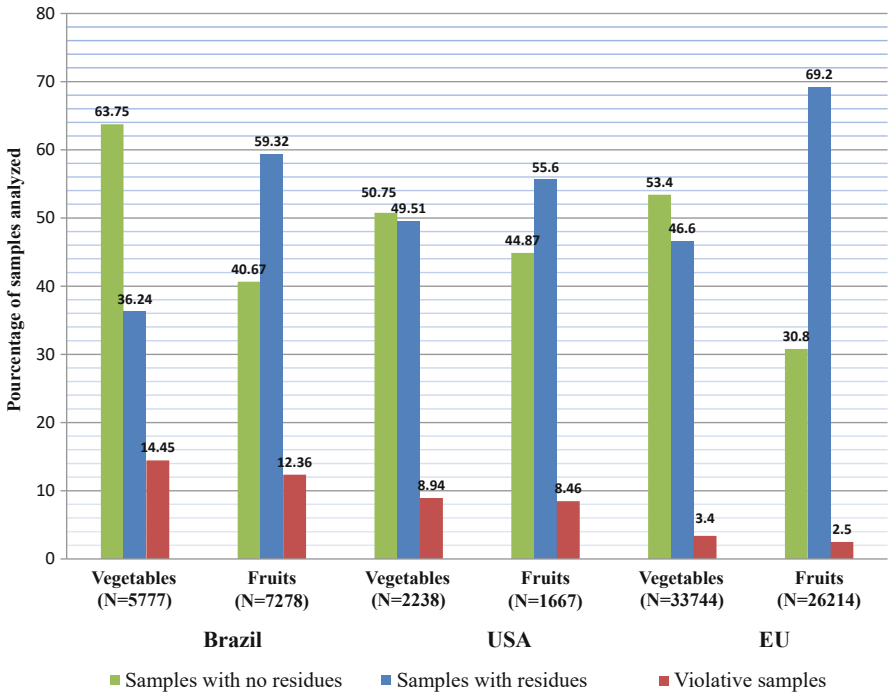

Fig. 2 Graphic presentation of pesticide residue monitoring results in Brazil, the USA, and EU

The TMDI is calculated as the sum of the daily average individual consumptions multiplied by the MRLs; it can be summarized by the following formula:

$$\text{TMDI} = \sum \text{MRLi} \times \text{Fi}$$

MRLi is the maximum residue limit for a given food commodity, and Fi is the average consumption of that food commodity per person [81].

This calculation is clearly maximalist because it is based on the assumption that all foods have residue levels equivalent to the MRLs. In reality, it must be considered that only a small percentage of food displays such levels. In 2008, according to the European Food Safety Authority (EFSA), 3.5% of the 70,000 samples analyzed for about 200 types of food exceeded the MRLs, compared to 4.2% in 2007 [82].

This calculation also recognizes that the entire crop is treated and that there is no reduction factors related to household or industrial processes during food preparation. If these studies lead to results far removed from reality, they still provide clues to identify priorities for food security and public health [55].

Recently, surveys that take into account actual data from pesticide concentration in commodities are being put in place and provide an image closer to reality. In this case, the long-term exposure is evaluated by calculating the estimated long-term dietary intake (ELTDI).

The ELTDI is determined by considering that all the food consumed daily is contaminated at the average level observed after the results of the quantification of pesticide residues; it is calculated according to this formula:

$$\text{ELTDI} = \Sigma\ (\text{RLi} \times \text{Fi})$$

RLi = the average residue concentration in a given commodity (mg kg^{-1})
Fi = the average daily consumption of this commodity per person (kg day^{-1})

12.2 Evaluation of Short-Term Exposure to Residues (Acute Risk)

The assessment of acute (short-term) exposure is based both on extreme food consumption and the highest residue level detected. In many studies, acute exposure was calculated only for pesticides exceeding the MRLs [83].

International estimated short-term intake (IESTI) values were calculated according to the WHO guidelines [84]. Depending on the food commodity, two groups were identified:

Group 1: It is the case where the residue in a composite sample reflects the residue level in a meal-sized portion of the commodity. This case shall apply to the commodity with a unit weight <25 g (e.g., strawberry, cherry).

$$\text{IESTI} = (\text{LP} \times \text{HR})\ \text{bw}^{-1}$$

Group 2: Meal-sized portion might have a higher residue level than the composite sample, when unit weight of a commodity is ≥25 g.

Case 2a: Unit weight U of a raw commodity is less than a large portion weight (e.g., apple, pear, peach).

$$\text{IESTI} = (\text{U} \times \text{HR} \times \text{v} + (\text{LP} - \text{U}) \times \text{HR})\ \text{bw}^{-1}$$

Case 2b: U is higher than a large portion weight (e.g., watermelon)

$$\text{IESTI} = (\text{U} \times \text{HR} \times \text{v})\ \text{bw}^{-1}$$

where LP represents highest large portion reported at the 97.5th percentile of eaters (kg of food day^{-1}), HR highest residue (mg kg^{-1}), bw body weight (adult = 60 kg, children = 15 kg), U unit weight of the edible portion (in kg), and v variability factor which is applied to the composite residue ($v = 7$ for a unit weight between 25 and 250 g, $v = 5$ for unit weight >250 g)

An example of assessment acute (short-term) exposure is given on Table 7.

Potential consumer short-term risk was identified for two pesticide/commodity combinations for children (chlorpyrifos/apple: 558.5% of ARfD; chlorpyrifos/

Table 7 Result of short-term exposure to chlorpyrifos residues

Pesticide residue	Crop	ARfD (mg kg^{-1} bw^{-1})	HR (mg kg^{-1})	IESTI children (mg kg^{-1} bw^{-1})	IESTI adult (mg kg^{-1} bw^{-1})	IESTI children/ ARfD (%)	IESTI adult/ ARfD (%)
Chlorpyrifos	Peach	0.1	0.747	0.0472	0.0138	47.2	13.8
	Apple		9.830	0.5585	0.2378	558.5	237.8

grapes, 147.75% of ARfD) and for one pesticide/commodity combination (chlorpyrifos/apple: 237.8%) for the adult population [78].

The exceedances of the ARfD are due mainly to the exceeding of the MRLs; these identified pesticide-commodity combinations should lead to an intensification of the controls of pesticides use and to the identification of the origin nonconformities and the implementation of corrective measures.

13 Conclusions

The use of pesticides in fruit and vegetable culture has become a common practice, and it is indispensable for intensive production. Unfortunately, this practice is not without risks; in fact, these pesticides generate residues that accumulate in fruits and vegetables, and they can constitute a danger to the consumer health. The pesticides used in fruit and legumes are numerous and are from different chemical families with also different modes of action. Among them, there are neurotoxin insecticides, endocrine disruptors, and others suspected to cause cancer. Residue analysis was performed using multi-residue research ensuring a rapid determination and sufficient sensibility. Many national and regional monitoring programs found that pesticide residues and multi-residues were detected in the majority of vegetables and fruits. Therefore, it is indispensable to know the degree of contamination of fruits and vegetables through a multi-residue research and to assess the risk of chronic and acute exposure for the general population and for the most vulnerable populations such as children and pregnant women.

Banana and Plantains: Improvement, Nutrition, and Health

59

Siddhesh B. Ghag and Thumballi R. Ganapathi

Contents

Abstract

Banana is one of the oldest cultivated plant known for its dietary and medicinal properties. Banana is grown in the tropical and subtropical regions of the world and constitutes the staple food of the people. They are classified as dessert or sweet bananas and cooking bananas or plantains depending on whether they can be eaten raw or not. Banana plant parts such as the roots, pseudostem, fruits, and inflorescence is used in some or the other way and therefore it is rightly called as the "Kalpatharu" in India. Banana and plantains contain important bioactive compounds such as phenolics, flavonoids, carotenoids, biogenic amines, sterols,

and antimicrobial compounds which make bananas a perfect functional food for health improvement. Presently, research is focused on exploring and identifying compounds, refining the techniques of isolation and purification, and using it in modern medicines. Moreover, bananas are also being used as a platform to produce and accumulate important nutrients like vitamins and minerals by biofortification strategies.

Keywords
Bananas · Bioactive compounds · Carotenoids · Dopamine · Antimicrobials · Biofortification

1 Introduction

Banana and plantains belong to the order Zingiberales and genus *Musa* [1]. These are large, perennial, monocotyledonous herbs that arise from the underground rhizomes. The fruits are usually elongate, cylindrical, and curved at the ends enclosed in thin or thick skin with color ranging from yellow to green. The fruits of dessert banana are sweet whereas those of plantains are starchy. Banana and plantains are listed as the fourth most important crop grown all across the globe along the tropical and subtropical regions [2]. The annual world production of banana was about 113.28 million tons in the year 2016 [3]. India is the largest producer with a production of about 29.124 million tones that accounts approximately one-third of total world production [3]. Banana and plantains are the staple food of the developing regions of Africa and South East Asia. This plant has numerable uses other than being a source of food. Different parts of the plant are used in medicines, preparing beverages, flavorings, clothing, and in various religious and ceremonial practices [2, 4]. Several varieties are grown across the world but only a few of these are categorized as superior ones for international markets. The ones belonging to this category are the Cavendish cultivars namely, Grand Naine, Dwarf and Giant Cavendish, Robusta, etc. Banana is the first solid food recommended for infants and so it is the most practical crop for biofortification programs to eliminate nutrient deficiency that is prevalent in most developing regions [5]. Inherently, hundred grams of raw banana contains 22.84 g carbohydrates, 2.6 g fiber, 64 IU vitamin A, 8.7 mg vitamin C, and 358 mg potassium [6]. Moreover, banana plant parts such as fruit, peel, flower, and stem have been used orally or topically as remedies in folk medicine in Africa, India, Asia, and America for the treatment of ulcers, hyperglycemia, and stomach disorders [7]. Presence of some specific bioactive compounds such as apigenin glycosides, myricetin glycoside, myricetin-3-*O*-rutinoside, naringenin glycosides, kaempferol-3-*O*-rutinoside, dopamine, *N*-acetyl serotonin, and rutin has been reported in different species of *Musa* [8]. Presently, the trend is to identify and characterize unique bioactive compounds demonstrating therapeutic potential. Moreover, deficiency of important nutrients in the diet results in chronic ailments which increase the mortality rate. Supplementation of these nutrients through natural foods is the most viable approach to alleviate nutrient deficiencies. Great progress

has been made in the recent past to identify wild cultivars or biofortify domesticated varieties through biotechnology and generate nutritionally improved food crops [9, 10]. Few banana cultivars which have high market value are cultivated worldwide and grown as monocultures in the major banana growing regions. However, each region has its own set of varieties which are mostly cultivated for domestic consumption. These exotic varieties are source of a few vital nutrients. Such varieties can be identified as supplement food to curb nutrient deficiency. Moreover, the genes responsible for these nutrients in these varieties can be identified and engineered into the Cavendish varieties. This chapter will comprehensively describe the natural bioactive compounds present in bananas and its biofortification by genetic modification imparting health benefits.

2 Bioactive Compounds in Banana and their Health Benefits

2.1 Phenolics

Phenolic compounds such as flavonoids (including flavones, flavonols, and flavanones), anthocyanins, and condensed tannins are present in banana tissues [11–13]. Basically these are involved in defense mechanisms and are known to have health promoting effects. Phenolic compounds act as antioxidants and provide protection against microbial infections thereby contributing towards mitigation of chronic and infectious diseases. The antioxidant activity is attributed to the ability of phenolic compounds to scavenge free radicals or chelate metal ions [14–16]. Thus, addition of natural phenolic compounds to dietary supplements, food components, and drugs has gained importance. Particular phenolic compounds and their derivatives are present at different concentrations in different banana tissues at different points of their growth cycle [17–19]. Anthocyanin pigments such as petunidin, malvidin, pelargonidin, delphinidin, cyanidin, and peonidin have been observed in banana bracts and fruits [20–22]. Condensed tannins are more prominently present in the pulps of unripe fruits of diverse dessert and plantain banana cultivars. Flavonoids, such as apigenin, naringenin, myricetin, kaempferol, and quercetin were found in the sap of dessert banana species [8]. The extract of banana peel has around 29 mg/g as gallic acid equivalents of total phenolic, gallocatechin around 158 mg/100 g dry weight, prodelphinidins of around 3952 mg/kg, and a few hundred mg of flavonol glycosides per kg [23, 24]. There is considerable level of total free phenolics in the pulp ranging from 11.8 to 90.4 mg of gallic acid equivalents per 100 g of fresh weight [25]. There are significant levels of tannins in unripe and ripe banana fruits; however, the levels are lower in the latter than the former. Banana pulp is a rich source of catecholamines such as dopamine which is a strong water soluble antioxidant. Dopamine levels ranged from 80 to 560 mg per 100 g in peel and 2.5 to 10 mg in pulp [26]. Soluble condensed tannins such as epicatechin, epigallocatechin, and gallocatechin-catechin dimer were reported in banana pulp [27, 28]. Banana inflorescence is also a rich source of phenolic compounds such as anthocyanidins, tannins, and other glycosides. The total phenolic content was around 1690 mg

equivalent of gallic acid per100 g of the dry sample [18]. The banana flower extract have a strong antioxidant activity, iron chelation, and antihemolytic activity [29].

2.2 Carotenoids

Carotenoids are noteworthy for their wide distribution and structural diversity. Carotenoids are often described as provitamin A and are 40-carbon terpenoids having isoprene as their basic structural unit. These includes α and β carotenes, lycopenes, lutein, and xanthin; among which α and β carotenes predominate and are easily converted to vitamin A [30, 31]. However, out of the 600 carotenoids identified in nature 50 possess provitamin activity and they exist as red, orange, and yellow pigments in plants and animal tissues, fungi, and algae [31, 32]. Dietary supplements of provitamin A are recommended in the treatment of cancer and eye diseases. Vitamin deficiency is a serious issue among children and women especially in the developing regions of the world. Lack of vitamin A in the diet leads to increased mortality associated with vision, anemia, and normal growth and development. Supplementing vitamin A through natural food sources is still the sustainable approach to alleviate vitamin A deficiency. Banana being the staple food in the developing countries of Asia and Africa, the content of provitamin A was determined in several known cultivars of banana. However, the famous Cavendish cultivar has very low levels of provitamin A content of about 21–70 μg of β-carotene per 100 g of edible portion as compared to other nonpopular varieties such as Fe'i bananas (Asupina) and karat [5, 33–37]. Bananas found in the Micronesia and eastern Africa have higher levels of carotenoids which can be included in the diet as vitamin A supplement [38, 39]. Bananas found in some regions of Australia with yellow or yellow-orange flesh have shown to contain high levels of carotenoids such as Asupina, Kirkirnan, Pisang Raja, Horn Plantain, Pacific Plantain, Kluai Khai Bonng, Wain, Red Dacca, Lakatan, and Sucrier [36]. Edible banana genotypes from Papua New Guinea have the highest levels of β-carotene with values as high as 2594 μg/100 g of the pulp [40]. Indian cultivars such as Red banana and Karpooravalli showed maximum accumulation of carotenoid content in the pulp and peels followed by Rasthali and Hill banana [41]. Another Indian cultivar, Nendran which has orange-colored flesh, has high β-carotene content (1362 μg/100 g) in the edible pulp [42]. There are two isoforms of phytoene synthase gene observed in banana fruits; however, only one isoform is expressed in the edible pulp. Interestingly, a recent report proved that both the isoforms were expressed in the Nendran pulp and thus the increased β-carotene content [42]. The carotenoids content in banana fruit increases during ripening. The mean total provitamin A carotenoids ranged from 560 to 4680 mg/100 g fresh weight when estimated in unripe fruit and was from 1680 to 10,630 mg/100 g fresh weight in ripe fruit [43]. The change of banana peel from green to yellow during ripening is due to change in the contents of chlorophylls and carotenoids. Therefore carotenoids content of banana peel was estimated and was found to be 3–4 μg per gram as lutein equivalent [44]. Yellow banana (*Musa paradisiaca sapientum*) contains around

6.2 mg/g of carotenoid in the peels and was shown to increase the serum retinol levels in mice fed with purified carotenoids from the peels [45]. Xanthophyll compounds such as neoxanthin, violaxanthin, zeaxanthin, and lutein were also detected in banana tissues [46]. Intake of dietary carotenoids is associated with protection against chronic diseases such as certain cancers, cardiovascular diseases, diabetes, inflammatory diseases, arteriosclerosis, and age-related degeneration [38, 47].

2.3 Fatty Acids and Phytosterols

The major lipophilic compounds present in banana include the fatty acids, sterols, and steryl esters. Bananas are very low in saturated fat content and have almost no cholesterol. However, the total omega-6 fatty acids content is doubled than the omega-3 fatty acids content. A total of 0.2–0.4% of fatty acids is present in banana which consists of a mixture of palmitic, oleic, linoleic, and linolenic acids together with lower amount of phytosterol [48–50]. Oliviera et al. [51] identified compounds such as campesterol, stigmasterol, sitosterol and fatty acids, such as palmitic, stearic, linoleic, linolenic, 22-hydroxydocosanoic, 24-hydroxytetracosanoic, and 26-hydroxyhexacosanoic acids in the lipophilic extract (in dichloromethane) of Dwarf Cavendish. Fatty acids are abundantly present in the banana pulp as compared to the peels; however, the phytosterol content is high in peels than in the pulp tissues [52]. β-sitosterol followed by campesterol and stigmasterol are the major sterols found in banana pulp, whereas cycloeucalenone and 31-norcyclolaudenone are abundantly present in the banana peel tissues [52, 53]. Villaverde et al. [54] analyzed the lipophilic extractives of the unripe peel of ten banana cultivars namely "Giant Cavendish," "Chinese Cavendish," "Grand Nain," "Gruesa," "Williams," "Ricasa," "Eilon," "Zelig," "Dwarf Red," and "Silver" and found that the content ranged from 2% to 3%. Cycloeucalenone was the chief sterol identified in peels of "Williams" and "Dwarf Red" varieties. Vilela et al. [49] determined the lipophilic extract from the ripe pulp of banana fruit of the same ten cultivars by gas chromatography-mass spectrometry and showed that fatty acids constitute 68.6–84.3%, whereas sterols are 11.1–28.0% of the total amount of lipophilic components.

Phytosterols have numerous health benefits such as lowering the cholesterol level in the blood, lowering cardiovascular disease, and they also act as immune system modulators and possess anticancer properties [55–58]. A daily intake of 1.6–2 g/day of phytosterols is known to reduce cholesterol absorption from the gut by about 30% and plasma LDL cholesterol levels by 8–10% [56, 59]. Lowering the low-density lipoprotein cholesterol uptake and thereby decreasing its level in the blood lowers the risk of cardiovascular diseases [58]. β-sitosterol and its glycoside complex appears to target specific T-helper lymphocytes, increases T_H1-related cytokines and decreases T_H2-related cytokines, increases lymphocyte proliferation, and improves natural killer cell activity [60]. Moreover, phytosterols have shown to subside overactive antibody responses, and this property can be exploited in numerous disease conditions such as chronic viral infections, tuberculosis, rheumatoid

arthritis, allergies, cancer, and auto-immune diseases to ameliorate clinical manifestations [60, 61]. Phytosterols are described as one of the anticancer compounds in plants known to target cancers of breast, prostate, lung, liver, colon, stomach, and ovary [62]. The precise mechanism of action of these phytosterols on cancer cells is poorly understood; however, it seems to target cancerous cells through multiple ways such as inhibition of carcinogen production, cancer cell growth and multiplication, invasion and metastasis and induction of cell cycle arrest and apoptosis, boosting of immune recognition of cancer, influencing hormonal dependent growth of endocrine tumors, and altering sterol biosynthesis [62–64]. Three phytosterols purified from banana flowers, β-sitosterol, 31-norcyclolaudenone, and (24R)-4α,14α,24-trimethyl-5α-cholesta-8,25(27)-dien-3β-ol, had the inhibitory activity against α-glucosidase and α-amylase and thus are capable in prevention of the diseases associated with abnormal blood sugar such as diabetes [65].

2.4 Amines

Biologically active amines or biogenic amines are nitrogenous compounds formed mainly by decarboxylation of amino acids or by amination and transamination of aldehydes and ketones and may act as either psychoactive or vasoactive. They possess a 3,4-dihydroxyphenyl (catechol) nucleus and are generally called catecholamines. Bananas are a rich source of catecholamines such as dopamine, epinephrine, and norepinephrine which are formed from L-tyrosine [66–68]. Eating bananas has shown to significantly increase catecholamines in the urinary excretion and norepinephrine and dopamine levels in blood and urine [69, 70]. Banana pulp and peel both contains substantial amount of dopamine which has a strong antioxidant activity [26]. Dopamine levels ranged from 80 to 560 mg per 100 g in peel and 2.5–10 mg in ripe pulp of Cavendish banana. Dopamine levels decrease with increased ripening [71]. DOPA was also produced in the in vitro banana cultures supplemented with L-phenylalanine [72]. The catecholamines, epinephrine, and norepinephrine are involved predominantly in the sympathetic control of blood pressure and metabolic processes especially fat and glucose turnover [73, 74]. Dopamine is an important neurotransmitter for controlling behavior and motor functions [75, 76]. Insufficient dopamine can lead to depression, loss of motor control, and lack of motivation to carry out routine tasks. Increasing dopamine directly through dietary sources can help in alleviating these symptoms. Banana being the rich dietary source of dopamine and L-tyrosine, it can be used as a natural food supplement to restore low dopamine levels. Serotonin, another neurotransmitter which is formed from L-tryptophan, is present in appreciable amounts in both pulp and peel of ripe and unripe bananas [77, 78]. Moreover, the serotonin levels in pulp reduced during ripening in Cavendish and "Prata" banana varieties [79, 80]. Few reports claim that increasing dietary serotonin alleviates mood and reduces anxiety; however, dietary serotonin cannot cross the blood brain barrier [81]. Furthermore, banana in addition to serotonin also contains ample L-tryptophan which can be assimilated and converted to serotonin. However, more research is necessary in this

aspect to understand the role of such dietary supplements on brain activity. Bananas contain tyramine (1667 ng/g) which is known to increase blood pressure [71, 82, 83]. Bananas also contain diamines and polyamines such as putrescine, cadaverine, spermine, spermidine which are known to play key role as cytoprotectants in various cellular functions [80, 84, 85].

2.5 Antimicrobial Compounds

Banana plant extract derived from roots, leaves, fruit pulp and peels, inflorescence, and pseudostem have shown to possess antibacterial, antifungal, and antiviral activity [19, 86, 87]. The acetone and methanolic extract obtained from pulp of three banana species Pisang Berangan (*Musa acuminate* AA/AAA), Pisang Mas (*Musa acuminate* AA), and Pisang Nipah (*Musa balbisiana* BBB) demonstrated antibacterial activity against thre Gram-negative bacteria namely, *Pseudomonas aeruginosa* and *Escherichia coli* but not against gram positive bacteria *Staphylococcus aureus* and *Streptococcus mutans.*[88]. The ethanolic extracts of *Musa paradisiaca* L. cv. puttabale leaves showed broad spectrum antibacterial activity against *Bacillus subtilis*, *E. coli*, *P. aeruginosa,* and *S. aureus* with high inhibitory potency against *E. coli* and *S. aureus* [89]. However, [90] showed that the aqueous extracts of *Musa paradisiaca* leaf possess better antibacterial activity than the ethanolic one. The methanolic extracts of *Musa sapientum* L. subsp. *sylvestris* pulp, peel, and seeds were investigated for its antibacterial property against five Gram-positive and eight Gram-negative bacteria wherein the pulp extract showed best antibacterial activity among the three [91]. Ethyl acetate and ethanolic extract of dried pulp and peel of *Musa sapientum* L. subsp. *sylvestris* exhibited antibacterial activity against four Gram-positive and four Gram-negative bacteria whereas only ethyl acetate extract of seeds showed antibacterial activity against the same group of bacteria [92]. In yet another study, ethanolic extracts of *Musa sapientum* peels were effective in inhibiting *Salmonella typhi*, *E. coli*, *Klebsiella pneumoniae*, and *S. aureus* [93]. An alcoholic extract of banana peels was also effective against periodontal pathogens such as *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* [94]. Moreover the decoction of banana peels were used along with chitosan in wound healing management [95]. Tin et al. [96] tested the antibacterial activity of the methanolic extracts obtained from *Musa balbisiana* cv. Saba inflorescence against Gram-positive bacteria (*S. aureus*, *B. cereus*, *Listeria monocytogenes*, and *Brochothrix thermosphacta*) and Gram-negative bacteria (*S. typhimurium*, *S. enteritidis*, *E. coli* O157:H7, *Enterobacter sakazakii*, *Yersinia enterocolitica*, and *Vibrio parahaemolyticus*). The buds and bracts of the inflorescence of Mysore banana (*Musa paradisiaca* cv. *Mysore*) showed a wide spectrum of inhibition against foodborne pathogenic bacteria such as *S. aureus*, *B. cereus*, *L. monocytogenes*, and *Vibrio parahaemolyticus* [97]. The methanolic extract of *Musa acuminata* flower showed antimicrobial activity against bacteria like *S. aureus*, *Proteus mirabilis*, *Bacillus subtilis*, *Micrococcus* sp. and *Salmonella* sp. and fungi like *Aspergillus niger* and *Candida albicans* [98]. The ethanolic extracts derived

from corm tissues of *Musa acuminate* cv. *Grand naine* and *Musa paradisiaca* cv. Puttabale showed significant inhibition against *P. vulgaris*, *P. aeruginosa*, and *S. aureus*; moderate activity against *S. typhi*, *S. paratyphi*, *K. pneumoniae*, and *B. subtilis*; and very less against *E. coli* [99]. Ethyl acetate extract of leaf of *Musa acuminata* Colla, *Musa troglodytarum* L., *Musa sapientum* L., and *Musa paradisiaca* L. displayed antibacterial activity against multidrug resistant clinical pathogens causing nosocomial infection such as *E. coli*, *P. aeruginosa*, *Enterobacter aerogenes*, *K. pneumoneae*, *P. mirabilis*, *Shigella flexneri*, *Citrobacter* sp., *S. aureus* MRSA, and *Enterococcus faecalis* [100]. Methanolic extracts of banana (*Musa sapientum* and *Musa acuminata* colla) peels were shown to contain oils having stearic, palmitic, oleic, and linoleic acids and their methyl esters as well as 2,3-dihydro-3,5-dihydroxy-6-methyl-4H-pyran-4-one, 5-(hydroxymethyl)-2-furancarboxyaldehyde, cyclododecane, dibutyl phthalate, b-sitosterol, sesamin, and episesamin as fatty acids which were speculated to be responsible for the antibacterial activity against *Bacillus* spp., *Pseudomonas* spp., *E. coli*, *S. aureus*, *Streptococcus* spp., *Klebsiella* spp., *Proteus* spp., and *Salmonella* spp. [101]. Aqueous extract of banana pseudostem showed 21 mm diameter zone of inhibition to *Streptococcus aureus* and 17 mm to *P. aerugenosa* [102]. The methanolic extract of pseudostem of *Musa acuminata* showed inhibitory activity against the drug-sensitive and drug-resistant variants of *Mycobacterium tuberculosis* H37Rv at a concentration of 200 μg/mL [103].

Banana tissue extracts show significant antibacterial and antifungal activity owing to the high content of tannins and other phenolic compounds [104, 105]. The ethanol, acetone, and petroleum ether extracts of banana leaves showed inhibition of *Aspergillus terreus* and *Penicillium solitum* growth [106]. The phenolic compounds extracted in acetone from *Musa acuminata* leaves were prepared as a hydrogel formulation which showed strong antifungal activity against *C. albicans* [107].

Banana plant extracts have also demonstrated antiviral activity against important human viruses. The ethanolic extract of *Musa acuminata* inflorescence showed antiviral activity against simple human herpesvirus type 1 and simple human herpesvirus type 2, both resistant to Acyclovir [108]. Many naturally occurring lectins show antiviral activity wherein they specifically bind to the oligosaccharides present on the viral envelope thereby preventing viral entry [109]. BanLec is a jacalin-related lectin isolated from the fruits of *Musa acuminata* that recognizes the high mannose structures and binds to gp120 of human immunodeficiency virus type-1 (HIV-1). Binding of BanLec to gp120 prevents the entry of the HIV-1 into the cells [86]. Besides, BanLec is known to stimulate T-cell proliferation and act as T-cell mitogen which induces the formation of IgG4 antibodies [110–112]. BanLec was also shown to be interacting with insulin receptors on M210B4 cells and induced a mitogen-activated protein kinase (MEK)-dependent ERK signaling in these cells [113]. Another homodimeric fructose-binding lectin was isolated from *Musa acuminata* (Del Monte banana) which was capable of eliciting a mitogenic response in murine splenocytes and inducing the expression of the cytokines interferon-gamma, tumor necrosis factor-alpha, and interleukin-2 in splenocytes. Further,

it also inhibited proliferation of leukemia cells (L1210) and hepatoma cells (HepG2) and the activity of HIV-1 reverse transcriptase [114]. Thus, banana plant waste which includes the roots, pseudostem, fruit peels, flower buds, and leaves are the potential source of bioactive compounds and nutraceuticals which can be extracted, purified, and valorized into value-added products.

2.6 Antioxidant Compounds

It is a well-established concept that plant-based diet reduces oxidative stress related diseases such as cancer, diabetes, obesity, cardiac diseases, and Parkinson's disease [115, 116]. Antioxidants are the compounds which can efficiently scavenge and eliminate free radicals and reactive oxygen or nitrogen species which contribute to such chronic diseases [117]. Banana is a rich source of antioxidants and is known to have a stronger antioxidant activity even in the simulated gastrointestinal extracts in vitro [118]. Banana pulp and peel contains phenolics, flavonols, dopamine, carotenoids, and vitamin C which are the potent antioxidants and known to scavenge free radicals [26, 119–122]. The pulp tissues from *Musa sapientum* (Latundan banana) and *Musa acuminata* (Red Dacca) showed higher radical scavenging activity than *Musa acuminata* (Cavendish banana) [123]. Fifteen banana varieties were evaluated for their antioxidant potential and found that the ripe pulp is more efficient in removal of free radicals as compared to the unripe pulp. Moreover, the antioxidant property was also found to be genotype specific as "Ouro" (AA) cultivar seemed to be superior to the other cultivars analyzed, presenting 95.36% of free radical removal percentage; while "Marmelo" (ABB) was the least efficient in free radical removal [124]. However, the antioxidant potential was found to be higher in ripe peel than in unripe peel in these 15 varieties. Herein the antioxidant property in these varieties was also attributed to the phenolic compounds, carotenoids, vitamin C, and minerals present in the extracts [124]. The total antioxidant activity, radical scavenging activity, and CUPRAC was tested with the methanolic extract of peel, pulp, and seed of *Musa sapientum* L. ssp. *sylvestris* fruits wherein the seed extract showed better free radical scavenging activity compared to the other two extracts [125]. Vijaykumar et al. [126] showed that when normal and high fat diet-fed rats when fed with flavonoids from raw banana have high glutathione and increased catalase and superoxide dismutase activity. This increase was characteristically correlated with the decreased levels of peroxidation products such as malondialdehyde, hydroperoxides, and conjugated dienes. Ethanolic extract of peels from Monthan (AAB), Karpooravalli (ABB) Nendran (AAB), Kadali (AB), Pachainadan (AABS), Poovan (AAB), Rasthali (AAB), Robusta (AAB), and Sevvazhai (AAA) were tested for their free radical scavenging activity by DPPH, ABTS, and lipid peroxidation inhibition assay [127]. Authors speculated that the high ABTS scavenging activity in Rasthali was due to its high total phenol content whereas the high lipid peroxidation inhibition activity of Poovan was because of its high flavonoid content. Another antioxidant, gallocatechin was identified in banana fruits. Abundance of gallocatechin in the peel (158 mg/100 g dry wt) than in pulp (29.6 mg/100 g dry wt) described the

strong antioxidant activity of the banana peel extract, against lipid auto oxidation, than that of the banana pulp extract [23]. Banana inflorescence which is another by-product of banana industry is loaded with bioactive compounds with potent antioxidant activity [128–130]. Ethanolic extracts of banana flowers have maximum antioxidant activity because of the presence of flavonoid and polyphenols [129, 131]. Ethanolic extract of inflorescence of two Indian varieties Poovan and Monthan was tested for their antioxidant potential and correlated with the phenolic, flavonoid, and vitamin E content. The flower sample of Poovan showed a higher phenolic content (13.45 ± 0.35 mg/g) than samples extracted from the Monthan (9.3 ± 0.36 mg/g) variety. Moreover, the flavonoid content was 6.4 ± 0.2 mg/100 g, 5.53 ± 0.42 mg/100 g and vitamin E content was 1.42 ± 0.11 mg/kg, 1.04 ± 0.07 mg/kg for Poovan and Monthan, respectively [130]. Schmidt et al. [18] optimized the extraction method for obtaining high levels of phenolic compounds and flavonoids from inflorescence of *Musa cavendishii*. A temperature of 60 °C, ethanol concentration of 50%, time of 30 min, and stirring extraction without the use of ultrasound gave highest amounts of phenolic compounds and flavonoids and thus best antioxidant activity. Carotenoids and tocopherols present in banana also impart antioxidant properties [35, 36, 132]. All these studies designate banana as an important source for bioactive molecules having strong antioxidant property.

Other health benefits of banana have been summarized in Table 1.

3 Banana and Plantains: Improvement Through Genetic Engineering for Biofortification

Numerous plant foods or bioactive ingredients derived from plants have been investigated for their role in disease prevention and health. Bananas have long been known as a medicinal plant in the Indian medicine and is effective and advantageous in the treatment of several diseases [4]. Banana is also a suitable crop to achieve biofortification of vitamins and minerals. Biofortification can be achieved by conventional breeding or through transgenic approaches. Edible cultivars of banana being sterile, transgenic strategy to achieve biofortification is primarily exercised in this crop. Queensland University of Technology and the National Agricultural Research Organization of Uganda developed transgenic bananas with elevated levels of provitamin A by expressing the phytoene synthase 1 gene [5]. These provitamin A biofortified transgenic Cavendish bananas lines were field tested in Australia to achieve a level of 55 μg/g dw β-carotene equivalent in the fruit. Moreover, biofortification of banana to alleviate minerals deficiency (such as iron and zinc) is also underway in some research laboratories. Transgenic banana cv. Rasthali plants were generated by expressing soybean ferritin gene. These lines showed a 6.32-fold increase in iron accumulation and a 4.58-fold increase in the zinc levels in the leaves [154]. In yet another study, banana ferritin gene *MusaFer1* when overexpressed in transgenic banana plants showed increased levels of iron in the leaf and root tissues [155]. However, the increased content of iron or other minerals in the edible fruit tissues has not been estimated till now. These genes can be driven by fruit

Table 1 Other health benefits of banana

Health benefit	Source material	Activity	Reference
Anticancer	*Musa acuminata* bract	Antiproliferative activity against breast cancer cell line	[133]
	Musa sapientum fruits	Inhibit the growth of colon cancer cell line HCT-116	[134]
	Musa paradisiaca flower	Antiproliferative effect on the cervical cancer cell line HeLa	[135]
Antidiabetic	*Musa nana* Lour peel	Antihyperglycemic activity in alloxan-induced diabetic mice	[136]
	Musa sapientum infructescence stalks	Reduced blood glucose levels in diabetic rats and glucose transport across rat jejuna and Caco-2 monolayers; induced a 50% decrease in their Na^+/K^+ ATPase activity	[137]
	Musa sapientum, Musa acuminata, and Musa acuminate pulp	α-amylase and α-glucosidase inhibitory activities	[123]
	Musa x *paradisiaca* L.	Regulation of glucose homeostasis and the presence of rutin as the major compound having antidiabetic properties	[138]
	"Prata" variety fruits	Antihyperglycemic effects; protection against oxidative damage, the protein oxidation in both the liver and kidneys were prevented in diabetic rats, lipid peroxidation was prevented in the liver	[139]
	Musa sp. var. Nanjangud rasa bale flower	Antihyperglycemic activity via inhibition of α-glucosidase and in antidiabetogenic effect by inhibition of polyol pathway and protein glycation; increasing the hepatic glucose utilization in diabetic rats by stimulating insulin secretion from the remnant β-cells	[140, 141]
	Musa paradisiaca flowers	Reversed the permanent hyperglycemia within a week in alloxan-induced diabetic rats	[142]
	Musa paradisiaca root	Recovery of the serum insulin level in streptozotocin-induced diabetic rat	[143]
Anti-inflammatory	*Musa sapientum* peel	Exhibited the most potent NO inhibitory activity	[144]
	Green dwarf banana flour (*Musa* sp. AAA)	Prevented the glutathione depletion and inhibited myeloperoxidase activity and lipid peroxidation; inhibition of alkaline phosphatase activity	[145]

(*continued*)

Table 1 (continued)

Health benefit	Source material	Activity	Reference
Antiulcer	*Musa sapientum* var. Paradisiaca	Antiulcerogenic and mucosal protective actions	[146]
	Musa sapientum fruit	Antiulcerogenic activity	[147]
	Musa sapientum peel	Antiulcer and ulcer healing activity	[148]
	Musa paradisiaca tepal and peel	Strengthening the gastric mucosa and decreasing the gastric juice acidity	[149]
	Musa sp. Palo and Horn varieties	Gastroprotective effect	[150]
	Musa paradisiaca leaves	Antiulcer activity	[151]
	Musa sapientum Linn.	Reduction in the number of ulcer and ulcer index	[152]
	Musa sapientum var. Paradisiaca	Antiulcer activity and anti-*Helicobacter pylori* activity	[153]

pulp specific promoter to accumulate vital minerals in the banana fruit tissues [156, 157]. Attempts have also been made to increase the anthocyanidin content in transgenic banana plants and decrease proanthocyanidin content by targeting the branch point enzyme anthocyanidin reductase (MusaANR1) by RNA interference [158]. Downregulation of *MusaANR1* gene did not increase the anthocyanin levels in the transgenic plants. Better understanding of the complex network of regulation in pigment production and accumulation in plant tissues would help to achieve the desired goal. Biofortification has a long way to go and is yet to be fully exploited to reap its benefits in near future. However, few proof of principle studies have provided evidences and support its effectiveness [5, 159–161].

4 Conclusion

Bananas and plantains are largely consumed all over the world as a staple food and for medicinal purposes. There are more than 1000 banana cultivars identified around the globe each having a peculiar phytochemical characteristic. The medicinal properties of banana have always been acknowledged in the ancient texts against diseases and ailments. Current research is focused on the identification and characterization of pharmacological active compounds in banana. Banana contains considerable amount of bioactive compounds for health promotion and thus the phytochemical and pharmacological studies of bananas and plantains have received much interest. Many studies have demonstrated and proved the beneficial properties of banana as an antioxidant, anticancer, antidiabetic, and antimicrobial. Although different cultivars and different tissues of banana have demonstrated difference in the production and activity of bioactive molecules, it is necessary to further identify, characterize, and use them for generating biofortified varieties. Moreover, bananas are rich source

of flavonoids, carotenoids, and biogenic amines which can be explored as functional food source against serious ailments. Utilizing banana tissue extracts for medical application needs rigorous understanding of efficacy, safety, and toxicity. However, considering the seminal work published in the last decade on the use of banana plant extracts for series of ailments, one could expect the use of banana bioactive compounds in modern medicine in near future.

Abstract

Residues of veterinary antibiotics in the environment pose a risk for aquatic and terrestrial ecosystems. The degradation of antibiotics in the environment has not been fully characterized in spite of the long periods of persistence of residues in the environment. This chapter reviews the main antibiotics found in water bodies and on land as well as its effects on microbial communities, along with some strategies that have been proposed by global organizations to control the use of antibiotics in the livestock production industry.

1 Introduction

Antibiotics play an important role in the treatment of diseases of food-producing animals (livestock, poultry, and aquaculture), as well as being used as growth promoters [1]. There are approximately 250 types of antibiotics registered for veterinary use [2, 3], including more than 2000 different products that contain over 400 active ingredients [4]. Tetracyclines appear to be the most widely used veterinary antibiotics, followed by sulfonamides and macrolides [5].

In 2010, approximately 63,151 tons of antibiotics were consumed by livestock industry worldwide. This number is expected to increase by 67% as 105,596 tons per year in 2030 [6]. China is one of the main consumers and producers of antibiotics, with the consumption that was 21,000 tons of antibiotics in 2015 [7] (Fig. 1). The majority of veterinary antibiotics are destined for pig production worldwide [8].

The presence of pharmaceutical antibiotics in terrestrial and aquatic systems has increased concerns [9, 10] of the potential risks of promoting bacterial resistance [11, 12] and contamination [13]. In addition, these antibiotic residues may have toxic effects on marine and terrestrial ecosystems due to the potential physiological effects on organisms. These negative effects were not given enough attention in the past; leading to concerns of antibiotics has been primarily on farms use antibiotics [14]. The antibiotic residues are released into the environment through manure and urine [15, 16] either as its original form or as metabolites that have similar biological activities as its original form [17, 18]. Figure 2 shows the typical route of the antibiotics once they enter a farm. Antibiotics are poorly absorbed in the animal's intestine, and approximately 40–90% are excreted as parenteral compounds or metabolites into water or soil [8, 19].

According to different studies, antibiotics can accumulate in the soil for indeterminate periods of time when their entry rate exceeds the dispersion rate [20]. For example, accumulated antibiotics were detected for a period of up to 20 years in Mexican soil [21]. Similarly, antibiotics have been found in the mangrove areas located in the provinces of Thai Binh, Nam Dinh, and Ca Mau and in the forests of Can Gio in Vietnam. It has been reported that 0.73 g kg^{-1} of trimethoprim, 0.82 g kg^{-1} of sulfamethoxazole, and 2.62 g kg^{-1} of norfloxacin were detected in mud samples in these locations [22] as well as in other parts of the world (Table 1).

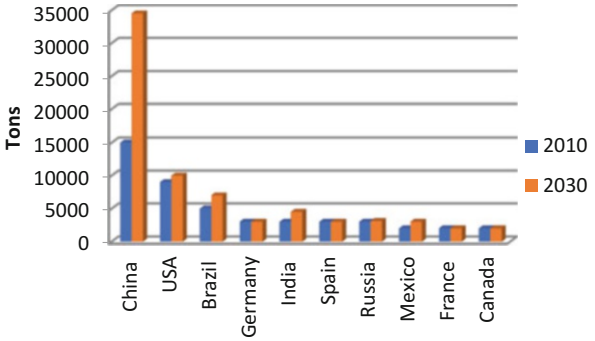

Fig. 1 Consumption of antibiotics in the livestock industry by the top ten countries in 2010–2030 (projected for 2030) [6]

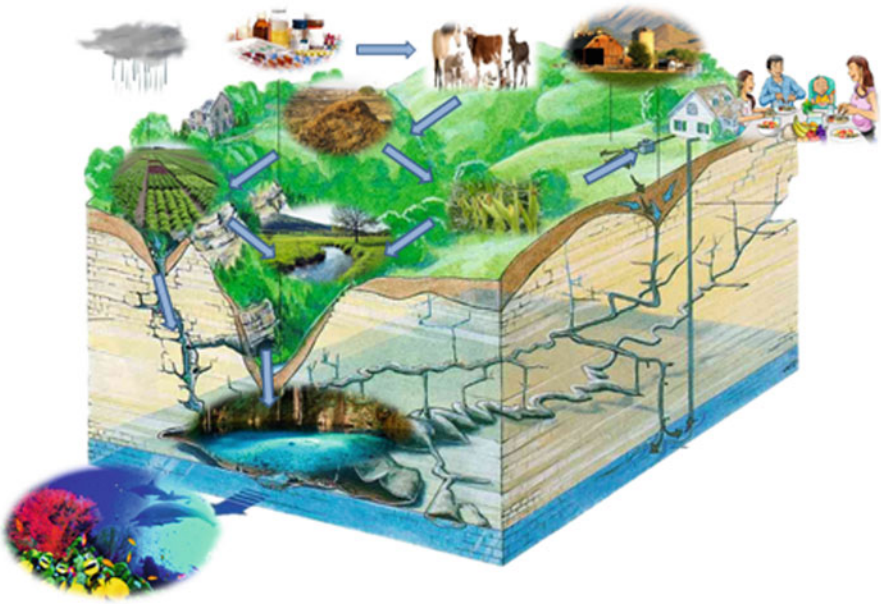

Fig. 2 Route of the antibiotics, from their entrance to a farm to their excretion to the environment through manure system. Antibiotic residues could be incorporated into the fields and plants, as well as enter into the aquifer

Therefore, the aim of the present review is to provide an overview of the fate of antibiotics in the environment, the time of degradation, and the potential damage to ecosystems.

2 Destination of Antibiotics in the Soil

Antibiotics have been globally implemented in animal feed to treat disease, improve resistance to disease, and promote growth since 1950 [39–41]. In 2013, 48,400 tons of antibiotics were used in China, mainly for swine production, of which 49.5% was discharged to the environment after being metabolized by the animal [42]. It is estimated that the Chinese swine industry generated 3190 million tons of manure every year [43].

The residual levels of veterinary pharmaceutical products are generally higher in the soil than in the water. For instance, it has been reported that the concentration of tetracycline was 900 μg/kg in soil but 0.4 μg/L in water, and the levels of ciprofloxacin were 52 μg/kg in soil but 0.4 μg/L in water [15].

Not all antibiotics found in environmental samples have detrimental effects on the ecosystems and agroecosystems [44]. It is important to identify which ones are harmful. Antibiotics' persistence in the environment can vary due to its half-life, which is affected by several factors such as water pH, temperature, geographical

Table 1 Antibiotics found in samples of soil, mud, and manure

Family	Name	Concentration	Localization	Country	Reference
Quinolones	Norfloxacin	0.43 g/ kg	Mud	Vietnam	Tuan and Munekage [22]
	Norfloxacin	225.45 mg/kg	Manure	China	Zhao et al. [23]
	Ofloxacin	1.6 μg/kg	Soil	China	Hu et al. [24]
Fluoroquinolones		0.13–0.75 mg/kg	Manure	Austria	Martínez Cerballo et al. [25]
		33. 56 μg kg	Soil	China	Shi et al. [26]
	Ciprofloxacin	808.3 μg/kg	Manure	China	Hou et al. [27]
		75.6 μg/kg	Manure	China	Ma and Chen, [28]
		0.1 mg kg	Soil	China	Hu et al. [24]
	Enrofloxacin	1420.76 mg/kg	Manure	China	Zhao et al. [23]
		140.71 μg/kg	Soil	China	Ma and Chen [28]
Sulfonamides	Sulfamethoxazole	2.62 g/ kg	Mud	Vietnam	Tuan and Munekage [22]
		18.9 μg/kg	Manure	China	Hou et al. [27]
		0.9 μg/kg	Soil	China	Hu et al. [24]
	Sulfachloropyridazine	34.9 μg/kg	Manure	China	Hou et al. [27]
	Sulfadimidine	1–2 mg/kg	Manure	Germany	Chistian et al. [29]
	Sulfadoxine	9.1 mg/kg	Soil	China	Hu et al. [24]

Trimethoprim		0.82 g/ kg	Mud	Vietnam	Tuan and Munekage [22]
Tetracyclines	Chlortetracycline	2668.9 μg/kg	Manure	China	Hou et al. [27]
		754.4 mg/kg	Manure	China	Pan et al. [30]
		0.039 mg/kg	Soil	Germany	Hamschert et al. [31]
		0.88 μg/kg	Soil	Korea	Awad et al. [32]
		1079 μg/kg	Soil	China	Hu et al. [24]
		0.19–208.9 mg kg	Soil	China	Lin et al. [33]
		119–307 9 mg kg	Soil	China	Xie et al. [34]
		11,440 μg/kg	Soil	China	Tang et al. [35]
	Oxytetracycline	0.3 mg/kg	Soil	UK	Boxall et al. [36]
		183.5 mg kg	Soil	China	Hu et al. [24]
		2690 μg/kg	Soil	China	Tang et al. [35]
		397.6 μg kg	Soil	China	Zhang et al. [37]
Macrolides	Tylosin	1.4 μg/kg	Manure	China	Hou et al. [27]
		0.0–37.1 μg/kg	Manure	Italy	Liguoro et al. [38]
Nitrofurans		85.1 μg/kg	Manure	China	Hou et al. [27]

location, etc. [45]. Persistence is also influenced by the animal species from which they come, their respective nutrition and intestinal microbiota [21, 23]. Some antibiotics, such as penicillin, are easily degraded in a matter of hours or few days. Other antibiotics, such as macrolides (i.e., tylosin), fluoroquinolones (i.e., ciprofloxacin), and tetracyclines, may persist for several months or even years. Those antibiotics will be more harmful to the environment due to the greater accumulation [46]; some antibiotics can even be transformed from the metabolites back into the original compound [47].

Veterinary antibiotics have been monitored in manure or sludge that is routinely applied to crops, which is the first stage of degradation or transformation when interacting with microorganisms [48, 49]. A process known as "sequestration" can be presented, which is given by kinetic absorption and diffusion in micro- and nanopores that are too small for microorganisms' enzymes to remove antibiotics temporarily from contact and biological absorption; due to this process the antibiotics decrease over the time, but there is a transient storage for time not yet defined [21, 50].

Antibiotics are currently considered as emerging contaminants [51], which can affect the structure and function of indigenous bacterial communities and increase the abundance of antibiotic-resistant bacteria by stimulating the expression of resistant genes [52]. An experiment investigating the interaction of antibiotics and microorganisms found that the soil microorganisms could utilize some antibiotics as their organic substrates; however, the enzymatic activities of dehydrogenase and urease were obviously inhibited by the antibiotic over the time [53].

In addition, insufficient attentions has been presented to the effect caused by antibiotics in the soil on the bacterial communities responsible for anoxic denitrification [54], which is due to the very short half-life (hours to months) of the drug in anoxic soils [8, 55]. One study showed that the presence of antibiotics could inhibit denitrification and the activity of denitrifying genes in soils [56]. Photo degradation of antibiotics or metabolites is unlikely to occur in soils, because light penetration is limited [57]. However, runoff and transport facilitated by particles can dissipate all antibiotics in the environment [58, 59].

Vertical leaching or percolation in groundwater occurs mainly in preferential flow paths; however, it is restricted to a few antibiotics such as sulfonamides; therefore most of the antibiotics applied with manure to soil is retained in the surface soil [60, 61].

Plants absorb small amounts of antibiotics (Fig. 3). Kumar et al. [62] observed an accumulation in plant tissue (2–17 ng/g fresh weight) of chlortetracycline, and Grote et al. [63] found the same antibiotic in wheat grain (~44 ng/g). Therefore, the elimination of antibiotics from the soil by means of plants absorption does not represent an effective alternative since the amount of absorption is very small. However, the antibiotics may cause risks to plants, because they may have toxic effects on the vegetal organism [64, 65].

These toxic effects vary from organism to organism. Migliore et al. [66] observed that the leaves and internodes of Lythrum salicaria absorb and accumulate antibiotics at low concentrations and present toxicity at high concentrations, while roots, cotyledons, and cotyledon petioles always exhibit toxic effects regardless of concentration. Migliore et al. [67] found that sulfadimethoxine at

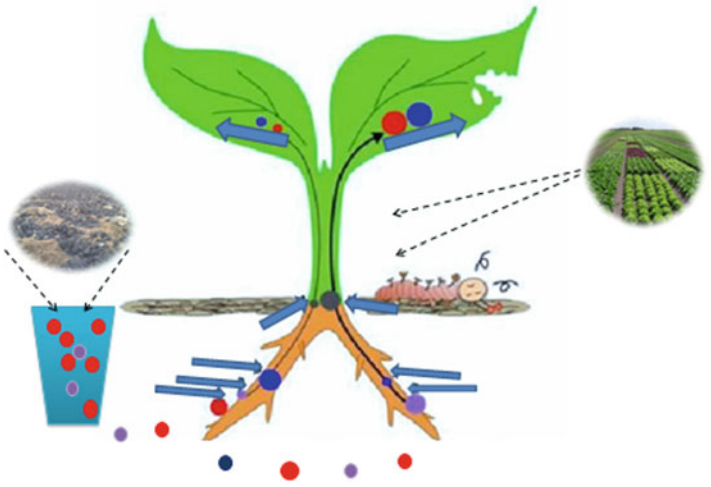

Fig. 3 Absorption of antibiotics in plants from roots to leaves

concentrations of 300 mg L^{-1} reduces the growth of leaves and roots in corn, peas, and millet. Overall, plant species, growth stage, stationary variations, and different antibiotics affect absorption, distribution, and accumulation in plants and soil microorganisms [17, 68].

3 Antibiotics in the Water

Since the 1940s, antibiotics have played an important role in human and animal health [69]. The discharge of wastewater is the major route for antibiotic residues to enter into the aquatic environment [70]. As a consequence, a fraction of these compounds ends up in the sea, which is the main receptor of terrestrial pollutants [71, 72]. Additionally, antibiotics are introduced in aquaculture through feed or water immersion en masse as treatment or prophylaxis of disease in farmed species. In aquatic ecosystems, cyanobacteria, an essential group of prokaryotic organisms which represent for the majority of the phytoplankton mass, are responsible for producing a large amount of free oxygen, in addition to fixing the carbon dioxide in marine habitats, terrestrial habitats, and fixation of atmospheric nitrogen [73, 74]. However, cyanobacteria are very sensitive to antibiotics, which increase the concern about the contamination of drugs in the aquatic habitat [44, 75].

The most commonly found antibiotics in water are quinolones, sulfonamides, and trimethoprim, which exceed 1 μg/L in environmental samples [76]. Those antibiotics have toxic effects even in very low concentrations, both through its active ingredients and additives used in its formulation [77]. It has been reported that the minimum inhibitory concentrations of 122 antibiotics in water ranges from 0.64 to 32,000 μg/L, whereas the unforeseen effect concentrations were between 0.008 and 64 μg/L [12].

The European Medicines Agency suggests that the concentration limit for surface water is of 10 ng/L, and it is not necessary to carry out further drug toxicity tests if the level is lower than 10 ng/L. However, there may be antibiotic resistance even at lower concentrations (<1 ng L^{-1}) [78, 79] (Table 2).

Organisms in the aquatic environment are generally not exposed to individual compounds but rather to mixture of various chemicals [77]. Magdaleno et al. [100] showed that the effects of the mixture were stronger than the effects of a single substance for green algae. Also, Long et al. [101] reported that there are synergistic effects between sulfonamides and sodium cefotaxime and antagonistic effect between sulfonamides and tetracyclines or potassium penicillin V.

4 Strategies to Control the Use of Antibiotics in the Livestock Industry

The use of antibiotics in animals cannot be demonized because they have protected public health and food safety by reducing the transmission of zoonotic pathogens [102], and judicious use of antibiotics is recognized as a way to sustain livestock production [103, 104]. However, the growing world population is leading to increased demand for animal protein, and this in turn is putting pressure on the chains of food supply systems, which have to implement antibiotics to meet their demands [1]. In addition, pharmaceutical manufacturing of antibiotics will continue as long as there is a market need, or until the discovery of new or more efficient alternatives, which in turn will have their challenges [17].

Strategies must be implemented to promote the judicious use of antibiotics in agriculture. Examples of these strategies are prohibiting and reducing the use of specific antibiotics; limiting their use to specific situations or conditions; avoiding use of antibiotics in regular patterns; purchasing and application antibiotics with licenses; developing partnerships between veterinarians and farmers; reducing the need for antibiotics by improving vaccination and using alternative growth enhancers; as well as improving animal husbandry, hygiene, and health management of farms [1, 17]. In the United States, use of in-feed antibiotics for production purpose in livestock is banned starting January 2017. In the state of California, beginning January 2018 medically important antibiotics cannot be administered to livestock unless ordered by a licensed veterinarian.

Application of vaccination programs, good hygiene, higher animal welfare practices, and a better feeding design can reduce the use of antibiotics in livestock production. A clear example being the some French animal nutrition companies, which produced 105,000 finishing pigs in 2016 for the antibiotic-free markets and its plan for 2017, is to increase to 155,000 and even 200,000 in 2018 [105].

The global organizations (FAO, WHO, OIE) as well as international governments work in close collaboration to promote a unique approach to the reduction in the use of antibiotics globally. The international partnerships are also striving to increase the awareness of using antibiotics and the effects of antibiotics on the ecosystems [1].

Table 2 Antibiotics found in water samples (adapted from Välitalo et al. [44])

Family	Name	Concentration (μg/L)	Localization	Country	Bibliography

		0.30	Effluent	Australia	Leung et al. [82]

5 Conclusion

The primary strategy is to control the use of antibiotics in animal production, followed by increase public and agricultural community's awareness of and promote judicious use of antibiotics in animals. If we start by providing farmers with the correct knowledge of use antibiotics in animals, they will have more alternatives to use antibiotics in animals, thus reducing antibiotics in the ecosystems and agroecosystems.

Insecticide Residues in Foods

61

Ramesh Kumar Sharma

Contents

Abstract

The conventional agriculture which excessively employs synthetic insecticides for crop protection, sidelining traditionally known agri-friendly environmental factors like biodiversity and soil conservation, of course led to bumper crop yield in farms. But synthetic insecticide molecule residues in foods and water have posed serious threat to biosphere and public health. Therefore traditionally known agri-friendly and environmentally safe natural insecticides like *neem* (*Azadirachta indica*) leaf juice or *neem* oil are again in limelight in India.

The natural insecticides of pyrethrum, derris, ryania, sabadilla, and tobacco sources are worldwide considered to replace synthetic insecticides for crop protection in farms; and a new kind of agriculture called organic farming has

evolved. Still there does not seem ample scope for natural biomolecules of plant and bacterial origin with insecticidal property like azadirachtin, pyrethrins, spinosad, milbemycins, ryanodine, etc. perhaps due to limited legal acceptance to natural insecticides on account of their unfavorable effects in the human body.

1 Introduction

The environmental factors, biodiversity and soil conservation, contribute to agricultural yield and crop or food quality; this traditionally well-known fact had been sidelined since the mid-twentieth century when Swiss scientist Paul Muller noticed in 1939 the insecticidal property of DDT (dichlorodiphenyltrichloroethane), the first discovered synthetic organic insecticide in 1873 by German scientist Ziedler [1]. With the increasing farm-level applications of synthetic insecticides to control pest population and protect crops, their polluting impact on environment – water, soil, and biosphere – and negative effect on public health soon became self-evident. The 1960s is described by environmentalists as the decade of anti-insecticide movement led by Rachel Carson (1907–1964) in the West, particularly the USA and the European countries [2]. Unfortunately that time when the Western world prepared itself for minimum synthetic insecticide applications at farm level, the eastern (including Indian) leadership was perhaps unaware of this fact and continued to use synthetic insecticides. In the same decade (1960s), Deen Dayal Upadhyay (1916–1968) came forward with the theory of integral humanism – humans are the integral part of biosphere, not of robotic network – questioning why synthetic insecticides should be applied in Indian farms, when US agriculture is going to eliminate those as much as possible [3]. Fortunately, nowadays all the governments, the world over, strongly wish to adopt organic farming (or bio farming, as called Jaivik Krushi in India) concerned with avoidance of synthetic insecticides and adoption of natural plant-based insecticides like *neem* (*Azadirachta indica*) leaf juice or *neem* oil. Synthetic insecticide molecules grouped as organochlorines, organophosphorus, and carbamates are nowadays facing stringent legal limitations, but still there does not seem a scope for biomolecules of plant and bacterial nature with insecticidal property like azadirachtin, nicotine sulfate, pyrethrins, rotenone, etc. for farm applications. It is essential for food processing industries to ensure that synthetic as well as natural insecticide contents in their food products are within the limits established by the food law (Food Safety and Standards Regulation, 2011 in India). However low-toxic natural insecticide molecules like azadirachtin, spinosad, and ryanodine are not found capable to get legal tolerance limit advantage of their high LD_{50} values and facilitate organic (or bio) farming.

2 Insecticide Molecules: Configurations

A human utility- and chemical configuration-oriented definition of insecticides, provided by the Condensed Chemical Dictionary (Reinhold Publishing Corporation, New York), is as follows:

> Chemical compounds which are used to control insects which are harmful, directly or indirectly, to man are called insecticides.

However this definition of insecticides is limited to chemical compounds with insecticide controlling property that are synthetically prepared or isolated from natural sources. With due consideration of holistic insecticide application of natural products, the definition might be revised as follows:

> The substances which are used to control insects that are harmful, directly or indirectly, to public health and professions mainly agriculture are called insecticides.

Farming is the essential human activity which utilizes insecticides to control insect population and protect crop yield. Insecticides (insect-controlling substances), fungicides (fungi-controlling substances), and herbicides (weed-controlling substances) are collectively called pesticides. Contrary to global demand for herbicides in high amounts, India's demand more for insecticides is worth mentioning. However India's share in global pesticide market is around 10% in financial year 2017 (CARE rating, 31 May 2017). Indian crop protection (pesticide) market has experienced story growth in the past and is expected to grow further at 12% per annum to reach at 6.8 billion US dollars in financial year 2017 (Tata Strategic Management Group; wap.business-staandard.com). India occupies the fifth place in the list of top 15 pesticide-exporting countries – after Germany USD 4 billion, China USD 3.7 billion, the USA USD 3.4 billion, and France USD 3.4 billion – with exports worth USD 2.1 billion, 6.7% share in global exports in financial year 2016 (World's Top Exporters, 28 July 2017).

The insecticide molecules which can protect crops from insects by killing them or damaging their biological system are capable to harm the entire biosphere due to their toxic nature. The water used in agriculture gets polluted with insecticide molecules and mixed in rivers and underground (well) water. This is considered a big factor in extinction of several creature species.

Despite being both organic and inorganic types, organic synthetic insecticides are more prevalent and might be classified in four main groups, namely, organochlorines, organophosphorus, carbamates, and pyrethroids. The natural insecticide molecules derived from plant and bacterial sources are structurally more complex and diverse in comparison to synthetic insecticides. They mostly are polynuclear compounds.

2.1 Synthetic Insecticide Molecules

The molecular configurations of synthetic insecticide molecules are as follows:

2.1.1 Organochlorines

The biodiversity and soil conservation contribute a lot to agricultural yield and crop quality; it is the traditionally known quintessence. But this important fact had been sidelined since the mid-twentieth century when Swiss scientist Paul Muller noticed in 1939 the insecticidal property of DDT (dichlorodiphenyltrichloroethane), the first discovered synthetic organic insecticide in 1873 by German scientist Ziedler [1].

DDT, BHC (benzene hexachloride), chlordane (octachloro methanoindene), aldrin (hexachloro dimethanonaphthalene), etc. belong to organochlorine class of synthetic insecticides. In the molecular configuration of organochlorine insecticides, there exist at least four chlorine atoms (Fig.1).

Organophosphorus

Since 1968 organophosphorus insecticides have been much more in use when those were claimed to be easily decomposed by Martin [4]. Structurally organophosphorus insecticides are phosphoric or phosphorothionic acid esters of various groups. Parathion (diethyl-p-nitrophenyl monothiophosphate), phosphamidon (dimethyl phosphoric acid ester with chlorodiethyl hydroxycrotonamide), and ethion (phosphorodithioic acid-SS-methylene-oooo-tetra ethyl ester) are some well-known examples of this category of synthetic insecticides (Fig. 2).

Carbamates

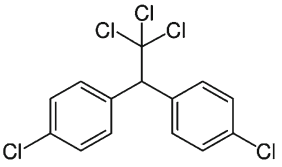
In 1980 Drum found that unlike organophosphorus insecticides, carbamates are insect species specific and reversible in the matter of inhibition of cholinesterase, an important enzyme present in the brain, nerve cells, and red blood cells capable of hydrolyzing acetylcholine to choline and acetic acid [5]. Since then, the carbamates, which are various groups of esters of amino acids, have been increasingly applied in farms. Examples are carbyl (naphthyl N-methylcarbamate), carbofuran (dimethyl benzofuranol methylcarbamate), etc. (Fig. 3).

2.1.2 Pyrethroids

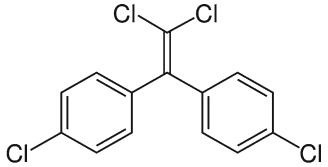
The synthetic analogues of pyrethrum insecticide (natural, obtained from pyrethrum flowers) molecules, called pyrethroids, have also been developed in 1980 onwards. According to Linde, despite powerful insecticidal action, pyrethroids are ecologically more unsafe than pyrethrum insecticides due to susceptibility to photochemical degradation [6]. Well-known pyrethroid structure molecule is 3-(2,2- dibromoethenyl)-2,2-dimethylcyclopropane carboxylic acid cyano (3-phenoxy phenyl) methyl ester known as deltamethrin or decamethrin (Fig. 4).

Miscellaneous Synthetic Insecticide Groups

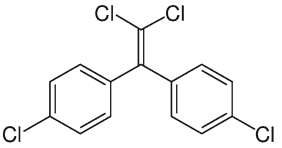
In addition to organochlorines, organophosphorus, carbamates, and pyrethroids, there are some more organic insecticides for crop protection such as phenoxyacetic acid and bipyridyls group of insecticides (Fig. 5).



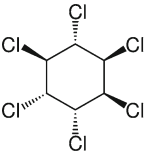
DDT: pp'-dichlorodiphenyltrichloroethane



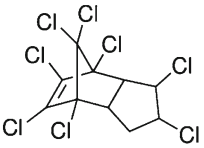
DDD: pp'-dichlorodiphenyldichloroethane



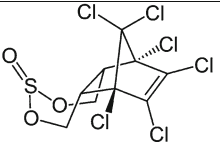
DDE:pp'- dichlorodiphenyldichloroethylene



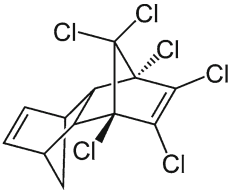
Lindane: gamma isomer of hexachloro-cyclohexane or benzene hexachloride (alpha and beta isomers are also used as insecticides)



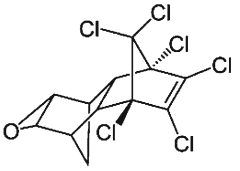
Chlordane:1,2,4,5,6,7,8,8-octachloro-2,3,3a,4,7,7a-hexahydro-4,7-methano-lH-indene.



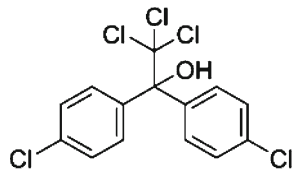
Endosulphan:1,4,5,6,7,7-hexachloro-5-nonbornene -2,3- dimethanol cyclic sulphite.



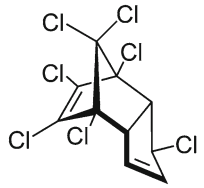
Aldrin:1,2,3,4,10,10-hexachloro-1,4,4a,5,8,8a-hexahydro-1,4:5,8- dimethanonaphthalene



Dieldrin:aldrin-6,7-monooxide

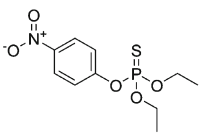


Dicofol: di (p-chlorophenyl) trichloromethyl carbinol (a chlorophenyl alcohol)

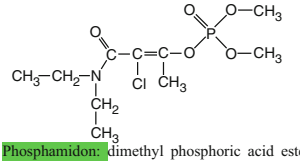


Heptachlor: 1H-1,4,5,6,7,8,8 heptachloro-3a,4,7,7a tetrahydro 4,7 methanoindene

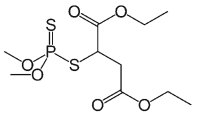
Fig. 1 Selected examples of organochlorine insecticides, with prevalent name and molecular formula/structure



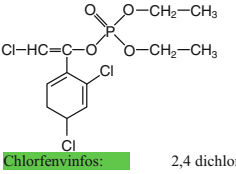
Parathion: di-methyl/ethyl-p-nitrophenyl monothiophosphate; locally known as Folidol



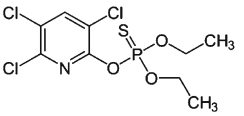
Phosphamidon: dimethyl phosphoric acid ester with 2-chloro-N,N-diethyl-3-hydroxy crotonamide.



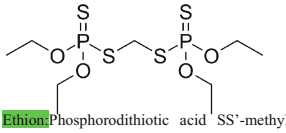
Malathion:diethyl mercaptosuccinate S-ester with O,O dimethyl phosphorothionate.



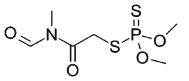
Chlorfenvinfos: 2,4 dichloro (dichloromethylene) benzyl alcohol diethyl phosphate



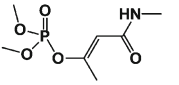
Chlorpyrifos: phosphorothiotic acid O,O diethyl O-(3,5,6 trichloro-2-pyridinyl) ester



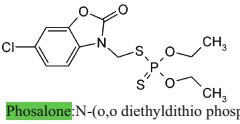
Ethion:Phosphorodithiotic acid SS'-methylene O,O,O',O'- tetra ethyl ester.



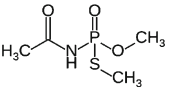
Formothion:Phosphorodithiotic acid, O,O-dimethyl ester, S-ester with N-formyl-2-mercapto-N-methyl acetamide.



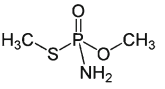
Monocrotophos:Phosphoric acid dimethyl ester, ester with 3-hydrory-N-methyl crotonamide



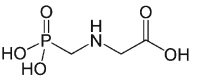
Phosalone:N-(o,o diethyldithio phosphoryl methyl) m-chlorobenzoxazolinone



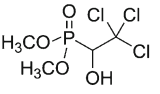
Acephate: acetylphosphoramidothiotic acid o,s-dimethyl ester.



Methamidophos: O,S-dimethyl phosphoramidothioate.

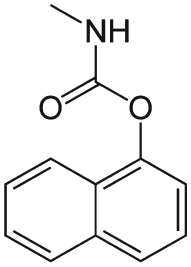


Glyphosate: Phospharomethyl aminoacetic acid.

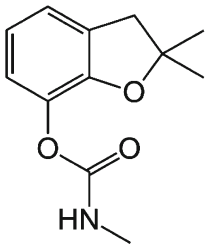


Trichlorfon: (2,2,2 trichloro-1-hydrory ethyl)-phosphoric acid dimethyl ester.

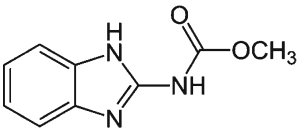
Fig. 2 Some of the leading organophosphorus insecticides with name and molecular formula/ structure



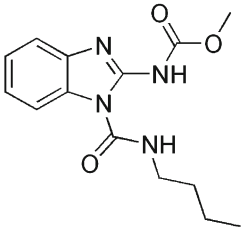
Carbaryl: 1-naphthyl N-methyl-carbamate



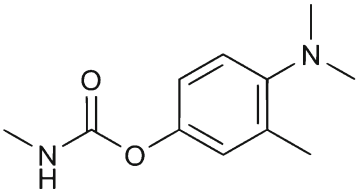
Carbofuran: 3 hydro -2,2 dimethyl -7-benzo furanol methyl carbamate.



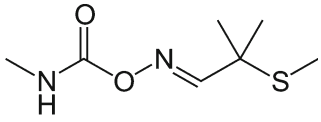
Carbendazim: 2-benzimidazolecarbamic acid methyl ester.



Benomyl: 1-(butylcarbamoyl)-2-benzimidazole carbamic acid methyl ester



Aminocarb: m-methyl p-dimethylamino-phenyl N-methyl earbamate.



Aldicarb: 2-methyl 2-(methylthio) propionaldehyde0-(methylcarbamoyl) oxime $CH_3SC(CH3)_2$ CH=NOCO-$NHCH_3$

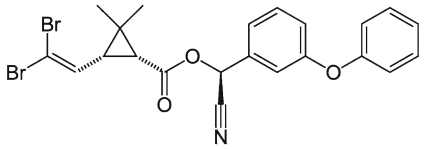
Fig. 3 A few examples of the important carbamate insecticides

2.2 Natural Insecticide Molecules

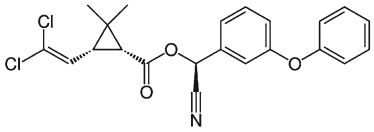
The natural insecticide molecules mostly are polynuclear compounds with structural diversity. Azadirachtin, pyrethrins, spinosads, milbemycins, rotenone, ryanodine, nicotine, etc. are the prominent natural insecticide molecules with configurations as follows:

2.2.1 Azadirachtin

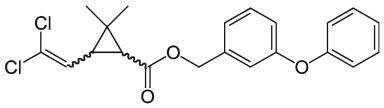
Azadirachtin is the insecticidal active ingredient of neem with oxidized tetra-nortriterpenoid molecular structure (Fig. 6) comprised of enol ether, acetal,



Deltamethrin **(Decamethrin):** 3-(2,2 dibromoethenyl)-2,2 dimethyl-cyclopropane carboxylic acid cyano (3-phenoxy phenyl) methyl ester.

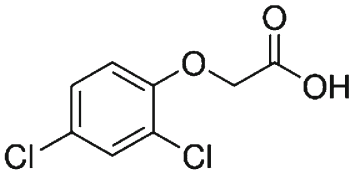


Cypermethrin: 3-(2,2-dichloroethenyl)-2,2-dimethyl cyclopropane-carboxylic acid cyano (3-phenoxy phenyl)-methyl ester.

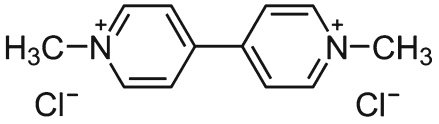


Permethrin: 3-(2,2-dichloroethenyl)-2,2-dimethyl cyclopropanylacetic acid (3-phenoxy phenyl)-methyl ester.

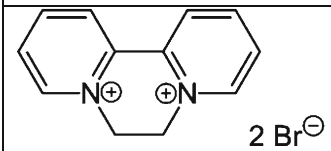
Fig. 4 A few prominent pyrethroid insecticides, developed as synthetic analogues of natural pyrethrum flower's active ingredients



2,4-D: 2,4-dichlorophenoxy acetic acid



Paraquat: 1,1' dimetyl-4,4'-bipyridium dichloride



Diquat: 1,1'-ethenyl -2,2' bipyridium dichloride

Fig. 5 Phenoxyacetic acid and bipyridyls group of insecticides

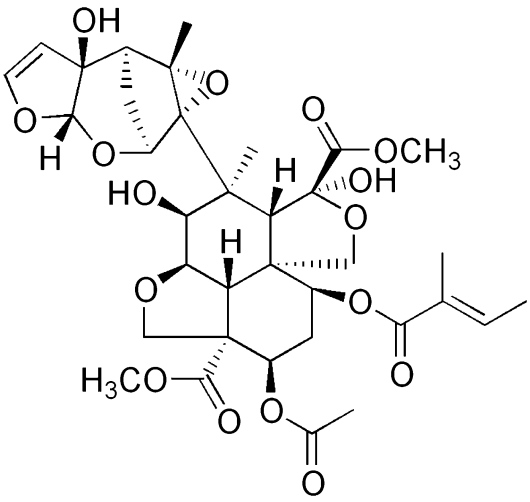


Fig. 6 Azadirachtin obtained from *A.indica*

hemiacetal, and tetra-substituted oxirane as well as a variety of carboxylic acid [7]. Neem leaf juice has been traditionally used in India for crop protection since centuries.

2.2.2 Pyrethrins

The widely legally accepted natural insecticides pyrethrins, extracted from pyrethrum (chrysanthemum cinerariaefolium) flowers, are pyrethrolone esters of chrysanthemum acids (monocarboxylic or dicarboxylic) [8]. These molecules could be structurally represented as follows (Fig.7):

2.2.3 Spinosads

The spinosad molecules derived from soil actinomycete represent tetracylic ring system attached to an amino sugar (D-forosamine) and neutral sugar (tri-O-methyl-L-rhamnose) [9].

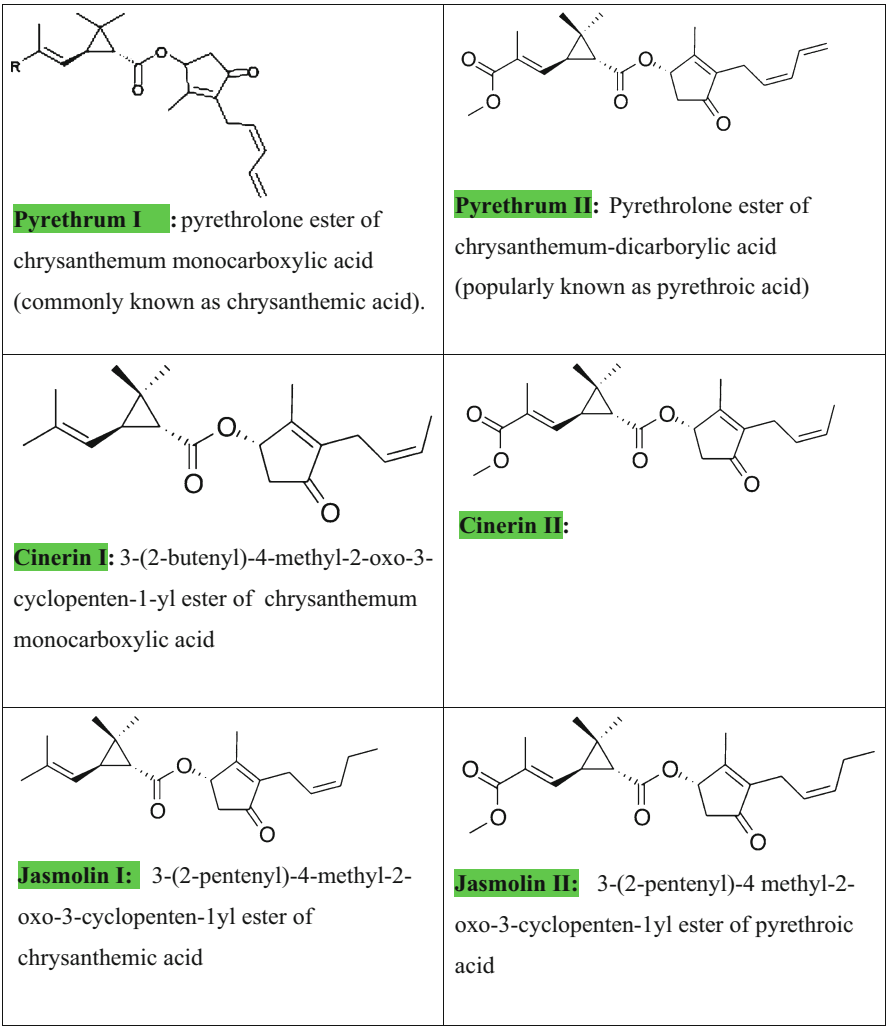
Spinosads, bioactive constituents isolated from the soil actinomycete, *Saccharopolyspora spinosa*, are known as spinosyn A and spinosyn D. These molecules could be structurally represented as follows (Fig.8):

2.2.4 Milbemycins and Avermectins

Avermectins and milbemycins isolated from *Streptomyces* sp. culture lead to diversely substituted pyran trioxy-tetracyclopentacosa tetraene ketonic configuration [10].

Milbemycins and avermectins are also called milbemectins and abamectins in mixtures. Milbemycin A4 has molecular structure as follows (Fig. 9):

6-ethyl-21′,24′ dihydroxy 5, 11′, 13′, 22′ tetramethyl 3, 4, 5, 6- tetrahydro -2h spiro [pyran -2,6′ –(3′, 7′, 19′) trioxy-tetracyclopentacosa (10, 14, 16, 22) tetraene)-2′ one (IUPAC name shortened by the author of the paper).



Pyrethrum I : pyrethrolone ester of chrysanthemum monocarboxylic acid (commonly known as chrysanthemic acid).

Pyrethrum II: Pyrethrolone ester of chrysanthemum-dicarborylic acid (popularly known as pyrethroic acid)

Cinerin I: 3-(2-butenyl)-4-methyl-2-oxo-3-cyclopenten-1-yl ester of chrysanthemum monocarboxylic acid

Cinerin II:

Jasmolin I: 3-(2-pentenyl)-4-methyl-2-oxo-3-cyclopenten-1yl ester of chrysanthemic acid

Jasmolin II: 3-(2-pentenyl)-4 methyl-2-oxo-3-cyclopenten-1yl ester of pyrethroic acid

Fig. 7 Six primary ingredients of pyrethrum flowers having insecticidal property are shown

2.2.5 Rotenone and Deguelin

The rotenone and deguelin molecules isolated from derris root and cube resin have benzopyrano furo benzopyranone and bis benzopyranopyranone configurations, respectively [11].

These molecules could be structurally represented as follows:

Rotenone: 1,2,12a,12b tetrahydro-8,9 dimethoxy-2-(1-methylethenyl)-benzopyrano furo [1] benzopyran-6-one

(IUPAC name shortened by author of paper) (Fig. 10).

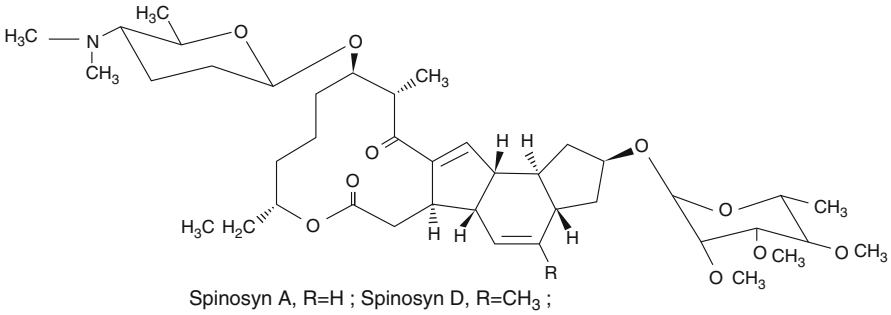


Fig. 8 Spinosad structure

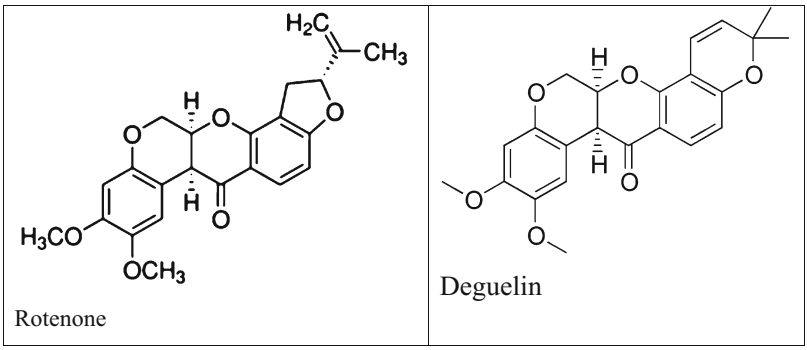

Fig. 10 Structure of rotenone and deguelin

Deguelin: 13a,13b dihydro-3,3-dimethyl-9,10-dimethoxy-3h bis[1] benzopyrano pyran-7-one

(IUPAC name shortened by author of the paper).

2.2.6 Ryanodine

Ryania insecticide obtained from roots and stems of South American shrub *Ryania speciosa* possesses the active ingredient ryanodine representing a complex polycyclic, polyhydroxylic diterpene structure with diversely substituted oxapentacyclo pentadecyl pyrrole-2-carboxylate configuration [12].

Ryanodine, the active ingredient of ryania insecticide derived from South American shrub *Ryania speciosa*, has the following molecular configuration (Fig. 11):

2,6,9,11,13,14-hexahydroxy-11-isopropyl-3,7,10-trimethyl-15-oxapentacyclo-pentadec-12-yl-1h-pyrrole-2′-carboxylate

(IUPAC name shortened by author of paper).

2.2.7 Nicotine

The molecular structure of nicotine derived from tobacco is as follows (Fig.12):

3′-(1-methyl-2-pyrrolidinyl)pyridine

[IUPAC name].

3 Social Concerns

The perception of harm to environment due to insecticides eventually led to anti-insecticide movement in the 1960s when Rachel Carson's popular book *Silent Spring* was published in 1962 [2]. In the same decade, the philosophy of integral humanism was propounded by Pandit Deen Dayal Upadhyay in India, probably in 1966–1967, for the sake of avoidance of anti-biosphere human activities, say use of insecticides [13].

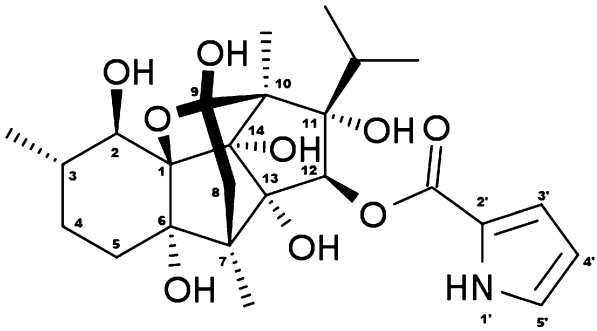

Fig. 11 Ryanodine isolated from *R. speciosa*

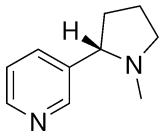

Fig. 12 Nicotine obtained from *Nicotiana tabacum*

3.1 Anti-insecticide Movement

Opposition to synthetic insecticides like DDT is considered to get strength with effect from 1962 when Rachel Carson's book *Silent Spring* was published. It is said that the public reaction to this best seller book, lucidly presenting arguments for how insecticides like DDT endanger wildlife and public health, launched a vigorous anti-insecticide movement. Carson's rationale for anti-biosphere action of insecticides, particularly DDT, was examined by US Science Advisory Committee, when President John F. Kennedy in 1963 ordered to investigate her claims [14]. Madam Carson passed away in 1964, but the anti-insecticide movement, her brain child, continued and led to ban on agricultural use of DDT in Hungary (1968), Cuba (1970), Norway (1970), West Germany (1970), and the USA (1972). Cuba exercised total ban on DDT including contagion control. Later on, total bans on DDT took place in several countries, the USA, Singapore, Chile, the UK, etc., in the 1980s (FAO/UNIP 1991) [15].

Rachel Carson (1907–1964) born on 27 May 1907 in Springdale, Pennsylvania, was a marine biologist, author, and environmentalist. Despite meeting fierce opposition by chemical companies, her book *Silent Spring* succeeded in spurring reversal in pesticide policies in US and Western nations. Carson mentioned a number of cases about toxic pesticide exposure, how exposed people fall ill and painfully die. She proved that these harmful chemicals move to succeeding generations of offspring through mother's milk and other biological processes. Her book also highlights the effects of pesticide spraying on wildlife in the environment. Carson believed in adopting biological control methods for insect population control as alternative to chemical spraying in farms. Her important quote is:

> It is an era dominated by industry in which the right to make dollar is seldom changed. This industry (insecticide industry) is a child of the Second World War. In the course of

> developing agents of chemical warfare some of the chemicals, created in the laboratory, were found lethal to insects. The discovery did not come by chance; insects were widely used to test chemicals as agents of death for men. [2]

Carson died on 14 April 1964 in Silver Spring, Maryland, USA.

3.2 Integral Humanism

In the 1960s, when the Western world began to prepare itself for minimum synthetic insecticide applications at farm level, unfortunately Indian leadership was perhaps unaware of this fact and continued to use synthetic insecticides like DDT and BHC. Questioning why synthetic insecticides be applied in Indian farms when US agriculture was going to eliminate those as much as possible, Pandit Deen Dayal Upadhyay (1916–1968) propounded the theory of integral humanism – humans are the integral part of biosphere, not of robotic network [13]. The postulates of integral humanism are [16]:

i. The humans are integral part of biosphere, not of robotic or mechanical network.
ii. The technical era is the most welcome, provided that innovations and advancements do not invade the biosphere nurtured by nature with the great sense of well-being.
iii. The biosphere – including humans – exists due to cooperation, not due to struggle (contrary to Darwin's survival of the fittest principle).
iv. Avoidance of anti-biosphere activities, say use of insecticides, and follow-up of technical approach toward human integrity to biosphere demand universal consumption patterns. That means humans being integral part of biosphere should consume the same kind (quality) of food and water and air which all the creatures do.

Deen Dayal Upadhyay, born on 25 September 1916 at Dhankya village of Jaipur district in Rajasthan, was a postgraduate in English literature and education. He is regarded as eminent sociologist, economist, historian, journalist, philosopher, and political leader (Bhartiya Jansangh leader). He was perhaps assassinated (thrown from compartment) on 11 February 1968 at Mughalsarai in UP, while traveling on train.

4 Legal Acceptances with Limitations for Insecticides

The Insecticide Act 1968, section 3, permits 890 insecticides for application in Indian farms. On the other hand, the FSSR 2011 enlists 199 insecticides, both synthetic and the natural, with commodity-wise acceptable maximum residue limits in agricultural products. However 219 insecticides (20 more to previously approved insecticides) are proposed in FSSR draft notification (August 2017), calling for suggestions, views, or comments from stakeholders, related to tolerance harmonization

of MRL (maximum residue limits) of insecticides. It means Indian farmers can use 890 insecticides enlisted in section 3 of Insecticide Act for crop protection, but food processing units should procure only those commodities which contain particular insecticide residues within specified limit as listed in Food Safety and Standards (Contaminants, Toxins, and Residues) Regulations 2011. The lethal dosage or LD_{50} value, measure of toxicity of insecticide or any substance, defined as the amount of insecticide at which 50% of test animals expire in the experiment conducted to judge its harmful effect on animals (mostly rats are employed, and LD_{50} is expressed as insecticide dosage milligrams per kilogram weight of test animals), obviously seems to be the basis of deciding the tolerance limit for an insecticide. But in fact, environmentally safe insecticides having high LD_{50} values whether synthetic like benomyl and carbendazim or natural like spinosad and azadirachtin are not capable to get high tolerance limit advantage. On the other hand, a few environmentally unsafe insecticides with low LD_{50} (high toxicity) value like DDT, carbyl, malathion, and dicofol (all synthetic) are advantaged of high tolerance limit in food law and therefore are more worth applying in farms. It means LD_{50} value is not the only criterion in deciding tolerance limit for an insecticide in food law. An attempt is made to understand LD_{50} tolerance limit correlation and analyze the graphical presentation.

4.1 LD_{50} V/S Tolerance Limit

The lethal dosage or LD_{50} value is the measure of toxicity of a substance where its construction kills 50% test animals. LD_{50} value is expressed as milligrams of substance per kilogram weight of animal employed in test. Normally rats, both the male and the female, are employed as test animals. LD_{50} value is experimentally determined by the scientists. Ethically it might be presumed that legally established tolerance limit for insecticide residues in food articles is proportional to their LD_{50} value. But truly it is not so. A graph of LD_{50} V/S tolerance limits (FSSR 2011) is shown here (Fig. 13).

It is worth mentioning that in this attempt of plotting tolerance limit – LD_{50} points – for insecticides, the former parameters belong to FSSR 2011, India, while the latter parameters generally belong to *Merck Index* [17], except in the cases of pyrethrins [18], azadirachtin [19], spinosad [20], rotenone (Agrochemical Handbook 1991, minimum value is taken) [21], nicotine [22], and ryanodine (EPA: archive) [23].

4.2 LD_{50} V/S Tolerance Limit: Analysis

A simple analysis of the graph LD_{50} oral mg/kg animal weight for female rat V/S tolerance limit (FSSR, India) in mg/kg in vegetables of insecticides reveals interesting facts. The graph is divided into four regions: (1) low LD_{50} (high toxicity), low tolerance limit (less worth applying) insecticides; (2) low LD_{50} (high toxicity), high tolerance limit (more worth applying) insecticides; (3) high LD_{50} (low toxicity), low tolerance limit (less worth applying) insecticides; and (4) high LD_{50} (low toxicity),

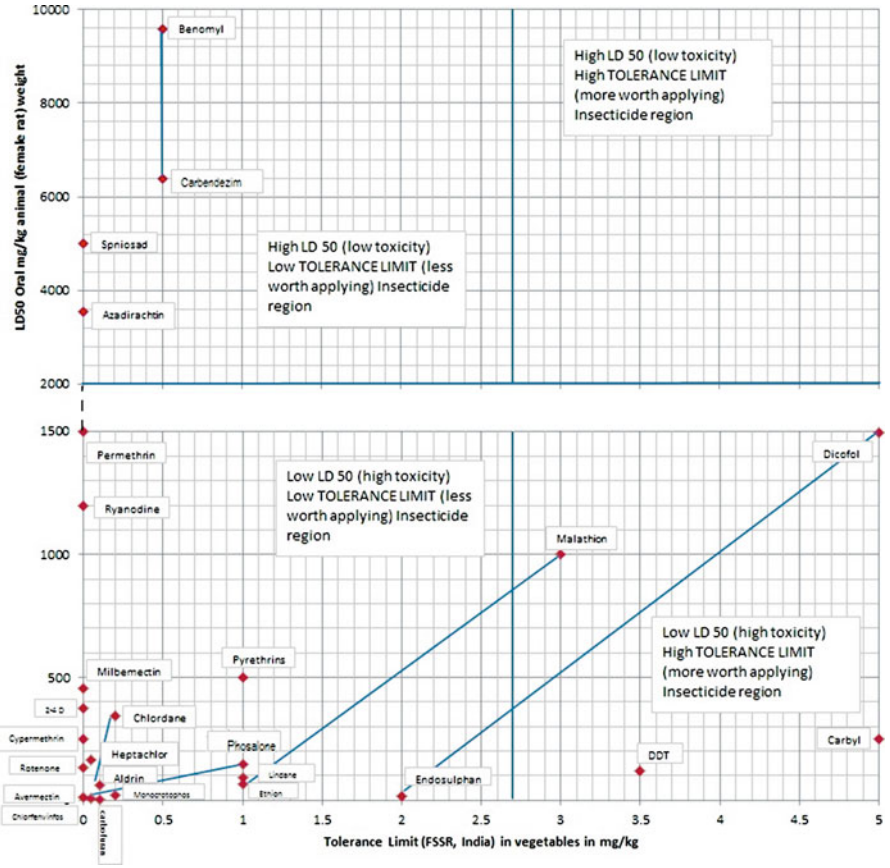

Fig. 13 A graphical representation of LD_{50} and FSSR tolerance limit (for vegetables) values of some of the tabulated insecticides

high tolerance limit (more worth applying) insecticides. The presumed dividing lines are $LD_{50} = 2000$ mg/kg animal weight and tolerance limit = 2.7 (FSSR) in mg/kg of vegetables. The main points of analysis are:

1. Most of the insecticides make a place in low LD_{50}, low tolerance limit region. Not only the most of popular synthetic organochlorines like aldrin, heptachlor, chlordane, and endosulfan, organophosphorus like monocrotophos, ethion, phosalone, and chlorfenvinphos, and pyrethroids like permethrin and cypermethrin but many natural insecticides like avermectins, rotenone, milbemycin, and ryanodine also fall in this region. It means most of the insecticides, both the synthetic and the natural, are much toxic and hence less applicable in the farms.
2. A few organophosphorus like malathion and dicofol and a few carbamates like carbyl and organochlorine DDT are placed in low LD_{50} (high toxicity), high tolerance limit (more worth applying region. Principle-wise high-toxic substances

should not be considered worth applying in farms. But sidelining the principle, Indian food regulation ascertains comparatively high MRL (maximum residue limit) or tolerance limit for these insecticides.

3. Most of the high LD_{50} (low toxicity) insecticides are considered less worth applying in the farms by the food lawmakers. Not only the synthetic environment-friendly carbamates like benomyl and carbendazim but natural low-toxic insecticides like spinosad and azadirachtin also occupy high LD_{50} (low toxicity), low tolerance limit (less worth applying) region.
4. Perhaps there is no such environment-friendly insecticide which is much more worth applying in farms in lawmakers' opinion. As such high LD_{50} (low toxicity), high tolerance limit (more worth applying) graphical region is quite empty.
5. Some of the insecticides are advantaged of tolerance limit proportionately to their LD_{50} values. The organophosphorus insecticides exhibit two prominent linear relationships: one covering ethion and malathion, while the other covering chlorfenvinphos, monocrotophos, and phosalone. However insecticides on former line are more slope-wise advantaged of tolerance limit than those on latter line. Almost parallel to the line joining chlorfenvinphos, ethion, and malathion toward high tolerance limits, there is a line joining organochlorines endosulfan and organophosphorus dicofol. Still more advantaged of tolerance limit to this line of insecticides, DDT (dichlorodiphenyltrichloroethane) makes the place in the graph. The well-known carbamate insecticide carbyl occupies the highest tolerance limit value 5 mg/kg (of vegetables) along with LD_{50} value equal to 250 mg/kg (animal weight).
6. The organochlorines aldrin, heptachlor, and chlordane also exhibit a linear relationship between LD_{50} and tolerance limit. But this line is quite near to LD_{50} axis, and these organochlorines are not advantaged of tolerance limit compared to organochlorines like DDT and endosulfan.
7. Quite near and parallel to LD_{50} axis, there is a line which joins the least toxic insecticides benomyl and carbendazim. Needless to say these carbamate insecticides which have LD_{50} values more than 6000 mg/kg of animal weight are very little advantaged of tolerance limit less than 0.3 mg/kg of vegetables.
8. Most of the natural insecticides, including the safest azadirachtin and spinosad (having high LD_{50} values between 3000 and 6000 mg/kg of animal weight), lie on the LD_{50} axis (tolerance limit being nil in case of vegetables). Avermectins, rotenone, milbemycins, and ryanodine (in increasing LD_{50} – 10–1200 mg/kg – that means decreasing toxicity order) all lie on LD_{50} axis.

5 Low Toxicity Advantage Factor (LTAF) in Tolerance Limits: Discussion

The food law authorities probably do not consider the high LD_{50} or low toxicity data alone while establishing tolerance limits or maximum residue limits for an insecticide in a food product. The biodegradability of an insecticide is also a criterion in this matter with a viewpoint of environmental safety. In general, natural insecticide

molecules possess low toxicity, indicated by low values of $LD_{50,}$ compared to synthetic insecticides. Needless to say, being the part of nature, the natural insecticides are biodegradable too. However there also seems one more criterion, taste agreeability or agreeable effects on human body, which might be prominently considered by lawmakers in assigning tolerance limits for insecticides. Therefore obviously the question arises how much an insecticide is capable of taking advantage of low toxicity (or high LD_{50} data) in tolerance limits. A convenient measure for toxicity consideration in tolerance limit establishment might be the ratio of tolerance limit to LD_{50} value of an insecticide.

LTAF in TLE (low toxicity advantage factor in tolerance limit establishment): It is a term devised by the author of this paper, the ratio of tolerance limit for a particular insecticide in case of a food article established by a food law to its LD_{50} value, to make an idea of positioning of taking advantage of low toxicity or high LD_{50} value in establishing tolerance limits.

Since higher LD_{50} values correspond to lower toxicity of insecticides, the aforementioned ratio is termed as low toxicity advantage factor in tolerance limit establishment or LTAF in TLE.

The well-known insecticides in descending LTAF order in TLE for vegetables are arranged as follows (Table 1):

A perusal of above tabulated data leads to the fact that high LD_{50} (low toxicity) insecticide molecules, most of which are natural including the safest azadirachtin, occupy the bottom positions in the list of insecticides arrayed in descending LTAF order. On the other hand, the top 3 insecticides, all synthetic, possess LD_{50} value less than 20 and hence are highly toxic. The most environment-unfriendly insecticide molecule DDT occupies the fifth position in the list of 34 well-known insecticides in descending LTAF order. It simply means that taste agreeability or agreeable effects on human body play the prominent role in establishment of tolerance limits for insecticides in food products.

6 Conclusion

Dicofol (synthetic organochlorine), malathion (synthetic organophosphorus), and pyrethrums (natural), which possess LD_{50} values more than 500, occupy the mid-positions (14th, 15th, and 16th) in the list of 34 well-known insecticides arranged in descending LTAF order. The least toxic insecticides benomyl and carbendazim (both synthetic carbamates) occupy 22nd and 23rd positions. At 32nd position is the eco-friendliest azadirachtin, active ingredient of *neem.* Spinosad, lesser toxic than azadirachtin, occupies the last position in this list. Azadirachtin, spinosad, pyrethrins, carbendazim, benomyl, malathion, and dicofol perhaps are the insecticides which might be so wisely applied in farms with the viewpoint of safe agriculture that food product does not cross their MRL (maximum residue limit) specified by FSSR. However bio-diversified forests and pastures seem necessary for soil conservation and effective bio-control of insects to facilitate traditional kind of farming utilizing safe natural insecticides for crop protection.

Table 1 Toxicity and LTAF (deceasing order) data

S.NO.	Name and type of insecticide	LD_{50} (female rat) mg/kg animal weight	LTAF in TLE
1.	Parathion (synthetic, organophosphorus)	3.6	1389
2.	Endosulfan (synthetic, organochlorines)	18	1111

Abstract

Mushrooms are globally appreciated for their nutritional value and medicinal properties. Their cultivation is an effective bioconversion technology of transforming wastes and woods into potentially valuable resources and could also be an important part of sustainable agriculture and forestry. Although India has the advantage of favorable agroclimate, abundance of agrowastes, relatively low-cost labor, and a rich fungal biodiversity, it has witnessed a lukewarm response in growth of mushroom cultivation. Out of the total mushroom produced in India, white button mushroom share is 73% followed by oyster mushroom (16%), paddy straw mushroom (7%), and milky mushroom (3%). The per capita consumption of mushrooms in India is also very meager and is even less than 100 g per year. Besides low fat and high protein and vitamin contents, mushrooms are rich sources of several minerals and trace elements, as well as dietary fibers. The reported medicinal effects of mushrooms include anti-inflammatory effects, with anti-inflammatory compounds of mushrooms comprising a highly diversified group in terms of their chemical structure. They include polysaccharides, terpenoids, phenolic compounds, and many other low molecular weight molecules. Of late, mushrooms have emerged as wonderful source of nutraceuticals, antioxidants, anticancer, prebiotic, immunomodulating, anti-inflammatory, cardiovascular, antimicrobial, and antidiabetic. Owing to the synergistic action of present bioactive molecules, majority of mushroom products possess beneficial health effects and can be used on a regular basis without harm. Therefore, they are considered as perspective organisms to develop different healthcare biotech product. Mushrooms could potentially be very important in future food supplies and in new dimensions of sustainable agriculture and forestry. In this chapter, an attempt has been made to provide an insight into the various aspects of cultivation of mushroom cultivation in India, nutritional benefits, therapeutic potential, and bioactive components present in edible mushrooms.

1 Mushroom: Structure, Growth, and Composition

In broad sense, "mushroom is a macro fungus with a distinctive fruiting body, which can be either epigeous or hypogeous and large enough to be seen with naked eye and to be picked by hand" [1]. It is perhaps the most well-known and documented edible forest product [2]. Mushrooms have been widely used as foods [3, 4] and very often as delicious and nutritious foods [5]. Approximately 14,000 described species of the 1.5 million fungi estimated in the world produce fruiting bodies that are large enough to be considered as mushrooms [6]. Mushrooms belong to basidiomycetes and ascomycetes with a cell cycle including the formation of sexual spores and have two growth phases, i.e., the vegetative phase (mycelia) and the reproductive phase (fruit bodies). The fungal spores are located in a special structure called the basidium (for Basidiomycetes) or the ascus (for Ascomycetes). The mushroom continues its life cycle in three key stages. viz., vegetative growth, reproductive growth, and spore production by fruit bodies of the mushrooms (Fig. 1).

Fungi lack the most important feature of plants, i.e., the ability to use energy from the sun directly through chlorophyll. Thus, fungi depend on other organisms for food, absorbing nutrients from the organic material in which they live. The living body of the fungus is mycelium made out of a tiny web of threads (or filaments) called hyphae. Hyphae absorb digestive products, penetrating the substrate to some extent. Under specific conditions, sexually compatible hyphae will fuse and start to form spores. The larger spore-producing structures are considered as mushrooms. The spores released from the gills again germinate and develop to form hyphae,

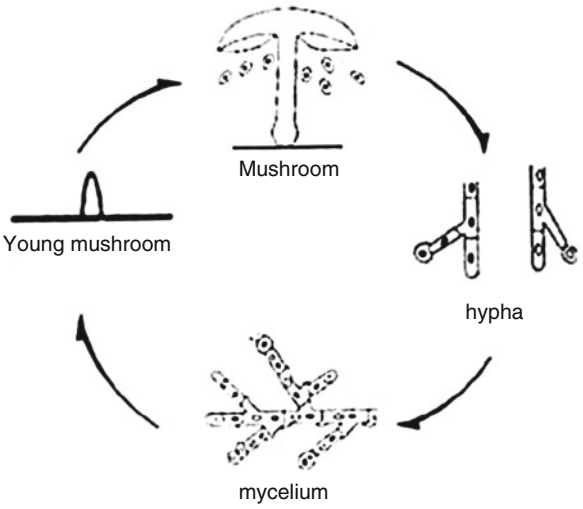

Fig. 1 Basic life cycle of mushroom

which is the main mode of fungal vegetative growth. The mushroom produces several million spores in its life, and this life cycle is repeated each time the spores germinate to form the mycelium. Mycelial growth is generally coupled with increased enzyme production and respiration.

2 Global Trends of Mushroom Cultivation

Mushrooms are the common components in folk medicine, especially in Africa, the Middle East, China, and Japan since ages. Earlier, edible mushrooms were only harvested wild and were difficult to domesticate and cultivate. Collection from wild woodlands is still important in the world and particularly in southern Asia [7, 8] and other developing countries [9]. Mushrooms such as *Auricularia*, *Flammulina*, and *Lentinula* were most likely cultivated for the first time around the year 600–800 AD in China and other Asian countries [10]. Their cultivation at large scale started only at the beginning of the twentieth century when pure cultures of mushroom were prepared from spore and tissue. As the amount of wild mushrooms shrink from both the degraded environment and natural resources and more costly labor, cultivated mushrooms would not only provide food security but also sustainable and more nutritious diets [5]. The commercial production of edible mushrooms represents the unique exploitation of a microbial technology for the bioconversion of agricultural, industrial, forestry, and household wastes into nutritious food (mushrooms). Mushrooms have the capacity to breakdown the lignin and utilize it as a food source, thus exposing the underlying cellulose and hemicellulose for food use by other organisms. Thus, mushroom cultivation represents a very basic natural process of fungal decay.

With the world's increasing population and its decrease in per capita arable land, along with rapid urbanization and industrialization, climate change, and a demand for quality and functional foods, it will be necessary to focus on secondary agriculture and novel crops, such as mushrooms. Mushroom cultivation could also be an important part of sustainable agriculture and forestry. Huge quantities of wide varieties of organic waste are generated from agriculture, forestry, and food processing. The impacts of the mushroom business on livelihoods and poverty reduction are significant and widespread. Mushroom cultivation does not require a lot of land, significant capital investment, but is a viable and attractive activity for both rural farmers and semi-urban dwellers. Mushroom cultivation strengthens the livelihood of poor and marginal farmers by generating constant farm income and reduces the vulnerability to poverty. The scale of cultivation can be large or small based on the capital and labor availability. It can be cultivated on a part-time basis with little maintenance. Indirectly, mushroom cultivation also provides opportunities for improving the sustainability of small farming systems through the recycling of organic matter, which can be used as a growing substrate and then returned to the land as fertilizer. There are hundreds of identified species of fungi which have made a significant contribution to human food and medicine. The total number of described fungi of all kinds is currently 110,000 species [11] of which 16,000

(15%) species are mushrooms [11–13]. Out of these, more than 3000 species from 231 genera are regarded as prime edible mushrooms [13–15] of which only about 200 are experimentally grown, 100 economically cultivated, around 60 commercially cultivated, and more than 10 produced on an industrial scale in many countries [16]. Approximately 700 mushroom species out of the known 16,000 are considered to be safe and have medicinal properties [13]. The number of poisonous mushrooms approximates 500 species. The most acceptable varieties among the cultivated types are *Agaricus bisporus* (button mushroom), *Pleurotus* spp. (oyster mushroom), *Lentinus edodes* (Shiitake), and *Volvariella* spp. (paddy straw mushrooms). In the second half of the twentieth century, there were rapid changes in rate of growth of mushroom production and number of species like shiitake, oyster mushrooms, and wood ear mushroom, and *Flammulina* were brought under commercial cultivation. By the end of the twentieth century, the share of button mushroom in total world production was less than 40%, which in next 10 years became around 30%. Presently shiitake, oyster, wood ear, and button mushrooms contribute 22%, 19%, 18%, and 15%, respectively in terms of total mushroom production in the world [17]. The contribution of medicinal mushrooms in world trade has also increased over last few decades.

Mushroom farming is today being practiced in more than 100 countries, and its production is increasing at an annual rate of 6–7%. Cultivated mushrooms have now become popular all over the world. In 1999, the world production of cultivated edible mushrooms was estimated to be >7 million tons, showing a steady increase over the last two decades. China is the largest producer, consumer, and exporter of mushrooms in the world, followed by the United States and the Netherlands (Table 1). In China, mushroom is the 6th important crop in the country as far as revenue generation for the nation is concerned. Mushroom production in China in 2010 was 21,524,473 t [18]. The last few decades have witnessed a sharp rise in diversification in number of mushroom species that have been cultivated, world mushroom production, commercialization accompanied with mechanization, and in

[37]

many cases automation. Mushroom cultivation and its processing have been beneficial to millions of people in China, India, and other developing countries in terms of financial, social, and health improvement. The global mushroom industry has expanded very rapidly in the last two decades by the addition of newer types of mushrooms for commercial cultivation. In addition, cultivation and development of mushroom industries have positively impacted on economic growth, and this impact of mushroom cultivation and mushroom derivatives and products on human welfare in the twenty-first century can be considered globally as a "nongreen revolution."

3 History and Status of Mushroom Cultivation in India

The history of mushroom cultivation in India goes back to the ages of "Vedas," wherein the mention was made in the classical religious scriptures like "Rig Veda" and "Atharva Veda" about the use of juice from fly agaric mushroom (*Amanita muscaria*) as an intoxicating drink, named "Soma." Vegetarianism is assumed to be the norm of Indian diet and is primarily based on cereals (wheat, rice, and maize) which are deficient in protein. Incorporation of mushrooms in Indian diet has the potential to bridge this protein gap and reduce the problem of malnutrition to a great extent. For people in a developing country like India, the two main issues are the quality food and the level of unemployment, in addition to environmental concerns, which can be very well resolved by popularizing mushroom cultivation among rural masses and the younger generation [19]. Although time to time, small efforts and simple research were conducted to introduce mushroom cultivation in India, scientific and systematic research only started in 1961, when the Indian Council of Agricultural Research, New Delhi, first cultivated *Agaricus bisporus* at Solan in Himachal Pradesh, a hilly state of North India. India, primarily being an agrarian economy, is rich in terms of agrowastes that are not properly utilized by the nation's farmers. India produces nearly 700 million tons of agricultural residues which can profitably be utilized for mushroom cultivation. Even if India uses 2% of its total agroresidues for mushroom production, the production would be 7.0 million tons of fresh mushrooms, which will be equal to current global button mushroom production. Currently, India is using only 0.03% of these residues to produce about 0.13 million tons of mushrooms and contributes $<1\%$ of the total world mushroom production. Though mushroom production in Asian countries started 1000 years ago, cultivation of mushrooms is a relatively new phenomenon in India. There has been significant increase in production of mushrooms in the last few years, especially of the oyster and paddy straw mushrooms in India. By considering the present production data, mushroom industry in India recorded an average annual growth rate of 4.3% per annum. During this period, the productivity has raised from 20% to 24.5% by the releasing of improved strains in commercial edible mushroom. The total white button mushroom produced in India from both seasonal and high-tech cultivation units is estimated at 94,676 mt. There has been significant increase in production and productivity of mushrooms (Fig. 2) in the last few years, especially of the oyster and paddy straw mushrooms in India. The country's production in 2010

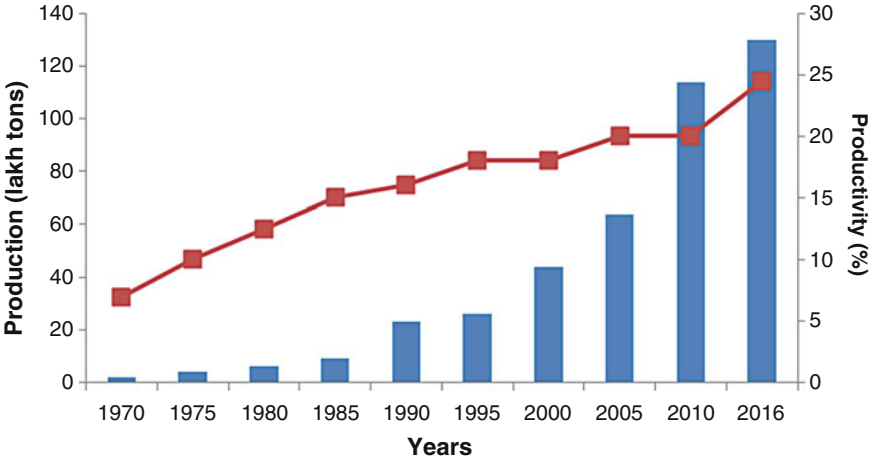

Fig. 2 Production and productivity of mushrooms in India [20]

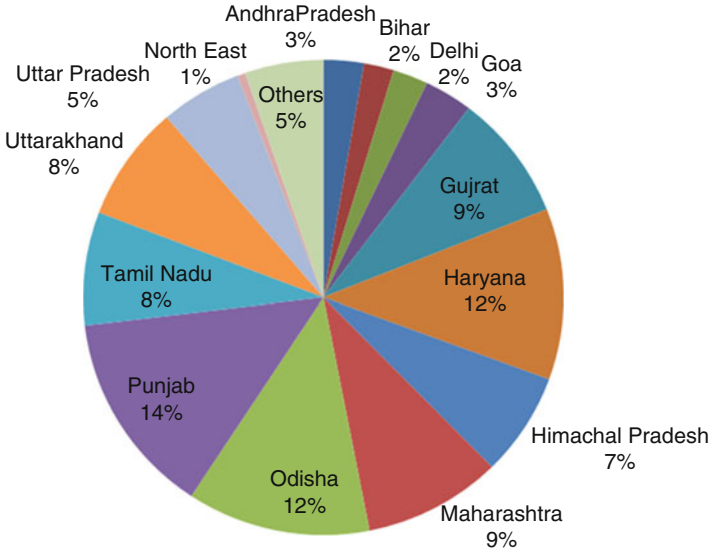

Fig. 3 Share of different states of India in National mushroom production [20]

was 1.00 lakh metric tons, of which button mushroom accounted for 89% of the total production, followed by oyster (6%), milky (1%), and others (4%). Punjab, Uttarakhand, Haryana, Uttar Pradesh, and Tamil Nadu were the leading producers of the mushroom in the country at the time of 2010. The present production status revealed that Punjab, Haryana, and Odisha are emerging as the leading states in mushroom production (Fig. 3).

3.1 Relative Contribution of Different Mushroom Species

In India, there are five mushroom species, viz., white button mushroom (*Agaricus bisporus*), oyster (*Pleurotus* spp.), paddy straw (*Volvariella volvacea*), milky (*Calocybe indica*), and shiitake (*Lentinula edodes*), which are under commercial cultivation. Even though cultivation technologies of many exotic mushrooms have been standardized, the commercial markets are still dominated by *Agaricus bisporus*, *Pleurotus* spp., and *Volvariella volvacea.* These three mushrooms are contributing about 96% of total mushroom produced in India (Fig. 4). Milky mushroom (*Calocybe indica*) is indigenous tropical mushroom of the country [21]. However, the commercial cultivation is restricted to southern states of India and contributing up to 3% to the total mushroom production. Production of paddy straw mushroom became more popular in the states of Odisha and Chhattisgarh, and its production was registered at 7% to the total mushroom production. Two to three crops of button mushroom are grown seasonally in temperate regions with minor adjustments of temperature in the growing rooms, while one crop of button mushroom is raised in the northwestern plains of India seasonally. Oyster, paddy straw, and milky mushrooms are grown seasonally in the tropical/subtropical areas. In Northeastern states, Uttarakhand and Chhattisgarh, oyster mushroom cultivation is emerging as one of the leading cottage industry. Hence, for choosing a species for commercial cultivation, the grower must consider the availability of waste materials to use as a growth medium, the prevailing environmental conditions, available expertise, available resources, and market demand.

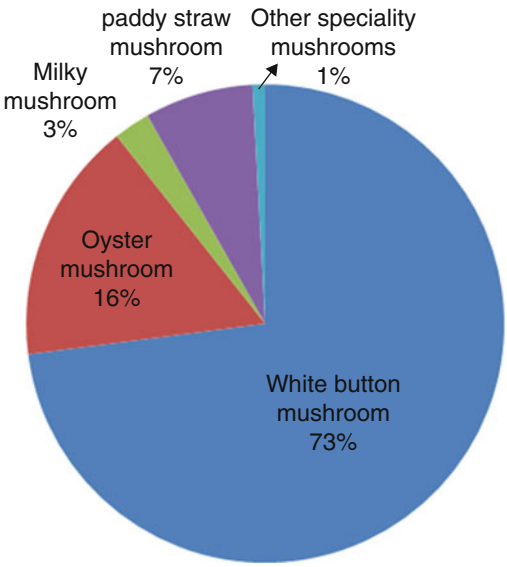

Fig. 4 Relative contribution of different mushroom species in total production [20]

4 Marketing of Mushrooms

Mushroom cultivation provides an opportunity to generate a highly tradable commodity, thereby contributing to income generation. But, majority of the farmers fail to make profits out of their mushroom production activity due to the poor marketing strategy [22]. It is the simple system of producers selling directly to retailer or even to consumer, which has its own limitations like seasonal cultivation of mushrooms and glut of mushrooms at a particular time especially in North India during the winter months forcing the distress sale of the mushrooms. This reinforces that effort to increase the production without solving its marketing problems would be counterproductive. For successful marketing, it is necessary to explore various marketing options for fresh mushrooms and selling them after processing as value-added products like pickles, nuggets, dry powder, etc. which could fetch good returns.

5 Types of Cultivated Mushrooms

The most basic concept of mushroom cultivation is that we need to produce an environment in the substrate that is selectively preferential to the growth of our target mushroom species and less amenable to other types of microorganisms and pests. This involves sterilization or pasteurization. Once the substrate is treated in this way and the majority of the microorganisms are killed, the substrate is suitable for the introduction of our target species of mushroom. Another potential treatment method is simply to soak the substrate in water. It prepares a substrate which is more selective to the higher cellulose-degrading organisms such as oyster mushrooms. This is the simplest method of substrate preparation, but the chemical treatment methods are much more effective and not considerably more difficult or expensive.

5.1 Mushrooms Under Cultivation in India

A brief account of some popularly grown mushrooms in India is as follows:

5.1.1 Button Mushroom

The white button mushroom is the most popular of the cultivated mushrooms. This was the first mushroom to be commercially exploited on an industrial scale and ranks first at the global level.

The genus *Agaricus* has two cultivated species, namely, *A. bisporus* (temperate button mushroom) and *A. bitorquis* (tropical or high temperature-tolerant white button mushroom). A partially decomposed organic matter prepared under aerobic conditions is using as a substrate for growing button mushroom. This substrate is generally termed as compost. The purpose of composting is to prepare a physically and chemically homogeneous medium for the growth of mushroom mycelium. The composting can be done either by long method of composting (LMC) or by short method of composting (SMC). In LMC, the entire composting operation is carried

out in open, and pasteurization required for conditioning of compost is achieved by natural means. SMC is followed by the commercial button mushroom units with environmental control facilities for composting and cropping.

In SMC, the compost is prepared in two phases. During the first phase, outdoor composting for 10–12 days followed by indoor pasteurization and conditioning for 7 days in the second phase. During the phase I, the cereal straw is thoroughly wetted on the cemented floor. This pre-wetted straw is then mixed with the chicken manure and wheat bran and kept as such for 2 days in the form of a pile. After that, the pile is broken and restacked. Four days later, the pile is once again broken and the entire quantity of urea is added. After 2 days, the stack is again turned and watered and gypsum is added in the third turning. During this stage, the temperature of pile raises to 70–80 °C. The final turning is given on the 12th day when the color of the compost changes into dark brown and it starts emitting a strong smell of ammonia. The compost prepared as a result of microbial fermentation process needs to be pasteurized in order to kill undesirable microbes and competitors. The compost from phase I is then filled in the pasteurization tunnels to the height of 2–2.3 m. At this stage, temperature inside the tunnel is set at a range of 45–48 °C which is then raised to 48–52 °C and maintained for 48 h. After 48 h, the compost temperature is raised to 58–62 °C and maintained for 4–6 h by inducting the steam. Thereafter, the temperature is brought down to 48–52 °C, and the compost is retained at this temperature for 3 days. The ammonia level in the compost is monitored regularly and if no ammonia persists in the compost, the compost temperature is brought down to room temperature. At this stage, the final compost should be granular in structure with 65–70% moisture and pH in the range of 7.2–7.5.

Spawning and Spawn Run

After phase II of SMC, the compost is thoroughly mixed with the spawn at 0.5–0.75% (500–750 g) in polypropylene bags and kept in the cropping room where the moisture content of substrate is maintained at 65–70% and temperature at 23 $\pm$ 1 °C. It takes about 12–14 days for the complete colonization of mycelium.

Casing and Case Run

Once mycelium completely colonizes the compost, it can be switched over to fruiting stage by covering the surface of the substrate with a thin layer of casing material. Mixture of 2-year-old FYM and garden soil in 1:1 ratio is most preferable casing material.

Crop Management

Environmental conditions after casing should be the same as during spawn running. Within 3 days of application, the mycelium starts growing into the casing layer. Once mycelial growth is firmly established, the casing is gradually watered up to its optimum moisture-holding capacity.

At this stage, the microclimate in the cropping room which includes substrates and air temperatures in the range of 16–18 °C and humidity to 85% should be adjusted. Besides this, carbon dioxide content of the room should be reduced to less

than 1000 ppm by the induction of fresh air, and the room is lighted on a 12-h on/off cycle as mentioned below to promote the fruiting. This change in environmental parameters helps to the initiation of pinning and subsequent development of pinheads into solid fruit bodies within 3–4 days. The mushroom crop grows in cycles called as "flushes or breaks." The uniform fruit bodies of 4–5 cm in diameter should be handpicked in a twisting motion. Daily watering is required after harvesting the first flush. 18–20 kg of fresh mushrooms can be harvested from 100 kg of prepared compost in a total of three flushes.

5.1.2 Oyster Mushroom

Pleurotus mushroom, which is generally referred to as "oyster mushroom" the world over and as "dhingri" in India, has its origin from the Greek word "pleuro," which means formed laterally or in a sideway position, particularly referring to the lateral position of the stipe (stem) in relation to the pileus (cap). Species of the genus *Pleurotus* are well appreciated for their broad adaptability under varied agroclimatic conditions. The several species of this mushroom occur commonly as wood decomposers in forests throughout the world. *Pleurotus* has always been most attractive to commercial mushroom growers because of the ease by which most of these species can be cultivated. This mushroom consists of species that are suitable for both temperate and subtropical regions. For temperate regions, *Pleurotus ostreatus*, *P. florida* (winter strain), and *P. fossulatus* and *P. eryngii* (king oyster) are ideal. The areas suitable for the button mushroom are equally suitable for the cultivation of these species. The majority of the oyster species can be best grown in the temperature range of 20–30 °C with high relative humidity in excess of 85%. The majority of the *Pleurotus* species require 25–30 °C for spawn runs and 20–25 °C for fruiting. The oyster mushroom is a low-investment, low-risk, low labor-intensive, and moderate-profit enterprise. The greatest advantage of the oyster mushroom is that its production technology is simple and that it can be easily grown at the village level in small makeshift sheds (huts). Growing the oyster mushroom is less expensive and more convenient compared to other species, such as the button mushroom. The method of cultivation is also very simple; unlike the button mushroom, it does not need any compost preparation or precise temperature control. It can be sold both in fresh and dried form.

Substrate Preparation

The oyster mushroom has less specificity toward the substrate. Hence, it can be cultivated on a large number of agrowastes such as cereal straw, sugarcane bagasse, saw dust, dried grasses, discarded wastepaper, etc. The pasteurization of the substrate can be achieved either by steam pasteurization or hot-water treatment. Chemical pasteurization also results in elimination of competitor fungi, but its use is discouraged due to the residual levels in the mushroom fruit bodies.

Spawning and Incubation

Freshly prepared grain spawn is mixed thoroughly at 2–3% of the substrate on wet weight basis, and the spawned substrate is filled in the polythene bags. 10 to 15 small

holes made on all sides of the bag facilitate the aeration and drainage of excess water. During the spawn run stage, the bags are not to be opened, and it doesn't require much ventilation or water sprays.

Crop Management

Optimum temperature for mycelia growth of oyster ranges between 22 °C and 26 °C. Once the mycelium fully colonizes the substrate, it forms a thick mycelial mat indicating the readiness for fruiting. During the fruiting period, a relative humidity of 80–85% needs to be maintained by spraying the water two to three times, and sufficient ventilation should be provided for air circulation. The color of the oyster is also influenced by the light intensity and its duration. Fruit bodies raised in bright light appears in dark brown or gray in color, and the fruit bodies raised in less intensity of light appears in pale yellowish color.

With suitable crop management practices, mushroom fruit bodies are ready for harvesting in 6–8 days after pinhead formation. Mushrooms may be harvested while the edges of the caps are still curled down. Under normal room temperature conditions, fresh mushrooms can be stored for 2–3 days without any deterioration. The fruit bodies can be dried under sunlight to the moisture level of 8–10%. The dried oyster mushroom can be successfully stored for 4–6 months without losing its original properties.

5.1.3 Milky Mushroom

The milky white mushroom grows during the summer, and it is a tropical mushroom known for its nutritional value. Its robust size, sustainable yield, attractive color, delicacy, long shelf life, and lucrative market value have attracted the attention of both mushroom consumers and prospective growers. *Calocybe indica* is rich in protein, lipids, fiber, carbohydrates, and vitamins, and it contains an abundant amount of essential amino acids and is low in fat. These qualities make it suitable as a dietary food supplement. The milky mushroom (*Calocybe indica*) is purely of Indian origin and highly suitable for the tropical climatic conditions of Central India, North India, and South India. Its cultivation is now spreading quickly in many Indian states, including Tamil Nadu, Kerala, Orissa, Haryana, and West Bengal due to its longer shelf life and adaptability to warm and humid conditions. At present, Tamil Nadu is the major producer of the milky mushroom in India.

Milky mushrooms can be grown on a wide range of lignocellulosic residues, but commercial cultivation is done on paddy straw or wheat straw. The cultivation technology of milky mushroom is a mixture of button and oyster mushroom cultivation technologies. It does not require compost for its growth specially as the substrate is prepared as per the technique used for oyster mushroom. Spawning is done at 4–5% of wet weight of substrate, and the spawned bags are then shifted to incubation room at 28–32 °C under dark conditions. It takes 20–25 days for completion of spawn run. However, once the spawn run is complete, a layer of casing material needs to be applied for induction of fruiting. Thereafter temperature of 30–35 °C, R.H. 80–90%, and light intensity at 600–1000 lux is required to be maintained for cropping. Primordia formation and fruit body maturation takes place

within 8–10 days after casing. Mushrooms are harvested when the stipe length reaches 7–8 cm by twisting with hand. Harvested fruit bodies can be consumed fresh or store the clean mushrooms by wrapping in film for 7–10 days at room temperature.

5.1.4 Paddy Straw Mushroom

The paddy straw mushroom *Volvariella* sp. prefers to grow on paddy straw; hence, it is known as paddy straw mushroom. Chinese growers developed its cultivation more than 300 years ago. Therefore, it was named "Chinese mushroom" [23]. The paddy straw mushroom is the sixth most important cultivated mushroom in the world [24]. Paddy straw mushroom (*Volvariella volvacea*) is a world famous edible mushroom variety that enjoys high demand due to its deliciousness and nutritive value. It is the only mushroom which can be cultivated both indoor and outdoor. It is a popular variety among growers because of short cropping season compared to other cultivated mushrooms. No other vegetable or cultivated mushroom can be served as a table dish within a short time after planting, but *V. volvacea* can do this as it comes to harvest 10-days post-planting. The climatic conditions prevailing in India are best suited for the cultivation of this mushroom. Currently, Orissa is the leader in commercial cultivation of this mushroom.

Outdoor Cultivation

The traditional outdoor cultivation is done seasonally under the shades of trees by making mushroom beds on the raised platform made from bricks and bamboo poles. Straw bundles of 45 cm length and 10 cm width are prepared by cutting the top leafy portion and part of thick stalk near the roots by hand or motorized cutter. The bundles are soaked in water or in 2% $CaCO_3$ solution for 12–14 h. Then these bundles are placed side by side followed by placing the mushroom spawn at six to eight spots and covering of spawn with red gram dal powder. 12–15 beds are prepared in the similar manner, and the whole lot of beds prepared in a line are compressed a little and covered with clean plastic sheet.

The spawn run requires a temperature of above 39 °C, and spawn run will be completed in 6–7 days. After the completion of spawn run, the plastic sheet is kept loosely covered over the beds. The mushrooms start coming from all sides of the bed after 12–13 days of spawning. They can be harvested at egg stage by holding between forefinger and thumb followed by twisting clockwise or anticlockwise direction. The harvested mushrooms can be cleaned and packed in polythene bags or in paper bags, but the bags should not to be sealed. These packed mushrooms must be sold for consumption preferably on the same day.

Indoor Cultivation

Indoor cultivation can be done on a substrate/compost prepared by mixing cotton ginning mill waste and paddy straw in 1:1 ratio on weight basis. The substrate after mixing is wetted for 2 days, and later the poultry manure is added at 5%. The substrate is mixed thoroughly and made into a pile. First two turnings are given at an interval of 1 day each, and calcium carbonate at 1.50% is added at third turning, and

the substrate is left for fermentation for next 2 days. After 4 days of outdoor composting, the compost is spread on the shelves to a thickness of 10–15 cm. The steam is introduced inside the cropping room for heat conditioning of the compost. Temperature is maintained at 62 °C for 4–5 h. After a day, the compost is spawned at 1.5% on wet weight basis, and the beds will be covered with the plastic sheet. The room temperature is maintained at 32–34 °C during spawn run period. The compost gets colonized within next 4–5 days, and then the beds are sprinkled with water by removing the plastic sheet. The pinhead starts appearing on 5th–6th day of spawning. After another 4–5 days, the first flush of mushroom gets ready for harvesting. The paddy straw mushroom is not suitable for storing in refrigerator and must be consumed fresh immediately after harvesting or may be stored at room temperature for few hours.

5.1.5 Shiitake Mushroom

Shiitake mushroom is one of the world's most popular edible mushroom species known for its nutrition, flavor, and medicinal properties. It contains a bioactive compound – lentinan – which has anticarcinogenic and tumor-suppressing properties. Traditionally shiitake mushroom was cultivated on fallen wood logs stacked in evergreen forests in China since centuries. But its commercial cultivation gained the momentum after developing the synthetic log cultivation technology.

Synthetic Log Cultivation

Saw dust obtained from the broad-leaved trees such as tuni, poplar, mango, safeda, oak, maple, etc. is the main basal ingredient for the preparation of synthetic logs. For preparation of synthetic logs, saw dust is supplemented with the wheat bran or rice bran in the ratio of 80:20, and calcium carbonate is mixed at 1% on dry weight basis to maintain the pH levels below 7.0. Ingredients are thoroughly mixed and moistened to a level of 60–65%. The prepared substrate is filled in the heat-resistant polypropylene bags and then sterilized for 2 h at 121 °C and 22 psi of pressure. After sterilization, the bags are cooled for a day and thereafter seeded with fresh grain spawn at 45–50 g per bag. Spawning is done under aseptic conditions using laminar airflow chamber. After inoculation, the bags are shifted to incubation room where the temperature is maintained at 22–26 °C. Spawn run is generally completed within 30–35 days, and a thick mycelia coat will develop on the surface of the substrate after 6–8 weeks of spawning. This mycelial coat will eventually turn into brown color with some exudates. Clumps of mycelium will form on the surface of the mycelial coat 10–12 days after mycelial coat formation. These clumps will turn into mushroom fruit bodies at the later stage. The temperature of about 18–20 °C and relative humidity of more than 85% are required to be maintained till the maturity of the fruit bodies. The fruit bodies keep coming for 15–20 days in a flush after each shock treatment of cold water. Cold water treatment should be repeated for the subsequent three to four flushes also till the exhaustion of nutrients in the substrate. The harvested fresh fruiting bodies of shiitake mushroom can be stored for 3–4 days at 18–20 °C, and keeping them at 4–6 °C will extend their shelf life up to 14 days. The shiitake mushroom can also be stored up to 1 year by drying.

6 Nutrition in Mushrooms

Edible mushrooms have been widely utilized as human food for centuries and appreciated for texture, flavor, as well as medicinal and tonic attributes [25]. In general, mushrooms contain 90% water and 10% dry matter [26]. They have a chemical composition, which is attractive from the nutritional point of view [27]. Mushrooms are nutritionally important as they are rich in protein, fibers, and minerals, while poor in fats. The mushroom protein contains all the nine essential amino acids required by humans. Mushrooms are considered as a potential substitute of muscle protein on account of their high digestibility [28]. Besides this, mushrooms are also rich source of vitamin B1, B2, B12, C, D, and E [29, 30] and a relatively good source of nutrients like phosphorus, iron, and vitamins, including thiamine, riboflavin, ascorbic acid, ergosterol, and niacin [31]. Mushrooms are also an excellent source of vitamin D which is otherwise not available in other food supplements [32].

Mushrooms are low in calories, fat-free, cholesterol-free, gluten-free, and very low in sodium. Minerals such as potassium, iron, copper, zinc, and manganese are high in fruit bodies. They also have ash, glycosides, volatile oils, tocopherols, phenolic compounds, flavonoids, carotenoids, folates, organic acids, etc. [33]. Mushrooms are also important from nutraceutical point of view, as they contain several compounds like unsaturated fatty acids, phenolic compounds, tocopherols, ascorbic acid, and carotenoids. The nutritional attributes of edible mushrooms and the health-benefiting effects of the bioactive compounds they contain make mushrooms a health food [34–36].

Consumers are now deeply interested in food bioactives that provide beneficial effects to humans in terms of health promotion and disease risk reduction. Mushrooms can be considered as functional food which provides health benefits in addition to nutritional value [38]. The concept of "functional foods" was first introduced as a factor in the analysis of foods after nutrients [39].

The most common nutrients of mushrooms are discussed as follows:

6.1 Proteins and Amino Acids

The crude protein content of edible mushrooms is usually high but varies greatly and is affected by factors such as species and stage of development of the mushroom [40]. The free amino acid level of mushrooms is usually low ranging from 7.14 to 12.3 mg/g in dry edible mushrooms and contributes to the main flavor properties of mushrooms [41]. The essential amino acid profiles of mushrooms reveal that the proteins are deficient in sulfur-containing amino acids, including methionine and cysteine. However, these edible mushrooms are comparatively rich in threonine and valine.

6.2 Vitamins

Cultivated mushrooms are a good source of several vitamins, such as riboflavin, niacin, and folates. The vitamin B2 content in mushrooms is higher than that

generally found in vegetables, [30]. Mushrooms contain moderately high amounts of folates, and their bioavailability is as good as that for folic acids [42]. In addition to riboflavin, niacin, and folates, cultivated mushrooms also contain small amounts of vitamin C and vitamin B1 and traces of vitamins B12 and D2 [30].

6.3 Carbohydrates

Edible mushrooms contain high levels of oligosaccharides and only a low level of total soluble sugars [43]. The carbohydrate content of edible mushrooms varies with species and ranges from 35% to 70% DW [44].

6.4 Fatty Acids

The fatty acid level in mushrooms is generally low around 2–8% of distilled water. The level of polyunsaturated fatty acids as compared to saturated fatty acids is quite high, constituting more than 75% of total fatty acids of which oleic and linoleic acids are the most significant, while palmitic acid is the main saturated fatty acid [45].

7 Therapeutic Potential of Mushrooms

The major attribute of mushrooms is their medicinal properties and presence of bioactive compounds. The pharmacological properties of mushrooms include immunity enhancement, maintenance of homeostasis, regulation of biorhythm, and most importantly cure and prevention of various life-threatening diseases such as cancer, stroke, and heart diseases. Medicinal properties of mushrooms including anti-inflammatory, antioxidant, immunomodulatory, anticarcinogenic, antiviral, antibacterial, antifungal, hepatoprotective, antidiabetic, anti-angiogenic, hypoglycemic, etc. have been reported [46]. Immunomodulatory and antitumor activities of polysaccharide–protein complex (PSPC) from mycelial cultures of mushrooms have been extensively studied [47–49]. The pharmacological potential of mushrooms includes the following:

7.1 Mushrooms as Antioxidants

Edible mushrooms possess potent antioxidants. A study of methanolic extracts from black, red, and snow ear mushrooms found that mushrooms possess an inhibitory effect on lipid peroxidation, 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging and hydroxyl radical scavenging, and a strong reducing power and ability to chelate ferrous ions [50]. Similar studies on other mushrooms, including *D. indusiata*, *G. frondosa*, *H. erinaceus*, *T. giganteum*, *F. velutipes*, *L. edodes*, *P. cystidiosus*, and *P. ostreatus*, *Agrocybe cylindracea* also reported antioxidant properties of these mushrooms [44, 51].

7.2 Mushrooms as Hypocholesterolemic Agents

Regulation of the cholesterol level is important for the prevention and treatment of cardiovascular diseases. Edible mushrooms are an ideal food for the dietetic prevention of atherosclerosis due to their high fiber and low fat content. Initial research on the cholesterol-lowering effects of mushrooms was conducted in Japan in the 1960s, and it was demonstrated that when rats were fed with a high fat and high-cholesterol diet supplemented with 5% water of the fruiting bodies of *L. edodes* for 10 weeks, the plasma cholesterol levels of the animals decreased significantly [52]. Several other studies on *Lentinula* extracts have shown them to cause a significant decrease in serum cholesterol in young women and old people [53]. In another study, dietary fiber extracted from *P. cornucopiae* had a marked in vitro anti-atherosclerotic effect and patients with coronary disease showed a decreased atherogenic activity (20–40%) in their sera after the consumption of this mushroom, which confirms its property of natural cholesterol-lowering agent [54]. It has been suggested that the fruiting bodies of oyster mushrooms could be recommended for consumption as a natural cholesterol-lowering agent in the human diet [55]. Dietary fiber isolated from *Auricularia auricula* and *Tremella fuciformis* significantly decreases the serum total cholesterol (TC) and LDL cholesterol levels [56]. Various studies have shown that *Lentinula* mushrooms can lower both the blood pressure and the free cholesterol level in plasma and can accelerate the accumulation of lipids in the liver by removing them from circulation [57]. Mushroom like *A. auricula-judae* displays anti-coagulation, anti-aggregatory activity in the blood platelets of mice and rats, thus serving to lower their total cholesterol, total triacylglyceride, and lipid levels [58, 59]. *Grifola frondosa* has been reported to reduce blood pressure in rats without changing the plasma high-density lipoprotein (HDL) level or serum cholesterol level [60].

7.3 Mushrooms as Hypoglycemic Agents

Edible mushrooms are an ideal food for the dietetic prevention of hyperglycemia because of their high dietary fiber and protein and low fat content [61]. Lectins isolated from mushrooms (*Agaricus campestris* and *A. bisporus*) have been shown to enhance insulin release in isolated Langerhans rat islets [62]. The presence of a non-lectin-type component in *A. campestris* that displays insulin-releasing and insulin-like activity has also been reported [63]. Guanidine, which is a known hypoglycemic substance related to the biguanide class of oral antidiabetic drugs, has been found in edible mushrooms [64].

7.4 Mushrooms as Antitumor Agents

Cordyceps militaris has been used for a long time in Eastern Asia as a nutraceutical and in traditional Chinese medicine as a treatment for cancer patients. Searching

for new antitumor agents including mushrooms has become a topic of research. It was reported that *Ganoderma lucidum*, *Phellinus rimosus*, *Pleurotus florida*, and *Pleurotus pulmonarius* possess profound antioxidant and antitumor activities [65]. The antitumor activities of the higher basidiomycetes extracts of fruiting bodies of *Boletus edulis* and other Homobasidiomycetes were tested against the Sarcoma 180 line in mice and were found to have significant activity [66]. Calvacin was isolated from the giant puffball (*Calvatia gigantea*), and it was found effective against many experimental tumors, including Sarcoma 180, mammary adeno carcinoma 755, leukemia L-1210, and HeLa cell lines [67]. There are approximately 650 species of higher basidiomycetes that have been found to possess significant antitumor activity [14, 60].

7.5 Mushrooms as Immunomodulators

Immunomodulators are the most important medicinal mushroom drugs used especially in Japan, China, Korea, and other East Asian countries today. Some polysaccharides or polysaccharide–protein complexes from mushrooms are able to stimulate the non-specific immune system and to exert antitumor activity through the stimulation of the host's defense mechanism [68]. These drugs activate effector cells like macrophages, T lymphocytes, and NK cells to secrete cytokines like TNF-a, IFN-g, IL-1b, etc. which are antiproliferative and induce apoptosis and differentiation in tumor cells [68].

7.6 Mushrooms as Antimicrobial Agents

Mushrooms need antibacterial and antifungal compounds for survival in natural environment. Hence, they are rich sources of natural antibiotics. Many of the extracellular secretions by the mushroom mycelium are known to combat bacteria [69] and viruses [70]. Considerable antifungal and antibacterial activity against *Staphylococcus aureus*, *Bacillus subtilis*, and *Escherichia coli* has been reported in several compounds extracted from various mushrooms [71]. It was observed that whole extracts of *Ganoderma pfeifferi* inhibit the growth of microorganisms responsible for skin problems [72]. Oxalic acid has been found to be the compound responsible for the antimicrobial effect of *Lentinula edodes* (Berk.) against *S. aureus* and other bacteria [73]. Ethanolic mycelial extracts from *L. edodes* possess antiprotozoal activity against *Paramecium caudatum* [74].

7.7 Mushrooms as Antiviral Agents

Specific drugs are urgently needed for cure of viral diseases as they cannot be treated by common antibiotics. Antiviral effects are described not only for whole extracts of mushrooms but also for isolated compounds. They may act directly by inhibition of

viral enzymes, synthesis of viral nucleic acids, or adsorption and uptake of viruses into mammalian cells. These direct antiviral effects are exhibited especially by smaller molecules. Indirect antiviral effects are the result of the immune-stimulating activity of polysaccharides or other complex molecules [75]. Small molecular compounds with antiviral activities, several triterpenes from *Ganoderma lucidum* (i.e., ganoderiol F, ganodermanon triol, ganoderic acid B), are active as antiviral agents against human immunodeficiency virus type 1 (HIV-1) [76].

7.8 Mushrooms as Antiallergic Agents

Although extracts of many mushrooms can stimulate the immune system, some have been reported to suppress immune responses also. This property could be of benefit for the treatment of allergic diseases that are nowadays increasing worldwide. Ethanolic extracts of the edible Japanese basidiomycetes *H. marmoreus*, *F. velutipes*, *Pholiota nameko*, and *Pleurotus eryngii* show significant antiallergic effects in mice [77]. Some compounds from *G. lucidum* (ganoderic acids C and D) have been shown to inhibit the histamine release from rat mast cells [78, 79]. Eating of *Tricholoma populinum* led to the regression of severe allergic symptoms in a patient with thromboangiitis obliterans and in another patient with urticaria [80]. Hispolon and hispidin, isolated from fruit bodies of *Inonotus hispidus*, have been reported to inhibit the chemiluminescence response of human mononuclear blood cells and the mitogen-induced proliferation of spleen lymphocytes of mice [81].

7.9 Mushrooms as Anti-inflammatory Agents

Whole mushrooms and extracts may show anti-inflammatory activity due to the presence of bioactive compounds. Ethanolic extracts from *P. linteus* and a proteoglycan have been shown to induce anti-inflammatory effect in the collagen-induced arthritis and in the croton oil-induced ear edema test in mice and antinociceptive effect in the writhing test [82]. The edible mushroom *G. frondosa* contains ergosterol; ergosta-4-6-8(14), 22-tetraen-3-one; and 1-oleoyl-2-linoleoyl-3-palmitoyl glycerol which inhibits cyclooxygenases I and II activity [83].

7.10 Mushrooms as Hepatoprotective Agents

Ganoderic acids *R* and *S* and ganosporeric acid A from *G. lucidum* showed in vitro antihepatotoxic activity in the galactosamine-induced cytotoxic test with primary cultured rat hepatocytes [84]. In vivo study of two fractions of total triterpenoids extract of *G. lucidum* protected mice against hepatic necrosis induced by chloroform and D-galactosamine, and these hepatoprotective effects were perhaps related to the ability to promote the activity of scavenging enzymes for hepatic-free radicals in mice and thus to raise the ability of anti-oxidation in mice [85].

8 Bioactive Compounds in Mushroom

Mushrooms are widely used for their high nutritional value as a functional food. Additionally, they have been highly appreciated for their medicinal and therapeutic applications [86]. Interestingly, mushrooms are a rich source of biologically active compounds providing medicinal or health benefits such as the prevention and treatment of diseases to humans [38]. Edible mushrooms produce a vast diversity of bioactive compounds such as polysaccharides, proteoglycans, terpenoids, phenolic compounds, steroids, and lectins. These compounds have a wide range of therapeutic effects and can act as immunomodulatory, anticarcinogenic, antiviral, antioxidant, and anti-inflammatory agents [87].

Specific bioactive compounds in mushrooms are responsible for improving human health in a number of ways. Bioactive compounds can be found in mushrooms as well as their cell wall components as polysaccharides (β-glucans) and proteins or as secondary metabolites such as phenolic compounds, terpenes, and steroids. The concentration and efficacy of bioactive compounds are varied and depend on the type of mushroom, substrate, fruiting conditions, stage of development, age of mushroom, storage conditions, and of course cooking procedures [88]. On the basis of their chemical structure, bioactive compounds of mushrooms may be classified as peptides and proteins, phenolic compounds, polysaccharides, polysaccharides protein complexes, terpenes, terpenoids, etc.

8.1 Peptides and Proteins

Mushrooms produce many bioactive proteins and peptides, primarily lectins which are non-immune proteins or glycol proteins that bind specifically to fungal cell wall carbohydrates and have the ability of cell agglutination. These bioactive proteins possess enzymatic activities such as fungal immunomodulatory proteins (FIPs), ribosome-inactivating proteins (RIPs), and laccases. Anti-inflammatory peptides of different molecular weights have been isolated from mushrooms. Chu et al. [89] isolated an antifungal peptide (pleurostrin) from *P. ostreatus*, which exhibited antifungal activity. Wang et al. [90] isolated a peptide (SU2) from *Russula paludosa*, which showed antiviral properties. Ngai et al. [91] isolated an antifungal peptide (agrocybin) from fresh fruiting bodies of the mushroom *Agrocybe cylindracea* which exhibited antifungal activity against *Mycosphaerella arachidicola*, with an IC50 value of 125 μMat different temperatures up to 80 °C [92]. Cordymin, a low molecular weight peptide (10,906 Da) which shows anti-inflammatory activity, has been purified from *Cordyceps sinensis* [93, 94] and from *Cordyceps militaris* [95]. Liu et al. [96] isolated a xylose-specific lectin showing potent antimitogenic and antitumor activities from fresh fruiting bodies of *Xylaria hypoxylon*. It has been reported that lectins isolated from *Pholiota adiposa* and *H. erinaceum* exhibited antiviral and antitumor activities [97, 98]. Zhang et al. [99] isolated a lectin (32 kDa) from *Russula lepida*, which exhibited antitumor activity. Ribosome-inactivating proteins (RIPs) are enzymes that inactivate ribosomes by eliminating adenosine residues from rRNA. It has been reported that a ribosome-inactivating protein (marmorin) was isolated

from *Hypsizygus marmoreus* and showed antitumor activity [100]. Laccases are phenol oxidases widely diffused in basidiomycete and ascomycete fungi which they use to degrade lignocellulosic substrates. Laccases with antiviral activities have been isolated from *Pleurotus eryngii* [101] to *P. ostreatus* [102]. Zhang et al. [103] purified a laccase from *Clitocybe maxima*, which also showed antitumor activity. Some proteins targeting immune cells known as fungal immunomodulatory proteins (FIPs) are a new of group bioactive proteins and have been isolated from *F. velutipes* [104], *Ganoderma tsugae* [105], and *Volvariella volvacea* [106]. Lin et al. [98] isolated an immunomodulatory protein GM I from *Ganoderma microsporum*, which showed antimetastasis activity. Du et al. [107] purified a water-soluble Se-containing protein Se-GL-P (36 kDa) from the Se-enriched *G. lucidum*, which exhibited antitumor activity. A glycoprotein (PCP-3A), purified from *Pleurotus citrinopileatus*, showed antitumor activity [108]. Kodama et al. [109] isolated a low molecular weight protein fraction from *Grifola frondosa*, which showed antitumor activity.

8.2 Phenolic Compounds

Phenolic compounds are aromatic hydroxylated compounds with one or more aromatic rings and hydroxyl groups. Anti-inflammatory properties of many mushrooms have been attributed to the presence of some phenolic compounds which include phenolic acids, hydroxycinnamic acids, lignans, tannins, flavonoids, hydroxybenzoic acids, stilbenes, and oxidized polyphenols [110, 111]. It has been reported that these compounds exhibited act as free radical inhibitors, peroxide decomposers, metal inactivators, or oxygen scavengers [112, 113]. Palacios et al. [114] studied the antioxidant activity of phenolic compounds in various mushrooms and reported that *C. cibarius* and *C. cornucopioides* exhibited the greatest antioxidant effect with respect to the other mushroom species studied. The phenolic molecule pyrogallol has been extracted from *A. bisporus*, *C. cibarius*, and *L. deliciosus* [115, 116] which has been found to exhibit anti-inflammatory activity. Grifolin and grifolin derivatives are farnesyl phenolic compounds which showed anti-inflammatory properties and have been isolated from the edible mushroom *Albatrellus ovinus* [117]. It has been reported that phenol analogous compounds (hericenones C, D, E, F, G, H) isolated from *H. erinaceus* had antineurodegenerative properties [46] and antioxidant activity [118]. Attarat and Phermthai [119] reported that catechin, a major group of phenolic compounds isolated from *Lentinus squarrosulus*, *Lentinus polychrous*, and *L. edodes*, exhibited antioxidant activity. Chowdhury et al. [120] isolated phenolic compounds and flavonoids from *P. ostreatus*, *L. edodes*, and *Hypsizygus tessellatus*, which showed antioxidant, antifungal, and antibacterial properties. Dai et al. [121] reported that hispidin, a class of polyphenols, is an important medicinal metabolite from *Phellinus* spp. In most of these studies, a positive correlation was found between the total phenolic content in the mushroom extracts and their antioxidative properties, which confirms that edible mushrooms have a potential as natural antioxidants due to the ability of their phenolics to inhibit lipid oxidation.

8.3 Polysaccharides

Polysaccharides are the major class of bioactive compounds found in mushrooms and possess significant immune-stimulating, antitumor, antioxidant, antibacterial, and antiviral activities [122]. Fungal polysaccharides are the most potent mushroom-derived substances with antitumor and immunomodulating properties. They are present in cell wall with different types of glycosidic linkages. Mushroom polysaccharides with anti-inflammatory properties have been reported in crude extracts of *Lentinus polychrous*, *Termitomyces albuminosus*, and *Phellinus linteus*. Fungal pigment melanin possesses antioxidant, immunomodulating, antimutagenic, and radioprotective properties [123]. The polysaccharides of *Flammulina velutipes* are composed of three monosaccharides (glucose, mannose, and xylose) and have been found to have anti-inflammatory activities [124].

8.4 Glucans

β-glucan is one of the key components of several basidiomycetes and ascomycetes cell wall. It is a long-chain polysaccharide with β-D glucose as basic subunit linked to one another by one to three glycosidic chain with one to six glycosidic branches. β-glucans are able to enhance the immune system and prevent and treat several common diseases to promote health [125]. Fruit body extracts of *Pleurotus pulmonarius* showed mixed α-linkages and β-anomeric carbon linkages, whereas polysaccharide from mycelial extracts has mainly α-glucan linkages [126]. Lentinan, the bioactive glucan from *Lentinula edodes* showed immunomodulatory and antitumor activities [127]. Schizophyllan is the active β-glucan from *Schizophyllum commune* [128]. Glucans such as (1,3)-glucopyranosyl from *Pleurotus pulmonarius* have been reported to exhibit anti-inflammatory properties [38]. Lavi et al. [129] reported that ganoderan A and B glucans of *Ganoderma lucidum* fruiting bodies showed hypoglycemic effects. On the other hand, ganopoly, the polysaccharide-containing preparation of *G. lucidum*, exhibited hepatoprotective effects in patients with chronic hepatitis B [130]. A β-glucan isolated from the fruiting bodies of *P. ostreatus* has also been proven to exert antitumor activity against Hela tumor cell [131]. Additionally, glucans such as (1,3)- D-glucopyranosyl from *P. pulmonarius* have been reported to exhibit anti-inflammatory properties [124]. Lavi et al. [129] reported that polysaccharides of *Flammulina velutipes* are found to have anti-inflammatory activities [124].

8.5 Polysaccharide: Protein Complexes

Some polysaccharides such as polysaccharide-K (polysaccharide-Kureha; PSK) also known as krestin isolated from *Trametes versicolor* have been identified as

polysaccharide–protein complexes and showed antimetastatic activity [14]. Coriolan, a β-glucanprotein complex obtained from submerged grown *T. versicolor* biomass, exhibited hypoglycemic effects and ameliorated the symptoms of diabetes [38]. Chatterjee et al. [132] isolated calvacin, a moderately heat stable, nondiffusible basic mucoprotein from *Calvatia gigantea* which showed antitumor activity. On the other hand, ethanolic extracts and a proteoglycan purified from *Phellinus linteus* showed anti-inflammatory properties [82, 133].

8.6 Terpenes and Triterpenoids

Terpenes are the largest group of anti-inflammatory compounds in mushrooms. Several terpenes isolated from *G. lucidum* showed anti-inflammatory activity. Some triterpenes from *G. lucidum* (ganoderic acid C and derivatives) are able to inhibit the biosynthesis of cholesterol [109], while other triterpenes (ganoderic acid F) contribute to atherosclerosis protection [134]. The antioxidative and free radical effects of triterpenoids from *G. lucidum* have also been shown [38]. El-Mekkawy et al. [76] reported that different triterpenes from *G. lucidum* (i.e., ganoderiol, ganodermanontriol, and ganoderic acid) showed antiviral activity. Sterols and triterpenes (lucialdehyde D, ganoderone A, and ganoderone C) have been isolated from the fruiting bodies of *Ganoderma pfeifferi*. Several triterpenes (trametenolic acid; ergosterol peroxide; 3b-hydroxy-8, 24-dien-21-al; ergosterol; and inotodiol) isolated from the sclerotia of *I. obliquus* exhibited anti-inflammatory and anticancer activities [135]. Han et al. [136] isolated five novel cyathane diterpenes (identified as cyathins DH) and three diterpenes (neosarcodonin, cyathatriol, and 11-*O*-acetylcyathatriol) from *Cyathus Africans*, which showed potent anti-inflammatory properties. Chen et al. [137] reported that several triterpenes isolated from *Antrodia camphorata* which showed neuroprotective activity.

9 Mushroom-Based Biotech Products

Mushroom-based healthcare commercial biotech products with preventive and curative effects are today available in dried forms as functional food additives (nutraceuticals) and are largely sold and consumed in the world market. Owing to the synergistic action of bioactive molecules, majority of mushroom products possess beneficial health effects and can be used on a regular basis without undesirable side effects. Healthy food developed from biotechnologically cultivated mycelia of medicinal edible mushrooms *Hericium erinaceus* and *Tremella* spp. in combination with other natural substances (medicinal plants, algae, etc.) possess antioxidant and immune-stimulating activity and regulate the level of blood lipids and sugar [138, 139]. Some mushroom products are able to decrease high glucose and lipid levels in blood and are recommended as neuro- and vasotonics,

hepatoprotective, and thrombolytic agents [87]. Nutritive, anti-inflammatory, regenerative, and antioxidant properties of several mushrooms make their usage perspective in manufacturing of cosmetic products [140]. Mushrooms are currently proposed as highly active ingredients in world production of hair and skin care products. *Tremella* mushrooms contain hydrophilic agent–polysaccharide glucuronoxylomannan (GXM) with anti-inflammatory and wound healing properties largely used in cosmetology [141]. *Tremella* cosmetic products are applicable in treatment of neurodermatitis and sclerodermatitis. They prevent skin pigmentation and stimulate blood circulation. Biological characteristics of mycelia, particularly fast growth and easy reproduction in culture conditions, are assisting biotechnological cultivation of medicinal mushrooms to obtain desired bioactive molecules and biotech products. Thus, mushrooms have significant biotechnological potential.

10 Role of Mushroom Culture Collections

Currently, two different approaches in biotechnological cultivation of mushrooms are used. First is fruit body production which is a long-term process and takes 1–2 months, while cultivation of mycelia takes a few days. Establishment and maintenance of culture collections of different group of mushrooms are of valuable importance to study their biodiversity, genetic resources, and biotechnological potential. The submerged cultivation of mycelia is the best technique to obtain biomass and desired bioactive molecules for further development of consistent and safe healthcare mushroom biotech products and thus has significant industrial potential.

11 Future Trends

Mushrooms can make an important contribution to the livelihoods of rural and semi-urban dwellers through food security and income generation, and mushrooms can make a valuable dietary addition through their protein and micronutrient content as well as their medicinal properties. Its cultivation is highly compatible with a variety of other traditional agricultural and domestic activities and can make a particularly important contribution to the livelihoods of the disabled, of women, and of the landless poor who, with appropriate training and access to inputs, can increase their independence and self. The high benefit/cost ratio, the easily obtained and inexpensive agrowastes, and congenial weather conditions make adoption of mushroom cultivation a lucrative means of societal development. Mushroom cultivation can represent a valuable small-scale enterprise option. The FAO has been actively promoting mushroom cultivation for rural development and food security in developing countries [142].

India has tremendous potential for mushroom production, and all commercial edible and medicinal mushrooms can be easily grown here. Although, India is not a

major producer of any of the mushroom varieties, it does cultivate all edible and medicinal mushrooms in one or other part, due to its diverse climatic conditions. Mushroom cultivation is based on recycling of agricultural residues, which are available in huge quantities in every nook and corner of the country. At present, the areas with rice–wheat cropping system of India are facing tough challenge to handle the mounting crop residues. Mushroom cultivation can effectively utilize these agroresidues for production of protein rich food and plays crucial role in management of these agroresidues. The supply and demand gap in the world trade of mushrooms and the shrinkage of production in western countries due to high labor costs have resulted in better market prices for Indian mushroom producers. With a domestic population of more than 1.2 billion, India itself is a large market for mushrooms. To be successful in both domestic and export market, it is essential to produce quality fresh mushrooms and mushroom fortified value-added products at competitive rates without any agrochemical residues. Efforts should also be made to exploit the commercial utilization of mushroom substrate left after cultivation for preparation of organic manure, vermicompost, briquettes, etc. One final reason for optimism concerning India's potential as a major mushroom producer is its strategic geographical location, making it more convenient to export mushrooms to the Middle East, Southeast Asia, and European countries. To be successful in both domestic and export markets, it is essential to produce quality fresh mushrooms and processed products devoid of pesticide residues and at competitive prices. However, mushroom cultivation is yet to be adopted by Indian farmers and mushroom growers on a large scale. The gap in technology knowledge and its adoption needs to be bridged by providing training to farmers regarding various aspects of mushroom cultivation.

Mushrooms are functional food and are a source of biologically valuable components that offer great therapeutic potential for the prevention and control of several diseases. Further research and clinical trials needs to be carried out to validate that mushrooms are source of bioactive molecules with medicinal applications. They may be used directly in the diet to promote health, taking advantage of the additive and synergistic effects of the bioactive compounds present in them. Research is needed to elucidate the different roles of multiple active compounds and the pathways involved. The potential therapeutic implications of mushrooms are enormous but detailed mechanisms of the various health benefits of mushrooms to humans still require intensive investigation, especially with the emergence of new evidence of their health benefit effects. The exploration of newly cultivated mushrooms and isolation of their active ingredients with mechanism-based potential therapeutic value remains a challenge, and hence mushrooms will keep on to be the foremost spotlight of research in the upcoming prospect as well. Medicinal mushrooms represent a growing segment of today's pharmaceutical industry owing to the plethora of useful bioactive compounds. Conservation and cloning of therapeutic mushrooms is needed for sustainable development. Dedicated research should be undertaken to isolate, purify, and structural1ly investigate of novel anticancer and immune-stimulator compounds.

White button mushroom (*Agaricus bisporus*)

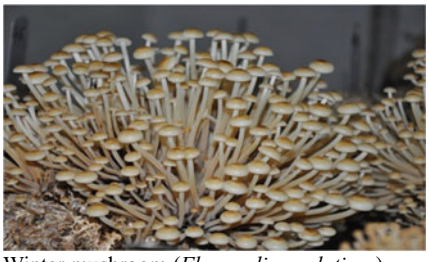
Brown button mushroom (*Agaricus bisporus*)

Milky mushroom (*Calocybe indica*)

Macrocybe mushroom (*Macrocybe gigantea*)

Shiitake mushroom (*Lentinula edodes*)

Paddy straw mushroom (*Volvariella volvacea*)



Winter mushroom (*Flammulina velutipes*)

Reishi mushroom (*Ganoderma lucidum*)

(*continued*)

Gray oyster (*Pleurotus pulmonarius*)

Pink oyster (*Pleurotus djamor*)

Blue oyster (*Hypsizygus ulmarius*)

Yellow oyster (*Pleurotus cornucopiae*)

Abstract

Plant probiotics are bacteria capable of improving crop yields reducing or even eliminating chemical fertilizers. During the last years, several studies show that many of these bacteria can improve not just production, but also food quality, through the increase of some nutrients as well as some plant bioactive compounds, which are beneficial to human health. This chapter compiles some of the recent research focused on the capabilities of several bacterial plant probiotics to enhance the production of more functional foods, and therefore benefiting our health.

Keywords

Food quality · Biofertilizers · Bacterial inoculants · Nutritional content · Horticultural crops

1 Introduction

According to Shahzad et al. [1], more than 175 million tons of chemical pesticides and fertilizers are applied every year to soils to improve crop yields. Nowadays, farming systems are mainly based on this type of products to satisfy worldwide food demand. However, chemical fertilizers are very costly and produce many environmental and human health problems [2, 3].

Moreover, an increasing percentage of consumers around the world are more aware of the production systems, food safety, and nutritional contents [4]. During last years, food quality and safety are one of the aim issues on the European political agenda [5]. Different production systems are being developed according to the new green politics, which many countries are implementing and including within their legislations.

One of the green new production systems is based on the use of bacterial inoculants, due to their ability to promote plant growth and development and therefor to produce healthier foodstuff. Currently, there are a substantial number of published studies which show significant increased yields and enhanced quality crops [3].

Haas and Keel [6] described the group of beneficial bacteria for plants as plant probiotic bacteria (PPB), according to their effectiveness in niche colonization, ability to induce systemic resistance in their host, improve plant nutritional content, and increase crop quality [7]. Many studies have focused on understanding how these bacteria interact with their plant host and measure the improvements in crop yields [8–10].

Interestingly, apart from the widely known capability to increase crop yields, several studies published in recent years show how bacterial plant probiotics can improve C and increase several plant compounds which augment human health and aid in the prevention of diseases [11]. This is a less-known potential of these bacterial biofertilizers, and therefore, this chapter is focused on the capabilities of plant probiotics to enhance not only crop yields, but also food quality, allowing the production of more functional products benefiting our health.

2 Effects of Microbial Inoculants in Bioactive Compounds Content in Legumes

Legume seeds are undoubtedly one of the most important sources of vegetable proteins in human nutrition [12]. Grains such as soya, beans, chickpeas, lentils, peas are the main source of proteins for many people in developing countries [13–16]. Apart from that, they are excellence source of nutrients such as fiber, vitamins, and minerals [12]. Moreover, several legume grains contain polysaccharides, such as fructooligosaccharides and starch which act as prebiotics [17–21].

Also, some legume seeds, mainly soybeans, but also peanuts, mung beans, lupine grains, green grams, pigeon peas, groundnuts, and bambara, are used to obtain milky drinks, after their extrusion and fermentation with bifidobacteria, lactic bacteria, or yeasts, which are excellent probiotics [22–28].

In addition to their nutritional value, several recent research studies show the importance of the presence of bioactive compounds in legumes, such as flavonoids, tocopherols, carotenoids, fatty acids, and anthocyanins, because of their multiple benefits for human health [12, 29, 30], having been reported how the consumption of legumes reduces the LDL cholesterol levels, preventing heart diseases [31, 32], gastrointestinal cancer [33], hypercholesterolemia [34], diabetes and stroke [32].

Legumes have the capability to establish symbiosis with nitrogen-fixing bacteria. These bacteria, which are currently distributed in several families and genera, are collectively known as rhizobia and have the capability to fix atmospheric nitrogen for the plant [24] inside some organs formed in the roots or stems of the legume plants termed as nodules [25, 26]. The capability of rhizobia to fix nitrogen on legume plants was the first described and characterized bacterial mechanism of plant growth promotion, with the first reports about this symbiosis dating from the beginning of the XIX Century [35]. From that time, many studies have reported yield increments in different legume crops after the application of rhizobial inoculants, reducing or even replacing chemical fertilization [36–38]; thus, the application of rhizobia-based biofertilizers is an efficient agronomic practice to fertilize legume crops in a friendly and sustainable manner, avoiding the environmental contamination and the human health risks derived from chemical fertilization. In these studies, the commonly analyzed parameters are shoot and root weight, nodule number and weight, grain yields, and nutrients content [39].

Moreover, during the last decade, several studies have focused on the analysis of changes in the bioactive substances content of legumes after inoculation with rhizobial strains. Legumes are historically known to contain bioactive compounds such as isoflavones, phenolic acids, and procyanidins, which constitute the major phenolic compounds present in their grains and have been proved to protect against different diseases, such as cancer, obesity, and other metabolic diseases, as well can reduce menopausal symptoms [30, 40, 41]. The molecular structure of isoflavones is similar to that of 17-β-estradiol molecules, so isoflavones can induce similar effects to those of estrogens, but they lack the risks associated with these drugs treatments [42]. Related to the isoflavones content in legumes, several recent studies have found

a positive effect of soybean intake in women for the prevention of cancer diseases related with estrogenic levels, such as endometrial and breast cancers [43, 44]. Soy-based foods consumption has also been correlated with a lower risk of prostate and colorectal cancers [42, 45, 46]. Proanthocyanidins are other phenolic compounds with antioxidant potential present in legume seeds [47–51] and have been related to the prevention of cancer, diabetes, and cardiovascular diseases [52–54]. Tocopherols, compounds with vitamin E activity, are present in important amounts in legume grains [55–58] helping in the prevention of several diseases related with vitamin E deficiency, such as neuromuscular problems [59]. Legume seeds also contain different carotenoids, such as lutein, zeaxanthin, and β-carotene [55], which have been described as potent antioxidants [56] and are precursors of vitamin A, which plays an important role in the prevention of macular degeneration and other eye diseases [60]. Finally, some legume seeds, such as soybeans, peanuts, chickpeas, lentils, beans, and lupins, constitute an important source of unsaturated fatty acids, such as oleic and linoleic [55–57, 61], which have an effect in the lowering of cholesterol levels [62], helping in the prevention of coronary diseases [63, 64].

Most of the research studies on the effects of the inoculation with rhizobial bacteria on the contents of bioactive compounds in legumes have been performed in soybean (*Glycine max*). Silva and collaborators [61] indicated that the inoculation of soybeans with *Bradyrhizobium japonicum* sv *glycinearum* induced an increase in some volatile compounds and organic acids in seeds, confirming the results previously obtained by Couto and collaborators [65], who showed that soybean plants inoculated with *B. japonicum* presented a higher increase in the content of phenolic compounds and organic acids. Besides, grains from inoculated plants presented a higher total fatty acids content, with an increase in both monounsaturated and polyunsaturated fatty acids [61]. On the other hand, the inoculation of faba bean (*Vicia faba*) induced a considerable augmentation in the antioxidant constituents and the total content of flavonoids, phenols, tannins, and proteins [66]. And moreover, a study performed using a *Mesorhizobium* strain to inoculate chickpea (*Cicer arietinum*) showed an increase of flavonoids content in the inoculated plants compared to those ones of the negative control [67].

Finally, some studies have been performed on medicinal legume plants, such as *Psoralea corylifolia* L. The seeds of this plant, known as "Buguzhi," are used in the traditional Chinese medicine for various disorders treatments, particularly vitiligo [68]. *Psoralea corylifolia* contents psoralen [69], a tricyclic furocoumarin, are used for the treatment of hypo-pigmented lesions of the skin for its potent photosensitizing capability [70]. The inoculation of *P. corylifolia* with *Ensifer meliloti* and *Rhizobium leguminosarum* strains has shown an increase in the psoralen content in the seeds of this legume [71].

Considering all these studies and the fact that legumes are regarded as functional foodstuff and recommended as nutraceuticals, we can assume the importance of deepening in the studies of how plant growth-promoting bacteria affect their content in bioactive molecules, not just the mentioned in the already performed studies, but also other not yet considered, which may greatly influence consumers' health.

3 Improvement of Beneficial Substances in Berries by Bacterial Inoculation of Theirs Crops

Berries-type fruits are a heterogeneous group of fruits widely consumed because of their nutraceuticals qualities. These fruits present low energy contents and high antioxidant activity due to high concentrations of bioactive compounds such as vitamins or phenolic compounds [3]. There are several species integrated in the group of the so-called berries-type fruits, i.e., bilberries (*Vaccinuim myrtillus*), lingonberries (*Vaccinium vitis-idaea*), blueberries (*Vaccinium corymbosum),* cranberries (*Vaccinuim macrocarpon* or *Vaccinuim oxycoccos*) strawberries (*Fragaria ananassa),* red raspberries (*Rubus idaeus),* cloudberries (*Rubus chamaemorus*), arctic brambles (*Rubus articus*), loganberies (*Rubus loganobaccus*), honeyberries (*Lonicera caeulea*), rowan berries (*Sorbus* spp.), or crowberries (*Empetrum nigrum*, *E. hermaphroditum*), which present different bioactive compounds profiles, for example, blue and black colored berries show the highest antioxidant activity, which is related to the highest content in anthocyanins [72]. Moreover, berry fruits show good nutritional characteristics, present low amounts of fat contents, high fiber concentration, and an excellent mineral profile [73].

Berries production is usually carried out using conventional agricultural systems, but consumers have started to demand new quality standards of production [74]. In this point, plant growth promotion rhizobacteria (PGPR) could be a key tool to improve their nutraceutical characteristics. However, compared to other type of crops, the number of yield experiences with PGPR is poor yet, but they show good expectations.

Probably, strawberry is the berry which more studies have received due to the relevance of this crop in agriculture. Alvarez-Suarez et al. [75] showed that the consumption of strawberries could improve cardiovascular health and induce an increase on immunological fitness [76]. For this reason, several PGPR studies have been focused on the biofertilizer influence in vitamin contents in strawberries. Different bacteria have been employed to improve nutraceutical qualities of strawberry as *Pseudomonas*, *Bacillus*, *Paenibacillus*, or *Phyllobacterium* [77–79]. The inoculation of *Pseudomonas* BA-8, *Bacillus* OSU-142, and *Bacillus* M-3 produces an increase of vitamin C concentration in strawberry when they are applied by root, foliar, or combined way [77]. Strawberry plants inoculated with *Paenibacillus polymyxa* RC05 produce fruits with high levels of vitamin C concentration [78]. Similar results have been obtained with *Phyllobacterium endophyticum* PEPV15 inoculation under greenhouse conditions. This strain can increase in a 79% the vitamin C concentration comparing with the uninoculated control [79]. Esikten et al. [80] showed that the application of *Pseudomonas* and *Bacillus* strains can increase plant biomass and nutrient content through the production of organic acids from bacteria.

Another important way reported to improve strawberry production is the co-inoculation of PGPR bacteria with mycorrhizal fungi. According to Bona and collaborators, the co-inoculation of *Pseudomonas* strains and an arbuscular mycorrhizal fungi (AMF) produces an increase in vitamin C with respect to the uninoculated control. The authors also show that the vitamin B9 content only

presents in a significant high level in double co-inoculation with AMF and PGPB treatment [81].

Other significant compounds in berries with nutraceutical qualities are flavonoids, which activity is directly related to their concentration [82]. Anthocyanins are the main flavonoids involved in antioxidant activity in berries as strawberry, blackberry or raspberry [83]. Reported results from experiments in strawberry when plants are inoculated with a mixture of plant growth promoting bacterial strains (*Pseudomonas fluorescens* Pf4 and 5Vm1K) and a mycorrhizal fungus (*Glomus* sp.) show how the co-inoculation produces an increment in anthocyanin contents [84]. Orham et al. [85] showed than *Bacillus* OSU-142 and *Bacillus* M3 are also efficient biofertilizers with the ability to improve raspberry production and nutrient quality, including their content in flavonoids.

Basu and Maier [86] showed that all different flavonoids presented in berries crops have antioxidant activity with potential to improve several aspects of human health. Raspberry, blackberry, and other dark berries have a relevant role as flavonoid sources [72]. The inoculation of blackberry plants with the strain *Pseudomonas fluorescens* N21.4 produces an increase in flavonoid content of 22% compared to the uninoculated treatment. These results are especially significant during summer and autumn months [87]. This strain of *Pseudomonas fluorescens* is also able to increase or stabilize total flavonoid content in blackberry fruits under adverse environmental conditions [88], and further experiments suggested that these results are based on differential expression of genes involved in flavonoid synthesis which suffer stimulation when blackberry plants are inoculated with *Pseudomonas fluorescens* N21.4 [89].

4 Increase of Nutrients and Bioactive Compounds in Horticultural Vegetables by PGPR Inoculants

Horticultural crops provide humans with a big variety of essential vitamins and indispensable elements [90]. According to Ramsay et al. [91], the consumption of a wide range of horticultural fruits is linked to overall diet quality.

In addition to be required for many physiological functions, vitamins prevent deficiency syndromes which can affect humans when there is an irregularity of their contents [92]. Scientists are developing different ways and methods to increase the total content of vitamins in horticultural crops. Here, we present some of the studies in which bacterial plant probiotic inoculation has been used to produce an improvement in food quality.

Bona et al. [93] reported that the inoculation of tomato plant with *Pseudomonas* sp. 19Fv1T enhances crop yield and improves vitamin C content in tomatoes, compared to the control treatment. Gül et al. [94] also reported that the highest levels of vitamins content in tomato fruits were obtained after the bacterial inoculation of two *Bacillus amyloliquefaciens* strains (FZB2 and FZB42). Additionally, Shen et al. [95] showed that a mixture of *Bacillus amyloliquefaciens*, *Bacillus megaterium*, and vermicompost also increased tomato yields and vitamin C fruit content. Although Tomato is one of the most horticultural cultivated crops in the

world [96], this fruit is also regarded as an excellent source of antioxidants compounds [97]. Ochoa-Velasco et al. [98] have described an important improvement in vitamin C and total phenols contents with a reduction of nitrogen doses after the inoculation with *Bacillus licheniformis*.

An increase in lycopene antioxidants levels have also been reported in tomato fruits after bacterial inoculation. According to Ordookhani et al. [99], the mix of *Pseudomonas putida*, *Azotobacter chroococcum*, *Azospirillum lipoferum*, *Glomus lipoferum, Glomus mossea*, and *Glomus etunicatum* not only increase lycopene antioxidants levels but also is related to an improvement in potassium fruit contents. The nutrient contents of nitrogen, calcium, magnesium, potassium, and phosphorus were significantly improved in tomato fruits after the inoculation with five combinations of plant growth promotion rhizobacteria such as *Pseudomonas*, *Azotobacter*, and *Azospirillum* [100].

Basil crop (*Ocimum basilicum* L.) is an interesting medicinal plant used worldwide for cooking. Its antioxidant activity has been improved with plant probiotics bacteria. Compared to the uninoculated treatment, the highest antioxidants levels were achieved after the inoculation with a mixture of *Pseudomonas putida*, *Azotobacter chroococcum*, and *Azospirillum lipoferum* strains [99]. Under water stress and after the inoculation with *Pseudomonas* sp., *Bacillus lentus*, and *Azospirillum brasilense*, the antioxidant activity in basil crops also improved [101].

5 Conclusion

Expansion and improvement of a more sustainable and at the same time proficient agriculture, which will guarantee food resources to feed the growing world populations, fighting the hunger in developing countries, with limited land and energy resources while at the same time protecting the environment, is one of the principal challenges of the nowadays human society. There is a plethora of research studies proving that certain bacteria improve yields in agricultural crops, by aiding in nutrients supply, producing growth-stimulating phytohormones, preventing pathogen-induced plant diseases, and inducing plant resistance to biotic or abiotic stresses, so the application of these bacteria as biofertilizers is one of the strategies that could help to achieve the goal.

In parallel, there is an increasing worry about food quality and heathy diets, and many people in developed countries and wealthy families in developing countries demand quality functional foods which improve human health and aid in the prevention of diseases. Consumers' demand of organic foodstuff is increasing, and at the same time most countries are developing several policies to limit or banish the application of chemical fertilizers in crop production.

As shown in this chapter, contrasting chemical fertilizers, the application of plant probiotic bacteria as crops biofertilizers increases not only yields, but also the nutritional quality of seeds, fruits, and horticultural vegetables. Research in this field showed how several bacterial inoculants interact with different plant species, and as a result there is an increase of some plant compounds, which are beneficial to

human health. Thus, the application of probiotic bacteria to reduce chemical fertilizers is an excellent alternative, not just to sustain crop production while limiting chemical fertilizers, but also to improve food quality.

The still scarce number of studies orientated to the application of plant probiotic bacteria to improve the quality of fruits, grains, and horticultural crops has showed an increase in the levels of vitamins, antioxidants, and flavonoids, among other values. Still, there are many other bioactive compounds which could also be enriched by the application of bacterial inoculants. Therefore, new research approaches such as metabolomics, comparing plant foodstuffs produced with and without the application of plant probiotic bacteria, may reveal additional bioactive compounds whose quantity may be enlarged by the applications of bacterial inoculants. Also, more studies on the effects of different bacterial strains on the food quality increase in different plant species are necessary; this would allow for a better selection of plant probiotic bacteria with the potential to increase not just crops yields, but also their quality and health benefiting properties.

Abstract

Ganoderma lucidum is a highly praised medicinal mushroom having high demand worldwide. Intense research activities are being carried out on the medicinal applications of this mushroom that include anticancer, antiallergic, antioxidant potential, etc. This wonder mushroom contains many bioactive compounds such as polysaccharides, triterpenes, polyphenols, proteins, amino acids, and organic germanium. Ancient Chinese use this mushroom in their medicinal preparations and declared good health and longevity. Health benefits of this mushroom are highly praised in ancient manuscripts. Many pharmaceutical and beauty products made from this mushroom are available in the markets and demands high price. Cultivation and production of this mushroom are limited to certain countries, which leads to an increase in its market value. This chapter describes the details of this special mushroom, including its taxonomy, morphology, ecological and economic status, cultivation, bioactive molecules, and its medicinal applications.

Keywords

Ganoderma lucidum · Bioactive compounds · Cultivation · Therapeutic applications · Polysaccharides · Triterpenes

Abbreviations

C:N	Carbon nitrogen ratio
EPS	Extracellular polysaccharides
G. lucidum	*Ganoderma lucidum*
GA	Ganoderic acid
GTS	Ganoderma triterpenes
HDP	Host Defense Potentiators
IPS	Intracellular polysaccharides
LSC	Liquid state cultivation
LSF	Liquid state fermentation
LZ	Lingzhi
PBP	Protein-bound polysaccharide
RIP	Ribosome inactivating proteins
ROS	Reactive oxygen species
SOD	Superoxide dismutase
SSC	Solid state cultivation
SSF	Solid state fermentation

1 Introduction

Mushrooms are progressively being evaluated in the East and West for their nutritional value. Many of the mushrooms are nutritionally considered as functional foods and some of which are purely evaluated as a source of medicinally beneficial compounds called "nutraceuticals." *Ganoderma lucidum* (Fig. 1) is such a popular mushroom worshipped for its medicinal use and the history of its usage goes back to many thousands of years in the orient. *Ganoderma lucidum* holds a prominent place in traditional Chinese medicine and is well documented in ancient scripts [1, 2]. It has a long record of use in promoting health and longevity in China, Japan, and other Asian countries. Its medicinal activity is usually localized, for example, moderating the immune system by reducing its activity when overstimulated, and proliferating the immune system by increasing the number of active cells. For Chinese people, *G. lucidum* symbolizes the combination of spiritual potency and essence of immortality and thus called as "herb of spiritual potency." Among the cultivated mushrooms, the nutritional and pharmaceutical values of *G. lucidum* are paramount.

Ganoderma lucidum is consumed as a herbal extract like concoctions of tea and tonics. A variety of Ganoderma products are available in the market in various forms such as powders, dietary supplements, soaps, ointments, antiseptic creams, and herbal soaps. The products of this mushroom are available in the market but are expensive as efforts and processes required for the cultivation of this mushroom are intensive. *Ganoderma lucidum* described as a fungal bio-factory by eminent scientists as well as medical practitioners. But the amount of this wild mushroom is not sufficient to meet its demand in the international market. In the mushroom industries through various trial and errors, cultivation of *G. lucidum* has been achieved a considerable progress in the last 40 years. For faster and efficient production, various methods are practiced in these days [3]. Traditional and modern cultivation methods are used for large-scale production. Traditional methods include bag, bottle, and wood log cultivation which acquire more time, whereas modern techniques such as solid and liquid state cultivation could be carried out within a limited period.

Fig. 1 *Ganoderma lucidum*

The benefits of *G. lucidum* are entrusted from generation to generation, as an anticancer, a symbol of divine power, good fortune, good health, and longevity. It is used for various ailments such as allergy, hypertension, cardiac diseases, cancer, viral (HIV), and bacterial infections. It is an annual mushroom belongs to the family of Ganodermataceae. All parts of the mushroom viz., fruiting body, mycelia, and spores, contain bioactive compounds and are useful for the above-mentioned treatments. Polysaccharides, triterpenoids, proteins, amino acids, nucleotides, alkaloids, steroids, lactones, fatty acids, and enzymes are the major components that are responsible for the wide array of bioactive properties shown by this mushroom [4]. A single chemical compound cannot be responsible for the bioactivity which in turn is brought about by a combination of two or more active compounds. Polysaccharides, triterpenoids, and polyphenols are the major active compounds in *G. lucidum* [5]. Polysaccharides are water-soluble fragments which can be extracted with hot water, whereas polyphenols and triterpenoids are more soluble in polar organic solvents such as ethanol and methanol. *Ganoderma lucidum* is considered to be a useful source of protein (7–8%), carbohydrates (3–5%), crude fat (3–5%), crude fiber (59%), ash (1.8%), and other trace elements on a dry weight basis [6, 7]. *Ganoderma lucidum* also contains a higher amount of chitin which makes it hard to chew and digest. Apart from the nutraceutical benefits, it also plays a key role in the environment as decomposers in nutrient cycle. *Ganoderma lucidum* decomposes dead wood of coniferous or hardwood species by producing enzymes such as laccase, manganese peroxidase, and lignin peroxidase which degrade the compounds of lignin and cellulose in the wood. These wood degrading enzymes are of special interest for industrial applications, i.e., bioremediation, biopulping, and biosorption of heavy metals [8].

2 History

The history of *G. lucidum* can be traced back to 2000 years. During ancient times, *G. lucidum* had been worshipped as one of the herbal medicines and believed to heal all kinds of diseases. It was first used by the emperor of China, Shih-Huang of Ch'in Dynasty (221-207 BC), who made the Great Wall of China. Special teas or concoctions made from this mushroom were used by the emperors of Great China and Japan for vitality and healthy life [2]. Those who presented this mushroom to the king were highly rewarded. *Ganoderma lucidum* is popular in folk medicine because of its promising medicinal properties including its potential to extend the lifetime. *Ganoderma lucidum* was first introduced by a famous Chinese medicinal practitioner *Shen Nongs*, who is known as the "Father of Chinese medicine." Medicinal value of this mushroom is well described in his book "Materia Medica" [9, 10]. One of the key features of this mushroom is the absence of side effects. Due to this, *G. lucidum* has attained a reputation as an ultimate health supplement. The popularity of this mushroom has given it a place in "American Pharmacopoeia and Therapeutic Compendium." In addition to its medicinal properties, people of ancient China had a spiritual belief of protecting the people and their homes from evil spirit [11].

3 Scientific Classification

Kingdom	Fungi
Phylum	Basidiomycota
Class	Agaricomycetes
Order	Polyporales
Family	Ganodermataceae
Genus	*Ganoderma*
Species	*lucidum*
Binomial name	*Ganoderma lucidum* (Curtis) P. Karst.

Petter Adolf Karsten in 1881 named the genus as Ganoderma. *Ganoderma lucidum* has several names based on its geographical location and its traditional and historical applications. In Japan, this mushroom is commonly known as Reishi, Mannentake, or 10,000 years mushroom, and symbol to happiness, fortune, immortality, and good health. It has been known as Lingzhi in the Korean and Chinese ancients for more than 4000 years. It has also been called as a "mushroom of herb and immortality." However, the concept of this mushroom as an herb of immortality was described in transcripts of the first ancient empire of China (221-207 B.C) and illustrated in their literature and art perspectives. Botanically, the Latin name is *Ganoderma lucidum*, where lucidum was derived from its shiny surface [2, 9]. There are around 6 species of Ganoderma which are similar to *G. lucidum*. They are *G. atrum, G. tsugae, G. tropicum, G. applanatum, G. capense*, and *G. sinensis*.

4 World Production of *G. lucidum*

Worldwide consumption of *G. lucidum* is several thousand tons, and the market is growing rapidly. A decade ago, more than 90 brands of *G. lucidum* products were registered and marketed internationally [12]. Numerous *G. lucidum* products prepared from various parts of the mushroom are currently available on the market [13]. The simplest type of product available in the market consists of intact fruiting bodies ground to powder and then processed to capsule form. Other products are prepared from the following sources: (1) dried and powdered mycelia harvested from submerged liquid cultures grown in fermentation tanks; (2) dried and powdered combinations of substrate, mycelia, and mushroom primordia, following inoculation and incubation of a semisolid medium with fungal mycelia; and (3) intact fungal spores or spores that have been broken by mechanical means or have had the spore walls removed. Preparations made of spore have been promoted in the recent years because of the faster medicinal effects. It is generally hard to remove the spore wall; therefore, modern techniques, such as ultrasonic extraction, enzyme-based extraction methods are used which represent an additional and often a costly step in the production, are still controversial. Other products that are available in the market are prepared with extracted bioactive compounds such as polysaccharides and triterpenes. These compounds are usually extracted with hot water or ethanol

from fruiting bodies or mycelia and then evaporated to dryness and encapsulated either separately or integrated together in designated proportions. The adoption of supercritical CO_2 extraction technologies has enlarged the spectrum of extracted substances due to the low temperature required during processing [14]. Several other products have been prepared from antler, the deformed type mushroom fruiting body, which is claimed to be highly medicinal.

5 Morphological Characteristics

G. lucidum is a kidney-shaped mushroom with varnished and colored outer surface and has an elegant appearance. They produce pores on the underneath of mushroom cap instead of gills, thereby making them to be differentiated from other polypores which produce gills underneath. But similar to other annual mushrooms they do not grow frequently. This difference makes them rare and special among other mushrooms. The upper side of this mushroom is shiny and dark red. Sometimes it shows varying color depending on the natural habitats and environmental conditions. All the three parts of *G. lucidum* such as mycelium, fruiting body, and spores (Fig. 2a, b, and c) are very important source of bioactive compounds.

5.1 Mycelium

Mycelium of a mushroom is the branching vegetative network which can spread like a mat on the medium or wood logs. Ganoderma mycelium appears to contain many of the bioactive compounds as that of fruiting body [15]. The polysaccharides from the mycelia also have the similar efficacy as that of the fruiting body [16, 17]. The spores of *G. lucidum* shred from the fruiting bodies would land on dead, decaying woods, and under adequate conditions they germinate into mycelium. Mycelia undergo three developmental stages, from primary to secondary and then to tertiary mycelia and eventually the fruiting body will sprout out. In the late phase, formation of basidium and then basidiospores are produced.

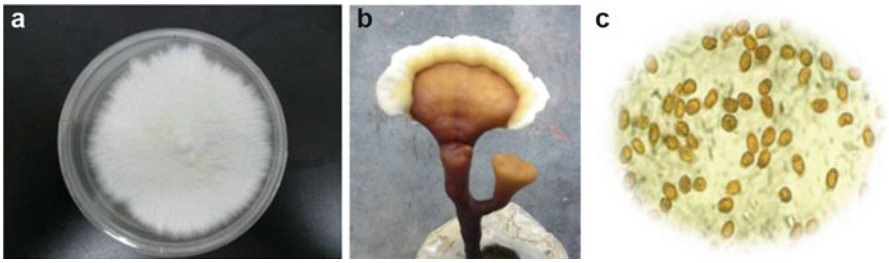

Fig. 2 Mycelium (**a**), fruiting body/basidiocarp (**b**) and spores (**c**) of *G. lucidum*

5.2 Fruiting Body

Basidiocarps or fruiting bodies of the mushroom vary from 2 to 10 cm in diameter. They are kidney-shaped and have shiny outer surface with yellow white striations at the margin which make them beautiful. In their initial stage of growth, they show yellow to white color. Later, with maturity they turn to reddish brown. The stipe (stem) is usually present, but sometimes it maybe with or without a reduced stipe. The length of stipe varies based on the conditions in which they grow as well as the nutrition available in the growth medium. The abaxial side of mushroom cap has several pores which are usually white. The matured mushroom shed spores through these tiny pores [18].

5.3 Spores

The spores of *G. lucidum* are slightly brown in the size range of 1–10 micron. The spore wall is composed of chitin. The spores are reported to contain higher amounts of bioactive compounds than the fruiting body. But the spores are hard to break due to the thicker chitin wall. Possessing a thicker chitin wall is the major characteristic of polypore mushroom as they protect the mushroom from adverse conditions. The sporoderm of *G. lucidum* is made-up of silica (19.01%), calcium (17%), and chitin (52.08–57.64%) [19]. The outer thick coating of sporoderm is resistant to acids giving it an extended shelf-life in the nature.

6 The Ecological Habitat of *Ganoderma lucidum*

This annual mushroom could be found growing on the decaying and dead bodies of a variety of trees. It grows on the decaying logs of deciduous trees like oak, maple, elm, willow, sweet gum, magnolia, and locust. Besides, it grows on the decaying logs of certain coniferous trees such as Larix, ptea, and pinus, in the subtropical regions such as Europe, Asia, and North and South America [20]. In the oriental countries, the mushroom has been found to grow mainly on the plum trees on the stumps near the soil surface and occasionally on soils arising from buried roots [2]. In temperate and subtropical regions of Asia, Europe, and South and North America, this mushroom can be found on the coniferous trees such as Larix, pinus, and picea. They cause white rot disease at the base of trees either alone or in a group. Its natural growth considerably takes longer time, which makes the mushroom very rare, treasured, and exclusive for the rich people and highly ranked powerful individuals. The above limitations push the scientists to find alternative artificial cultivation methods.

7 Nutrition and Growth

Ganoderma lucidum which is used as a folk medicine or nutrition is a saprophyte. They cannot carry out photosynthesis due to the absence of chlorophyll. Mycelia can directly absorb simple sugars, organic acids, and other carbohydrates that are present

in the growth substrate. Mushroom mycelia cannot use inorganic carbon. The growth of mycelium requires the presence of nitrogen approximately 0.016–0.064%. For the production of fruiting body, the requirement of nitrogen is approximately 0.032–0.016%. Growth of mushroom needs the presence of minerals such as P, K, Ca, Mg, S, Fe, Mn, Zn, and other inorganic compounds. Temperature is another crucial factor which determines the growth, quality, and yield of the mushroom. Mushroom at various stages of growth and development requires different temperatures. For the germination of mycelia, the suitable temperature employed is in between 25 °C and 30 °C [21]. Primordia require 15–23 °C, whereas the fruiting bodies require 28–30 °C. Temperatures below 12 °C result in a slower growth, reduced stipe, and thicker flesh. Spores require 22–26 °C for their growth. All the stages of mushroom growth need the presence of water. For the mycelia growth, 45–65% of water is appropriate, but for the fruiting body development a relative humidity of 75–95% is necessary. Humidity more than 95% results in the chances for bacterial contamination. Presence of light is negligible for the growth of mushroom mycelia, whereas spore and primordia formation take place under low intensity of light. Similarly, light is very essential for the better development of fruiting body and its quality [22]. An optimum pH is the other limiting factor which affects the mushroom growth. Almost all the saprophytes including *G. lucidum* grow slightly under an acidic pH of 4–6.

8 Cultivation

Ganoderma lucidum cultivation was first introduced from China in 1980s. Currently there are a diverse range of cultivation methods based on the employed substrates. The three most common traditional methods of cultivation are wood pulp, wooden box, and natural wood log cultivation [23, 24]. Techniques such as wood log or wood chip cultivation are not applicable to produce *G. lucidum* in the commercial practice, as they raise ecological problems such as cutting and processing of trees, and thus there is a concern. It is therefore necessary to find an effective and a reliable way of cultivation as well as to produce in larger-scale to meet the market demands.

8.1 Wood Pulp Cultivation (Bottle Cultivation)

It is the simplest method of cultivation which involves placing the sterilized wood pulp in a glass bottle along with spawns of *G. lucidum*. Mushrooms along with the bottle are incubated for 3 months. This method usually yields smaller-sized mushrooms of relatively inferior quality.

8.2 Box Cultivation

This method involves grafting the fungi into drilled wooden logs (1 m), which are then placed in the wooden boxes. This method takes about 3–6 months for the

generation of fruiting body. Mushrooms of medium-size and moderate quality are generally produced through this method.

8.3 The Natural Wood Log Method

Natural wood log cultivation could be carried out by the following two methods. One utilizes cultivation on longer unsterilized wood logs and the other uses shorter sterilized logs. First method was the common cultivation practice in China until the new development using short logs which was introduced in the late 1980s. Natural wood logs of 1 m were used for long woods without any sterilization. This method takes longer incubation periods (2–3 years) besides requiring more labor to produce matured fruiting bodies. Short wood log cultivation method was introduced from Japan. It is the common cultivation strategy adopted by natural log growers in China, Japan, Korea, and USA. This method offers the production of a larger basidiocarp with superior quality which involves the preparation of wood logs, especially broad-leaf hard woods of 15 cm in diameter with the length of 14–24 cm. The moisture content should be about 35–40%. The wood logs are then enclosed in polypropylene bags and sterilized. They are incubated with precultured mushroom spawns of 5–10 g. Mycelial run is usually carried out with less oxygen and under dark condition. Formation of mushroom primordia occurs during 50–60 days after spawning. The mushroom colonized wood logs are then buried under nutrient rich soil leaving the primordia above the soil in a green house. Regular monitoring is essential to ensure mushrooms of high quality. Harvesting of mushroom takes approximately 25–30 days after the formation of primordia [5].

8.4 Cultivation on Sawdust

The processing of wood logs is expensive and requires special kind of woods and expertise which make the farmers to think about using sawdust as a cultivating medium. Sawdust is the wood dust produced after processing of woods in the mills. In this method, *G. lucidum* is cultivated on sawdust filled in the polypropylene bags along with rice bran (10%) and $CaCO_3$ (3%). They are moistened to 60% and filled into polybags (700–1000 g). Finally, the bags are plugged with a cotton cap. Steaming of the bags is then carried out for 5 h at 95–100 °C. The bags are then kept at room temperature overnight and inoculated with mushroom spawns. About 3–4 weeks is an essential period for the mushroom mycelia to colonize on the substrate. The bags are then opened for the formation of primordia at 28 °C. The relative humidity is maintained at 85–90% during primordia development. Approximately after 2–3 months from the appearance of primordia, matured basidiocarps will be ready for harvest [25].

Following sawdust cultivation, new substrate compositions were proposed by various researchers. Chen [26] recommended a substrate media containing oak sawdust (80%), unprocessed wheat bran (18%), sucrose (1%), calcium carbonate

Table 1 Growth requirements for the cultivation of *G. lucidum*

Mycelial colonization
Temperature – 25 °C (optimum)
Light – not needed
Duration – 3–4 weeks
Primordia formation
Temperature – 28–30 °C
Relative humidity – ~90–95%
Duration – 1 week after mycelia colonization
Light – Reduced light (100 lux)
CO_2 – >0.1%
Mushroom development
Temperature – 28–30 °C
Relative humidity – 80–85%
Duration – 25–30 days after primordia formation
Light – 150–200 lux
CO_2 – >0.1%

(1%), and 60–70% moisture for the cultivation of *G. lucidum*. Substrate media formulation using sunflower seed hulls [27], stillage grains [28] soy residue [29], etc., have been reported. Sawdust cultivation can be carried out in bags, trays or bed [30], bottles, and pots [31] based on the scale of production.

The growth of *G. lucidum* depends on cellulose and lignin that are present in the wood logs. They utilize these compounds by the production of enzymes which break down the bonds in the long cellulose chains into shorter chains so that the carbon become available for the growth of fungi. *Ganoderma lucidum* utilizes carbon resources from compounds such as sugar, starch, cellulose, hemicellulose, and lignin. Mycelia cultivation requires the presence of sugar and nitrogen sources. Compounds such as amino acids, urea, nitrogen can induce the mycelia growth [32]. Sawdust of broadleaf trees [33], cotton seed husk, corn cob, paddy straw, wheat and rice bran, corn powder, ammonium sulfate, and urea are used in the substrate media to produce fruiting body [34]. Carbon to nitrogen ratio is a key factor for the growth of mushroom as well as for the formation of fruiting body. Appropriate ratio of C:N required is 15–45:1 for mycelia and 30–40:1 for fruiting body [35, 36]. The growth requirement of *G. lucidum* on the solid substrates is given in the Table 1.

8.5 Modern Cultivation Practices

In these days, industries are looking forward for faster and cheaper practicing methods for the cultivation of *G. lucidum*. Both solid state fermentation (SSF) and liquid state fermentation (LSF) techniques offer scope for large-scale production of this mushroom using cheaply available agricultural residues. The details obtained from solid state cultivation (SSC) can be applied to study the liquid state cultivation

(LSC) [37, 38]. Cultivation of fruiting bodies of *G. lucidum* takes several months and proper environmental conditions; hence, mycelia-based and culture broth-based products have assumed immense importance due to increased quality control and year-round production [39]. SSF is nowadays used to upgrade the valuable food supplements, enzyme production, and the feed values of waste materials [40]. In submerged state cultivation method, mycelia culture can be standardized easily under controlled conditions and simple processes are required for downstream processing of the bioactive compounds such as polysaccharides and other compounds released into the culture medium. Several researchers have reported the cultivation of mycelia using submerged/liquid state cultivation. Standardizing the culture conditions and medium composition strongly influence mycelial growth and production of bioactive compounds in this mushroom [5, 39, 41]. A novel three-stage light irradiation strategy has been developed in submerged cultures of *G. lucidum* for the efficient production of polysaccharides and ganoderic acid [42].

Development of bidirectional SSF technology is the recent focus in the modern mushroom science. It is a new type of fermentation technique emerged from China in the 1990s. The key of this technology is that the medicinal mushroom strains are cultured in the special substrate, which consisted of Chinese medicinal herbs as substrate instead of the traditionally cultured nutritious substrate. The fermentation products are known as the medicinal fungal substances. During fermentation, these medicinal compounds in the substrate provide nutrients for the fungal growth. At the same time, the fungal strains produce enzymes which change the tissue and components in the substrate to new functional components. Thus, by bidirectional fermentation, medicinal strains produce bioactive compounds of higher quality [43, 44].

Bidirectional SSF was applied by Chen and Chen [45] in *G. lucidum*. They designed three types of medium; *G. lucidum* in an ordinary growth medium, Chinese materia medica (CMM) medium containing *Radix astragali*, and selenium rich CMM-containing medium. Fermentation products from the three types of media were checked at fixed time intervals. Polysaccharide contents of fermentation products from these culture media were 4.65%, 3.76%, and 4.50%, respectively. By observing the changes in the concentration of polysaccharide, protein, and total saponin in fermentation products from the CMM-containing medium at various times, they concluded that the 28th fermentation day was the time during which secondary metabolism was the most active. Similar studies were carried out using *G. lucidum* with different medicinal herbs [46].

Another application of *G. lucidum* is in the functional food research and development. For this, the amount of polysaccharides, reducing sugars, amino acids, and protein contents were determined. The outcome indicates that the optimum production needs specific conditions, i.e., size of the granule, temperature, fermentation time, and inoculum size. The amount of polysaccharide was found to be 21.97 mg/g under optimum culture conditions [47]. Further research in the production of polysaccharides from *G. lucidum* was reported by You [48]. Moreover, *G. lucidum* cultivation opens a door to process forest and agricultural wastes into useful by-products and thus reduces the environmental pollution.

9 Bioactive Compounds in *G. lucidum*

Approximately 400 different bioactive compounds are present in this mushroom. Polysaccharides, triterpenoids, organic germanium, ergosterol, nucleotides, sterols, amino acids, fatty acids, proteins, intracellular/extracellular enzymes, and trace elements [2, 49] are the major active compounds possessing biological activities. All parts of *G. lucidum* viz., fruiting body, mycelia, and spores, are reported to contain these compounds. Mushroom-derived polysaccharides and triterpenes have increased demand in the market. The extracts of this mushroom are given as a health supplement or medicine for anticancer, antiviral, immunomodulating, hepatoprotective, and hypocholesterolemic agents [50, 51]. Absence of side effects and presumed health benefits give reputation for this mushroom to use as herbal medicine [39].

The bioactive compounds from *G. lucidum* have a long history and have received considerable attention in recent years. Intensive work on the therapeutic effects of *G. lucidum* has been reported in the literature.

Ganoderma lucidum possesses unique bioactive molecules which include

- Polysaccharides [52–54]: A variety of polysaccharides that tend to be the components to interact with the immune system and are subdivided into β-1,3-glucans and polysaccharide peptides such as peptidoglycan.
  - Water-soluble polysaccharide peptides include GLPS peptide (GLPP) [55], GLPG [56], GLIS [57], PGY [58] and F3 [59].
  - β-1,3-Glucan (a subset of polysaccharides) sometimes called Curdlan [53] and other Glucan molecules [60].
- Triterpenoids: Over 120 triterpenoids [61] were revealed which can be separated into two classes. Those with a carboxylic side chain (Ganoderma acids) and those without (Ganoderma alcohols). Some are referred to as lucidenic acids [62].
- Nucleotide bases such as thymine, uridine, inosine, guanosine, and adenosine are present in this mushroom. The sum of all ranging from 303 to 1217 mcg/g in the mushroom cap and 22–334 mcg/g in the stem [63].
- Bioactive proteins such as LZ-8 (Lingzhi-8) [64], Ganodermin A and 114 kDa hexameric lectin, a glycoprotein with 9.3% sugar [65] are present.
- A reversible and a highly specific competitive alpha-glucosidase inhibitor known as SKG-3 with an IC_{50} of 4.6 mcg/mL [66].
- Ergostane sterols and ergosterol, also known as pro-vitamin D2 [67].
- C19 fatty acids (nonadecenoic acid and cis-9-nonadecenoic acid) [68, 69].
- Riboflavin.
- Vitamin C.
- Copper and Zinc [70].
- Selenium of up to 72 mcg/g dry weight and can transform selenium into selenium-containing proteins [71].
- Germanium of up to 489 mcg/g based on dry weight.

9.1 Structure and Properties

Polysaccharides, triterpenoids, and peptidoglycans are the main sources that are responsible for the bioactivity of *G. lucidum*. Activities from other molecules have not been studied significantly. Major triterpenoids responsible for the bioactivity are Ganodermic acids, Ganodermic alcohols, and Lucidenic acids.

9.1.1 Polysaccharides

Polysaccharide is a long chain of monosaccharides linked by glycosidic bonds. More than 100 types of polysaccharides have been reported to be present in *G. lucidum*. Most of them belong to a group of β-glucan which consists of a linear backbone of β-(1,3) linked D-glucopyranosyl groups with varying degree of branching from the C-6 position. They are considered as the active agents to fight against cancer. The molecular weight ranges from 4×10^5 to 1×10^6 in the primary structure [2]. β-Glucans of higher molecular mass are more effective than that of glucans with low molecular mass [72, 73]. β-Glucans also exist with heteropolysaccharide chains of xylose, mannose, galactose, uronic acids, and β, D-glucan-protein complexes which are present in the dry fruiting body (10–50%) [74, 75].

Polysaccharides prevent oncogenesis by not attacking the cancer cells directly, but by activating the immune response in the host. Fang and Zhong [76] indicated that active immunomodulatory polysaccharides are water-soluble (β-1,3 and β-1,6) glucans which can be precipitated by ethanol. Other polysaccharides such as glycopeptides [77, 78] and proteoglycans [79, 80] are also reported to have immunomodulatory activities. Purified mushroom polysaccharides have been used worldwide especially in China, Japan, and Korea for years for clinical purposes without any side effects. Polysaccharides are reported to increase the quality of life of cancer patients and offer promising survival rates [81]. Mushroom extracts are used as tonic for the immune system. Polysaccharides are reported to be very effective for wound healing [82].

9.1.2 Triterpenoids

Other class of bioactive compounds are also present abundantly in *G. lucidum*. Approximately 140 types of triterpenes have been identified in *G. lucidum* [49, 83, 84]. Most of them are lanostane type triterpenes. Extract of *G. lucidum* tastes bitter due to the presence of these triterpenoids, especially Ganoderic acid which is the major type of triterpenoid present in this mushroom. There are several types of Ganoderic acids such as, GA-A, B, C, and F. Previous studies indicated that triterpenoids are present more in the spores as compared to other parts of the mushroom. The production of bioactive compounds is also affected by the area and conditions in which they grow [85]. The basic structure of triterpenoid depends on the structure of lanosterol, an important intermediate for the biosynthesis of steroid and triterpene. Triterpenes are divided into three groups based on the number of carbon atoms and functional groups which are C30, C27, and C24 compounds [86]. Many of them find useful as chemotherapeutic agents.

9.1.3 Phenolic Compounds

Phenolic compounds are one of the important and the most commonly extracted bioactive compounds from *G. lucidum*. They can be classified as simple phenols and phenolic acids such as gallic acid, benzoic acid, syringic acid, chlorogenic acid, and polyphenols which are classified into many distinct groups such as flavonoids, tannins, stilbenes. Flavonoids are a group of polyphenolic compounds with known health-beneficial properties that include free radical scavenging, inhibition of hydrolytic and oxidative enzymes, and anti-inflammatory activity [87]. Research studies suggest that the biological activity of these compounds is related to their antioxidant activity. Phenolic compounds have significant biological and pharmacological properties, and some have demonstrated remarkable ability to alter sulfate conjugation. The bioactivity of phenolics may be related to their ability to chelate metals, inhibit lipoxygenase, and scavenge free radicals [88]. Methanolic extracts of *G. lucidum* have been reported to contain higher antioxidant activity [89, 90], and their radical scavenging mechanism has been revealed (c). Heleno et al. [91] revealed that the phenolic extracts of fruiting body and mycelia have higher antioxidant potential than their corresponding polysaccharide extracts, highlighting a higher contribution of free phenolic compounds than the antioxidants linked to polysaccharides.

9.1.4 Sterol and Ergosterol

Sterols are derivatives of triterpenoids. *Ganoderma lucidum* has been determined to contain ergosterol and 24-methylcholesta-7,22-trien-3-ol. 8,9-epoxyergosta-5,22-dien-3,15-diol from *G. lucidum* was reported as the first isolated free sterol [72].Hajjaj et al. [92] reported the isolation and identification of 26-oxygenosterols such as ganoderol A, ganoderol B, and ganoderic acid Y. They also determined that 26-oxygenosterols could lead to novel therapeutic agents that can lower the blood cholesterol.

Ergosterol is one of the important pharmaceutically relevant compounds. It is a vitamin D precursor. The integrity of fungal cell membrane is maintained by ergosterol. It also generates cellular energy. Measurement of Ergosterol is an important parameter in the biomass production. A new, highly oxygenated sterol, 22E, 24R-ergosta-7,22-diene-3beta, 5alpha, 6beta, 9alpha,14alpha-pentol was reported by Zang et al. [93]. Ergosterol was found to be higher in *G. lucidum* (median content, 705.0 μg/g; range, 189.1–1453.3 μg/g; $n = 19$) as compared to other species (median content, 80.1 μg/g; range, 16.0–409.8 μg/g; $n = 13$) [94].

9.1.5 Proteins

In addition to polysaccharides and triterpenoids, *G. lucidum* is a reservoir of proteins and peptides with biological activities [95]. LZ-8 is one of the proteins isolated from *G. lucidum* which appears to be related to an ancestral protein of the immunoglobulin superfamily. Confirmation of this protein was carried out by sequencing studies, and it resembled with the sequences and secondary structure of heavy chain region of immunoglobulin. The biological activities are almost similar to lectins which have mitogenic capacity [96] towards mouse spleen cells and human peripheral lymphocytes in vitro.

Other proteins are ribosome inactivating proteins (RIP), antimicrobial proteins, ribonucleases, and laccases. All these compounds play essential role in regulating

the body's immune mechanism directly or indirectly. Among these proteins, FIP plays a vital role in antitumor, antiallergic, proliferation of lymphocytes, and transplant rejection activities [97]. Seven FIPs have been identified till now from varied species of Ganoderma. They are LZ-8 (*G. lucidum*), FIP-gts (*G. tsugae*), FIP-fve (*Flammulina velutipes*), FIP-vvo (*Volvoriella volvacea*), FIP-gmi (*G. japonicum*), and FIP-gsi (*G. sinensis*) [98, 99]. One molecule of FIP composed of 110 to 114 amino acids and their molecular weights are around 13 kDa. Among the FIP proteins, LZ-8 contains low levels of carbohydrates, but other FIPs are pure proteins without any carbohydrates. The presence of a lower amount of FIP in *G. lucidum* is a problem for recovery to meet its growing demand. Nowadays it is the major concern among the researchers, and thus the focus is on the genetic engineering to develop FIP protein through cloning FIP genes in eukaryotes and prokaryotes [100, 101].

9.1.6 Nucleotides and Nucleosides

These are the nitrogenous compounds which play important roles in the metabolism and stimulate hemopoieses. Nucleosides include adenosine and 5-deoxy-50 methylsulfinyladenosine. Adenosine of *G. lucidum* suppresses platelet aggregation and prevents heart attacks and thrombosis [102].

9.1.7 Lipids and Fatty Acids

Phosphatidic acids are not the abundant lipid constituents in the living organisms, but they play significant role in the membrane trafficking events and defense mechanisms against infection and tissue damage during inflammation. Presence of these lipids makes this mushroom important among the medicinal species [103]. The main fatty acids in *G. lucidum* are palmitic acid, linoleic acid, oleic acid, and stearic acid. Fatty acids in the spores could inhibit tumor cell proliferation [94]. Nonadecanoic acid is another fatty acid present in this mushroom which has the highest inhibitory activity, followed by heptadecanoic acid, stearic acid, and palmitic acid [69]. Palmitic acid and stearic acid are the strong apoptotic agents [104].

9.1.8 Amino Acids

Nutritional analysis of *G. lucidum* showed the presence of 16 amino acids (Table 2), where glutamic acid (120), aspartic acid (117), glycine, and alanine show the highest relative abundance, whereas methionine shows the least [77].

9.1.9 Alkaloids and Other Compounds

Generally, alkaloid content is relatively less in *G. lucidum*. The alkaloids such as choline and betaine were isolated from the spores of *G. lucidum* [72]. Studies have showed the presence of alkaloids and their chemical allies, i.e., saponins, flavonoids, and tannins [105] in *G. lucidum*.

Studies by Mizuno [106] showed that the extracts of *G. lucidum* (% dry weight) consist of folin-positive material (68.9%), protein (7.3%), glucose (11.1%), and metals such as K, Ca, Ge, and Mg. The outcome of this study agrees well with the reports of other investigations [20, 107]. Moreover, there is a difference in the qualitative and quantitative results in the chemical composition of *G. lucidum* extracts. It is mainly

Table 2 Amino acid composition in *G. lucidum*

Amino acid	Relative abundance
Glutamic acid	120
Aspartic acid	117
Glycine	108
Alanine	100
Threonine	66
Valine	61
Proline	60
Leucine	55
Serine	54
Isoleucine	36
Phenylalanine	28
Arginine	22
Lysine	21
Tyrosine	16
Histidine	12
Methionine	6

affected by the factors such as quality of the strain, origin, cultivation conditions, stages of harvesting, and extraction processes [83]. Elemental analysis of log-cultivated fruiting bodies of *G. lucidum* revealed phosphorus, silica, sulfur, potassium, calcium, and magnesium to be their main mineral components. Iron, sodium, zinc, copper, manganese, and strontium were also detected in lower amounts, as were the heavy metals such as lead, cadmium, and mercury [108]. *Ganoderma lucidum* also contains soluble proteins, oleic acid, cyclo-octasulfur which is an ergosterol peroxide (5,8-epidioxy-ergosta-6,22E-dien-3-ol), and cerebrosides ((4E0,8E)-N-D-20-hydroxystearoyl-1-Ob-D-glucopyranosyl-9-methyl-4-8-sphingadienine, and (4E,8E)-N-D-20-hydroxypamitoyl-1-O-b-D-glucopyranosyl-9-methyl-4-8-sphingadienine [49, 106, 109]. Compounds such as choline, betaine, tetracosanoic acid, stearic acid, palmitic acid, ergosta-22-dien-3-ol, nonadecanoic acid, behenic acid, tetracosane, hentriacontane, ergosterol, and β-sitosterol have been reported in the spores of *G. lucidum* [110].

Some attention has been given to the germanium content of *Ganoderma* spp. Germanium was the fifth highest in terms of concentration (489 μg/g) among the minerals detected in *G. lucidum* fruiting bodies collected from the wild [111]. Germanium is not an essential element at low doses. It has been credited with immunopotentiating, antitumor, antioxidant, and antimutagenic activities [112]. Other compounds that have been isolated from *G. lucidum* include enzymes such as metalloprotease, which delays clotting time, ergosterol (provitamin D_2), nucleosides, and nucleotides (adenosine and guanosine) [2, 50].

9.2 Extraction, Product Recovery, and Analysis of Bioactive Compounds

Ganoderma lucidum is enriched with active compounds such as polysaccharides, triterpenoids, nucleotides, organic germanium, fatty acids, proteins, amino acids,

and sterols. Therefore, it is essential to develop a methodology for the effective recovery and easy analysis of these bioactive compounds. All these components have been reported to have pharmaceutical applications. Separation of individual components is difficult, time-consuming, and expensive; therefore, industries are looking for random isolation of compounds in the form of crude mushroom extract. In the past few years, it is being a challenge to develop a methodology for the elicitation, recovery, extraction, and analysis of bioactive compounds from *G. lucidum*. Triterpenoids appear to be hydrophobic and are present in ethanol or chloroform fractions, whereas the polysaccharides are water-soluble and are the major bioactive compounds in the water-soluble extract of Ganoderma.

9.2.1 Preparation of *G. lucidum* for the Extraction of Bioactive Compounds

Ganoderma lucidum should be first processed after collection. Preparing the raw materials for a process involves cleaning the material from dirt by washing or rinsing and removing the trunks either manually or by using a vegetable slicer. Thereafter, the material should be dried to reduce their moisture content, to avoid probability of degradation, and to facilitate the safe storage and transportation [113]. By removing the moisture content, the efficiency of extraction process will be enhanced remarkably.

9.2.2 Drying (Demoisturization)

Generally, many drying methods are used to dry the mushroom sample. These methods are classified into two groups: heating (baking, ovens, stoves, and infrared) and air-drying (drying chambers with air circulation) [113]. Classically, drying *G. lucidum* in an open air either under shading or direct sunshine is the most commonly used method due to its low-cost and simple preparation set-up. However, choosing the right drying method is limited by the type of desired bio-components and their physical properties. For example, for thermolabile components (thermally nonstable components), such as polyphenols and triterpenes, it is recommended to maintain the drying temperature below 40 °C to avoid thermal degradation of these components [114, 115]. Also, for some of the light sensitive components such as polyphenolics, it is important to keep the raw materials away from the sun light during the drying stage [115]. For industrial production, large-scale batches could be processed by hot air-drying method which is an economically cost-effective but physically may affect the products due to the probability of oxidation damage that can occur when exposed to air stream [116]. In general, to retain most of the bioactive components, a temperature range of 50–60 °C is the most commonly followed for drying the herbal materials [117–119].

Through an extended literature survey, different drying methods were reported to prepare the herbal materials for the extraction of bioactive compounds. *Ganoderma lucidum* under 60 °C for 24 h [120] is suitable to retain the bioactive compounds, while in many other reviews air drying chambers were used to dry *G. lucidum* under 105 °C [54, 121]. The flexibility of using different drying methods could be attributed to the ability of polysaccharides to withstand relatively a wider

range of temperatures, i.e., 30 °C [122], 45 °C [123], 50 °C [124], 90 °C [125], and 105 °C [126], depending on the matrix of the mushroom.

9.2.3 Size Reduction of Herbal Materials (Grinding)

Size reduction is the second important preparatory stage for any extraction process. It was found that cutting the mushroom into small pieces or reducing the particle size of the raw materials before extraction is essential to increase the mass transfer rate of the entire process. Reducing the particle size leads to an increase in the contact surface area between the solvent and the extracted mass, which increases the diffusion of bio-components in the solvent and thus results into an increase in the overall mass transfer rate. The size reduction can be implemented by inserting the mushroom sample into a hammer mill or disc pulverizer provided with sieves in different ranges of particle permeation. Many factors affect the grinding of mushroom samples such as adjusting the speed of the rotor clearance between the hammers and the lining of the grinders, the discharge capacity of the mill, and the sieve sizing which is preferable to be in between 30 and 40 mesh as an optimal range for the extraction of mushroom samples.

For *G. lucidum*, to improve the extraction process of polysaccharides, the fruiting body is preferably to be used in the powder form [121]. A 32 range of particle size (2–5 mm) is reported by several studies on the ultrasonic-assisted extraction of polysaccharides from *G. lucidum*. The fruiting bodies of *G. lucidum* were crushed to pass 2 mm screen [73, 120, 127], 5 mm [118] or cutting into small pieces of 3 to 2 cm of 2 mm thickness [128, 129]. Generally different grinding machines (pulverisers) are used to prepare fine particles in the powder form. Usually these grinding machines are provided with shaker and sifting-sieves of 12–120 mesh [130], such as 70 mesh [131], 40 mesh [132], and 60 mesh [133].

9.2.4 Pretreatment with Aqueous Ethanol

Many studies showed that pretreating the herbal materials with polar organic solvents (ethanol, methanol), or an aqueous alcoholic mixture, helps to exclude large amount of constituents (monosaccharides, fatty acids, amino acids, phenols, and endogenous enzymes), other than macromolecules such as polysaccharides, nucleic acids, and proteins which could be extracted in a later stage by the polar solvent such as water. The aqueous mixture of ethanol, 60–90% (v/v), has been used for this purpose due to its ability to extract a wide range of components with different polarity. The most important stage in the pretreatment with aqueous ethanol is the prior removal of hydrophobic constituents, such as fats that greatly influence the extraction stage and limit the penetration of water into the solid structure [134]. In the extraction of polysaccharides from *G. lucidum,* the raw materials are treated first with 80% ethanol, under shaking, at 30 °C for 24 h, to remove free sugars (monosaccharides), polyphenolics, and lipophilic components [116, 127, 135]. Another composition of aqueous ethanol, i.e., 95%, has been reported in the pre-treatment of *G. lucidum* relatively at a higher temperature (70 °C), to improve the removal of endogenous enzymes and to reduce the long time required as compared to 80% ethanol at room temperature [120, 124].

9.3 Polysaccharides

They are the major contributors of bioactivity in *G. lucidum* with a wide range of physicochemical properties. Major class of polysaccharides are β-1,3 and β-1,6-D glucans. They exist in two forms, i.e., water-soluble and water-insoluble. Polysaccharides are of two types: extracellular (EPS) and intracellular (IPS). Exopolysaccharides or extracellular polysaccharides are secreted by the microorganisms into the surrounding environment. Generally, IPS is extracted with 1 M NaOH at 60 °C for 1 h. Other solvents such as ammonium oxalate (1%) and NaOH (5%) could also be used for the extraction. EPS is usually extracted by precipitation with 3 to 4 volumes of ethanol of 95% [39]. To eliminate smaller molecules such as mono- and oligosaccharides, dialysis of the filtrate is sometimes preferred before applying precipitation using ethanol [76]. In case of solid-state fermentation (SSF), it is difficult to separate EPS from IPS as mycelia will be strongly bound with the substrate and EPS does not dissolve in the liquid phase. To recover the polysaccharides, the fermented substrate along with mycelia should be extracted with cold or hot water [41] for 5 h. However, such a method not only separates EPS and IPS produced by the organisms, but also some polysaccharides from the solid substrate. The resulted polysaccharides are analyzed by phenol-sulfuric acid method [136]. But it has been found out that the detection of polysaccharide by this method is not stable because along with polysaccharides the presence of some of the monosaccharides, oligosaccharides, and protein also give faulty positive result for phenol-sulfuric acid. Therefore, it is important to eliminate other molecules from the samples using techniques such as dialysis, gel exclusion chromatography, or column chromatography. Determination of proteins separately is also necessary to make sure the accuracy of phenol-sulfuric acid assay [39].

To isolate water-soluble polysaccharides from *G. lucidum*, the samples are extracted with hot water (95–100 °C). It is followed by three volumes of ethanol precipitation and the polysaccharide fractions are collected by centrifugation [77].Alkali-soluble polysaccharides are separated by 0.1–1.0 M sodium hydroxide [137, 138]. It has also been reported that to remove the lipids present in the sample, prior to the hot water or alkali extraction it is to be extracted first with ethanol under reflux [53]. This pretreatment also deactivates enzymes which hydrolyze the polysaccharides. Cheong et al. [75] reported that the biological activity of polysaccharide differs based on the types of extracting solvents as well as the fractionation methods employed.

The extracted polysaccharides are further isolated and purified by fractional precipitation, acidic precipitation, ion exchange chromatography, gel filtration, affinity chromatography, and TLC. Electrophoresis and gel filtration chromatography techniques are used as effective tools for determining the homogeneity and molecular weight. Paper chromatography, TLC, GC-MS, and HPLC are used for compositional analysis [72].

9.4 Triterpenoids

More than 130 oxygenated triterpenes have been isolated from *G. lucidum* [139] and most of them are lanostane-type triterpenes. There are two types of extraction

methods for the isolation of triterpenes from *G. lucidum*. One involves the extraction of total triterpenes using the organic solvents and water. Min et al. [85, 140] extracted the triterpenes from spores of *G. lucidum* by refluxing with methanol. Extraction of triterpenes is usually done by means of methanol, ethanol, acetone, chloroform, ether, or a mixture of these solvents.

The second approach is the selective isolation of acidic triterpenes from the fraction of total triterpene. Extraction of fruiting bodies with 95% aqueous ethanol under reflux has been reported [141]. The obtained ethanol fraction was evaporated under reduced pressure to obtain a residue which was then suspended in water followed by extraction with chloroform. 5% $NaHCO_3$ was added to the chloroform extract and the water phase was collected which was again extracted with chloroform after acidified with HCl (6 N) to a pH less than 3 [142]. The collected residue after chloroform evaporation was suspended in absolute ethanol and spectrophotometric measurements were made at 245 nm to determine the Ganoderic acid [143]. Triterpenes could be further purified by silica gel column chromatography and preparative HPLC [144, 145].

10 Therapeutic Effects of Bioactive Compounds of *G. lucidum*

Being worshipped as a herbal medicine, a great deal of work has been carried out on the therapeutic applications of this special mushroom [14]. Medicinal use of *G. lucidum* has been recorded in ancient Chinese manuscripts. Extracts of this mushroom have been included in the treatment of insomnia, dizziness, chronic hepatitis, coronary heart diseases, hypertension, carcinoma, and bronchial cough. One of the promising properties shown by this wonder medicine is the extended lifespan while increasing the vitality. *G. lucidum* has been used in the fields of antiaging, male sexual dysfunction, hypercholesterolemia, chemotherapy induced toxicity, anticarcinogenic, narcotic-induced immunosuppression, antitumor activity, radioprotective, sleep promoting, antiviral, antifibrotic, antiulcer, radical-scavenging, and in the immunostimulation [2]. It is widely used as an active adjuvant in the treatment of carcinoma and related symptoms.

Sliva [146] indicated that in Western medicine one of the major obstacles in accepting the mushroom based natural products is their complexity. Alternatively, this complexity can also bring significant advantages. Some of the components in the natural products could reduce the cytotoxicity of cells, and the interaction between some of the biologically active components may be responsible for their in vivo effects. Besides, different compounds could modulate the unrelated signaling and thereby exhibiting a synergistic effect. The triterpenes of *G. lucidum* directly suppress the growth and invasive behavior of cancer cells, whereas polysaccharides of *G. lucidum* stimulate the immune system resulting in the production of cytokines and activation of anticancer activities of immune cells. The data obtained from the research studies demonstrate the effect of *G. lucidum* only on the molecular level, and thus preclinical and clinical studies are necessary for the validation of this

natural product in the prevention and/or therapy of cancer. The important medicinal applications of *G. lucidum* are described below.

10.1 Anticancer Studies

Cancer is one the most concerned medical conditions among the human population and effective treatments are always sought which have least or no side effects. *Ganoderma lucidum* has been a popular supplement taken by healthy individuals to boost their immune system or by the cancer patients to reduce the side effects of chemotherapy. *Ganoderma lucidum* is considered to be a factory for bioactive compounds which can reduce the lethal effects of cancer. Fruiting body, mycelia, or spores are reported to contain these bioactive compounds. Polysaccharides and triterpenes are the two major classes of components in this mushroom which exhibit chemopreventive and/or tumoricidal effects as proved by numerous in vitro and in vivo studies [147]. Tumor implanted animal models have shown inhibitory effects on angiogenesis and metastasis. However, evidence from well-designed human trials is still scarce. Tomasi et al. [148] tested 58 basidiomycetes mushrooms, of which *G. lucidum* was shown to be the most effective in killing the cancer cells. *Ganoderma lucidum* induced cell-cycle arrest and apoptosis in various human and rodent tumor cells, including murine lymphocytic leukemia L1210 and Lewis lung carcinoma, have been reported [148].

Ganoderma lucidum also exhibits chemo-and radio preventive effects which are attributed to its effects on the immune system. *Ganoderma lucidum* extract showed better effect than Krestin (protein bound β-glucan isolated from *Coriolus versicolor*) in repairing the damage of subset T-cells in the spleen of irradiated mice [149]. One of the polysaccharide peptides from *G. lucidum* reported to restore the immunologic parameters depressed by morphine treatment beyond normal levels [150].

10.2 Antioxidant Activity

Antioxidants are natural or man-made substances which can prevent the activity of other chemicals known as free radicals that cause damage to the cells. *Ganoderma lucidum* is one such mushroom widely used due to its antioxidant activity. Consumption of antioxidants may help prevent cancer and other chronic diseases [151].Antioxidants protect cellular components from oxidative damage, decrease risk of mutations and carcinogenesis, and protect immune cells, allowing them to maintain immune surveillance and responses. The bioactive compounds such as polysaccharides and triterpenoids show antioxidant activity in vitro [58, 152, 153]. Antioxidants from *G. lucidum* were found to be absorbed quickly after ingestion, resulting in an increase in plasma total antioxidant activity [154].

Ooi and Liu [155] reported that protein-bound polysaccharide (PBP) and polysaccharide peptide could mimic the endogenous antioxidant superoxide dismutase (SOD) in cancer-bearing animals in vivo. These polysaccharides were also reported

to protect the immune cells from oxidative damage. The protective effects of *G. lucidum* on DNA strand scission induced by a metal-catalyzed Fenton reaction, ultraviolet irradiation, and hydroxyl radical attack were shown in agarose gel electrophoresis in vitro [156]. Hot water extracts of *G. lucidum* significantly protected Raji cells from hydrogen peroxide (H_2O_2)-induced DNA damage [157]. The aqueous extract protected cellular DNA from oxidative damage, whereas the ethanolic extract damaged the cellular DNA with increased H_2O_2 production and significant cell-killing effects were observed. The results suggested that different effects of *G. lucidum* could be exhibited by different components of extract in bladder chemoprevention. Methanol extracts of *G. lucidum* were reported to prevent kidney damage (induced by the anticancer drug cisplatin) through restoration of the renal antioxidant defense system [158]. In contrast, a fraction of Ganoderma triterpenes (GTS) was found to enhance the intracellular reactive oxygen species (ROS) in HeLa cells, leading to more DNA damage and apoptosis, whereas such a synergism was inhibited by a ROS scavenger [159]. In an animal study (diabetic rats), nonenzymic and enzymic antioxidant levels increased and lipid peroxidation levels decreased with *G. lucidum* treatment [160]. However, a direct link has not been established between the antioxidant properties of *G. lucidum* and its immunomodulatory and anticancer effects.

10.3 Antiallergic Property

Another important application of the fruiting bodies of *G. lucidum* is their application as anti-inflammatory agents for the treatment of asthma or allergy. *Ganoderma lucidum* has unique array of compounds called immunonutraceuticals, which play a leading role in the treatment of histamine-mediated allergic responses [161]. *Ganoderma lucidum* is reported to be as an effective agent to restore the normal balance between the cytokines TH1 and TH2 immune states in patients with histamine-mediated allergic responses [162]. In a case study of hay fever patients, Powell found that patients (male) of age 5 and 39 with different doses viz. 2 tablets × 500 mg a day and 6 tablets × 500 mg per day of *G. lucidum* resulted in a decrease in drowsiness, itchiness and sneezing.

10.4 Antibacterial and Antiviral Activity

Ganoderma lucidum has been widely reported as a good antibacterial agent. Aqueous as well as methanolic extracts of *G. lucidum* inhibited several types of gram-positive and gram-negative bacteria. Studies indicated that a combination of *G. lucidum* extract with different antibiotics has resulted in an additive effect in most of the instances [163]. Active compounds such as triterpenes, ganomycein, and other aqueous extracts have broad spectrum antibacterial activity in vitro [39]. A 15-kDa antifungal protein ganodermin isolated from *G. lucidum* is known to inhibit the mycelia growth of *Botrytis cinerea*, *Fusarium oxysporum*, and *Physalospora piricola* with an IC 50 value of 15.2 μM, 12.4 μM, and 18.1 μM, respectively [65].

10.5 Antidiabetic Effect

Few animal studies of polysaccharide fractions of *G. lucidum* demonstrated that they have the potential hypoglycemic and hypolipidemic activities. The aqueous extract (1000 mg/kg) of *G. lucidum* normalized the blood glucose levels in alloxan-induced diabetes in Wistar rats [164]. Water extract of *G. lucidum* reduced the increase in blood glucose levels in rats following oral glucose test. A clinical study aimed at evaluating the antidiabetic efficacy and safety of polysaccharide fractions extracted from *G. lucidum* (Ganopoly) by a patented technique in 71 patients with confirmed type II diabetes mellitus has been reported by Gao et al. [109]. Treatment with Ganopoly significantly decreased the mean HbA1c from 8.4% at baseline to 7.6% at 12 weeks which demonstrated that Ganopoly is efficacious and safe in lowering the concentration of blood glucose.

11 Conclusions

Ganoderma lucidum is a well-known medicine with remarkable range of applications. Though the global consumption of *G. lucidum* is high, the production rate is not satisfactory. The bioactive compounds in *G. lucidum* make it very special and are classified under Host Defense Potentiators (HDP) which can have immune system enhancement properties. Various products such as capsules, creams, tonics, and syrups are available in the market, which offer high health benefits. Many researches have been performed in this mushrooms on its cultivational and medicinal aspects. Its positive health benefits include anticancer effects, antioxidant, antibacterial, blood glucose regulation, and antiviral effects and protection against liver and gastric injury. Though many studies are performed on animal models, successful studies on human cell models are least reported. Human experimental studies have often been small, and the results are not always supportive of the in vitro findings. Therefore, Ganoderma research on its clinical aspects need more supportive clarifications for the dosage and side effects in the human beings. Similarly, the mechanism of action of different bioactive molecules isolated from this mushroom is yet to be elucidated.

Minas Frescal Cheese as a Probiotic Carrier 65

Tatiana Colombo Pimentel, Vanessa Aparecida Marcolino, Carlos Eduardo Barão, Suellen Jensen Klososki, and Michele Rosset

Contents

Abstract

Minas Frescal cheese is one of the most popular cheeses consumed in Brazil, has mild and pleasant flavor and aroma, is slightly acidic and whitish in color, and presents soft texture. It has characteristics that allow the incorporation of probiotic cultures and maintenance of the viability until the end of the shelf life.

However, the addition of probiotic cultures can have a negative impact on the physicochemical and sensory characteristics of the products. The purpose of this chapter is to present the technology involved in the development of probiotic Minas Frescal cheese. First, it presented the starter and probiotic cultures commonly used in Minas Frescal cheese, the criteria to classify a strain as probiotic, and the health-related benefits. Then, it discussed the technological process and the forms of addition of the probiotic cultures to the cheeses. Finally, it demonstrated the effect of probiotic addition on the physicochemical and sensory properties, the probiotic stability during storage, and the main challenges to maintain the viability.

Keywords
Fresh cheese · Probiotic culture · Sensory properties · Physicochemical · Viability

Abbreviations

Cfu	Colony-forming unit
HDL-C	High-density lipoprotein cholesterol
HTST	High-temperature short time
IgA	Immunoglobulin A
LDL-C	Low-density lipoprotein cholesterol
LTLT	Low-temperature long time
NK	Natural killer
SCFA	Short-chain fatty acids
VLDL	Very low-density lipoprotein

1 Introduction

Probiotics are living microorganisms, which, when administered in adequate amounts, confer benefits to the host health [1]. Probiotic cultures are usually added to dairy products, such as fermented milks, yogurts, and cheeses. This is because dairy products are regarded as healthy products by consumers, assist in the digestion process, are essential for bones, and help the immune system. Furthermore, the consumers are used to the application of microorganisms in the preparation of these types of products.

Minas Frescal cheese is one of the most popular cheeses consumed in Brazil, because of the high yield, relatively low production costs, easy manufacturing process, and acceptable sensory characteristics [2, 3]. It has mild and pleasant flavor and aroma, is slightly acidic and whitish in color, and presents soft texture. The presence of holes and a thin crust can be observed in some commercialized products. According to the Technical Identification and Quality Regulation [4], Minas Frescal cheese is a fresh cheese obtained by enzymatic coagulation with rennet and/or other appropriate coagulant enzymes, supplemented or not with the action of specific lactic acid bacteria. It is classified as a semi-fat cheese (25–44.9%

fat in the dry matter) and has very high moisture content (over 55%) [5]. Due to the characteristics of moisture content and pH, it has a short shelf life (20–30 days) and should be stored under refrigeration.

The production of Minas Frescal cheese requires the pre-pasteurization of the milk for the elimination of pathogens. However, some producers insist on the use of raw milk for the manufacture of this type of cheese, which can compromise the food safety. The pasteurization of the milk also promotes the reduction of the spoilage microbiota, reducing the competition between these cultures and the health cultures, improving the environment for the development and maintenance of the probiotic cultures. The Minas Frescal cheese has characteristics that allow the incorporation of probiotic cultures and maintenance of the viability until the end of the shelf life, such as the presence of nutrients that can be assimilated by the probiotic cultures, high pH (in the range of 5–6), high moisture content, low salt content (1.4–1.6%), medium fat content, capability of protecting the microorganisms from the adverse conditions during the digestion process, refrigerated storage, and short shelf life.

Considering the technology of manufacture of the Minas Frescal cheese, its chemical composition, the method of preservation, and the interest in functional foods, this product has the potential to be added with probiotic cultures. The purpose of this chapter is to present the technology involved in the development of probiotic Minas Frescal cheese. First, it presented the starter and probiotic cultures commonly used in Minas Frescal cheese, the criteria to classify a strain as probiotic, and the health-related benefits. Then, it discussed the technological process and the forms of addition of the probiotic cultures to the cheeses. Finally, it demonstrated the effect of probiotic addition on the physicochemical and sensory properties, the probiotic stability during storage, and the main challenges to maintain the viability.

2 Probiotic Cultures

Probiotics are living microorganisms, which, when administered in adequate amounts, confer benefits to the health of the host [1]. A possible probiotic culture should be identified and characterized, and its infective potential and related interference with the host metabolism evaluated. Up to now, infective capacity and resistance to antibiotics have comprised the main focus in traditional safety criteria [6]. Furthermore, the microorganism should be able to remain viable during technological processing and storage and throughout the shelf life of the product. In addition, when the food is consumed, this microorganism must be able to survive during the passage through the gastrointestinal tract, supporting the pH of the stomach and the bile salts in the small intestine, and, finally, it needs to be able to populate the large intestine of the host and confer the expected health benefits.

In the preparation of Minas Frescal cheeses, some microorganisms can be used, which could be single or mixed strains, such as *Lactococcus lactis* spp. *lactis* [7, 8]; *Lactococcus lactis* spp. *lactis* and *Lactococcus lactis* spp. *cremoris* [7–10];

Lactobacillus acidophilus [11, 12]; *Bifidobacterium lactis* [11]; *Bifidobacterium lactis* and *Lactobacillus acidophilus* [11]; *Lactobacillus plantarum* [8]; *Enterococcus faecium* [8]; *Lactobacillus acidophilus*, *Bifidobacterium animalis*, and *Streptococcus thermophilus* [9]; and *Lactobacillus casei*, *Lactococcus lactis* spp. *lactis*, and *Lactococcus lactis* spp. *cremoris* [9]. Some of the cultures mentioned above present probiotic potential, which can impart functional properties to the product. The species used as starter cultures in the manufacture of Minas Frescal cheese (*Lactococcus lactis*, *Streptococcus thermophilus*, and others) do not generally grow in the gastrointestinal tract and, therefore, would have low probiotic potential.

The insertion of probiotic strains in Minas Frescal cheese can transform it into a functional food, conferring health benefits to individuals with a habit of consuming it. Table 1 shows the main potential probiotic strains used in previous studies with Minas Frescal cheese. The combination of some strains showed synergism and improved probiotic survival throughout the product's shelf life. However, the use of probiotic cultures can lead to changes in the characteristics of the products, reducing their acceptance by consumers by causing changes in the quality parameters of the product. These interferences will be discussed in this chapter.

The addition of probiotic cultures does not ensure the transformation of the Minas Frescal cheese into a functional food. The product, at the time of consumption, must present viable microorganisms in suitable amounts, and, preferably, these microorganisms should resist along the gastrointestinal tract during the digestion process, so that they can exert the probiotic effect on the individual's intestine. This latter characteristic is advised, but there are probiotic cultures with health benefits not related to the colonization of the intestine.

Table 1 Potential probiotic cultures used in Minas Frescal cheese

Lactobacillus acidophilus and *Streptococcus thermophilus*	[16]
Lactobacillus acidophilus and *Lactococcus lactis*	[18]
Lactobacillus casei	[2]
Lactobacillus casei and *Lactococcus R704*	[2]
Lactobacillus casei, *Lactococcus lactis* ssp. *lactis*, and *Lactococcus lactis* ssp. *cremoris*[a]	[9]
Lactobacillus plantarum	[8]

[a]Starter cultures. Low probiotic potential

A probiotic food should have counts of 10^6–10^7 colony-forming unit (cfu) g^{-1} or mL^{-1} in the final product or 10^8–10^9 cfu in a portion of 100 g or mL [19]. The Brazilian legislation does not establish the number of microorganisms that must be present in the product. It requires an analysis report to establish the minimum viable quantity of the microorganism to exert functional property at the end of the shelf life of the product and under the conditions of use, storage, and distribution. Therefore, the studies of functionality should be based on robust scientific evidence, constructed through randomized, double-blind, and placebo-controlled clinical studies whose outcomes demonstrate the proposed relationship between the product consumption and the functional effect [20].

3 Health Benefits of Probiotic Cultures

Probiotic culture ingestion is associated with many health benefits, such as reduction in gastrointestinal infections; antimicrobial activity; improvement in lactose metabolism; reduction in serum cholesterol; stimulation of the immune system; antimutagenic, anticarcinogenic, and antidiarrheal properties; improvement in the symptoms of irritable bowel syndrome; suppression of *Helicobacter pylori* infections; and reduction of obesity and atopic dermatitis, among others. The type of health benefit is associated with the strain; therefore, there is no strain capable of providing all the benefits suggested for probiotics. Figure 1 presents the target organs of probiotic action and the health-related benefit.

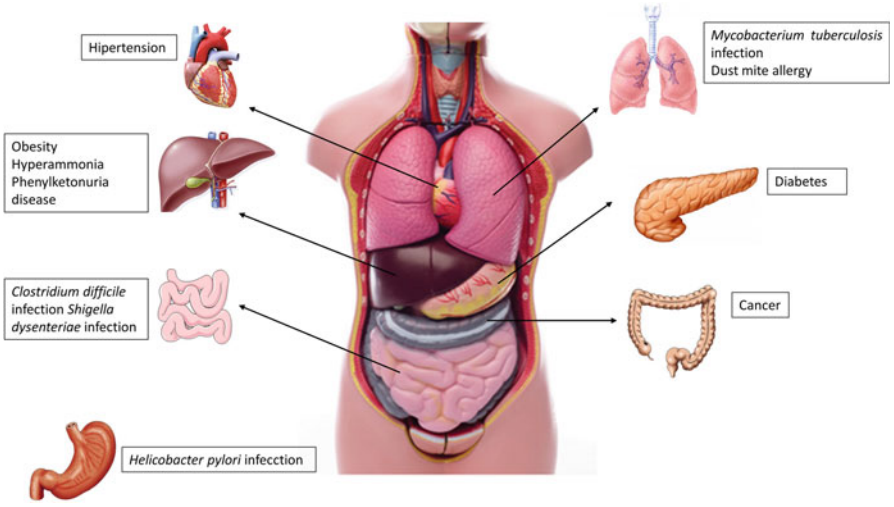

Fig. 1 Target organs of probiotic action and the health-related benefit (Adapted from Chua et al. [21])

3.1 Modulation of the Intestinal Microbiota

The human gastrointestinal tract is a kinetic micro-system that enables the normal performance of the physiological functions of the host, unless harmful and potentially pathogenic microorganisms dominate the microbiota [22].

The human gastrointestinal microbiota plays a key role in nutrition and health. By the fermentation process, the intestinal bacteria metabolize various substrates (mainly dietary components) forming end products, such as short-chain fatty acids (SCFA) and gases. This metabolism contributes positively to the daily energy needs of the host. The human large intestine is a metabolically very active organ, a fact attributed to the resident microbiota and its activities. Normally, the host organism lives in harmony with the complex microbiota of the intestine [23].

When in equilibrium, the intestinal microbiota prevents potentially pathogenic microorganisms from exerting their effects. On the other hand, the imbalance of this microbiota can result in the proliferation of pathogens, with consequent bacterial infection [23, 24]. The beneficial influence of probiotics on human intestinal microbiota includes factors such as antagonistic effects, competition against undesirable microorganisms, and immunological effects [25, 26].

The intestinal microbiota is also susceptible to contamination by passive pathogens, which alters the structure of normal colonization and can lead to acute and/or chronic intestinal disorders. Thus, the large intestine is the focus for functional foods, allowing the strengthening of the normal bowel functions and helping to prevent organic deficiencies. The colonization of the microbiota is determined by the susceptible action of certain dietary groups and mechanisms [27].

Hydrolysis and metabolism of carbohydrate in the large intestine are influenced by a variety of physical, chemical, biological, and environmental factors. The nature and quantity of available substrate have a greater influence, making diet the main and easiest mechanism by which the fermentation profile can be influenced. Other factors affecting the colonization and growth of bacteria in the gut are intestinal pH, production of inhibitory metabolites (acids and peroxides) and specific inhibitory substances (bacteriocins), bile salts, and immunological events [23].

The knowledge of the intestinal microbiota and its interactions led to the development of strategies aiming the maintenance and the stimulation of the resident bacteria. It is possible to increase the number of health-promoting microorganisms in the gastrointestinal tract by introducing probiotics included in food products or by consuming prebiotic food components, which will selectively modify the composition of the microbiota, providing the probiotic competitive advantage over other bacteria in the ecosystem [28].

The binding of probiotic bacteria to enterocyte cell surface receptors also initiates cascade reactions that result in the synthesis of cytokines. Experimental data indicate that several probiotics can modulate some characteristics of digestive physiology, such as mucosal immunity and intestinal permeability. One of the actions attributed to probiotics is the ability to adhere to certain types of receptors present in the intestinal mucosa, precluding their elimination by peristaltic movements and preventing pathogenic bacteria, such as *Salmonella typhimurium* and *Yersinia*

enterocolitica and pathogenic strains of *Escherichia coli* from exerting their enteropathogenic effects [29].

In the case of probiotics, consumption of adequate doses of *Lactobacillus* strains often results in a measurable increase in lactobacilli in feces, and in some cases, even undesirable organisms, such as *Staphylococci*, may be reduced. Bifidobacteria and lactobacilli in the colon ferment mainly the carbohydrates that escape the digestion in the upper gastrointestinal tract, resulting in a reduced pH in the colon. Bifidobacteria can ferment fructans because they have β-fructofuranosidase enzyme, which, in other bacteria, does not exist or has low activity. This confers competitive advantages to bifidobacteria when exposed to fructans in the human intestine.

Not all studies are conclusive regarding the administration of probiotics and alteration of the intestinal microbiota. Bartran et al. [30] argued that the fecal microbiota is relatively stable and generally unaffected by the use of probiotics. In an intervention study, 12 subjects consumed yogurt (500 mL) enriched with *Bifidobacterium longum*, and no significant difference was found for fecal weight, pH, fecal concentration of SCFA, bile acids, and neutral sterols after 3 weeks of intervention. Although there was an increase in fecal concentration of *B. longum*, the results suggest little or no modulation of the resident microbiota.

3.2 Improvement in Lactose Intolerance

Lactose intolerance is the condition in which there is partial or complete inability to digest the main milk sugar (lactose), because the body does not or insufficiently produce the digestive enzyme lactase, responsible for breaking down the lactose. Consequently, this substance reaches the large intestine unchanged and is accumulated and fermented by the resident bacteria, originating lactic acid and gases. These metabolites promote greater water retention and the appearance of diarrhea and abdominal discomfort. In addition to the clinical evaluation, the diagnosis of lactose intolerance can count on three specific tests: lactose intolerance test, hydrogen breath test, and fecal acid test.

There is evidence that probiotics may alleviate symptoms of lactose intolerance due to increased lactose hydrolysis in the dairy products and small intestine or through manipulation of colonic metabolism. Mechanisms of action may be related to increased activity of the enzyme lactase in bacterial preparations used in the manufacture of the products, by the decrease in lactose concentration in fermented products, and to the increased activity of the lactase enzyme that reaches the small intestine together with the fermented product or among the viable bacteria capable of surviving the acidity and the bile salts [31].

The alteration of the microbial metabolism by probiotics can occur through the increase or decrease of the enzymatic activity. A vital function of lactic bacteria in the intestinal microbiota is to produce the enzyme β-D-galactosidase (lactase), aiding the breakdown of lactose in the intestine. Several evidences have shown that the consumption of adequate amounts of appropriate strains of lactic acid bacteria

(including non-probiotic strains such as *Lactobacillus bulgaricus* and *Streptococcus thermophilus*) can alleviate symptoms of lactose intolerance [32].

Studies have shown that people with lactose intolerance have higher tolerance to probiotic yogurt than to milk. It was assumed that the presence of lactase-producing bacteria in probiotic yogurt, especially *Lactobacillus acidophilus*, contributed to the digestion and absorption of lactose. In a study conducted with adolescents aged 12–14 years, a 200 mL of whole milk (Dancow®) was served twice a day for 7 days, and, in the sequence, 200 mL of whole milk (Dancow®) + two sachets of Lacto-B® probiotic (*Lactobacillus acidophilus*, *Bifidobacterium longum*, and *Streptococcus faecium*) was served for 14 days twice a day. The results demonstrated that in the 2 weeks of probiotic therapy, there was an improvement in the symptoms of lactose intolerance, verified by breath hydrogen tests [33].

One specific strain that has been shown to be effective in lactose intolerance is *Lactobacillus rhamnosus*, a gram-positive anaerobic probiotic bacterium. When administered to lactose-intolerant infants, this bacterium could colonize the intestinal tract and produced positive changes within the intestinal microbiota [34].

3.3 Relief of Constipation

Constipation is one of the most common digestive complaints in the general population. It is not considered a disease but a symptom present in many diseases and can be defined as the condition of the digestive system where an individual has hard feces and difficulty to evacuate [35]. Symptoms of constipation are irregular bowel movements, hard stools, difficulty to evacuate, cramps, bloating, flatulence, and abdominal pain, which can affect patients' quality of life. In most cases, constipation is related to (1) inadequate eating habits, (2) sedentary lifestyle, (3) socioeconomic status, (4) psychological parameters, (5) medications, (6) age, and (7) gender.

One of the causes of constipation is intestinal dysbiosis, which is defined as an imbalance in the intestinal microbiota, with prevalence of pathogenic bacteria. Picard et al. [36] and Szajewska et al. [37] suggested that dysbiosis can be improved by the consumption of probiotics. Nutritional improvement with inclusion of probiotics in the diet represents an interesting non-pharmacological alternative to reduce the symptoms of constipation. In addition, bifidobacteria can lower the pH of the colon, because they produce lactic acid, acetic acid, and others. A lower pH tends to increase colonic peristalsis and, consequently, decreases the transit time of the colon, with a beneficial effect in the treatment of constipation symptoms. Since dietary modification is the main approach to improve constipation, probiotic or prebiotic therapy, in principle, fits well into the regimen.

The efficiency of probiotic cultures in the reduction of symptoms of constipation is associated with the strain used. Lactobacilli, bifidobacteria, and a combination of lactobacilli and propionibacteria have been clinically investigated in the treatment of patients. There is evidence that ingestion of probiotics may increase defecation frequency; however, these findings are not universal, with varying efficacy among strains of probiotic bacteria and among different studies. Two different strains *of*

Lactobacillus rhamnosus and *Propionibacterium freudenreichii* were used with constipated elderly, and a significant increase in defecation frequency was observed, whereas the use of a single strain did not affect the frequency of defecation [38]. Studies with constipated children showed that there were an increase in the frequency of defecation and a decrease of abdominal pain using *L. rhamnosus* as probiotic culture [39]. In contrast, another study conducted with *Lactobacillus rhamnosus* GG strain showed no significant effect on the symptoms of constipation when used as an adjunct in lactulose therapy [40].

A reduction in the symptoms and a better frequency of bowel movement and consistency of feces in constipated healthy individuals after consumption of a fermented milk containing *Lactobacillus casei* Shirota were observed. More recent studies have shown that the consumption of a fermented milk containing multiple probiotic strains such as *Streptococcus salivarius* subsp. *thermophilus*, *Enterococcus faecium*, *Lactobacillus rhamnosus* GG, *Lactobacillus acidophilus*, *Lactobacillus plantarum*, *Lactobacillus paracasei*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, and *Bifidobacterium* (*breve* and *animalis* subsp. *lactis*) and prebiotic fiber (fructooligosaccharides) was superior to placebo in improving constipation in patients with Parkinson disease [41].

Modifying the intestinal lumen with certain probiotic species and strains can affect motility and secretion in the intestine and thus provide benefits for patients with constipation. However, most of the current evidence is derived from animal studies, as its effect on humans is unclear because of lack of human studies. Additional high-quality methodological research is needed to fully establish the complex interactions of the luminal environment, immune system, and nervous system on intestinal motility and constipation and how different species and probiotic strains affect them. Further studies are needed to determine which species and strains of probiotics, dose, and duration of treatment are particularly effective in constipation, as well as to examine potential probiotic interactions and interindividual variability that may lead to differential probiotic responses [42].

3.4 Stimulation of the Immune System

The effect of probiotics on the immune response has been well studied. Much of the evidence from in vitro systems and animal and human models suggests that probiotics may stimulate both nonspecific and specific immune responses. Three possible mechanisms of action are attributed to probiotics: (1) the suppression of harmful microorganisms through the production of compounds with antimicrobial activity, competition for nutrients, and competition for adhesion sites; (2) the alteration of the microbial metabolism, through the increase or the decrease of the enzymatic activity; and (3) the stimulation of the host immunity by increasing antibody levels and macrophage activity [22].

Many researches have pointed out that certain strains of probiotic cultures are able to stimulate and regulate various aspects of natural and acquired immune responses. These include, for example, increased leukocyte phagocytic activity,

stimulation of nonspecific immunoglobulin A (IgA) and specific (antibody) response, and increased cytokine production in vivo. It is believed that these effects are mediated by macrophage activation, increases in cytokine levels, and increases in the activity of natural killer (NK) cells and/or immunoglobulin levels.

Olivares et al. [43] evaluated the effect of a fermented milk with two probiotic strains (*Lactobacillus gasseri* (CECT 5715) and *Lactobacillus coryniformis* (CECT 5711)) on the immune system of adult subjects for 4 weeks. It was used in a randomized, double-blind, placebo-controlled clinical trial. The probiotic fermented milk was compared to a standard fermented milk. Thirty healthy volunteers aged 23–43 years were recruited. Blood samples were collected before and after the experimental period, and stool samples were collected weekly. Consumption of the probiotic or the conventional products increased the proportion of phagocytic cells, including monocytes and neutrophils, as well as their phagocytic activity. However, the probiotic product containing the strains *L. gasseri* CECT 5714 and *L. coryniformis* CECT 5711 also induced an increase in the proportion of NK cells and in IgA concentrations. The effects were higher after 2 weeks of treatment than after 4 weeks, which suggests regulation of the immune system. In addition, the new product enhanced immunity in the participants to a greater extent than did the control standard fermented milk. The study, however, does not present the amount of fermented milk administered.

Strauss and Caly [44] point out that it is possible to optionally prevent some recurrent infectious processes, such as spontaneous bacterial peritonitis caused by cirrhosis or hepatic insufficiency, with probiotic cultures. These cultures can promote a decrease in the number of pathogenic bacteria and an increase in the intestinal immunity, when used with continuously used antibiotics, such as norfloxacin, which is already used in classical treatment. Therefore, probiotic cultures would be one more option to minimize recurrent infection. Surawicz et al. [45] treated adults with recurrent diarrhea due to *C. difficile* with high vancomycin dose and subsequently with *S. boulardii* (1 g/day, $n = 18$) or placebo ($n = 14$) for 28 days. They observed that the risk of recurrence was 16.7% for the group receiving the probiotic and 50% for the placebo group.

Considering the intestinal infections, a therapeutic value is attributed to probiotic bacteria, because in this specific area, the studies are already based on mechanisms of action well established and recognized by the scientific community. The intestinal epithelium plays a role as an immunological barrier, establishing the interface between the luminal content and the subepithelial immune cells. Any disturbance to this barrier, triggered by dietary antigens, pathogenic microorganisms, chemical agents, or radiation, leads to increased intestinal permeability and to structural changes in the epithelium, which can cause an increase in the flow of antigens and several types of inflammation.

Arvola et al. [46] performed a double-blind controlled trial with 119 children (mean age 4.5 years) who received antibiotics for respiratory infections along with *L. rhamnosus* GG or placebo capsules. Diarrhea was observed in 5% of the children who received the probiotic and in 16% of those who received the placebo ($p = 0.05$). However, in another study, the reduction of the risk of diarrhea with probiotic ingestion could not be observed ($n = 267$ hospitalized adults, 29.3% with

probiotic vs. 29.9% in placebo). In this way, probiotic effect may vary depending on the region or age [47].

Rembacken et al. [48] conducted a controlled study with 116 patients who had ulcerative colitis in order to evaluate the efficacy of a nonpathogenic *E. coli* strain Nissle 1917 versus Mesalazine® (considered an effective anti-inflammatory) to prevent such disease. The authors observed that the nonpathogenic probiotic *E. coli* obtained the same efficiency as the pharmacological drug in reducing ulcerative colitis.

In relation to children assisted by specialized treatment centers, Weizman et al. [49] investigated the effect of two different probiotic species on the prevention of gastrointestinal and respiratory infections. In a double-blind, placebo-controlled, randomized study, 201 full-term infants between 4 and 10 months of age were randomized into three groups receiving different treatments for 12 weeks: (1) fed with formulas containing *Bifidobacterium lactis* ($n = 73$, test 1) or *Lactobacillus reuteri* ($n = 68$, test2) and placebo ($n = 60$). Children who received supplementation (test 1 or 2) compared to placebo showed fewer episodes of fever and diarrhea, and these episodes were shorter. These effects were more prominent for test 2. Regarding the respiratory infection, no modification was observed between the treatments.

3.5 Anticarcinogenic Effect

According to the National Cancer Institute, the number of new cases of colon cancer will be higher than 108 thousand per year, thus making this type of cancer the second most diagnosed type in both men and women. Risk factors for colon and rectal cancer include both genetic and environmental factors, and many studies have suggested that interactions among dietary factors, colonic epithelium, and intestinal microbiota are central to the development of this type of cancer [50].

In 1962, a study reported that *L. bulgaricus* would be able to produce bioactive substances with antagonist effect on tumor development. Since then, a series of researches in the same area were developed, aiming to find explanations on the mechanisms involved. Today, the anticarcinogenic properties of probiotic bacteria are already known and divided into three categories: (1) inhibition of tumor cells; (2) suppression of enzyme-producing bacteria (β-glucosidases, β-glucuronidases, and azoreductases), responsible for the release of carcinogenic substances; and (3) destruction of carcinogenic substances, such as nitrosamines, or suppression of nitroreductase (enzyme involved in the synthesis of nitrosamines).

Several mechanisms of action are suggested involving the anticarcinogenic potential of probiotic bacteria [51, 52]:

- Stimulation of host immune response, by increasing phagocytic activity, IgA synthesis, and activation of T and B lymphocytes
- Binding and degradation of compounds with carcinogenic potential
- Qualitative and/or quantitative changes in the intestinal microbiota involved in the production of carcinogens and promoters of carcinogen (e.g., degradation of bile acids)

- Production of antitumorigenic or antimutagenic compounds in the colon (such as butyrate)
- Alteration of the metabolic activity of the intestinal microbiota
- Alteration of the physicochemical conditions of the colon, with decrease in the pH and effects on the physiology of the host
- Reduction of the inflammatory response (with decreased cytokines and hypersensitivity and increased phagocytic activity)

Bacterial β-glucuronidase appears to play an important role in the initiation of colon cancer due to its ability to hydrolyze several components and release carcinogenic aglycones into the intestinal lumen. The nitroreductases and azoreductases are related to the formation of aromatic amines that are harmful to the organism. Marteau et al. [53] verified the ability of fermented milk containing *L. acidophilus* A1, *B. bifidum* B1, *Streptococcus lactis*, and *Streptococcus cremoris* to modify the metabolic activity of the human colonic microbiota. Nine individuals who consumed 100 g of the product three times a day for 3 weeks showed reductions in fecal concentrations of nitroreductase, azoreductase, and β-glucuronidase compared to the control group. Haberer et al. [54] found that animals fed a diet based on meat and fat showed a reduction in the activity of β-glucuronidase and azoreductase after consumption of *Lactobacillus* probiotic strains (*L. johnsonii* and *L. reuteri*) for a period of 5 weeks. Rowland et al. [55] concluded that *B. longum*-treated rats reduced β-glucuronidase enzyme activity by 30%, while a greater reduction of about 55% was observed in those treated with probiotic *B. longum* combined with prebiotic inulin. In agreement, human studies showed that the consumption of *Lactobacillus casei* Shirota and *Lactobacillus acidophilus* also significantly reduced the activity of these enzymes [56]. Similar results were obtained by Lidbeck et al. [57], who supplemented the diet of 14 patients with colon cancer with *L. acidophilus* (approximately 3×10^{11} lactobacilli per day) for a period of 6 weeks and obtained a 14% reduction in β-glucuronidase enzyme.

Guérin-Danan et al. [58] evaluated the influence of supplementation with fermented milk containing *Lactobacillus casei* for a period of 1 month (125 g/day) on the metabolic indexes and the intestinal microbiota of healthy children aged 10–18 months. There was a significant increase in the percentage of children who had populations of lactobacilli above 6 log cfu g^{-1} in feces among those who received milk fermented with *Lactobacillus casei*. In parallel, the potentially harmful enzymatic activity of β-glucuronidase and β-glucosidase decreased significantly in these children. The authors concluded that such effects represent a healthy influence of *Lactobacillus casei* on the host.

Marinelli et al. [59] published a review paper about probiotics and their anticancer activity. The authors reported that the major studies used mice models, and, therefore, the results must be interpreted with caution. Furthermore, they stated that the health effect is restricted to each strain and the data obtained with different bacteria strains need to be integrated into a multidimensional view of tumor, considering tumor microenvironment and the host factors involved in therapeutic efficacy of drugs. Moreover, the dose, the frequency, and the timing of assumption

need to be assessed. Finally, the precise molecular mechanisms behind the probiotic action and potential side effects are required to delineate a safe and optimal use in humans. Summing up, soon, probiotic will be a new powerful ally in the demanding fight against cancer.

3.6 Cholesterol Metabolism

Cardiovascular diseases represent a major problem for public health, leading to mortality in Brazil and in the world. The increase in the life expectancy of a population is directly related to the prevention of cardiovascular diseases. Furthermore, hypercholesterolemia is closely linked with the complications of diseases such as heart attack and atherosclerosis. Better quality of life can be achieved by lowering blood cholesterol levels.

Much of the circulating cholesterol is synthesized in the body from fatty acids, and only about one third comes from the diet. The excess of low-density lipoprotein cholesterol (LDL-C) in the bloodstream is oxidized by free radicals and damages the vessels, facilitating the deposition of lipids in these channels and increasing the risk of cardiovascular diseases.

Liong and Shah [60] investigated the cholesterol removal abilities of 11 probiotic strains (*Lactobacillus acidophilus* and *L. casei*) to understand the possible mechanisms of action. They concluded that all 11 strains had varying abilities to remove cholesterol in vitro and proposed as possible mechanisms of action in the assimilation of cholesterol during growth, the incorporation of cholesterol into the cell membrane, and the binding of cholesterol to the surface of the cell. *L. casei* ASCC 292 and *L. acidophilus* 4962 were the ones that removed the most cholesterol, indicating that these strains may be promising candidates to be used as a dietary supplement to lower serum cholesterol in vivo.

Greany et al. [61] evaluated the effect of probiotics *Lactobacillus acidophilus* and *Bifidobacterium longum* in improving the effect of soy isoflavones in reducing serum levels of blood lipids. The study included 37 women who received different treatments: soy protein isolate (with isoflavone), milk protein isolate (without isoflavone), and soy protein isolate with probiotics (isoflavone + probiotics). The effect of isoflavone intake was evident, with a reduction of 2.2% ($p = 0.02$) and 3.5% ($p = 0.005$) in total cholesterol and LDL-C levels, respectively, and an increase of 4.2% ($p = 0.006$) in the high-density lipoprotein cholesterol (HDL-C) level. However, the soy protein isolate added with probiotics had no additional effect on total cholesterol levels and LDL and HDL fractions.

One of the properties of bifidobacteria is their influence on lipid metabolism, that is, the possibility of acting in dyslipidemic processes. Several clinical studies have shown a significant decrease in total cholesterol levels as a result of the use of probiotics because of the decrease in LDL cholesterol, while the HDL cholesterol levels increase slightly. The hypocholesterolemic effect of bifidobacteria results from decreased absorption and transport of dietary cholesterol to the liver via chylomicrons and, on the other hand, from the disjunction of bile salts with

lower cholesterol absorption by the intestine. Niacin formed by bifidobacteria decreases the flow of free fatty acids which, by decreasing the biosynthesis of very low-density lipoprotein (VLDL), contributes to the reduction of plasma levels of triglycerides [62].

Aydas and Aslim [63] published a review about the cholesterol-lowering effects of probiotic bacteria. The authors state that despite controversial or unclear results of previous studies on the effect of probiotics on cholesterol levels, recent research has favored these compounds for possible beneficial effects on hypercholesterolemia. It may nevertheless be possible that a cholesterol-lowering rate of 10% may also be secondary to typical cholesterol variation and measurement differences. Moreover, all clinical studies to date have been conducted in subjects with hypercholesterolemia. Probiotics should also be tested in normocholesterolemic individuals.

3.7 Health Benefits of Probiotic Minas Frescal Cheese Consumption

Health benefits of probiotic products are related to the strains used and to the food matrix; therefore, it will be presented studies with probiotic Minas Frescal cheese.

Minas Frescal cheese containing *Lactobacillus acidophilus* LA14 and *Bifidobacterium longum* BL05 (20 g/d) was fed for 2 weeks to adult Wistar rats, which then were brought to exhaustion on the treadmill [63]. Two hours after exhaustion, the rats were killed, and material was collected and analyzed. Exercise reduced lymphocyte counts, and the decrease was 22% in the group fed the probiotic cheese and 48% in the animals fed regular cheese. Monocyte counts were unaltered in the rats fed probiotic cheese compared with a significant decrease in the rats fed the regular cheese. Most importantly, ingestion of the probiotic cheese resulted in a >100% increase in serum HDL-C and a 50% decrease in triacylglycerols. The authors concluded that probiotic Minas Frescal cheese may be a viable alternative to enhance the immune system and could be used to prevent infections, particularly those related to the physical overexertion of athletes.

Favretto et al. [64] evaluated the effect of the consumption of Minas Frescal cheese enriched with *Bifidobacterium lactis* Bi-07 on the symptoms of constipated women ($n = 30$). The patients were randomized into two groups who received, for 30 days, 30 g of the probiotic cheese ($n = 15$) or the regular cheese ($n = 15$). Constipation symptoms were evaluated according to ROMA III consensus, before and after the nutritional intervention. Also, data of clinical and anthropometric characteristics of the individuals were collected. After 30 days, it was observed that the ingestion of the probiotic cheese promoted beneficial effects on the symptoms of strength to evacuate. Therefore, the consumption of 30 g/day of Minas Frescal cheese enriched with *Bifidobacterium lactis* Bi-07 has beneficial effects on constipation symptoms.

Lollo et al. [65] investigated the effects of ingestion of probiotic Minas Frescal cheese on hypertension parameters in spontaneously hypertensive rats. Twenty-eight animals were divided into four groups fed with different experimental diets: control

initial (CI), control final (CF), traditional Minas Frescal cheese (CMFC), and probiotic minas Frescal cheese. The latter two groups were fed with 20 g of cheese per day for 15 days. All groups were assessed for blood pressure and health parameters. The group fed with probiotic cheese exhibited significantly lower blood pressure when compared to the group fed with CMFC, CI, and CF. Regarding the other health parameters, an improvement in blood lipids (triglycerides and cholesterol) was observed for the group fed with probiotic cheese as compared with CMFC. No significant differences were observed in renal function parameters. The authors suggest that consumption of probiotic cheese can be potentially useful to improve the cardiovascular health parameters.

4 Technological Processing of Minas Frescal Cheese

Minas Frescal cheese is a typical Brazilian fresh cheese, which presents high water activity, pH above 5.0, low salt content (1.4–1.6%), and the absence of preservatives. It offers excellent conditions for survival and growth of probiotic strains and is obtained by enzymatic coagulation of the milk with rennet and/or other appropriate coagulant enzymes. The supplementation with specific lactic bacteria is facultative [9, 66].

The Minas Frescal cheese has some specific characteristics:

- Classified as a semi-fat cheese (25–44.9% fat in the dry matter)
- High moisture content (not less than 55%)
- Consumed fresh
- Soft consistency
- Presence of holes or not
- Mild to slightly acidic
- Presence or not of a thin crust
- Cylindrical shape
- Weigh of 0.3–5.0 kg

The processing technology of the Minas Frescal cheese involves pasteurization, enzymatic coagulation, addition or not of starter cultures, cutting, forming, wheying off, and salting. Figure 2 represents, schematically, the technological process of obtaining probiotic Minas Frescal cheese. In a general view, the basic difference is the addition of the probiotic culture.

The milk used in the preparation of Minas Frescal cheese must be of good quality and free from high levels of contamination by microorganisms, chemical agents, antibiotics, herbicides, or pesticides. These components are harmful to the health of the consumer and can inhibit the coagulation of the milk or alter the storage stability of the products.

Milk pasteurization for cheesemaking can be accomplished by the rapid process on plate heat exchangers (HTST, 72–75°C/15 s) or by the slow process (LTLT, 65°C/30 min). The aim of the pasteurization is to eliminate pathogenic

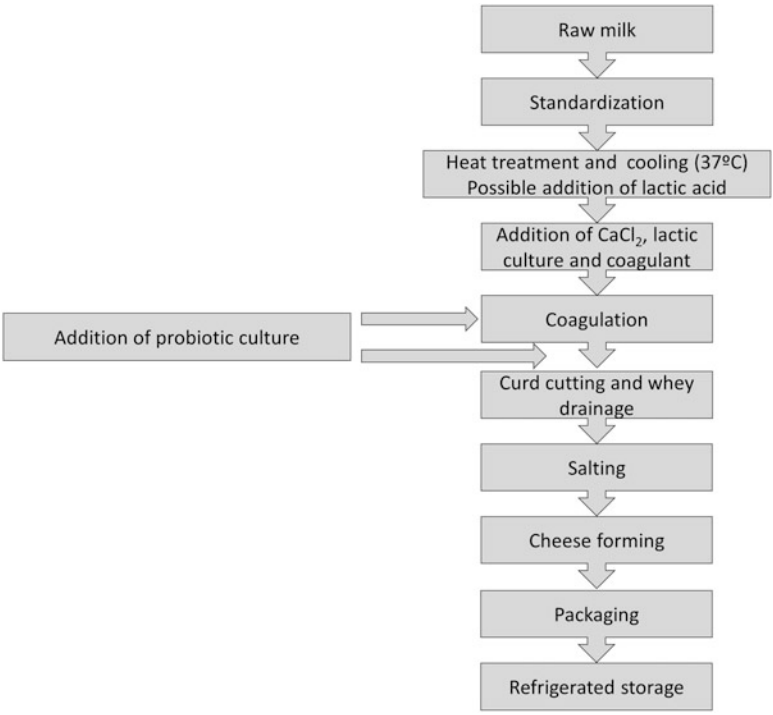

Fig. 2 Technological process of probiotic Minas Frescal cheese

bacteria and decrease the number of milk spoilage microorganism [67]. Pasteurization alters the microbiota of cheese, favoring the production of a more uniform cheese. However, it may impair the ability of the milk to coagulate, since it insolubilizes part of the soluble calcium, resulting in a weaker curd, which may increase the loss of whey from the curd. Thus, it is common to add calcium chloride (0.02%) to the pasteurized milk, aiming the replacement of the insolubilized calcium, increasing the firmness of the curd, and reducing the coagulation time [67].

The acidification of the product can be provided by the addition of lactic acid or starter culture, but this step is facultative. Lactic acid is added aiming to reduce the pH until 4.5 (isoelectric point of milk protein). At this pH, the casein micelles aggregate and precipitate, leaving the cheese with a firmer texture, besides a slightly acidic taste [68]. The direct acidification with lactic acid is commonly used by cheese industries, but it has the inconvenience that the final product has higher pH and moisture contents than the product made with starter cultures, making it more susceptible to contamination. Starter culture addition contributes to cheese aroma and flavor development during storage, by means of carbohydrate metabolism, proteolysis, and, to a lesser extent, lipolysis [16]. However, the presence of starter cultures in cheeses can influence the texture parameters, marked hardness, cohesiveness, chewiness, and gumminess, leading to more fragile cheeses, in addition to the

intense reduction of pH and increase of titratable acidity, due to the continuous production of lactic acid and other organic acids [9]. The addition of lactic acid or starter culture should be evaluated carefully, as this step is facultative. The higher acidity provided by both methodologies can increase the product shelf life, but it can impact negatively on the probiotic viability.

The process of cheese production requires the coagulation of the milk, in most cases, by the action of chymosin on k-casein, which is the layer that confers steric stability to the milk casein micelle. Rennet is, by definition, an extract from the stomach of ruminants and contains different amounts of chymosin and pepsin, depending on the age of the animal and its diet. However, to cope with the special needs of groups such as vegetarians and of certain religions, such as Muslims and Judaeans (kosher food), vegetable and microbial coagulants have been developed.

The coagulant is added to the milk, usually at 32–35°C and in sufficient quantity, to coagulate the milk within 30–40 min. Enzymatic coagulation occurs in two main phases. First, the addition of chymosin cleaves the link between amino acids Phe-105 and Met-106 of κ-casein, resulting in the destabilization of all casein micelles, which will subsequently aggregate to form the curd paste. After the hydrolysis of the peptide bonds of casein (with 60–85% of the total hydrolyzed casein), it becomes para-κ-casein, which precipitates in the presence of Ca^{2+} ions, forming the curd [68].

Milk coagulation for cheese production is influenced by temperature, pH, soluble calcium concentration, proteins, and enzymes. Some characteristics of the milk coagulation are:

- Coagulation does not occur at temperatures below 18°C and above 55–60°C.
- Temperatures near 40°C stimulate the action of the rennet and decrease the coagulation time.
- The closer to pH 6.0 (optimum enzyme action pH), the better the curd action, and the higher the curd strength.
- The greater the amount of soluble calcium present in the medium, the faster the formation of the curd, and the greater its firmness.
- The higher the percentage of milk proteins, the better the coagulation process.
- The higher the enzyme concentration, the shorter the milk coagulation time.

During cheese processing, probiotic cultures may be added prior to fermentation (along with the starter culture) or after this step. When added together with the starter culture, preliminary tests for knowledge of the concentrations of probiotic cells that are lost in the whey during the desorption process should be performed. This type of process has the advantage that the probiotic culture has time to adapt to the environment and participates from the decrease of the pH provided by the starter culture. The negative factor is that a higher concentration of probiotic should be used, as part of it is lost in whey. This contributes to the increase in the cost of the processing. If probiotic microorganisms are added after the addition of the starter culture, an immediate cooling (less than 8°C) should be performed, since the metabolic activity of the starter culture is drastically reduced at this temperature. When added after the addition of the starter culture, a resistant probiotic should be

selected, although cheese is not a harsh environment for its survival. Thus, the ideal amount of probiotic inoculum should be ascertained, according to the process to be employed [68].

When the end point in the tank is reached, i.e., the desired pH and moisture content is reached, the mass is cut, separated from the whey, and put into forms of specific size and shape so that whey drainage occurs. Salting can be performed after enzymatic coagulation of the milk through dry salting in the mass, dry salting on the surface, and salting in brine. Furthermore, it can be made in the milk. In addition to improving the sensory characteristics of the cheese, salt contributes to the occurrence of biochemical reactions during storage [68]. The characteristics of the salt addition are:

- Dry salting on the surface. It is the most archaic process, which consists of spraying refined salt on the two flat surfaces of the cheese after the forming process. The disadvantage of the dry-salting process is a possible irregularity in the salt distribution in the cheese.
- Salt in the mass. It is a practical process and consists of adding refined salt (which can be diluted in small amount of whey) to the mass of the cheese still in the manufacturing tank. The dosage is 1.2–1.5% refined salt calculated on the volume of milk to be manufactured.
- Salting in the milk. Some cheesemakers prefer the use of the salting in the milk before the addition of the ingredients by their practicality and final uniformity. Simply add about 2% refined salt to the milk. The disadvantage of the salting process in milk lies in the fact that more salt is expended (since some of it will be lost in the whey). Furthermore, the resulted whey will be salty and therefore unsuitable for use in other products.
- Salting in the brine. The cheese is immersed in brine (20% water and salt at a temperature of 8°C for a time of 60 min for pieces weighing 1 kg). The disadvantage of the brine salting process is a cheese with a less consistent characteristic, which can result in loss of moisture and loss of yield.

Whatever the choice of the salting process chosen, the curd should be shaped into its own forms as fast as possible, turning the cheese in 20 min after the deformation. Then, the cheeses are packaged and kept under refrigeration. The packaging aims to improve the stability and viability of the probiotic microorganisms that have been added in the cheese, which have anaerobic metabolism and, therefore, are sensitive to the presence of oxygen. Therefore, the choice of an appropriate packaging system, such as plastic films with low oxygen permeability and vacuum packaging, or the use of active packaging can be considered efficient alternatives to maintain the viability of probiotic bacteria [68].

4.1 Minas Frescal Cheese as a Probiotic Carrier

Fat content, concentration and type of proteins, sugar content, and pH are some factors that could affect probiotic growth and survival in food. Therefore,

product formulation can be manipulated to aid their efficacy. Dairy products are considered as an ideal vehicle for delivering probiotic bacteria to the human gastrointestinal tract.

Cheese is a dairy product with a strong potential for delivering probiotic microorganisms, because it presents a higher pH when compared to yogurts and fermented milks, making it a more stable matrix for the survival of probiotic microorganisms. In addition, cheeses, because they have a relatively high amount of fat, provide protection for probiotic bacteria during their passage through the gastrointestinal tract [66] and present lower titratable acidity, higher buffering capacity, more solid consistency, higher nutrient availability, and lower oxygen content than yogurts [69]. On the other hand, some cheeses have a very long maturation period, which hinders the survival of the probiotic microorganism. In the case of Minas Frescal cheese, because it is a fresh cheese with no maturation, it has a short shelf life (media of 20 days), making it a proper food for the incorporation of probiotic microorganisms [70]. In many parts of Brazil, Minas Frescal cheese is frequently consumed at least once a day, making it an excellent carrier for probiotic bacteria because of the high daily consumption.

Back et al. [66] evaluated the viability of probiotic microorganisms *Lactobacillus acidophilus* LA-5 and *Bifidobacterium* sp. BB-12 in Minas Frescal cheese with reduced lactose content. The cheeses were submitted to microbiological counts of probiotic microorganisms weekly during the storage period (21 days), as well as physical and chemical analyses of fat, protein, moisture, ash, fat in the dry matter, titratable acidity, and pH. *Lactobacillus acidophilus* counts (4.38 + 0.01 to 7.88 + 0.07 log cfu g^{-1}) did not reach the minimum values of 10^6 CFU.g^{-1} on all days of cheese storage, while the population of *Bifidobacterium* sp. (6.05 ± 0.08 and 7.90 ± 0.04 log cfu g^{-1}) remained above 6 log cfu g^{-1} in all formulations developed, thus conferring probiotic characteristics to the cheeses. The results demonstrate the possibility of the incorporation of probiotic bacteria in cheeses with reduced lactose content, thus being an innovative alternative to the market of intolerant to this carbohydrate.

Alves et al. [71] produced two different Minas Frescal cheeses: (1) with the addition of lactic acid culture and (2) with *Lactobacillus acidophilus*. The *L. acidophilus* count was above 10^8 cfu g^{-1}, considered a sufficient population to classify the cheese as a probiotic food. The Minas Frescal cheese was suitable for incorporation of probiotic and the use of *L. acidophilus.*

Buriti et al. [9] investigated the effect of a probiotic *Lactobacillus paracasei* culture on sensory performance and on the behavior of instrumental texture profile and related properties of Minas fresh cheese during storage at 5°C for 21 days. Viable counts of *L. paracasei* in probiotic cheeses started above 10^6–10^7 cfu g^{-1} and increased during storage. The authors concluded that Minas Frescal cheese with *L. paracasei* showed a great potential as a functional food.

Souza and Saad [16] examined the viability of a probiotic *L. acidophilus* culture added only in coculture with *S. thermophilus* during the manufacture of Minas Frescal cheese. The authors observed that Minas Frescal cheese showed efficacy as a vehicle for delivery of the probiotic culture and the counts of *L. acidophilus*

remained with populations above 6 log cfu g^{-1} during the whole storage period (21 days). The supplementation of cheeses with a starter culture of *S. thermophilus* resulted in more acid cheeses, but these results had no influence on the viability of the probiotic culture.

There are some technological hurdles to maintain the viability of the probiotic cultures on Minas Frescal cheese. Therefore, it is suggested to:

- Select strains that are resistant to oxygen, acid, and bile salts.
- Evaluate the compatibility of the probiotic and lactic cultures, if a starter is used in the process.
- Standardize the salt content considering the salt taste but also the probiotic survival.
- Select a plastic packaging made with a material with low oxygen permeability, or use vacuum package.
- Control the storage temperature at refrigerated conditions.

4.2 Effect of Probiotic Addition on the Physicochemical and Sensory Properties of Minas Frescal Cheese

The addition of probiotic cultures can alter the physicochemical and sensory characteristics of Minas Frescal cheese. Table 2 presents the studies that evaluated the impact of probiotic cultures on the physicochemical characteristics of the products. The addition of probiotic cultures has no effect on the yield and composition of Minas Frescal cheese [13, 16, 72]. Probiotic cultures do not have significant activity on the main components of the cheeses, and, therefore, their concentration could not affect the cheese composition [70].

The effect of probiotic addition on pH and titratable acidity is dependent on the strain and type of milk used, and different results were observed. No influence of probiotic culture addition (*Bifidobacterium* Bb-12, *Lactobacillus acidophilus* (*La-5*), *Lactobacillus paracasei*, or *Bifidobacterium animalis* subsp. *lactis)* on the pH and/or titratable acidity of Minas Frescal cheese made with buffalo or cow milk was observed [9, 13, 16, 72]. In other study [12], a higher pH was observed in probiotic Minas Frescal cheese (*L. acidophilus*) when compared to the conventional product. The authors stated that this result is possibly due to production of an increased amount of NH_3 among the products of proteolysis. Finally, Gomes et al. [17] reported that the probiotic cheeses were more acidic (lower pH and higher titratable acidity) than the conventional products. The acidification of the products was a consequence of the post-acidification, with consumption of the lactose by the probiotic cultures and production of organic acids, mainly lactic acid. The addition of higher quantities of probiotic cultures resulted in a more acid product, and acetic acid was also produced. The authors stated that *Lactobacillus* strains are predominantly homofermentative, but they also present a heterofermentative pathway, fermenting glucose in equimolar amounts of lactic acid, CO_2, and ethanol or acetic acid. More acid probiotic products were also observed by Dantas et al. [2] when using *L. casei* Zhang as probiotic culture.

Table 2 Studies involving probiotic Minas Frescal cheeses

Probiotic culture	Objective	Effect of probiotic addition	Reference
Lactobacillus acidophilus	The effect of *Lactobacillus acidophilus* on instrumental texture profile and related properties of Minas fresh cheese during storage at 5° C and on sensory performance was investigated	Probiotic cheeses behaved very similarly to their controls in relation to evolution of texture and physicochemical parameters during refrigerated storage of the product Probiotic cheeses presented a pH slightly higher, when compared to their controls, possibly due to production of an increased amount of NH_3 among the products of proteolysis	[12]
Lactobacillus paracasei	The effect of a probiotic *Lactobacillus paracasei* culture on sensory performance and on the behavior of instrumental texture profile and related properties of Minas fresh cheese during storage at 5° C was investigated	Probiotic cheeses were not significantly different from their controls in relation to general instrumental texture attributes The addition of *Lactobacillus paracasei* to Minas fresh cheese resulted in a product with great potential as a functional food, with instrumental texture and sensory features similar to control cheeses, and the best overall results were in cheeses prepared through direct acidification with lactic acid	[9]
Lactobacillus acidophilus La-5 and *Bifidobacterium animalis* Bb-12	The effect of a mixed probiotic culture on instrumental texture and on sensorial and related properties of Minas fresh cheese during refrigerated storage was investigated	Texture profile of Minas fresh cheeses manufactured with the addition of a probiotic culture revealed to have a greater stability in relation to the different texture parameters evaluated, during refrigerated storage for up to 21 days, when compared to texture profile of Minas fresh cheeses processed according to the traditional dairy technologies, involving addition of the type O lactic culture Cheeses supplemented with the probiotic culture, as well as those made adding lactic acid only, showed to be less brittle	[10]

(*continued*)

Table 2 (continued)

Probiotic culture	Objective	Effect of probiotic addition	Reference
Lactobacillus acidophilus (*La-5*)	The effect of a probiotic culture of *Lactobacillus acidophilus* (La-5), added solely or in coculture with a starter culture of *Streptococcus thermophilus*, on texture, proteolysis, and related properties during storage at 5° C for 21 days	No effect of probiotic addition on composition Probiotic addition resulted in a more acid product (lower pH and higher titratable acidity)	[16]
Lactobacillus acidophilus	Probiotic Brazilian Minas Frescal cheese was produced by ultrafiltration. Cheese was produced from retentates obtained from ultrafiltration of milk with a volumetric concentration factor of 5:1. The pasteurized retentates were inoculated with 10^6, 10^7, and 10^8 cfu.mL^{-1} of *Lactobacillus acidophilus*. The viability of probiotic, protein breakdown, and pH changes were monitored during cheese storage at 5° C for 1, 7, 14, 21, and 28 days	*L. acidophilus* did not significantly change cheese composition, pH, and proteolysis	[70]
Bifidobacterium Bb-12	The effects of a probiotic bacterium (*Bifidobacterium* Bb-12) and lactic acid on the microbiological, physicochemical, rheological, and microstructural properties of Minas Frescal cheese were evaluated after 1 day and after 28 days of storage (5 ± 1 C)	The addition of bifidobacteria to the cheese did not influence its yield, protein, or lipid levels 1 day after production The addition of *Bifidobacterium* Bb-12 to Minas Frescal cheese resulted in a product with great potential as a functional food, and the best overall results were in the cheese formulations prepared through direct acidification with lactic acid	[15]
Lactobacillus acidophilus	Evaluate the effect of the supplementation of increasing amounts of *Lactobacillus acidophilus* (0, 0.4, or 0.8 g/L of milk) on the physicochemical parameters and sensory	Lower pH values, increased proteolysis, and greater production of organic acids were found in the probiotic cheeses inoculated with increasing concentrations of *L. acidophilus* and in the	[17]

(*continued*)

Table 2 (continued)

Probiotic culture	Objective	Effect of probiotic addition	Reference
	acceptance of Minas Frescal cheese	commercial cheese supplemented with *B. animalis*	
Bifidobacterium animalis subsp. *lactis*	Physicochemical characteristics of a Brazilian fresh cheese samples with *Bifidobacterium animalis* subsp. *lactis* as well as samples with this probiotic and polydextrose, a prebiotic ingredient, were evaluated	No effect of probiotic addition on moisture, ashes, total protein, dry matter, salt, and pH	[72]
Bifidobacterium Bb-12	Buffalo Minas Frescal cheese produced with a probiotic culture was evaluated in relation to the viability of *Bifidobacterium* Bb-12, physicochemical, color, rheological, and microstructural properties during 30 days of storage	No effect of probiotic addition on yield, physicochemical composition, pH, syneresis, and rheological properties The probiotic cheese showed a greenish-white color	[13]
Lactobacillus casei Zhang	The addition of *Lactobacillus casei* Zhang in the manufacture of Minas Frescal cheese was investigated	The addition of probiotic resulted in low pH values and high proteolysis indexes during storage The addition of *L. casei* Zhang led to higher lactic acid and acetic acid levels The addition of probiotic culture decreases the rigidity, resulting in softer and less elastic cheeses when compared to cheese produced by direct acidification Probiotic cheeses were harder and stiffer than control cheeses manufactured by enzymatic coagulation	[2]

Therefore, there are conflicting results about pH and titratable acidity parameters. The alterations on the acidity (pH and titratable acidity) of the Minas Frescal cheese with probiotic addition have positive and negative impacts. The maintenance of these parameters suggests that the probiotic product keeps the conventional characteristics, as pH and acidity can alter the flavor and texture characteristics of the products. An acidification promoted by probiotic addition has the advantage to

possibly provide an increase in the shelf life of the products, which is important, considering that this product has short shelf life (20–30 days). However, it can impact on the acceptance, as Minas Frescal cheese has slightly acid taste.

The utilization of a starter culture with the probiotic culture is related to an increase in the acidity of the products. Souza and Saad [16] reported that the supplementation of the probiotic product with *S. thermophilus* resulted in the highest acidity, because this microorganism produces small amounts of CO_2 and formic acid from lactose. Therefore, the utilization of starter cultures together with the probiotic cultures must be previously evaluated, so that a product with low acidification can be obtained.

Probiotic and conventional Minas Frescal cheeses have similar behavior during storage, considering the decrease in the moisture content and increase in syneresis and firmness. According to Souza and Saad [16], the rate of syneresis is directly related to the acidity and therefore is inversely related to pH. As the concentration of hydrogen ions increases during acidification, the repulsive forces decrease, and the casein micelles begin to aggregate.

Minas Frescal cheese is a fresh cheese; therefore, it is not submitted to a ripening process. However, during refrigerated storage, events such proteolysis can occur, mainly primary proteolysis, promoted by the coagulant agents and other components (plasmin and microbial enzymes). According to Cruz et al. [73], probiotic cultures have influence only on the secondary proteolysis, with increases in the total free amino acid content, and consequent formation of aroma and flavor compounds. As secondary proteolysis occurs with frequency in ripened cheeses, the probiotic addition frequently does not alter the proteolytic profile of Minas Frescal cheese, that is, a fresh cheese. However, Dantas et al. [2] observed higher proteolytic activity in probiotic cheeses and stated that the probiotic culture *L. casei* Zhang has an enzymatic system with sufficient activity for the growth in milk.

The effect of the probiotic culture *L. casei* Zhang on the texture parameters of Minas Frescal cheese was studied by Dantas et al. [2]. The authors observed a decrease in the rigidity of the products with probiotic addition, resulting in a softer and less elastic product when compared to the products produced by direct acidification. However, probiotic cheeses were harder and stiffer than control cheeses manufactured by enzymatic coagulation. Consumers of Minas Frescal cheese expect products with soft texture, and alterations on the texture parameters, mainly increased firmness, have negative impact on the acceptance of the products. At the same time, too soft products or products with brittle texture are rejected by consumers [16]. It is suggested to evaluate the impact of the probiotic strain on the texture parameters of the products and its impact on the acceptance of the products by consumers.

Table 3 presents the studies that evaluated the impact of probiotic cultures on the sensory characteristic of the products. The effect of the addition of probiotic cultures on the acceptance of Minas Frescal cheese is related to the strain, quantity of probiotic culture, presence of starter culture, and technology used by cheese processor, among others.

Table 3 Studies with sensory properties of probiotic Minas Frescal cheese

Probiotic culture	Objective	Effect of probiotic addition	Reference
Lactobacillus acidophilus La-5 and *Bifidobacterium animalis* Bb-12	The effect of a mixed probiotic culture on instrumental texture and on sensorial and related properties of Minas fresh cheese during refrigerated storage was investigated	Cheeses supplemented with the probiotic culture, as well as those made adding lactic acid only, showed more favorable sensorial features (particularly expressed by means of higher pH values) for acceptance by consumers	[10]
Lactobacillus acidophilus	Sensory acceptance of formulations of probiotic Minas Frescal cheese was investigated. Cheeses were prepared and supplemented with *Lactobacillus acidophilus* (T1 probiotic) and *Lactobacillus acidophilus* + *Streptococcus thermophilus* (T2 – probiotic + starter) or produced with no addition of cultures (T3 – control). Sensory acceptance tests were performed after 7 and 14 days of storage at 5° C, using a 9-point hedonic scale (1 = dislike extremely; 9 = like extremely)	The addition of the probiotic *L. acidophilus* La-5 culture conferred sensory stability during storage of the product for up to 14 days, particularly in cheese produced with the addition of the probiotic in coculture with *S. thermophilus* All the three cheeses studied presented good acceptance in both sampling periods of sensory evaluation (after 7 and 14 days of storage) Control cheese T3, produced with no addition of cultures, was more susceptible to sensory alterations, reflected by a reduction of its acceptance between 7 and 14 days of storage	[74]
Lactobacillus acidophilus	Evaluate the effect of the supplementation of increasing amounts of *Lactobacillus acidophilus* (0, 0.4, or 0.8 g/L of milk) on the physicochemical parameters and sensory acceptance of Minas Frescal cheese. The sensory acceptance of probiotic cheeses was assessed using a consumer test and compared with commercial cheeses (conventional and probiotic)	The probiotic cheeses presented lower scores for appearance, aroma, and texture compared with conventional cheeses The use of 0.4% did not result in significant sensory differences, and a suitable mean value for acceptance was obtained The addition of 0.8% resulted in rejection by consumers with respect to taste and texture Internal preference mapping demonstrated the greater preference for the	[17]

(*continued*)

Table 3 (continued)

Probiotic culture	Objective	Effect of probiotic addition	Reference
		conventional samples The findings indicated that some negative sensory effects could occur when high level of supplementation with *L. acidophilus* is used in probiotic cheese processing	
Bifidobacterium animalis subsp. *lactis*	Sensorial and microbiological characteristics of a Brazilian fresh cheese samples with *Bifidobacterium animalis* subsp. *lactis* as well as samples with this probiotic and polydextrose, a prebiotic ingredient, were evaluated	No influence of probiotic addition on acceptance of the products	[72]
Lactobacillus casei Zhang	The addition of *Lactobacillus casei* Zhang in the manufacture of Minas Frescal cheese was investigated	Increased consumer acceptance was observed for the control sample produced by direct acidification (7.8), whereas the cheeses containing *L. casei* Zhang presented lower values for all sensory attributes, especially flavor and overall liking (5.37 and 4.61 for enzymatic coagulation and 5.57 and 4.72 for direct acidification, respectively) The optimization of *L. casei* Zhang dosage during the manufacturing of probiotic Minas Frescal cheese should be performed	[2]

The quantity of probiotic culture was evaluated in some studies [17, 73]. Gomes et al. [17] evaluated the effect of the supplementation of increasing amounts of *Lactobacillus acidophilus* (0, 0.4, or 0.8 g/L of milk) on the physicochemical parameters and sensory acceptance of Minas Frescal cheese. The sensory acceptance of probiotic cheeses was assessed using a consumer test and compared with commercial cheeses (conventional and probiotic). The authors reported that the amount of probiotic influenced the sensory acceptance of the products. The use of 0.4% did not result in significant sensory differences, and a suitable mean value for acceptance was obtained. The addition of 0.8% resulted in rejection by consumers with respect

to taste and texture. Ribeiro et al. [70] produced Brazilian Minas Frescal cheese using retentates obtained from ultrafiltration of milk with a volumetric concentration factor of 5:1. The authors evaluated the addition of 10^6, 10^7, or 10^8 cfu mL^{-1} of *Lactobacillus acidophilus*. The sensorial analysis showed a nonsignificant preference among the three types of cheese. Therefore, it seems that probiotic cultures in suitable quantities do not have a negative impact on the sensory acceptance, but, in excessive amounts, a decrease in the acceptance scores is observed.

The type of microorganism used as probiotic culture has importance on the acceptance of the products. Gomes et al. [11] observed that, among the commercial brands, supplementation with *B. animalis* significantly reduced ($P < 0.05$) the acceptance of probiotic Minas fresh cheese. A possible explanation was the interaction between the pH values and acetic acid concentration. The lower pH value allows a greater fraction of the acetic acid in an undissociated form, increasing the vinegar perception and resulting in an increased acetic taste. Dantas et al. [2] reported a reduction in the acceptance of probiotic products (*L. casei* Zhang) when compared to the conventional products. The intensified acidity of the products, the altered texture parameters, and the presence of off-flavors were the main factors associated with the negative impact. The impact of probiotic bacteria on the flavor profile of cheese is dependent on the species and strains added and their metabolic activity during cheese processing and storage. The metabolites produced by probiotic strains may enhance the bitter taste and negatively affect the cheese texture, depreciating the product's flavor. On the other hand, no negative impact of probiotic addition on acceptance was observed in other studies [72, 74].

There are some suggestions when considering the development of probiotic Minas Frescal cheeses, such as:

- Select a probiotic culture with low capacity of acidifying the product.
- Select a probiotic culture with low proteolytic capacity.
- Select a starter culture compatible with the probiotic culture and without negative impact on the sensory properties.
- Define the quantity of probiotic culture necessary to maintain the viability at suitable levels ($>10^6$ cfu/g) and not alter the acceptance of the products.
- Control the storage temperature.

5 Conclusion

The use of Minas Frescal cheeses as a food matrix for the administration of probiotic cultures has potential advantages, in addition to be an important alternative for the dairy industry. Minas Frescal cheese is one of the most popular cheeses consumed in Brazil, has mild and pleasant flavor and aroma, is slightly acidic and whitish in color, and presents soft texture. It has characteristics that allow the incorporation of probiotic cultures and maintenance of the viability until the end of the shelf life, such as the presence of nutrients that can be assimilated by the probiotic cultures, high pH (in the range of 5–6), high moisture content, low salt content (1.4–1.6%),

medium fat content, capability of protecting the microorganisms from the adverse conditions during the digestion process, refrigerated storage, and short shelf life. However, the development of the probiotic products on an industrial scale requires knowledge of all the technological steps involved in the traditional process of cheese production, as well as possible additional steps to adapt the protocol already used. Therefore, some suggestions are made aiming to obtain probiotic Minas Frescal cheeses with suitable counts of probiotic cultures and no negative impact on the physicochemical and sensory characteristics: (1) select strains that are resistant to oxygen, acid, and bile salts; (2) select probiotic strains with low capacity of acidifying the product and low proteolytic capacity; (3) evaluate the compatibility of the probiotic and lactic cultures, if a starter is used in the process; (4) define the quantity of probiotic culture necessary to maintain the viability at suitable levels ($>10^6$ cfu/g) and not alter the acceptance of the products; (5) standardize the salt content considering the salt taste intensity but also the probiotic survival; (6) select a plastic packaging made with a material with low oxygen permeability, or use vacuum package; and (6) control the storage temperature at refrigerated conditions.

Methods of Food Analysis and Quality Control

Dietary Phenolic Compounds in Biological Samples: Current Challenges in Analytical Chemistry

66

Maike Passon

Contents

Abstract

Phenolic compounds are bioactive molecules relevant in plant-derived foods and are associated with beneficial health effects in humans. The metabolism of these phytonutrients comprises of the absorption, distribution, metabolism, and excretion and is investigated in in vivo intervention or in vitro cell culture studies. Blood and urine samples are collected during animal or human trials, and matrix effects caused by high protein and salt concentration are a major challenge during analysis. This chapter describes the context between the matrix effects which arise during phenolic compound analysis from biological samples and possible analytical techniques to handle these challenges. Difficulties arise from interfering matrix compounds, low concentrations of chemically heterogeneous

metabolites, and the lack of reference compounds. Therefore, interactions of phenolic compounds with plasma proteins are reviewed, as well as ion suppression as one of the most common matrix effects during LC-MS analysis. Frequently used analytical techniques for sample preparation, compound synthesis, separation, and detection are described in this chapter.

Keywords

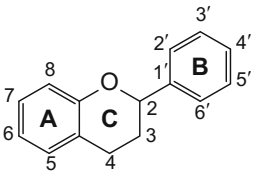
Polyphenols · Biological samples · Serum albumin interactions · Matrix effect · SPE · LC-MS

Abbreviations

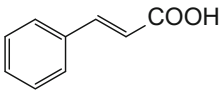
ADME	Absorption, distribution, metabolism, excretion
APCI	Atmospheric-pressure chemical ionization
BSA	Bovine serum albumin
CCS	Collision cross-section
CE	Capillary electrophoresis
CEAD	Coulometric electrode-array detection
COMT	Catechol-*O*-methyltransferase
DMF	Dimethylformamide
EC	Epicatechin
ECG	Epicatechin-3-gallate
EGC	Epigallocatechin
EGCG	Epigallocatechin-3-gallate
ESI	Electrospray ionization
HILIC	Hydrophilic interaction liquid chromatography
HSA	Human serum albumin
IT	Ion trap
LC	Liquid chromatography
m/z	Mass-to-charge ratio
MALDI	Matrix-assisted laser desorption ionization
MRM	Multiple reaction monitoring
MRP	Multidrug resistance protein family
MS	Mass spectrometry
NMR	Nuclear magnetic resonance spectroscopy
NP	Normal-phase
QqQ	Triple quadrupole
RP	Reversed-phase
SIM	Selected ion monitoring
SPE	Solid-phase extraction
SULT	Sulfotransferase
TFA	Trifluoroacetic acid
ToF	Time-of-flight
UGT	Uridine-5′-diphosphate glucuronosyltransferases
(U)HPLC	(Ultra)-High-performance liquid chromatography

1 Introduction

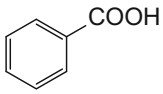
Phenolic compounds are secondary plant metabolites which strongly differ in their structure and physicochemical behavior. They can broadly be classified into flavonoids, including anthocyanins, hydroxycinnamic and hydroxybenzoic acids, stilbenes, and xanthones. Flavonoids (1), hydroxycinnamic acids (2), and hydroxybenzoic acids (3) consist of a C6-C3-C6, C6-C3, and C6-C1 backbone, respectively. A definition of "polyphenols" is still discussed in the literature and until today the term is inconsistently used [1]. In the following, the term "polyphenol" is used to subsume simple phenolic acids as well as flavonoids and oligomers.



1



2



3

Polyphenols are found in almost all plant-derived foods such as vegetables, fruits, cereals, legumes, spices, and herbs and are therefore an integral part of the human diet [2]. As part of the plant defense system, polyphenols show UV-protecting activities and serve as growth regulators or colorants, to name just a few [2, 3]. Due to solubility reasons, polyphenols are generally present as glycosides with the exception of, for example, flavanols in tea, where the aglycones are predominantly synthesized [4]. In addition, tannins are more complex polyphenols with intermediate to high molecular weight, which can be further classified into hydrolysable (e.g., gallotannins) and condensed (proanthocyanidins) tannins [2].

In former times, polyphenols have been considered antinutritive because of their bitterness, astringency, or browning reactions. Today, phenolic compounds are associated with a reduced risk of cardiovascular and neurodegenerative diseases, due to their antioxidative, antimicrobial, or, for example, antiproliferative effects [5]. However, our knowledge concerning the metabolic fate and the modes of action of dietary polyphenols is limited. As secondary plant compounds, phenolics are usually synthesized in small quantities so that the intake generally comprises 500–1700 mg per day [6]. After release from the food matrix, they undergo extensive metabolism in the small intestine, liver, or by the colonic microbiota, and as result, various metabolites of different chemical structures appear in very low concentrations (rarely exceeding nmol l^{-1} levels) in biological fluids like blood or urine.

Polyphenol metabolism in vivo roughly comprises of the absorption, distribution, metabolism, and excretion (ADME) [7]. Depending on a number of factors, for example, the food matrix, concentration, or individual compound structure, these molecules are subject to structural modifications due to the activity of hydrolytic,

phase II, and efflux transporting enzymes [8]. Metabolism starts when polyphenols enter the mouth and interactions with enzymes and proteins of the saliva take place [8, 9]. Then the compounds reach the acidic environment of the stomach, which affects the compound stability, especially in the case of anthocyanins. The structure of anthocyanins, or rather anthocyanidins, depends on the pH value and a comprehensive review about their bioavailability is given by Fernandes et al. [10].

In order to reach target cells, polyphenols must pass the epithelium via active, passive, or facilitated transport [11]. The phases of metabolic breakdown are roughly divided into three steps of detoxification. In phase I, the hydrophilicity is increased by oxidative or reductive reactions and hydrolysis through different types of enzymes. During phase II reactions, further functional groups are conjugated catalyzed by uridine-5′-diphosphate glucuronosyltransferases (UGT), sulfotransferases (SULT), and catechol-*O*-methyltransferases (COMT) [7]. When sulfation or glucuronidation is the preferred reaction, depending on the dose, a positive discrimination of sulfation at lower concentrations is possible [12]. Methylation reactions decrease the hydrophilicity, with the two exceptions of *N*- and *S*-methylation, and in general it is a minor pathway of polyphenol transformation. Nevertheless, methylated conjugates were found during in vitro and in vivo studies [13, 14]. To facilitate excretion and efflux into the small intestine, further structural modifications take place during phase III, indicating that transporters of the multidrug resistance protein family (MRP) are involved [15]. Phase I and phase II reactions occur in the enterocytes, but with the highest activity in the liver [16, 17]. In comparison to the phase II reactions, the CYP450-mediated metabolic pathway (phase I) of polyphenols has less frequently been investigated, for example, by Camilo Melo-Filho et al. [18].

Polyphenols which cannot be absorbed in the small intestine or which enter the enterohepatic circulation reach the colon and are metabolized by the microbiota enzymes. Small molecules including, for example, hydroxyphenylacetic acids, hydroxybenzoic acids, or γ-valerolactones were released as a result of ring cleavage of the flavonoid backbone [19]. The bidirectional relationship between polyphenols and the gut microbiome is one of the major topics in polyphenol research in recent years [7, 20]. Two comprehensive overviews about the whole metabolism and the bio availability of polyphenols are given by Manach and Williamson, who reviewed more than 90 intervention studies [21, 22].

The different transport forms and phase II reaction types, like glucuronidation, sulfation, or methylation, and the colon derived phenolic acids result in a complex profile of structurally diverse metabolites. The lack of knowledge about polyphenol metabolism and the growing interest in new analytical techniques are the result of the low concentration of numerous metabolites in a complex matrix consisting of proteins and salts [23]. Liquid chromatography (LC), and especiallyultra-high-performance liquid chromatography (UHPLC), coupled with mass spectrometric detection is the technique of choice to analyze polyphenolic metabolites in biological samples. Mass spectrometry (MS) is a powerful tool to identify and quantify the compounds of interest, but it is a misconception that due to the high selectivity and specificity, the chromatographic separation and extensive sample preparation can be minimized

or eliminated [24]. A prerequisite to develop efficient sample preparation methods is the knowledge about the interactions of the analyte (polyphenol) and the interfering matrix molecules (proteins, salts). Furthermore, implications of the sample preparation on the detections system must be monitored, because even highly sophisticated detection techniques can suffer from adverse effects of endogenous and exogenous matrix compounds.

To shade more light on polyphenol metabolism, targeted and untargeted studies were carried out to establish accurate methods for identification and quantification. In this chapter, the challenges of polyphenol analytical chemistry in biological samples will be emphasized.

2 Primary Considerations and Challenges

Biological fluids, like blood and urine, are valuable samples, which are collected during animal or human intervention trials. Especially in the case of blood samples, the amount of liquid is limited, due to justified ethical reasons. Therefore, primary considerations about the scientific outcome and the need of biological samples are necessary before the design of an intervention trial.

Intervention trials can be designed to investigate the metabolism (identification of unknown metabolites) or the bioavailability (quantification of metabolites) of phenolic compounds. Where asmetabolism studies often include the identification and characterization of unknown metabolites, bioavailability studies are focusing on the quantitative aspects of ADME of known metabolites. The former studies include the analysis of the intact metabolite profile, which is accompanied by low concentrations and numerous metabolites of different physicochemical nature. Methods for the latter type of studies often include enzymatic hydrolysis to release the phase II metabolites. It is quite evident that the enzymatic release entails the loss of biological information, but allows for increased concentration of the metabolites of interest [25].

In the case of bio availability studies, correct sampling is a crucial step as realistic plasma kinetics are only available when the whole metabolic processes from absorption to complete excretion are considered. To estimate the correct time point for blood sampling, it seems evident that all metabolites of interest must be known. Maximal plasma concentrations are reached between 0.5 and 7.5 h and depend on the chemical nature of the polyphenol, the food matrix, and the concentration [21]. In addition, it should be taken into account which type of metabolite is to be expected. Colon-derived metabolites may be reabsorbed and occur as free or conjugated forms in plasma at later time points in comparison to polyphenols which are absorbed in the small intestinal tract [15].

As it was mentioned above, the bidirectional relationship of polyphenols and the gut microbiota is a promising research area and by now feces samples are an integral part of long-term intervention studies. Monagas et al. [19] reviewed the metabolism and microbial biotransformation of flavan-3-ols and approximately 20 catabolites belonging to the subclasses of hydroxyphenylvalerolactones, valeric acids, hydroxyphenylpropionic, and hydroxybenzoic acids. Identification of polyphenol

catabolites is carried out by the analysis of feces samples from intervention trials or by in vitro fermentation studies [26, 27]. In vitro fermentation can be challenging, as an anaerobic environment should be present at all times directly after the sampling to simulate the conditions in the lower intestine. Human feces is comprised of various facultative anaerobic or obligate anaerobic microbial types, like *Lactobacillus* or *Clostridium*, respectively, and the presence of molecular oxygen may alter the composition of living microbes and thus the metabolic fate of polyphenols [28].

The extensive metabolism and catabolism of polyphenols depends on various factors, which lead to another challenging aspect. Among others, host genetics and thus the composition of the human gut microbiota differs decisively from person to person, and as a consequence, the results for polyphenol metabolites come along with high interindividual variations [20, 29].

At this point it is worth mentioning that the analysis of the mode of action of polyphenols in the human body is a prerequisite to understand the potential beneficial health effects of these phytonutrients. For this reason, bioavailability studies often include parameters like blood pressure or inflammation biomarkers to demonstrate the health effects. The mode of action is studied on the molecular level with in vitro studies including human intestinal epithelial caco-2-cells or brain endothelial cells forming the blood-brain barrier [30, 31]. In vitro studies are an integral part of the whole research area and were used to study the bio activity of polyphenols. However, implementation and interpretation of the results must be done very carefully, because among others the cellular metabolism, the concentration, and structure of the applied polyphenols may alter the metabolic fate and thus the bio activity [32]. For this reason, Aragonés and coworkers [32] proposed an experimental design which mainly includes the analysis of the culture media, culture media and cells, culture media and compounds, as well as culture media, cells, and the compounds at two different time points, respectively. With this approach, confounding reactions with, for example, the media are monitored and the identification of the bioactive metabolites is facilitated.

The accurate quantification is one of the most challenging aspects in the analysis of polyphenol metabolites in biological samples. In the case of enzymatic hydrolysis, phase II metabolites are released to their corresponding parent compounds, the aglycones, which are often commercially available. The use of reference compounds facilitates accurate polyphenol quantification. Accurate quantification of phase II metabolites is very difficult, because the availability of reference substance is highly decreased [23]. For example, anthocyanin glucuronides and phenolic sulfates need to be synthesized or isolated.

Furthermore, the complex matrix, including, for example, protein and salt, directly affects the sample preparation and detection of metabolites and consequently the quantification. The small concentrations of the chemically heterogeneous metabolites contribute to the complexity of sample preparation as well as the detection and should not be underestimated. Liquid extraction and/or solid-phase extraction (SPE) in combination with LC-MS is widely used for identification and quantification. Even though nuclear magnetic resonance spectroscopy

(NMR) is the technique of choice for identification, the application for the analysis of polyphenol metabolites is very limited. Lehtonen et al. [33] used an NMR-based metabolic fingerprinting of polyphenol urine metabolites. NMR analysis of synthesized reference compounds, used for quantification and identification reasons, is imperative.

The characterization of the physicochemical properties of both the analytes and the interfering compounds in the matrix to be extracted should be the first step. The former point comprises the different types of polyphenol metabolites, namely, phase II, glycosides, aglycones, and colonic-derived phenolic acids. These metabolites are very divergent in their physicochemical behavior, which must be considered by the simultaneous extraction of, for example, aglycones and polar metabolites like sulfated phenolics. Liquid extraction and/or SPE with or without hydrolysis are predominantly used as extraction methods and have extensively been reviewed by Day and Morgan [25].

Samples regardless of their nature, that is, plasma or urine, should immediately be stabilized with an antioxidant solution and frozen at −20 °C or −80 °C. However, degradation processes may take place, as it was shown by Felgines et al. [34] for anthocyaninmetabolites from strawberry. As a result, quantification of metabolites may be falsified and the best way to handle this issue is analyzing them immediately after sampling.

Sample amount and interindividual variationsare immutable, but current challenges in polyphenol analytical chemistry are:

- Interfering matrix compounds
- Low analyte concentration
- Chemical heterogeneity of the analytes
- Stability of analytes in biological samples
- Lack of reference compounds

3 Polyphenols and Interfering Compounds

The interaction of matrix compounds with the analyte and with the instrument is a yet neglected fact in polyphenol metabolite determination and can be the Achilles heel in quantitative analysis, as reported by Taylor [35] in the context of LC-MS analysis. The interfering compounds differ decisively in their nature and composition and therefore a short summary about the biological samples, namely, blood and urine, are given before interferences will be discussed in more detail.

3.1 Blood and Urine

Krebs [36] already described the chemical composition of blood plasma and serum in 1950. In general, blood is composed of 50% plasma, which is a yellowish fluid, and 50% formed elements, including erythrocytes, leukocytes, and platelets. Besides

water, the main compounds of plasma are proteins, enzymes, nutrients, waste, hormones, and gases. One of the main functions of blood is the transport of gases, mainly O_2 and CO_2, nutrients, waste products to be detoxified, hormones, and heat to skin. Besides the leukocytes, platelets and antibodies serve as protection agents in the case of, for example, inflammation. The regulation of pH value and water balance is the third main function of the whole blood.

Serum albumins are the major plasma proteins and serve both as solubiliziers of small molecules like amino acids, fatty acids, or hormones and as a transport "vehicle" [36]. Therefore, it seems obvious that plasma is the preferred matrix to study the metabolism of polyphenols. To reduce the risk of cardiovascular or neurodegenerative diseases, polyphenols must be able to reach the target tissue via the circulation system. In this context, Andres-Lacueva and coworkers [37] showed that anthocyanins in aged blueberry-fed rats are able to cross the blood-brain barrier and metabolites are localized in various brain regions. The blood-brain barrier is a highly selective, semipermeable membrane, which separates the blood from the brain and the extracellular fluid of the central nervous system. The interaction of proteins with polyphenols is a pivotal point to study both the mode of action of the beneficial health effects of polyphenols and the analytical chemistry of sample preparation and analysis.

Proteins, and more specific albumins, globulins, and fibrinogens, are responsible for clotting, defense, and transport [36, 38]. Globulins mainly transport lipids like cholesterol either as high density lipoprotein (HDL) or low density lipoprotein (LDL). Fibrinogens play a key role in coagulation of blood and are therefore responsible for clotting processes after vascular injury. Due to the transport of electrolytes and mainly of sodium ions, plasma proteins keep up the colloid osmotic pressure [38]. Albumins are the major plasma proteins and are responsible for the transport of micronutrients. Interactions of albumin from different origins with polyphenols will be reviewed in more detail under Sect. 3.2.

Besides human plasma, urine is one of the most analyzed biological fluids in case of polyphenol bioavailability studies, because it is easy to collect and high sample amounts are available. However, the large volume causes the dilution of the analyte to be detected so that selective sample preparation is needed.

The analysis of urinary excretion of phenolic compounds is often used to quantify a high number of metabolites. This is important for epidemiological studies, where the polyphenols from urine serve as biomarkers for food intake [39, 40]. Urine is a yellow biological fluid produced by the kidneys to remove water-soluble waste products from the organism and pH value depends on factors such as diet, drugs, or urinary disorders, but normally ranges from 5.5 to 7 [38]. It contains nitrogen end products like urea, uric acid, and creatinine and other compounds with variable chemical composition. Besides hormones, fatty acids, and pigments, the inorganic ions such as the cations sodium, potassium, magnesium, ammonium as well as the anions chloride, sulfates, phosphates, and hydrogen carbonate are compounds which can affect the analysis of polyphenols and their metabolites. In contrast to blood, high amounts of proteins and glucose are not part of urine from a healthy person.

3.2 Interactions of Bovine and Human Serum Albumin with Polyphenols

The constitution of serum albumins and the ligand binding was extensively reviewed by Kragh-Hansen [41] as early as 1981. Although bovine serum albumin (BSA) and human serum albumin (HSA) differ in their amino acid sequence, the structural organization of each protein is very similar. The primary structure of BSA is a sequence of 582 amino acid residues, while HSA consists of 585 amino acid residues. Both serum albumins share a high sequence homology and differences are due to the exchange of hydrophobic amino acids by other amino acids with comparable polarities. Furthermore, BSA contains two tryptophan residues, one in position 134 in the first and another in position 212 in the second domain as well as one single and eight pairs of disulfide bonds. In contrast, HSA contains only one tryptophan residue in position 214 and 17 disulfide bonds. Tryptophan residues are located in different positions of serum albumins, Trp-212 of BSA, for example, is located in the hydrophobic binding pocket, and Trp-134 is located on the protein surface.

The three dimensional structure of the serum albumins is influenced by the presence of cysteinyl residues in the primary sequence and, as a result, by the distribution of the disulfide bridges. BSA, for example, contains three domains and can be further subdivided into two subdomains with long loop and an intradomanial hinge region. Furthermore, subdomains are composed of three different helices. A comprehensive review about the structure of BSA and HSA as well as the molecular aspects of binding is given elsewhere [41].

Serum albumins possess different regions with high or weak affinity binding sites to interact with ligands. The association constant, or binding constant, describes the binding and unbinding reaction of, for example, serum albumin and its ligand and differs due to the chemical structure of the ligand. Several researchers conducted studies to investigate the different binding regions of serum albumins and binding specificities towards drugs, nutrients, and also polyphenols [42–46].

To determine the binding affinities of ligands to serum albumins, fluorescence quenching is the technique of choice. Recently, several studies using fluorescence quenching to investigate the interactions of polyphenols with BSA or HSA were published [47–50]. The principles of quenching fluorescence are given by Lakowicz [51]. The decrease in the quantum yield of fluorescence from a fluorophore, which is induced by a variety of molecular interactions with the quencher molecule, is called fluorescence quenching. The reduction of the fluorescence intensity includes several types of reactions, but the basic principles are either that the fluorophore returns to the ground state without emission of a photon or rather the transition of a photon to the excited state is disabled. Interactions that result in quenching comprise excited-state reactions, molecular rearrangements, energy transfer, ground-state complex formation, and collisional quenching [51]. Both the ground-state complex formation and the collisional quenching require molecular contact between the fluorophore and quencher and have been studied as a source of information about the interactions of serum albumins and, for example, resveratrol, genistein, ellagitannins, and epigallocatechin-3-gallate (EGCG) [50, 52, 53].

Collisional quenching, resulting from collisional encounters between the fluorophore and the quencher, is also called dynamic quenching. The ground-state complex between serum albumin and polyphenol is the so-called static quenching. Fluorescence quenching is described by the Stern-Volmer equation,and the Stern-Volmer plot can be linear in the case of a single class of fluorophores or the plot deviate from the linearity toward the x-axis in the case if two fluorophores are present, but one is not accessible to the quencher. For a detailed explanation of the Stern-Volmer equation and plot, see [51]. Especially the latter case is important for the studies of BSA with polyphenols. BSA contains two tryptophan residues located at different regions of the molecule. The accessibility of the Trp-212 is impeded as it is located in the hydrophobic binding pocket, so probably only Trp-134, which is located on the protein surface, will be quenched.

The binding affinity between fluorophore and quencher is determined by measuring the quenching constants using the Stern-Volmer equation. Temperature and viscosity are influencing factors of fluorescence quenching [51]. Higher temperatures facilitate the amounts of collisional quenching by faster diffusion. Furthermore, the dissociation of weakly bound complexes is increased, which results in a smaller amount of static quenching. In contrast, Liu and coworkers [54] investigated the interactions of different flavonoids with BSA at 25 °C and 36 °C, showing that the quenching constants are inversely correlated with temperature, and therefore, the quenching mechanism should follow the static quenching. In addition, more factors like the concentration of the quencher and the pH value should be considered by the interpretation of the data and make the comparison of results quite challenging. Another important fact is the composition of the serum albumin preparation, as the fatty acid content may influence the binding affinity, because these compounds can bound to albumin [41].

The differences of fluorescence intensity can be explained by both dynamic and static quenching. To distinguish the two types of quenching is rather difficult but can be done by the measurement of the fluorescence lifetimes and the examination of the absorption spectra of the fluorophores [51]. During static quenching, the number of fluorophores to be activated is merely reduced. In contrast, during dynamic quenching, the lifetime of the activated fluorophore is reduced. Therefore, the ratio of the lifetimes in the absence and presence of a quencher is constant during static quenching, whereas an important characteristic of dynamic quenching is the equivalent decrease in fluorescence intensity and lifetime. As mentioned above, the tryptophan residues of BSA are located in two separate domains of the protein and both tryptophan residues are differently accessible to the quencher. Due to the selective quenching, a spectral shift of the emission spectra is expected.

The quenching of the intrinsic fluorescence of the BSA tryptophan has been used by Papadopoulou et al. [47] to study the interaction of four different flavonoids. Two flavanols, catechin and epicatechin (EC), and two flavonols, quercetin and its rutinoside rutin, were used in this study. Both types of quenching, static and dynamic, were observed at high flavonoid concentrations. Quercetin and rutin had a higher binding affinity than catechin and EC. Differences in compound structure and concentration resulted in a lower molar ratio of quercetin (10:1) to cause total

quenching than for rutin (25:1). In addition, only the binding affinity of quercetin was significantly affected by changes of the pH value from 6.8 to 7.4. It was not surprising that binding constant of catechin, $K_{sv} = 12.5 \pm 2.8 \times 10^3\ M^{-1}$ (pH 7.4), and EC, $K_{sv} = 13.8 \pm 1.9 \times 10^3\ M^{-1}$ (pH 7.4), did not differ significantly, as these compounds are enantiomers. In contrast, binding constants of quercetin and rutin at the same pH value were $530 \pm 72 \times 10^3\ M^{-1}$ and $192 \pm 6 \times 10^3\ M^{-1}$, respectively. Similar quenching constants for quercetin were determined by other researchers, e. g., Skrt et al. [48] measured $400 \pm 1 \times 10^3\ M^{-1}$ at a pH value of 7.5. Both the exposed (Trp-134) and the buried (Trp-212) tryptophan residue were quenched with similar affinities in the study of Papadopoulou et al. [47]. As no significant shift in the emission spectra of BSA occurred in the presence of the flavonoids, the authors concluded that the molecular conformation of the protein was not affected. Other researchers also used the circular dichroism experiment to proof the fact that polyphenols do not alter the secondary structure of BSA [48, 55].

The polarity of the ligand plays an important role in the interaction of BSA and polyphenols, which was shown in the study conducted by Papadopoulou et al. [47], since different binding affinities were observed for the hydrophobic aglycone quercetin and the more polar glycoside rutin, respectively. Another reason for the lower affinity of rutin may be the steric hindrance of the sugar moiety [54]. Also Liu et al. [54] confirmed that the hydrophobic interactions are the major driving force. The authors studied the structural binding reactions of methoxylated phenolics (formononetin glucoside, calycosin, and its glucoside) and hydroxylated phenolics (quercetin and its rutinoside) with BSA. The quenching constant ranked in the order quercetin > rutin > calycosin > calycosin glucoside ≈ formononetin glucoside.

Besides fluorescence quenching, also ultracentrifugation was used to determine the equilibrium association for binding of [^{14}C]-quercetin to HSA [46]. The authors concluded that the primary binding site of quercetin to HSA was the subdomain IIA.

Another study, published by Skrt et al. [48], also investigated the interaction of BSA with different flavonoids and confirmed the influence of polyphenol structure on the binding affinity towards BSA. The authors concluded that the binding affinity is decreased with glycosylation and reduced numbers of hydroxyl groups of the B-ring. In addition, Xiao et al. [56] analyzed the degree of B-ring hydroxylation on the fluorescence quenching and also verified the increased binding affinity with higher number of hydroxyl groups. Glycosylation and the degree of hydroxylation of the B-ring directly affect the polarity of the flavonoids, which should be considered in the context of sample preparation. Within the group of the flavonols, differences occur between quercetin and quercetin glycosides and also between quercetin and myricetin [47, 56]. It remains to be clarified whether the differences in polarity are sufficient to impair the selectivity of sample preparation.

Seven flavonoids – EGCG, epigallocatechin (EGC), epicatechin-3-gallate (ECG), kaempferol, kaempferol-3-glucoside, quercetin, and naringenin – as well as three hydroxycinnamic acids – rosmarinic, caffeic, and *p*-coumaric acids – were deployed in the study conducted by Skrt et al. [48]. The authors observed a bathochromic shift (shift towards higher wavelengths) and a hypochromic shift (shift towards lower wavelengths) of the emission spectra as a function of the added polyphenols to BSA,

which is indicative of changes in polarity of the surrounding tryptophan residues. For EGCG and ECG, a red shift of 23 nm was observed, and therefore interactions with Trp-212 are assumed by the authors. Due to the interactions of quercetin and kaempferol, the environment of the tryptophan residues became less polar and as a result a blue shift was observed. The authors concluded that direct and indirect interactions of the polyphenols with Trp-212 are probable, but such shifts can also be caused by, for example, solvent relaxation or by intrinsic fluorescence, as shown previously for EC [47, 51].

In contrast to Papadopoulou et al. [47], Skrt et al. [48] assumed that the main driving forces of the binding affinity were the hydrogen bonds and electrostatic interactions instead of hydrophobic actions. Furthermore, the authors studied the potential binding sites for ECG with a blind-docking experiment. The results indicated two preferred binding sites of ECG to BSA and both were closed to the position of Trp-212, which is located in the hydrophobic binding pocket of BSA.

Soares and coworkers [49] investigated the interactions of different subclasses of polyphenols with BSA. Besides catechin, EC and ECG, malvidin-3-glucoside from the subclass of the anthocyanins, tannic acid (a hydrolysable gallotannin), procyanidin B4, procyanidin B2 gallate, and procyanidin oligomers from the subclass of condensed tannins were investigated. Soares et al. [49] corroborated the results of previous studies [57] that compounds with a high number of galloyl groups have a high binding affinity towards proteins. Tannic acid is a hydrolysable tannin rich in galloyl groups. Each galloyl residue comprises of three hydroxyl groups and a benzene ring, which increases the binding affinity to BSA due to hydrogen or rather hydrophobic bonds [49]. The interaction of five ellagitannins with BSA was determined by Dobreva et al. [53], showing a dependence of binding affinity towards tannin concentration and flexibility, as well as the presence of free galloyl groups. Furthermore, Minoda et al. [58] analyzed the binding affinities of EC, EGC, ECG, and EGCG to HSA and confirmed that the galloyl moiety favored the interactions, as ECG and EGCG showed the highest binding affinities to HSA.

The interaction of EGCG with HSA under physiological conditions was investigated by Maiti et al. [50]. As shown before for BSA, EGCG is also a strong quencher of fluorescence for the tryptophan residue 214 of HSA. However, this study indicated an alteration in the secondary structure of HSA. Docking studies showed that EGCG is within hydrogen bonding distance of Trp-214 and located within the binding pocket of subdomains IIa and IIIa.

Especially for anthocyanins, pH value is a crucial factor influencing the structure of anthocyanins. At pH below 2 anthocyanins exist predominantly as the positively charged flavylium ion and the color ranked as a function of B-ring substitution from magenta and red to purple. At pH values from 3 to 6, which was used in the aforementioned study (pH values 4.0 and 5.0), the flavylium cation is hydrated to the colorless carbinol pseudobase [49, 59]. This aspect should be mentioned, when studying the interaction of anthocyanins with serum albumins, as the interaction presumably takes place between BSA and the carbinol pseudobases of malvidin-3-glucoside. Nevertheless, the study showed that malvidin-3-glucoside affected the

tryptophan residues at both the interior hydrophobic pocket and the hydrophilic surface of BSA [49]. Cahyana and Gordon [60] investigated the interactions of different anthocyanins with HSA and concluded that the pH values affect the binding affinity due to the pH-dependent structure differences of the anthocyanins and because of the change of state of HSA. At pH 4, hydrophobic interactions are the major driving force of interactions, which confirmed the results from Soares et al. [49, 60]. Although for the aglycones electrostatic interactions and hydrogen bonding (hydrophilic) play a major role at pH 7.4, and binding affinity increased with the number of hydroxyl groups. In more detail, methoxylated anthocyanins like malvidin had a less strong binding affinity than delphinidin with three hydroxyl groups in the B-ring [60].

It should be noted that the comparison of studies on the interactions of serum albumins with polyphenols is quite challenging as the fluorescence quenching and thus the use of the Stern-Volmer equation depends on various factors. Concentration of serum albumins and quencher, the pH value, the temperature, and the viscosity are important influencing factors. The structure of the phenolic compound and serum albumins may be altered due to the different experiment conditions. The different quenching constants caused, for example, by the polarity and steric hindrance should be considered during extraction of polyphenols from plasma. Differences in the strength of interaction of polyphenols with BSA or HSA may influence the selectivity, not only during transport in the human body but also during liquid/liquid or solid-phase extraction. Recovery and accuracy of sample preparation may be influenced by the different binding affinities of polyphenols to serum albumins. However, it remains unclear if the different binding affinities are high enough to cause discrimination, for example, during SPE.

3.3 Matrix Effects During MS Analysis of Polyphenols in Biological Samples

Matrix effects, in particular ion suppression, in mass spectrometry are a major concern in the trace analysis of biological samples as shown by several review articles [24, 35, 61]. The advantage of tandem MS or multiple MS is the high specificity, but ion suppression occurs in the previous stage, that is, the ionization step. Therefore, single and tandem MS are equally susceptible to ion suppression. Matrix effects can be caused by endogenous compounds from the sample itself and furthermore, by exogenous molecules from contamination during sample preparation [62]. Both types of interference influence the extent of ionization, however, as a function of ionization technique [24]. Annesley [24] stated that electrospray ionization (ESI) is more prone to ion suppression than atmospheric-pressure chemical ionization (APCI), whereas Antignac et al. [63] pointed out that both techniques are equally affected since the composition of the mobile phase is known to impact the matrix effects to a much higher extent than the ionization technique. In general, matrix compounds cause a loss of analyte response.

Protein, salts, and ion-pairing agents like trifluoroacetic acid (TFA) are not or less volatile compounds, and during ESI, the efficiency of droplet formation and evaporation is affected, but required for gas phase ions to be emitted. Furthermore, the influence of commonly used anticoagulants like EDTA and heparin on the ion suppression needs to be evaluated [24]. As a matter of fact, ion suppression can lead to falsified results, both false negative and positive results are possible. The amount of endogenous interfering molecules varies from sample to sample and results in more or less pronounced matrix effects during analysis, which makes it even more important to determine and monitor the dimension of ion suppression [64]. For this reason, the monitoring of matrix effects on, among others, ion suppression is included in the guidance for bioanalytical method validation, provided by the US Department of Health and Human Services Food and Drug Administration (FDA, Guidance for Industry Bioanalytical Method Validation).

Handling ion suppression can be quite challenging, although different strategies including sample preparation, calibration techniques, and others exist. In general, the negative ionization mode is less subjected to ion suppression as the majority of molecules prefer positive ionization. Unfortunately, polyphenols and their metabolites are very good candidates for negative ionization, with the exception of the positively charged anthocyanins [65]. Alternative ionization techniques, which are less susceptible to ion suppression, and an efficient UHPLC to remove coeluting interfering molecules, may be a good way to reduce ion suppression [35, 63]. Over time, advanced source geometries have been developed and MS suppliers promise a decrease in ion suppression using different types of interface. For polyphenol analysis from biological samples, the influence of Z-spray, orthogonal spray, or linear spray geometry on matrix effects still needs to be examined.

Another more general strategy to reduce interfering compounds is the dilution of the sample amount to be injected. However, polyphenol metabolites occur in trace amounts and therefore concentration steps rather than dilution are recommended, depending on the sensitivity of the mass analyzer. One of the most efficient strategies is sample preparation, for example, SPE or protein precipitation. Bylda et al. [62] gave an overview about novel sample preparation techniques to overcome matrix effects during LC-MS analysis. However, their applicability in polyphenol analysis needs to be evaluated.

In case that matrix effects cannot be overcome by general strategies or sample preparation, special calibration techniques, for example, using internal isotopically labeled standard substances, are required [61]. Gosetti and coworkers described further calibration techniques including the echo-peak technique, external matrix-matched calibration (e.g., polyphenol-free plasma and urine), or the well-known standard addition [61].

Studies investigating the effects of matrix compounds on the analysis of trace amounts are often focusing on compounds with toxicological or environmental relevance, like drugs or pesticides, but investigations determining the matrix effect on polyphenol metabolite analysis are still missing.

4 Analysis of Polyphenols in Biological Samples

In the past decade, a vast number of manuscripts were published dealing with the metabolism and the bioavailability of polyphenols, but only few publications addressed the challenges of method developmentin biological samples [66–68]. Different separation and detection techniques allow the sensitive and selective detection, and therefore, targeted and untargeted metabolomic studies have gained increasing attention [69, 70]. In general, methods used for the analysis of polyphenol metabolites in biological samples include a sample preparation step as well as the separation and detection to ensure highly selective, sensitive, reliable, and accurate analysis [23]. A comprehensive validation comprised of specificity, linearity, accuracy, precision (repeatability and reproducibility), range, limit of detection, and limit of quantification needs to be an integral part of polyphenol analysis (U.S. Department of Health and Human Services Food and Drug Administration, Guidance for Industry Bioanalytical Method Validation).

4.1 Sample Preparation

Sample preparation commonly includes the steps sampling and extraction of the analyte of interest. During a human intervention trial, blood sampling is conducted by a physician and urine samples are collected by the subjects themselves, both in accordance with the specifications of the ethics proposal. Whole blood is taken from an antecubital vein, directly centrifuged to obtain the plasma and stabilized with an antioxidant solution, normally containing a buffer, ascorbic acid, and a chelating agent like EDTA or heparin. The objectives of the extraction process are to release the analyte from the matrix and to concentrate it prior to further separation and detection.

Removal of interfering compounds depends on the mode of interaction and the kind of linkage between the polyphenol and the matrix molecules. Primary chemical bonds include the ionic and metallic bonding as well as covalent bonds. More interesting in the case of polyphenols, however, are the secondary types of chemical bonds comprising of dipole-dipole interactions, especially hydrogen bonds, and van der Waals forces. The binding affinities of polyphenols and the tryptophan residues of serum albumin include different driving forces. As mentioned above, hydrophobic actions and hydrogen bonds are the main driving forces, and their intensity depends, among others, on polyphenol structure. The bonding between inorganic ions, e.g., calcium ions, to be transported by serum albumin is reversible and the binding affinity to serum albumins is very high [41, 71]. It seems promising to take advantage of these interactions to facilitate the release of polyphenols from HSA and increase the extraction efficiency.

Different extraction techniques are available to remove proteins, salts, and other matrix compounds from the sample. Extraction with solvents of different polarity as well as SPE with or without prior precipitation is the predominantly used techniques.

The solvent extraction of polyphenols from biological fluids and tissues is extensively reviewed by Day and Morgan [25] which is not covered in this chapter.

The application of SPE, including pretreatments like protein precipitation, and enzymatic hydrolysis to release phase II metabolites, will be reviewed in more detail.

4.1.1 Solid-Phase Extraction (SPE)

SPE has become an indispensable part of the sample preparation procedure and represents a reliable and selective approach in trace analysis. It can be performed off-line or on-line by direct connection to further analytical systems like LC-MS. SPE is a powerful chromatographic technique, which includes the separation of the analytes from interfering matrix compounds and a concentration step. The samples can be used directly for SPE or after solvent extraction. According to their physicochemical nature, polyphenols from a plasma or urine extract retain on the solid phase and interfering matrix compounds are removed. The stationary phase is rinsed with appropriate solvents to elute the polyphenols. By selecting the sorbent type and the elution solvent as well as the solvents for washing, improved analysis for polyphenols from biological samples can be accomplished [66, 67, 72]. Furthermore, optimization of an SPE method includes the amount of the stationary phase (as a function of analyte concentration), particle size, volume, and diameter of the cartridge. A comprehensive, not compound-specific review about the SPE technique is given by Hennion [73].

Polyphenol metabolites in plasma and even more in urine are polar analytes in an aqueous matrix, and therefore, hydrophobic so-called reversed stationary phases (RP) are commonly used.Reversed phases used for polyphenol metabolite analysis are silica-based or polymeric-based stationary phases with different surface functionalization. Until today, a high number of various functionalized sorbents, developed by different suppliers, are available with relevance to biological samples, for example, hydrophilic–lipophilic polymers, mixed-mode, or molecularly imprinted polymers [73]. The sorbents for SPE should be selected due to the chemistry of both the analyte which is supposed to be retained and the interfering compound of the matrix. Day and Morgan reviewed the use of SPE for biological samples and provide a good overview about the stationary phases used [25]. Furthermore, the authors emphasized the particular problem of the determination of sulfates. As a common phase II metabolite, polyphenols conjugated to sulfate have a high polarity and it seems evident that a special extraction procedure, including solvent and solid phases, is needed [25].

Although polyphenol metabolites differ in their polarity, high-throughput SPE methods were developed to analyze the structurally diverse metabolites in one run. Gasperotti and coworkers [66] investigated the application of different sorbents for SPE for the quantification of 23 colon-derived metabolites with spiked samples of animal liver, kidney, heart, brain, blood, and urine. The authors used a silica-based C18 and two polymeric-based stationary phases, one with a hyper crosslinked hydroxylated polystyrene-divinylbenzene copolymer and another polymer that contains *N*-vinylpyrrolidone. The three stationary phases were tested using an aqueous solution with H_2SO_4 (0.01 N), which was spiked with the polyphenol mixed

standard. The silica-based C18 and the hydroxylated polystyrene-divinylbenzene copolymer showed the same affinity towards the analytes, and recoveries were in the range of 70–120%. The copolymer was used for the validation of the sample preparation and LC-MS detection of the 23 metabolites in the above-mentioned biological samples. The results illustrate the challenges associated with such kind of metabolomic studies, as only 58% of the metabolites were within the acceptable range of 70–120%. The complexity arises on the one hand from the structurally heterogeneous metabolites and on the other hand from the matrix. Urolithin B showed recoveries from 1% to 2% in heart and kidneys, while in the other matrices, recoveries from 29% to 38% were achieved, which is neither in the acceptable range.

An advancement is the use of micro-SPE, a technique which was applied for phenolic compounds in food and in biological samples [72, 74]. Recently, Feliciano et al. [72] published a method for the use of micro-SPE for the identification and quantification of 67 phenolic metabolites in human plasma and urine. The study was performed using 2 mg of a polymeric sorbent with a semi-automated device and needed only 600 μL of plasma or rather urine. Method validation was performed with spiked plasma and urine showed recovery rates in a range of 70–110%. Several metabolites from the subclasses of benzoic acids, phenylacetic acids, phenylpropionic acids, benzaldehydes, pyrogallols, hippuric acids, cinnamic acids, valerolactones, and flavonoids like quercetin and epicatechin were analyzed. As part of the validation parameters, Feliciano et al. [72] also analyzed the matrix effects and identified 56 polyphenol metabolites in plasma and 58 in urine at baseline, respectively. Besides being a new, fast, and reliable methodology, the results of this study showed the difficulties of such metabolomic approaches, because more than half of the analyzed metabolites were detected at baseline. It seems obvious that a 72 h low-polyphenol diet is insufficient to reach a baseline without any polyphenol metabolites. The baseline issue can be overcome by the use of, for example, isotopically labeled polyphenols, as the different mass-to-charge ratio (*m/z*) allows the distinction of polyphenols originating from the diet (not labeled) and those given with a bolus ingestion (labeled) [75].

Furthermore, the results of this study demonstrated the above-mentioned issue of the simultaneous analysis of sulfated metabolites beside others, as the recovery of sulfates of methylpyrogallols and dihydrocinnamic acids was less than 20% in urine. Nevertheless, methods for phenolic metabolite fingerprinting are needed for sample analysis from epidemiological cohort studies, and the repeatability of 1.7–9.2% in plasma and 2.2–10.4% in urine allows the comparison of plasma and urine samples of different individuals [72].

Although SPE combines the advantages of cleanup, trace concentration, metabolite fractionation, and the possibility of automatization, the methodology is not without challenges [73]. Frequently occurring problems are the poor batch-to-batch reproducibility or the leaching of solid-phase material that impact MS response. High concentrations of proteins may lead to plugging of the stationary phase. For this reason, a previous precipitation step may be included in sample preparation. However, it needs to be noted that due to the high molecular weight and the resulting voluminous precipitate, co-precipitation (entrapment or adsorption) of polyphenol

metabolites may cause high losses and poor recovery [76]. Protein precipitation is often used due to its simplicity, but results in analyte losses and incomplete precipitation. Plugging of the LC column and decreased ionization efficiency are the consequences. For precipitation, solvents like dimethylformamide (DMF), acetonitrile, methanol or acids like formic acid are used and should be given priority, as the commonly employed TFA negatively impacts the spray stability during ionization, reduces signal response, and causes severe memory effects in MS [24, 77].

Quercetin is extensively bound to human serum albumin and the extent of binding differs significantly between individuals [46]. Due to the right selection of a sorbent, the binding affinity of quercetin to the stationary phase may exceed the affinity to HSA, but as it was shown for EGCG, polyphenols may interact with the Trp-214 residue of HSA, which is located within the binding pocket of subdomains IIa and IIIa [50]. HSA is a high molecular weight protein and poor retention of polyphenols on the stationary phase may occur due to steric hindrance of the polyphenol-HSA complex. A new approach to reduce the interactions of polyphenols and HSA to increase the analytical recovery may include the step of protein degradation by proteases. Proteases release shorter fragments by cleaving the peptide bonds and it is a widely used technique for the identification of proteins via peptide mass fingerprinting [78]. Decreased binding affinities of polyphenols towards the shorter protein fragments and the lower steric hindrance may facilitate the extraction efficiency and result in higher recoveries. However, side activities of proteases and reactions with their cofactors need to be monitored. It is well known that L-cysteine, the cofactor of the endopeptidase papain, may interact with polyphenols under specific oxidative conditions, which would result in a loss of analyte [79].

4.1.2 Enzymatic Hydrolysis to Release Phase II Metabolites

Enzymatic hydrolysis is used to cleave the glucuronate and sulfate moieties and release the parent compounds, which were conjugated during phase II metabolism. Researchers employed this approach to facilitate metabolite analysis, because after enzymatic hydrolysis, the complex metabolite profile is broken down to the aglycones. Higher concentrations and quantification with commercially available reference compounds are the main advantages, but enzymatic hydrolysis has to be used with care [25]. Although this approach is not suitable to remove interfering matrix compounds, it is often employed prior to SPE and therefore it is part of the sample preparation.

The biological source, specific enzyme activities and side activities, as well as the purity of the enzyme preparation need to be monitored. Even if highly selective-multiple reaction monitoring (MRM) is employed during MS detection, the results will be falsified if the biological source of the enzymes is contaminated with polyphenols or substances of similar molecular weight. Nakamura and coworkers [80] observed contamination of enzymes from *Helix pomatia* and abalone entrails (*Haliotis rufescens*) with different flavanols. Catechin and EC were detected in the preparation of β-glucuronidase derived from *Helix pomatia*, and in the preparation of sulfatase derived from abalone entrails even 7 flavanols were detected. Flavanol concentrations ranged between 0.5 and 380 fmol unit^{-1} with highest levels for

catechin, EGCand EGCG. In contrast, the biological sources of the enzymes derived from *Escherichia coli* and *Aerobacter aerogenes* were free from flavonols [80]. *Helix pomatia* (Roman snail) and abalone entrails are living organisms and subsist mainly on plants, which makes a contamination with secondary plant compounds much more likely than in the case of bacteria-derived enzyme preparations.

At this point it should be mentioned that the enzymatic release of phase II metabolites comes along with the loss of biological information. The aglycones derived only from the cleaved glucuronide and sulfate metabolites, but, for example, methylated metabolites need to be detected separately. However, it was shown for quercetin that different isomers of quercetin conjugated to glucuronic acid alone or in combination with sulfate are present in human plasma and urine [13].

4.2 Synthesis of Reference Compounds

Authentic reference compounds are a prerequisite for the accurate quantification not only of polyphenols in biological samples. The FDA recommend reference standards of known identity and purity to perform the quantification during bioanalytical methods (U.S. Department of Health and Human Services Food and Drug Administration, Guidance for Industry Bioanalytical Method Validation). Ideally, an identical isotopically labeled reference standard is used. Unfortunately, phenolic phase II metabolites are neither available as certified nor as commercially-supplied substances. Custom-synthesized or isolated compounds are the only choice. Not only for quantification purposes, but also for the application in in vitro assays to investigate the mode of action and the bioactivity of polyphenols on a molecular level, reference compounds are mandatory [81].

Polyphenols occur mainly as glycosides in plants and the isolation of, for example, glucuronides is limited due to the small quantities of the raw material [4]. Nevertheless, isolation of precursor molecules is commonly the first step of compound synthesis. In general, glucuronated, sulfated, or methylated (other than the naturally occurring compounds) polyphenols can be synthesized using a chemical or enzymatic approach.

4.2.1 Chemical Synthesis

The chemical synthesis of polyphenols is not new. As early as 1987, Barron and Ibrahim [82] published an article describing the dicyclohexylcarbodiimide-mediated esterification of flavones and flavonols with tetrabutylammonium hydrogen sulfate, which was used by other authors to characterize quercetin metabolites in human plasma [83]. The sulfate was predominantly linked at positions 7, 4′, and 3 of the polyphenol and beside mono-, also di- and tri-esters could be confirmed by NMR [82]. Jones et al. [84] synthesized quercetin sulfate analogues including mono- and disulfates. In comparison the purchased sulfates, which provide a purity of over 98%, the synthesized sulfates were 90% pure as determined by HPLC. The yield of monosulfates ranked between 1% and 16% and disulfates were synthesized to a much lesser extent, namely, 0.8–3.8%.

A lot of research was conducted on the stereoselective synthesis of EGCG, one of the most investigated flavanols in tea, and is reviewed by Nagle et al. [85]. Sulfates, glucuronides, and methyl ethers of catechin were synthesized by González-Manzano et al. [86] and more than 10 polyphenols of metabolic interest were prepared. The Koenigs-Knorr reaction was used to synthesize five monoglucuronide analogues, including A- and B-ring substitution at positions 5, 7, 3 and 4′, 3′ respectively, with highest reactivity at the B-ring. In addition, monosulfates and methyl ethers of catechin were obtained.

Recently, Zhang, and coworkers [87] focused on metabolites resulting from structural modifications of the B-ring of different flavonoids during phase II metabolismas well as during colonic degradation and synthesized several compounds, among others glucuronated, methylated, and sulfated conjugates of 4-hydroxybenzoic acid, protocatechuic acid, and vanillic acid.

Especially the synthesis of anthocyanin phase II metabolites is challenging, as the stability and structure of anthocyanins depends on the pH value of the solution [10]. Cruz et al. [88] described the chemical synthesis of an in vivo occurring anthocyanin metabolite, namely, cyanidin-4′-*O*-methyl-3-glucoside. The synthesis comprises several steps beginning with the generation of the A-ring (2,4-diacetyl-6-hydroxybenzaldehyde, "Western") and the B-ring (2-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyloxy)-3′-benzyloxy-4′-methoxyacetophenon "Eastern"), respectively. The C-ring was obtained by an aldol-type condensation between the "Western" and the "Eastern" part. After the removal of the protection group and further purification steps via reversed phase, cyanidin-4′-*O*-methyl-3-glucoside was synthesized with a purity of 99.9% (HPLC) and confirmed by NMR. The anthocyanin was synthesized with a yield of 18%, thus provides the opportunity to enhance identification and accurate quantification of anthocyanin-derived metabolites.

4.2.2 Enzymatic Synthesis

Besides chemical synthesis, enzymatic approaches for the synthesis with higher specificity are used by some authors. Blount et al. [89] published the enzymatic synthesis of conjugated EC as well as 3′-*O*-methyl epicatechin to generate metabolites occurring in human and rat plasma, for example, epicatechin 3′-*O*-glucuronide or 3′-*O*-methyl-epicatechin 5-*O*-glucuronide. The authors tested 12 enzymes belonging to the human glucuronosyl transferases of the UGT1A and UGT2B families, a mouse liver microsomal preparation, and the human COMT. The glucuronosyl transferases have different activities towards EC and UGT1A9 produced two possible epicatechin glucuronides, epicatechin 3′-*O*-glucuronide, which was identified by NMR analysis, and epicatechin 5-*O*-glucuronide tentatively identified via LC-MS. In addition, the authors showed that the yield was influenced by various factors like temperature, pH, reaction time, and concentration of enzyme and cofactors. Using UGT1A9, 3′-*O*-methyl-epicatechin-5-*O*-glucuronide was synthesized and produced approximately 50% of substance, whereas for UGT1A8, only a yield of 15% was obtained, based on 50 mM EC [89].

In addition to the application of pure enzymes, the use of animal liver enzyme preparations is a promising approach to synthesize polyphenol metabolites. S9 and

microsome fractions from liver are employed in clinical trials to simulate the metabolism of liver derived enzymes in vitro and commercially available from mice, rats, and humans [90]. The enzymatic synthesis of reference compounds using liver preparations was shown before by Crespy and coworkers [91], who successfully used hepatic, jejunal, and ileal microsomes from rats for the glucuronidation of quercetin, ECG, and EGCG. Highest rates for glucuronidation were found in the liver for quercetin with 96.3 ± 0.1%, ECG with 12.2 ± 0.2%, and EGCG with 7.5 ± 0.2% (approximately 300 μL L^{-1} quercetin, ECG, and EGCG, respectively). The authors stated that the structural difference of the flavonoid, especially the galloyl moiety, influenced the binding affinity towards UGT, resulting in the low glucuronidation rates for ECG and EGCG.

The use of chemically or enzymatically synthesized polyphenol metabolites will facilitate the quantification, if these substances are used in bioavailability studies. In addition, new potential metabolites may be synthesized and then be identified in biological samples to shade more light on the metabolic fate of polyphenols.

4.3 Separation and Detection of Polyphenol Metabolites

In recent years, several articles were published dealing with the polyphenol metabolome [92]. Metabolomics is gaining more and more popularity, and with this approach, researchers attempted to analyze the overall systematic fingerprint of metabolites in an organism [93]. This "omics" approach is implemented as targeted and untargeted metabolomics to characterize as many polyphenol derived metabolites as possible in biological samples to identify potential biomarkers of food intake [66, 70, 94]. To identify and quantify polyphenol metabolites, efficient sample preparation and powerful separation and detection techniques are needed. Several analytical instruments are available, and besides capillary electrophoresis (CE), LC-MS is indisputably the most widespread and important method. CE is a powerful tool, for example, to separate chiral flavan-3-ols in biological samples, but coupling to MS is much more challenging due to high salt concentrations in the mobile phase [95].

4.3.1 Separation

HPLC, or more recently UHPLC, is the most widely used separation technique, and improved chromatographic conditions were shown to be very effective to reduce matrix effects and enhance metabolite analysis [61, 96]. Chromatographic efficiency in UHPLC is increased using short columns with small internal diameter and particle sizes below 2 μm, resulting in very high operating pressures. This column technology, if correctly applied, raises sensitivity and resolution, which is indispensable in high-throughput trace analysis. The stationary phases available for metabolite separation with UHPLC comprise, among others, RPs, normal phases (NP), and an alternative stationary phase based on hydrophilic interaction liquid chromatography (HILIC) [96]. In addition, chiral stationary phases are used to separate flavanol enantiomers, as shown by Ritter et al. [97]. Numerous different stationary phases

with advanced configurations and chemistry, like core shell silica particles or surface modifications, are introduced by the suppliers, promising good separation of a wide range of analytes. The selection of the stationary phase depends on the chemical nature of the metabolite of interest. For example, very polar sulfated metabolites will less interact with RP, in contrast to moderately and nonpolar analytes like polyphenol aglycones. Nevertheless, modern RPs allow the separation of a wide range of polyphenolic metabolites and are applied during most of the studies [66, 70, 72].

4.3.2 Detection

After chromatographic separation, different types of detectors are coupled to identify and quantify polyphenol metabolites in biological samples. In case of previous enzymatic release of phase II metabolites, coulometric electrode-array detection (CEAD) is used more frequently than diode array detection (DAD) [97, 98]. While for plant polyphenols the application of a DAD can be useful to differentiate between the polyphenol subclasses, in biological samples coelution of matrix compounds makes the use of UV spectra unfeasible. Moreover, it is state of the art to use MS to simultaneously identify and quantify polyphenol metabolites with enhanced sensitivity, resolution, and selectivity.

The principle of MS is comprehensively described by Gross [99]. Briefly, the basic steps of MS include the generation, separation, and detection of ions. As mentioned above, two main ionization techniques, able to operate in both negative and positive ionization mode, exist to analyze polyphenol metabolites in biological samples, namely, ESI and APCI. Nevertheless, for solid biological materials like tissues, matrix-assisted laser desorption ionization (MALDI) is widely applied for drugs [100]. Mass analyzers including triple quadrupole (QqQ), ion traps (IT), and time-of-flight (ToF) are predominantly used in polyphenol metabolite analysis [37, 72, 101]. The ion separation of these analyzers is based on different physical principles. Specifically with QqQ and IT, ions are filtered in an alternating electrical field, and with ToF analyzers, the separation of ions takes place in a field-free region after acceleration through a fixed accelerating potential [99]. Recently, Orbitrap instruments, which are based on the same separation technique like QqQs and ITs, have been employed for the metabolite analysis and provide accurate mass and the calculation of the chemical formula through multiple stage fragmentation [102].

Multiple steps of mass spectrometric selection and fragmentation are realized with the so-called tandem MS, which can be divided in the tandem-in-space MS (ToF, QqQ) and the tandem-in-time MS. Tandem-in-time MS are trapping instruments like the linear IT (LIT). LIT, or ITs in general, are powerful techniques to elucidate the tentative structure of unknown polyphenol metabolites, by the acquisition of spectra of product ions after multiple steps of analysis (MS^n). In contrast, QqQs are scanning instruments with a high potential for quantification via selected ion monitoring (SIM) or MRM mode. In the past, ToF MS analyzers were only used with MADLI interface, but due to improvements, the combination of continuous ionization sources, like ESI, is possible with orthogonal acceleration ToF analyzers. With ToFs, the measurement of accurate mass and the calculation of the derived

molecular formula are possible, and this technique is characterized by high resolution power and sensitivity [99].

A yet neglected fact is the integration of ion mobility, a technique to calculate the compound-specific collision cross-section (CCS). The determination of the CCS values may provide more confidence for the identification, as the separation of isobaric metabolites, for example, glucuronide isomers is possible. The combination of CCS value, *m/z*, fragmentation pattern and accurate mass seems to be promising to enhance metabolite analysis. Recently, Chalet et al. [103] published results for phase II metabolites of flavonoids, revealing the potential of ion mobility in combination with MS and the measurement of CCS values.

5 Conclusions

Polyphenols are secondary plant compounds ubiquitously found in plant-derived foods and are associated with several beneficial health effects [2, 5]. These phytonutrients are associated with various biological activities, for example, the antioxidative, anti-inflammatory, or antiproliferative effects may be responsible for the reduced risk to suffer from cardiovascular and neurodegenerative diseases [5]. The bioavailability and thus the ADME of polyphenols in the human body were extensively investigated with in vivo and in vitro approaches in the recent decades. Intervention studies were conducted to identify polyphenol metabolites with certain biological activity, as well as to quantify the analytes in biological samples like blood and urine, and both are subject to the limitations of analytical chemistry. Current challenges in polyphenol analytical chemistry in biological samples include the interfering matrix compounds (protein, salt), low analyte concentrations, chemical heterogeneity of the analytes, as well as the lack of reference compounds [23]. In addition, confounding reactions during cell metabolism should be monitored in the case of in vitro studies [32].

Efficient analysis of polyphenol metabolites requires in depth knowledge about the interference which can occur during extraction of the analyte from the matrix or through detection for example with MS. Therefore, the binding affinities of polyphenols were determined via fluorescence quenching, circular dichroism, or docking experiments with BSA or HSA. Flavonols, like quercetin and rutin, as well as flavanols, like catechin and ECG, are predominantly used to describe binding affinities to serum albumins. Main driving forces for the bonding are hydrophobic interactions and to some extent hydrogen bonds and electrostatic interactions [47, 48, 54]. The binding affinity depends, among others, on the polyphenol structure and is decreased by glycosylation but increased with high numbers of hydroxyl groups of the B-ring [48, 56]. Due to the different mechanism of static and dynamic quenching during fluorescence quenching, further parameters like quencher concentration, pH value, and temperature should be carefully monitored and considered during interpretation [51].

The binding affinity of polyphenol to serum albumins varies with compound polarity and therefore, the efficiency of metabolite extraction from plasma may be

affected. Techniques to remove proteins and other interfering compounds should be free of discrimination and can be handled during effective sample preparation. The deployment of different sample preparation methods, like solvent extraction, SPE, or protein precipitation, is necessary, but matrix effects should be determined and monitored. Ion suppression is a major problem during analysis of biological samples, as the method of choice for trace analysis in this area is the LC coupled with MS [35]. A number of strategies exist to handle matrix effects, but extensive sample preparation in combination with LC seems to be most promising [63]. Source geometry, ionization technique (ESI, APCI), and ionization mode (positive, negative) are limited to the instrument configuration and analyte structure, respectively. Furthermore, a number of calibration techniques, like matrix matched, echo-peak technique, or the use of an isotopically labeled internal standard, are available, but should not be used to compensate for poor sample preparation.

Solvent extraction, SPE, and protein extraction, occasionally also in combination, are the preferred techniques for sample cleanup and analyte concentration. SPE with silica-based or polymeric-based stationary phases with different surface functionalization is widely used. The simultaneous extraction of several metabolites with one stationary phase is quite challenging due to the different polarities of, for example, phase II metabolites (especially sulfates) and colonic derived phenolic acids. However, promising SPE and micro-SPE approaches were established with recoveries ranging between 70% and 120% [66, 67, 72]. In the case of pretreatment with glucuronidases and sulfatases, it is highly recommended to monitor and determine the enzyme activity and possible contamination, especially in the case of enzymes derived from *Helix pomatia* and abalone entrails [25, 80].

Syntheses of reference compounds for identification and quantification purposes were established during the last years and chemical and enzymatic approaches are described, especially for flavanols, flavonols, and anthocyanins [84, 88, 89, 91]. In combination with highly sensitive LC-MS techniques like UHPLC-ESI-TOF-MS, the use of enzymatic hydrolysis to facilitate analysis decreased in importance. The integration of ion mobility to high resolution MS allows the determination of isobaric polyphenol metabolites via the CCS values, and ion mobility is a promising technique to expanded the knowledge of polyphenol metabolism [103].

The use of polyphenol metabolites as biomarkers for food intake is quite challenging, due to analytical and physiological aspects. The accuracy of the results depends on the chemical nature of the metabolite and is directly correlated with the method used and is further complicated by the interindividual variability of polyphenol metabolism and occurring metabolites. Approaches for the simultaneous analysis of numerous polyphenol metabolites in biological samples are often required in large intervention or cohort studies. In case that the used methodology provides good repeatability of polyphenol metabolites, there is nothing wrong with it. Regrettably, the occurrence of metabolites at baseline, which makes them less suitable as biomarkers, is an often neglected fact. Nevertheless, phenolic compounds are bioactive molecules in food and therefore, an integral part of the human diet. The fate of these phytonutrients during the human body is extensively investigated by researchers of multidisciplinary nature and scientists working in the field of

analytical chemistry, nutrition and health sciences, microbiology, and epidemiology. Future studies should include in vivo, in vitro, and observational studies, as well as further investigations which address the analysis of phenolic compounds in biological samples.

Abstract

This introductory chapter provides an overview of three main rheological properties of food gums including dilute solution, steady shear, and viscoelastic rheological properties. Examples of a number of different food gums are given, and a brief introduction to the rheological properties of them at three mentioned rheological aspects is provided. Different circumstances such as temperature, concentration, presence of ions and sugars, which affect the rheological behavior of food gums, are summarized. Dilute regime properties determine the molecular role of gums in food products. Steady shear rheological properties of food gum manifest useful data to evaluate the flow behavior, quality control, and processing/storage stability of food products consisting food gums. Dynamic rheological characteristics of food gums illustrate the viscoelasticity, stability, and textural features of final formulated foods. To sum up, the results showed that various food gums, with variety of structure and nature at different situations, exhibit different rheological behavior.

Keywords

Biopolymer · Dilute regime · Concentration dependency · Steady shear · Temperature dependency · Time dependency · Viscoelasticity

List of Abbreviations

[η]	Intrinsic viscosity
BSG	Basil seed gum
CSG	Cress seed gum
GG	Guar gum
LBG	Locust bean gum
LPSG	*Lepidium perfoliatum* seed gum
LVE	Linear viscoelastic region
M_w	Molecular weight
SSG	Sage seed gum
XG	Xanthan gum

1 Introduction

The word gum is widely used to depict a range of polysaccharides, which have the ability of causing a large increase in a solution viscosity, even at small concentration. In food industry, commercial gums are usually utilized as thickener, stabilizer, fat-replacer, and gelling agents. Most of them are water-soluble macromolecules and then are used in the water-continuous systems. In some sectors of the food industry like dairy, having products with a special texture and mouthfeel is crucial, in which gums play an important role to provide those characters. Generally, gums are used in relatively small portion to expose proper rheological or textural properties of food products.

In many studies, the effect of food elements (certain sugars and ions) or systems (temperature and pH) on rheological performance of gums were determined. In particular, measuring rheological responses of food gums at macroscopic level are related to the changes and properties of them at microscopic level [1]. Thus, rheological properties of food gum dispersions can provide useful information about their structures and behaviors at different conditions used in food processing [2]. This chapter describes some rheological properties of a couple of food gums including dilute solution, steady shear, and dynamic rheological properties.

2 Dilute Solution Properties

2.1 Introduction

In dilute solution, each macromolecules' coils are separated from each other and freely moved. In this situation, measurement of the viscosity can provide some extremely useful information about molecular properties, biopolymer behavior, and its interaction with solvents or copolymers. The intrinsic viscosity demonstrates the hydrodynamic volume occupied by each unit of macromolecule which is related to the molecular size, conformation, molecular weight, and solvent quality [3]. Hence, intrinsic viscosity determination can supply deep understanding of molecular properties of macromolecules in solution [4]. Intrinsic viscosity, [η], is defined as the ratio of the specific viscosity (η_{sp}) or natural logarithm of relative viscosity (η_{sp}) to the mass concentration of the polymer in the limit of "infinite dilution" or zero concentration:

$$[\eta] = \lim_{c\to\infty}\left(\frac{\eta_{sp}}{c}\right) = \lim_{c\to\infty}\left(\frac{ln\eta_{rel}}{c}\right) \tag{1}$$

where, $\eta_{rel} = \eta/\eta_s$ and $\eta_{sp} = (\eta - \eta_s)/\eta_s$. The parameters of η_s and η are the solvent viscosity and solution viscosity, respectively. There are different equations to determine [η], including intercept-based models (Huggins and Kraemer models) and slope-based models (Tanglertpaibul-Rao and Higiro models) which are represented as Eqs. 2, 3, 4, 5, and 6:

Huggins' equation [5]:

$$\eta_{sp}/C = [\eta] + K_H[\eta]^2 C \tag{2}$$

Kraemer's equation [6]:

$$ln\eta_{rel}/C = [\eta] + K_K[\eta]^2 C \tag{3}$$

Tanglertpaibul-Rao's equation [7]:

$$\eta_{rel} = 1 + [\eta]C \tag{4}$$

Higiro's equations [8]:

$$\eta_{rel} = e^{[\eta]C} \tag{5}$$

$$\eta_{rel} = 1/(1 - [\eta]C) \tag{6}$$

where, K_H, K_K, and C are Huggins constant, Kraemer constant, and solute concentration, respectively.

2.2 Intrinsic Viscosity

The intrinsic viscosity and molecular weight values of some commercial and novel food gums are shown in Table 1. It is noticeable that differences of intrinsic viscosity magnitudes are dependent on structural features, like different degree of substitution and molecular mass [9]. As seen in Table 1, xanthan gum represents the highest [η] among reported gums (155.7 dl.g^{-1}), which is related to the higher molecular weight (M_w) and stronger chain stiffness of it [10]. In contrast, starch samples have high M_w (24–360 × 10^6 Da) and then should be resulted in higher [η], but they have lowest amount of [η] between selected gums (Table 1). The low intrinsic viscosity of starches rather than other gums such as xanthan is related to high portion of amylopectin with low volume in starches. Actually, amylopectin is a highly branched polysaccharide with high M_w and low molecular extension, then in dilute regime, the volume of amylopectin molecules is less than linear polysaccharide with the same Mw [11].

The [η] of biopolymers can be affected by different situations, like changing temperature and pH, presence of salts and sugars, etc. As seen in Table 1, with increasing temperature, the intrinsic viscosity of some gums increase, some decrease, and some of them roughly change. For example, [η] of xanthan gum increase from 155 to 173 (dl.g^{-1}) by increasing temperature from 25 °C to 80 °C (Table 1) which is related to increased chain dimension of it at higher temperatures [10]. On the other hand, the intrinsic viscosity of some gums like Balangu seed gum, sage seed gum, and basil seed gum decline with increasing temperature (Table 1). For instance, [η] of Balangu seed gum goes down from 72 to 50 (dl.g^{-1}) by changing temperature from 20 °C to 50 °C, which is related to increasing kinetic energy, phase separation, decreasing solvent quality, and debranching of the gum [3].

Both increasing and decreasing of [η] have reported for food gums in the presence of sugars. As shown in Table 1, [η] of cress seed gum increased from 2.4 to 2.8 and 2.9 (dl.g^{-1}) with adding lactose (up to 15% w/v) and sucrose (up to 40% w/v). Decreasing solvent dielectric constant, sugar dehydration, and aggregation formation of gum molecules were reported to explain this phenomena [19]. In contrast, the intrinsic viscosity of Balangu seed and basil seed gums decreased from 72.4 and 11.4 (dl.g^{-1}) to 12 and 8.8 (dl.g^{-1}), respectively, with adding 15% lactose to the solution (Table 1). To elucidate this trend, the literatures used the explanation: the competition between sugar and gum molecules for water and likely less free water molecules

Table 1 Dilute solution properties of some food gums

Gum	Solution	M_w (Da)	[η] (dl/g)	K_H	Used model	Reference
Guar gum	Distilled water (25 °C)	1.45×10^6	9.25	–	Huggins and Kraemer	[10, 12–14]
	Distilled water (25 °C)		12.0	–		
	Distilled water (80 °C)		11.5	–		
	Distilled water (25 °C)		11.0	0.215

	KCl (200 mM, 25 °C)		4.86	–		
Cress seed gum	Distilled water (25 °C)	5.4×10^5	2.42	–	Higiro 1	[19, 20]
	NaCl (100 mM, 25 °C)		1.88	–		
	$CaCl_2$ (15 mM, 25 °C)		1.54	–		
	Lactose (15% w/v, 25 °C)		2.83	–		
	Sucrose (40% w/v, 25 °C)		2.89	–		
Basil seed gum	Distilled water (25 °C)	1.73×10^6	11.38	–	Higiro 2	[21]
	Distilled water (65 °C)		8.76	–		
	Lactose (15% w/v, 25 °C)		8.74	–		
	Sucrose (40% w/v, 25 °C)		6.79	–		
Waxy corn starch	90%DMSO-10%water (25 °C)	$37–360 \times 10^6$	1.26	1.22	Huggins and Kraemer	[11, 22]
Rice starch	90%DMSO-10%water (25 °C)	$59–88 \times 10^6$	1.04	1.89	Huggins and Kraemer	[23, 24]
Canary seed starch	90%DMSO-10%water (30 °C)	24.6×10^6	1.17	1.32	Higiro 1	[25]

to interact with gum molecules causing more intermolecular association in gum molecules and result in less intrinsic viscosity of them [3, 19, 21].

With a glance to the Table 1, it is easy to notice that by adding salts to the solution (regardless of the ion type), the intrinsic viscosity of all gums decreased except locust bean gum. For instance, [η] of xanthan gum decreased from 214 to 68, 74, and 60 ($dl.g^{-1}$) by adding NaCl, KCl, and $CaCl_2$ (at 50 mM), respectively. This behavior has been regarded to the shielding effect of charges (Na^+ & Ca^{2+}) on macromolecular chains. In other words, with adding salts to the solution and the effect of shielding of charges, the molecular repulsion is going to be reduced and cause more aggregation between molecular gums and finally result in reducing intrinsic viscosity [3, 26]. In contrast, unchanging or low changing intrinsic viscosity of locust bean gum in presence of salts is related to non-polyelectrolyte nature of this gum, whose salts have little effect on the hydrodynamic volume [11]. Again, we should repeat this sentence according to the information provided above that intrinsic viscosity supplies deep understanding of molecular properties of macromolecules in solution and consequently the role of gums in final food products in real systems.

2.3 Huggins' Constant

The Huggins' constant (K_H) is a key parameter of Huggins equation, which differs from solvent to solvent for a special polymer [11]. The values of K_H can be affected by molecular architecture and extent of coil expansion of the polymer coil [12, 27]. K_H generally is the range of 0.3–1, which at good solvent it would be from 0.3 to 0.4 for flexible macromolecules with extended shape [4, 12, 28]. However, the K_H more than 1 would endorse the aggregate formation of the polymer [29]. The K_H value of some food gums is shown in Table 1. Like intrinsic viscosity, the K_H can be impacted by different circumstances such as different temperatures, presence of salts and sugars and various solvents. As seen in Table 1, with increasing temperature from 25 °C to 50 °C, the K_H of Balangu seed gum decreases from 0.333 (value in good solvent condition) to 0.077, which shows temperature makes the solvent quality worse and molecular association happen [30]. A decline in space prohibition among adjacent molecules via debranching that allows them to associate easier than branched form was stated to elucidate this behavior [3]. The presence of sugar, as seen in Table 1, changes the K_H from 0.33, related to the good solvent, to 0.53. It was stated that an increase in the interaction between Balangu seed gum molecules may be the cause, and they have less tendency to interact with solvent [3]. The influence of increasing salts (ionic strength), in contrast to the temperature, increased the K_H of LBG, xanthan, and Balangu seed gum (Table 1). For LBG and xanthan gum, a reduced tendency to aggregate was suggested [15]. However, as the K_H approached to unity by increasing ionic strength, the aggregation form was proposed for Balangu seed gum (Table 1). As shown in Table 1, all selected starches have K_H values more than unity, indicating the presence of aggregates. The compact structures for the branched molecules of starches that

major fraction of them is amylopectin was illustrated to clarify this behavior [25]. Also, it was mentioned that amylopectin would behave in 90% DMSO-10% water like an aggregate of linear polymer [11].

3 Steady Shear Rheological Properties

3.1 Introduction

Determination of steady shear rheological properties of food gums is needed to design the fluid transportation and pumping calculations, quality control, and processing/storage stability evaluation of food products. Thickening and stabilizing roles of gums are depended on shear rate, time of shearing, concentration, and temperature. Generally, to describe or predict the rheological behavior of gums, numerous mathematical models can be used. For example in shear rate dependency, the power-law, Herschel–Bulkley, Bingham plastic, Casson, and Mizrahi–Berk models, and for time dependency, the Weltman model, first-order stress decay models, and structural kinetic models are applied. To elucidate concentration dependency, the concentration-sensitive models like linear, power-low, exponential, and polynomial models were encountered. Also, to depict the temperature dependency, the Arrhenius-type model is usually applied.

3.2 Shear Rate Dependency

Most of hydrocolloids are non-Newtonian materials which usually show shear-thinning behavior. Pseudoplastic is the popular name of shear-thinning fluids; however, the expression of shear-thinning is preferred. During shearing, the hydrodynamic forces generate and the structural units of gums start to breakdown which assume as shear-thinning behavior [9].

Figure 1 demonstrates the shear-thinning behavior of some selected hydrocolloids. Marcotte et al. [31] reported the same trend, e.g., shear-thinning behavior, at other concentrations and temperatures. They used the power-law model (Eq. 7) and Herschel-Bulkley model (Eq. 8) to describe the shear-thinning behavior of starch and pectin, and carrageenan and xanthan, respectively.

$$\tau = \tau_{0H} + k_H \dot{\gamma}^{n_H} \tag{7}$$

where τ_{0H} is the yield stress (Pa), k_H is the consistency coefficient (Pa s^n), and n_H is flow behavior index for Herschel-Bulkley model.

$$\tau = k_P \dot{\gamma}^{n_P} \tag{8}$$

where k_p is the power-law consistency coefficient (Pa s^n) and n_p is the power-law flow behavior index.

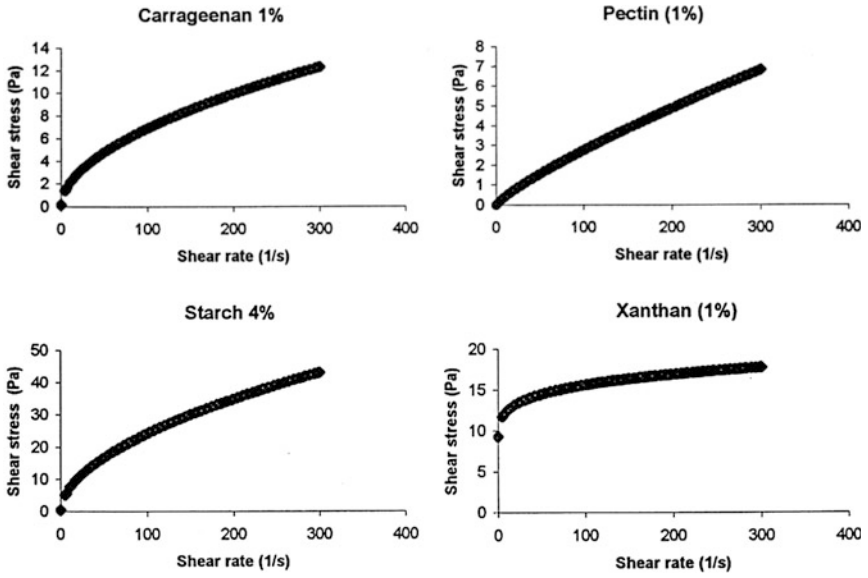

Fig. 1 Typical flow curves for some selected hydrocolloids at 20 °C [34]

Table 2 The steady shear rheological properties of some gums represented by the power-law model

Gum	k_p (Pa.s^n)	n_p	γ (s^{-1})	Reference
Xanthan (1% w/w)	14.43	0.22	0.01–300	[33]
Guar (1% w/w)	4.13	0.76	0.01–316	[34]
Sage seed (1% w/w)	8.72	0.28	0.01–300	[33]
Balangu seed (1% w/w)	0.22	0.42	6.12–245	[35]
Cress seed (1% w/w)	0.65	0.44	10–500	[36]
Sweet potato starch (gel 5% w/w)	20.4	0.38	0.4–1000	[37]
Canary seed starch (gel 6% w/w)	22.5	0.30	0.1–400	[38]

k_p, the consistency coefficient; n_p, flow behavior index

Among selected hydrocolloids, xanthan and guar gum showed yield stress along with shear-thinning behavior. The yield stress of selected gums increased with increasing concentration and decreasing temperature [31]. One of the useful properties of food gums is yield stress which can help to keep ingredients of food formulation in place. For instance, high yield stress of food gums is useful as stabilizer in products like mayonnaise and salad dressings [32].

The power-law model parameters of some hydrocolloids, one of the common models which is used to describe rheological properties of food gums, are shown in Table 2. All the selected hydrocolloids showed n_p value less than 1. Comparatively,

the magnitude of flow behavior index of xanthan (0.22) and sage seed gum (0.24) were the lowest and guar gum (0.76) was the highest. Starches, cress seed, and Balangu seed gum had intermediate values (0.30–0.44). Food gums with high pseudoplasticity expose the slimy feeling in the mouth, then for food products with high viscosity and good mouth feeling, the food gums with lower n_p values are the option.

3.3 Concentration Dependency

It was reported that the values and changes of flow behavior index (n_p) with concentration are efficiently dependent on the molecular size [39, 40]. Table 3 illustrates the model parameters *a* and *b* for power-law (Eq. 9), exponential (Eq. 10), and polynomial (Eq. 11) models of some selected hydrocolloids at different temperatures.

$$\eta = aC^b \tag{9}$$

$$\eta = a \exp(bC) \tag{10}$$

$$\eta = 1 + aC + bC^2 \tag{11}$$

where, *a* and *b* are models' constants and *C* is the concentration of gum.

As seen in Table 3, based on R^2 (coefficient of determination) values (0.78–1.00), all the three models properly described concentration dependency of selected hydrocolloids. Although in some cases just one of the models was selected to describe concentration dependency, for example, for basil seed gum [41] and sage seed gum [42], the power and exponential models were chosen. Marcotte et al. [31] related to power-law model, reported the decrease of *a* value with increasing temperature for carrageenan, pectin, starch, and xanthan gums (Table 3). Also, they informed the decrease of *b* value for carrageenan and pectin, but for xanthan and starch, the related changes were very small. Moreover, they depicted that polynomial model described concentration dependency of selected gums well. For all selected gums, except xanthan, parameters *a* and *b* decreased at higher temperatures. Marcotte et al. [31] concluded that there is a strong interaction between concentration and temperature for xanthan gum.

The increase of apparent viscosity with increasing concentration was reported for carrageenan, pectin, starch, xanthan gums [31], basil seed gum [41], and sage seed gum [42]. Then, food gums have high potential of being a good thickener or stabilizer in increasing the consistency of food systems as it has been reported that higher viscosity of food products implied a better mouth feel [43].

3.4 Temperature Dependency

Commonly, the consistency coefficient (k) of food gums decreased with increasing temperature like carrageenan, pectin, xanthan gums [31], basil seed gum [41], sage

seed gum [42], and canary seed starch [38]. However, the story for flow behavior index (n) is different. For example, n value increased with temperature increase for xanthan, carrageenan, pectin, and starch [31], but Hosseini-Paravar et al. [41], Razavi et al. [42], Irani et al. [38], Moreira et al. [44], and Albano et al. [45] reported unclear trend of it for basil seed gum, sage seed gum, canary seed starch, chestnut starch, and Peruvian carrot starch, respectively.

Table 4 shows the parameters of Arrhenius-type model (Eq. 12) determined for some selected food gums.

$$\eta = A \exp\left(E_a/RT_a\right) \tag{12}$$

where A is the proportionality constant (or apparent viscosity at infinite temperature, Pa.s), E_a is the activation energy (kJ/mol), R is the universal gas constant (kJ/mol K), and T_a is the absolute temperature (K).

As seen in Table 4, temperature dependency of all selected gums follows an Arrhenius-type model (acceptable R^2 values). The lower amount of activation energy (E_a) is related to the less temperature sensitivity of rheological properties of food gum [38].

Among selected food gums, xanthan gum illustrated the lower value of E_a at same concentration in comparison with other food gums like carrageenan, pectin, starch, sage seed gum, and basil seed gum (Table 4). Van Wazer et al. [46] informed that the more pseudoplastic behavior, the less temperature dependency. With a quick glance to the Table 2, it was noticed that xanthan and sage seed gums showed lower amount of n value and therefore they exhibited low values of E_a. Some literature presented the increase of E_a values with increasing concentration like carrageenan, xanthan, starch [31], basil seed gum [41], and sage seed gum [42]. However in some studies, the decrease of E_a values was observed by concentration for Salep [47], cress seed gum [20], and gelatin [31].

3.5 Time Dependency

Thixotropy is a key property of non-Newtonian fluid and has been described as the decrease in viscosity as a function of shearing time, which is going to be recovered when shearing is eliminated based on breaking down and later partial building up of some form of structure [48]. The time-dependent parameters of some selected food gums fitted with three famous models including second-order structural kinetic model (Eq. 13), first-order stress decay model, with a non-zero equilibrium stress value (Eq. 14), and Weltman model (Eq. 15) which are shown in Table 5.

$$\left[\frac{\boldsymbol{\eta} - \boldsymbol{\eta}_\infty}{\boldsymbol{\eta}_0 - \boldsymbol{\eta}_\infty}\right]^{(\mathbf{1}-\boldsymbol{n})} = (\boldsymbol{n} - \mathbf{1})\boldsymbol{kt} + 1 \tag{13}$$

where $\boldsymbol{\eta}_0$ and $\boldsymbol{\eta}_\infty$ (Pa s) are the initial (at t = 0) and equilibrium ($t \to \infty$) apparent viscosities, respectively, and k (1/s) is the rate constant of the thixotropic breakdown

Table 4 The activation energy determined for temperature dependence of apparent viscosity of some selected food gums

which is the function of shear rate, and eventually n is the breakdown order (generally $n = 2$).

$$\boldsymbol{\tau} - \boldsymbol{\tau}_{eq} = \left(\boldsymbol{\tau}_0 - \boldsymbol{\tau}_{eq}\right)\boldsymbol{e}^{-kt} \tag{14}$$

where $\boldsymbol{\tau}_0$ and $\boldsymbol{\tau}_{eq}$ (Pa) are the initial and equilibrium shear stresses, respectively; k (1/s) is the breakdown rate constant.

$$\boldsymbol{\tau} = \boldsymbol{A} + \boldsymbol{Blnt} \tag{15}$$

where, A (Pa) is the initial shear stress parameter and B (Pa) is the time coefficient of thixotropic breakdown.

Koocheki and Razavi [49] investigated the effect of shear rate, concentration, and temperature on thixotropic properties of *Alyssum homolocarpum* seed gum (AHSG). As seen in Table 5, the rate constant and extent of thixotropy were affected by concentration and temperature. The first order model was chosen to describe thixotropy behavior of AHSG and according to the results shown in Table 5, the structural breakdown value did not show any clear trend with increasing

concentration, but it decreased with increasing temperature. However, the extent of thixotropy raised with gum concentration increase and decrease with increasing temperature. In another study, the time dependency of Salep and Balangu seed gums were affected by different shear rates [50] (Table 5). They introduced the first-order stress decay model with non-zero equilibrium as adequate model to describe thixotropy behavior of the selected gums. The rate of thixotropic breakdown of Salep increased with increasing shear rates; however, the extent of thixotropy increased and decreased for Salep and Balangu seed gum, respectively. Naji et al. [36] did research on time dependency of cress seed gum (CSG) and xanthan gum (XG) as a function of different heat treatments (Table 5). CSG exhibited higher rate of breakdown and lower values of initial stress (τ_0) and equilibrium stress (τ_{eq}) against XG. Opposite to XG, the heat treatment increased initial and equilibrium shear stresses of CSG, and it was concluded that at higher temperatures, links between polymeric chains of CSG become stronger. As can be seen in Table 5, the effect of concentration on thixotropic behavior of wheat starch gel was studied by Yousefi and Razavi [51]. The first-order stress decay model with a non-zero equilibrium stress value and the second-order structure kinetic models predicted time dependency well. It was reported that the both initial and equilibrium stress values increased by increasing concentration. On the other hand, decay rate constant (k), which determines how fast the gel gets in the equilibrium stress value, decreased with increasing concentration.

4 Dynamic Rheological Properties

4.1 Introduction

In many literatures, it was announced that dynamic rheological properties of food gums can provide practical information of their structure [52]. Actually, investigation of the viscoelastic proprieties of food gum dispersions is vital for food producer to adjust and recognize the processing parameters, consistency, stability, and textural features of formulated products. This is why dynamic rheology is one of the crucial methods which is used to evaluate the viscoelastic characteristic of polysaccharide dispersions or gels. In this section, oscillatory testing operating modes including amplitude sweep, frequency sweep, and time-temperature sweep of some food gums would be considered.

4.2 Amplitude Dependency

Table 6 shows some stress/strain ramp test parameters of some food gums including limiting values of strain (γ_c), loss tangent (tan δ_{LVE}), yield stress or stress at LVE range (τ_y), storage modulus (G'_{LVE}) and loss modulus (G''_{LVE}) along with flow-point stress (τ_f), and modulus at crossover point (G_f, $G' = G''$). It is obvious that different

conditions like changing temperature, concentration, and the source of the gums would change amplitude-dependent parameters.

In the linear viscoelastic region (LVE), storage modulus (G') and loss modulus (G'') are constant. However, in nonlinear viscoelastic region, both moduli (G' and G'') begin to decrease. The stress/strain point that moduli start to decrease is called critical point (critical stress (τ_y) or strain (γ_c)), which demonstrates the structural strength/deformability of the food gums.

As seen in Table 6, increasing gum concentration resulted in increase of the strength and rigidity of the *Lepidium perfoliatum* seed gum and wheat starch gel. Also, the magnitudes of G'_{LVE} and G''_{LVE} increased with increasing gum concentration. The ratio of G''_{LVE} to G''_{LVE} ($\tan \delta_{LVE}$) is a rheological parameter that shows the physical behavior of a gum system. The selected gum showed decreasing or unchanged $\tan \delta_{LVE}$ values by increasing gum concentration for wheat starch gel and *Lepidium perfoliatum* seed gum, respectively. Another important criterion which could be determined through stress sweep is yield stress (τ_y).

Yield stress of food gums is a criterion of the capacity or the ability of them to stabilize food systems [53]. By increasing gum concentration, the yield stress usually increases which means the stronger gel network formed. For example, the τ_y of wheat starch gel declined from 12 to 83 Pa as the concentration increased from 8% to 12% (Table 6). When the storage modulus is equal to loss modulus, called yield stress at flow point (τ_f), the structure rupture happened and with following the escalating of stress, the loss modulus is going to be more than storage modulus and then flow is occurred. The selected food gums (wheat starch and *Lepidium perfoliatum* seed gum) showed that the value of τ_f increased with increasing gum concentration. Finally, the stress at the crossover of the moduli (G_f, $G' = G''$) indicates the gel strength at the start of flow point which is also raised by increasing selected gums concentration.

The effect of temperature on stress sweep properties is different in various food gums. As seen in Table 6, Behrouzian et al. [33] reported completely different behavior of sage seed gum (SSG) and xanthan gum (XG) with increasing temperature. For example, G'_{LVE}, G''_{LVE}, γ_c, τ_y, and τ_f of SSG and XG increased and decreased, respectively, as temperature raised from 10 °C to 90 °C. In contrast, the values of $\tan \delta_{LVE}$ for SSG and XG decreased and increased, respectively. The effect of raising temperature for *Lepidium perfoliatum* seed gum was similar to SSG (Table 6), which demonstrated that increasing temperature strengthened the structure of SSG and *Lepidium perfoliatum* seed gum, while it weakened the XG structure. The different behavior of food gums with increasing temperature may be related to their molecular conformation changes. With a glance to the Sect. 2.2 (Table 1), it is obvious that the intrinsic viscosity of XG increased with increasing temperature, but SSG showed reversed trend. It was reported that increasing temperature transformed XG conformation from rigid rod to random coil, and in contrast it increased the rigidity of SSG [55].

As demonstrated in Table 6, SSG, BSG, and guar gum at the same experimental condition (1%, 20 °C, 1 Hz) showed different amplitude dependency behaviors. Obviously, these differences are related to different nature of them like molecular weight, molecular conformation, and so on.

Table 6 Dynamic moduli in the linear viscoelastic range (G'_{LVE} and G''_{LVE}), limiting strain (γ_c), and loss-tangent in the LVE range (tan δ_{LVE}), yield stress in the LVE range (τ_y), and flow-point stress (τ_f), with corresponding moduli (G_f: $G' = G''$) for some food gums

4.3 Frequency Dependency

Frequency sweep data can help to classify dispersions including dilute solution, entanglement network systems (concentrated solution), weak gel, and finally strong gel [48]. Strong gels of food gums behave like viscoelastic solids at small frequencies while they start to rupture above a critical frequency or deformation value. However, their weak gels behave like strong gels at small frequencies, but with increasing frequencies or deformation values, three-dimensional networks start to progressively breakdown into smaller clusters [51]. In weak gels, storage (G′) and loss moduli (G″) exhibit slight frequency dependency and G′ exceeding G″ at all frequencies [57]. Weak gel behavior was reported for *Lepidium perfoliatum* seed gum (1.5–3% concentration) [54], wheat starch gel (8–12% concentration) [51], basil seed gum (1 and 3% concentration) [56, 58, 59], sage seed gum, and xanthan gum (1% concentration) [19, 60], as the magnitudes of G′ and G″ slightly increase with frequency increasing, and G′ is always higher than G″ within frequency range and no crossover point occurred (Fig. 2). However, guar gum (1% concentration) [34], mucilage gum of *Opuntia ficus indica* (3% concentration) [61], and xanthan gum at 90 °C (1% concentration) [33] behave like entangled polymer solutions as a crossover point occurred at low frequency and G′ was higher than G″ at high frequency range (Fig. 3).

Commonly, when concentration of food gums increases in a solution, the magnitudes of both storage and loss moduli increase. At high concentrations, the formation of complex structure grows in the network system. The parallel increase of dynamic moduli (G′ and G″) is linked to the network defects [62]. In other words, in low concentration, there are lots of intermolecular zones, which could not take a part in

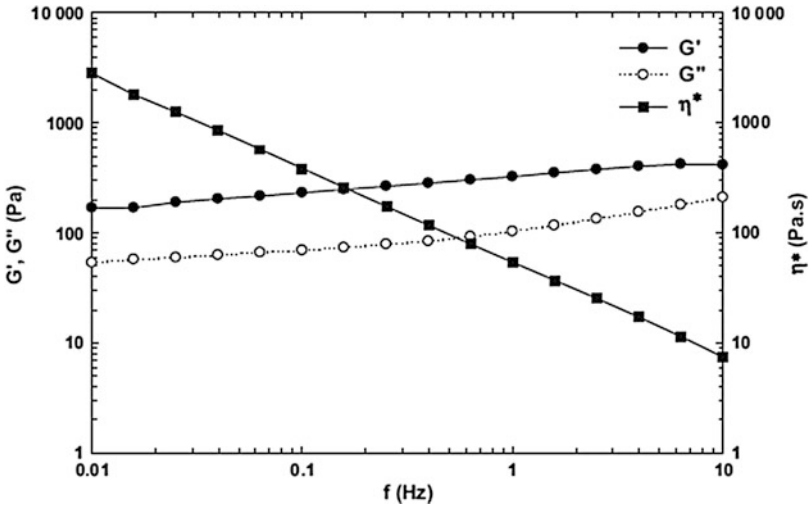

Fig. 2 Frequency sweep of 3% basil seed gum (20 °C; 0.5% strain), showing the variation of storage modulus (G′), loss modulus (G″) and complex viscosity (η*) with frequency (f, Hz) [63]

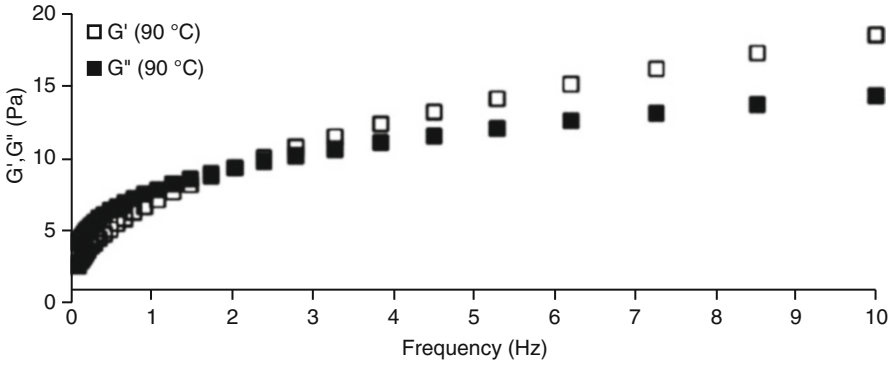

Fig. 3 The mechanical spectra for 1–3 sage seed gum-xanthan gum (1%w/w) at 90 °C [60]

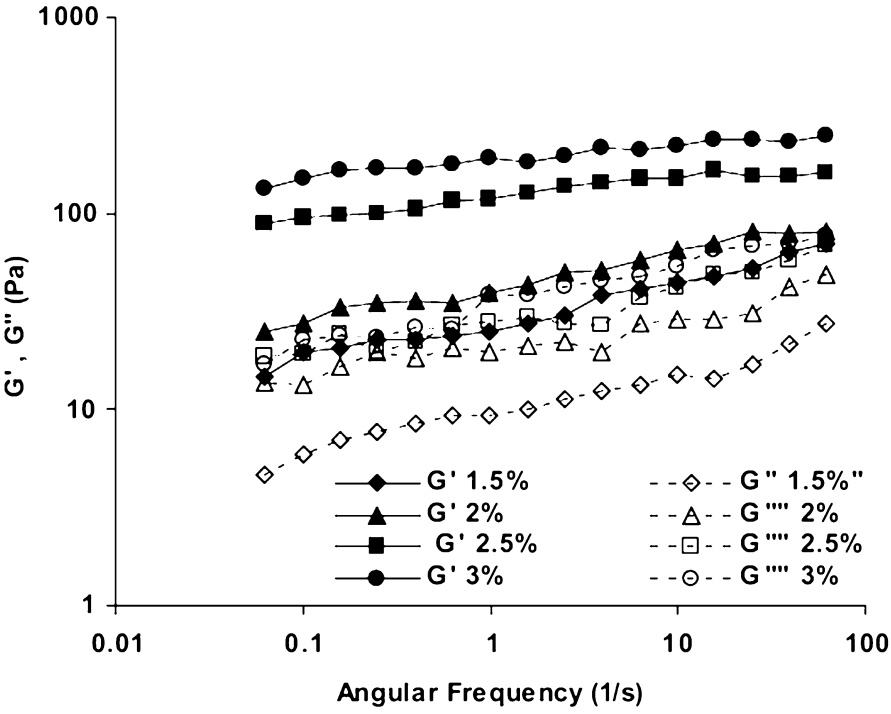

Fig. 4 The typical effect of concentration of *lipidium perfoliatum* seed gum on storage (G′) and loss (G″) moduli as functions of frequency at 5 °C [59]

noncovalence cross-junction [62–64]. However, at higher concentrations, the formation of junction zones increase. With increasing concentration, the values of G′ become higher than G″ (Fig. 4) showing a tendency to form macromolecular networks. This trend was reported for sage seed gum [60], wheat starch gel [51], basil seed gum [58],

Lepidium perfoliatum seed gum [54], gellan gum gels [65], psyllium gels [66], and xanthan gum [61]. It was observed that random coil polysaccharides have no dependency on frequency regardless of temperature [67] like *Lepidium perfoliatum* seed gum [54], mucilage gum of *opuntia ficus indica* [61], and sage seed gum [55].

According to polymer dynamics theory, there is a frequency dependency of G′ values based on power-law relation for a physical gel [68]. Thus, the power-law parameters can be used to describe the frequency dependency of G′ values of food gums:

$$G' = K' (\omega)^{n'} \tag{16}$$

where, ω (rad/s) is the oscillation frequency, K' is a constant, and the exponent n′ is the slope of log-log plot of G' versus ω. From structural perspective, $n' = 0$ is a covalent gel or a true gel, meanwhile for a physical gel, n' is larger than 0. Actually, the n′ value can be used as a criterion to compare a physical gel to a true gel. Lower n' values near to 0 are characteristic of an elastic gel, while n′ values near to 1 are considered as a viscous gel [51]. It was informed that the n' value is connected to the strength and nature of the food gum gel [69]. Some food gums showed decreasing n' with increasing concentration like wheat starch gel [51], *Lepidium perfoliatum* seed gum [54], and basil seed gum [58]; however, sage seed gum [60] showed no effect of concentration on n'. Also, different outcomes were reported for the effect of increasing temperature on n' values. A decrease in n' values was observed in *Lepidium perfoliatum* seed gum [54] and sage seed gum [55], when temperature increases from 5 °C to 85 °C and 10 °C to 50 °C, respectively, while Behrozian et al. [55] reported an increase in n' value for xanthan gum with escalating temperature from 10 °C to 90 °C.

The other dynamic rheological property is loss tangent (tan δ), the ratio of G″/G′, which describes the viscoelastic behavior. Tan δ is directly related to the energy lost per cycle divided by the energy stored per cycle. The values of tan δ <1 and tan δ >1 indicate predominantly elastic and viscous behaviors, respectively. Observations of polymer systems give the following numerical ranges for tan δ: very high for dilute solutions, 0.2–0.3 for amorphous polymers, low (near 0.01) for glassy crystalline polymers and true gels [48]. The *literatures demonstrated decreasing of tan δ with increasing concentration, like Lepidium perfoliatum seed gum* [54]*, psyllium gels* [66]*, and sage seed gum* [60]. With increasing temperature, tan δ changes similar to the n' of food gums mentioned in previous paragraph.

Since food gums are utilized as thickener or stabilizer in food products, the complex viscosity (η*) in frequency dependency becomes prominent. A linear decrease in η* was observed with increase in frequency for some food gums like wheat starch [51], corn starch [70], acorn starch [71], Peruvian carrot starch [45], sweet potato starch [72], sage seed gum, xanthan gum [55], and basil seed gum [56, 58], indicating non-Newtonian shear-thinning flow behavior of them. With increasing temperature, the η* of some gums like sage seed gum [55] and *Lepidium perfoliatum* seed gum [54] increased; however, xanthan gum [55] shows decreasing of η* with rising temperature. Morris [63] nominated that η* with slope near to

−0.76 describes "weak gel" characteristics of a polysaccharide gel formed by overlapping and entangled flexible random coil chains. Basil seed gum and xanthan gum, which generate "weak-gel" networks by tenuous association of rigid and ordered molecular structures in solution, show higher slope of η* than −0.76.

4.4 Time/Temperature Dependency

The melting temperature of a biopolymer could be determined as the temperature when G′ equals G″ (gel-sol transition). This feature easily can be measured by using a controlled stress rheometer in oscillatory mode. Distinguishing the temperature/time dependency of viscoelastic moduli is vital, and this dependency should be recognized when measuring the melting or gelling points [73].

Hesarinejad et al. [54] studied the effect of temperature ramp (5–85 °C) on *Lepidium perfoliatum* seed gum (LPSG) at different concentrations. The LPSG solution showed elastic-like behavior and stayed in the solid-like state in the whole temperature range. An increase in G′ was observed with increasing concentration, which connected to the creation of three-dimensional network structure and also conversion of the sol fraction into gel. Moreover, the thickening effect of gums can restrict the mobility of fluids. It may be clarified by the increase of G′ during heating/cooling, which related to get stronger of hydrophobic interaction with temperature. Also, a hysteresis was observed between heating and cooling curves. Because of the different energy requirements for association and disassociation of junction zones, the thermal hysteresis between gelation and melting occurs [74]. Rafe and Razavi [58] reported an increase in G′ value during heating/cooling (20–90 °C) for basil seed gum (BSG) (Fig. 5). G′ values during cooling were greater than heating; therefore, thermal hysteresis indicates the gel formation of BSG during cooling period [58]. Similar trends were reported in formation and melting of k-carrageenan [75–77] and xanthan-LBG mixture [78]. A decrease of dynamic moduli (G′ and G″) for xanthan gum (1% XG + Nacl (0.08 and 0.008 M)) and gellan gum (0.5%) was observed during heating from 25 °C to 80 °C and 5 °C to 85 °C, respectively. This trend was against the results reported for BSG and LPSG. As mentioned in Sect. 4.2, it may be related to the changing of XG conformation from rigid rod to random coil with increasing temperature.

4.5 Cox-Merz Rule

There is an empirical relationship between the apparent viscosity (η_a) of polymers as a function of shear rate ($\dot{\gamma}$) and the complex viscosity (η*) as a function of frequency (ω) developed by Cox and Merz (1958) as follows:

$$|\eta^*|\ (\omega) = \eta(\dot{\gamma})|_{\omega} = \dot{\gamma} \tag{17}$$

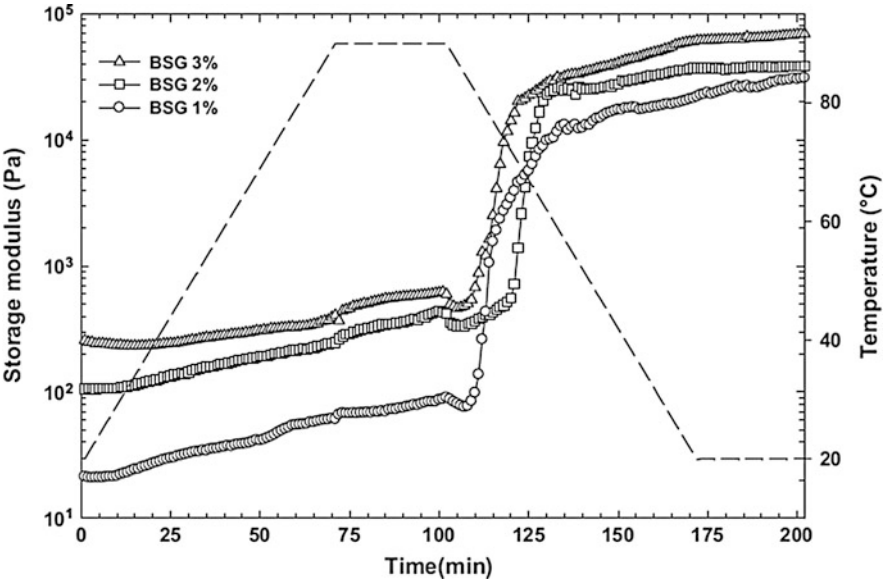

Fig. 5 Variation of storage modulus at different concentrations of basil seed gum as a result of heating (from 20 °C to 90 °C) at rate of 1 °C min^{-1} and holding for 30 min; then cooling to 20 °C with the same rate and keeping at 20 °C for 30 min ($f = 1$ Hz and 0.5% strain) [63]

The *Cox-Merz* rule equates η_a measured in shear flow to η^* measured with oscillatory rheometry, where ω is taken as $\dot{\gamma}$ in the frequency sweep test. It has been proved that the *Cox-Merz* rule can be used to forecast the steady shear properties of a material from the dynamic rheological properties [79]. Dynamic and steady shear flow curves should be the same when polymer solutions are devoid of strong interaction. Opposite to irregular biopolymers, polysaccharide solution with regular chains and rigid conformation that show gel-like behavior do not obey this law like gellan and xanthan gum [80–82]. A typical obey and disobey *Cox-Merz* rule is shown in Fig. 6. LBG and guar gum obey the *Cox-Merz* rule by using shift factor ($\eta^*(\alpha\omega) = \eta(\dot{\gamma})$) [83]. The deviations from *Cox-Merz* rule for galactomannans were reported at low shear rate frequencies [30]. It was related to the creation of high density of entanglements resulted from specific polymer/polymer interaction [84]. However, basil seed gum [56], Salep [83], and sage seed gum [34] disobey the *Cox-Merz* rule, suggesting a self-structured and ordered conformation for these gums.

5 Conclusion

Dilute regime, steady shear, and dynamic rheological properties of some different food gums in different situations were studied. Dilute solution properties of food gums provide deep understanding of molecular properties of their macromolecules in dilute regime and consequently the role of them in final food products as real

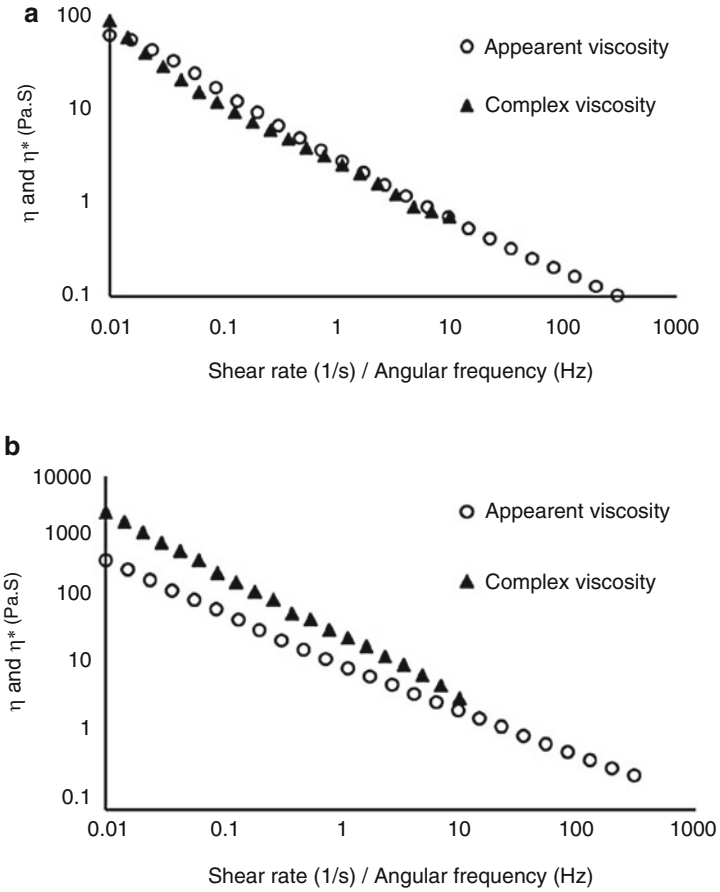

Fig. 6 Cox-Merz plot of complex viscosity (η*) against apparent viscosity (η_a) for SUPER-BSG (**a**) and PF-BSG (**b**). (SUPER-BSG, low molecular weight fraction of basil seed gum; PF-BSG, protein- free basil seed gum) [61]

systems. Also, steady shear and dynamic rheological features of food gums illustrate the high potential of them as thickener, stabilizer, and fat-replacer in food systems. So, knowing rheological features of food gums at different circumstances can help food companies to save time, choose appropriate gum for their food formulations, and produce new products with better mouth feeling.

the isolation, identification, quantification, and analysis of saffron components. Although there are various kinds of chromatographic techniques, more recently a gas chromatography (GC) with a mass spectrometer (MS) detector for the volatile compounds and reversed-phase high-performance liquid chromatography (RP-HPLC) coupled with a UV-Vis detector are the techniques of choice, permitting the isolation on an analytical value and the quantification and identification of the metabolites of interest in saffron. However, this chapter principally conducted the analysis of saffron compounds comprising the aroma and most aroma-active compounds using GC-MS and GC-MS-olfactometry setups and bioactive compounds such as carotenoids, flavonoids, and phenolic compounds using HPLC techniques.

1 Introduction

Saffron (*Crocus sativus* L.) is provided from the dried and dark-red stigmas of flowers belonging to the Iridaceae family. The taxonomic categorization of *C. sativus* is described as follows:

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Asparagales
Family: Iridaceae
Genus: *Crocus*
Species: *sativus*

Among the 85 species of *Crocus* distributed around the world, *C. sativus* is the most expensive at nearly US$50–60 per gram with its characteristic color, aroma, and taste in addition to medicinal features which has received more cultivation interest in numerous countries [1–4]. To produce 1 pound of this valuable crop, nearly 75,000 blossoms of flowers or a number of 225,000 stigmas are required [2].

Regarding the total content of saffron production, the biggest producer in the world is Iran, which has cultivated and traded the spice for centuries around the world. After Iran, Spain, India, Italy, Greece, and Morocco are the main producers [5]. Furthermore, saffron has successfully been cultivated in France, Pakistan, Turkey, Azerbaijan, Egypt, the United Arab Emirates, Japan, and Switzerland, and lately this unique spice has also been introduced to nontraditional areas such as the USA, Chile, Argentina, New Zealand, and Australia [4]. Today, Iran produces approximately more than 90% of the total production of saffron in the world [5, 6].

Saffron (*Crocus sativus* L.) has been applied as a main dietary ingredient in diverse regions worldwide since ancient times; however, over the last decade, saffron consumption has experienced an extensive increase worldwide. The main saffron-importing countries include the USA, Germany, Italy, France, Switzerland, and the UK (International Trade Centre, 2006). Spain also imports large amounts of saffron, particularly from Iran, Morocco, and Greece, for its internal market consumptions and for re-export [7].

Saffron usage historically predates around 3,000 years, covering plenty of cultures, civilizations, and continents [8]. Today, the usage of saffron is well-known not only for coloring and flavoring food agents but also for the therapeutic interests and

even in the mediation of the different health disorders [2]. Moreover, saffron is less widely applied as an ink or dye, especially in the textile, perfume, and cosmetics industries [4, 9]. Saffron provides a luminous yellow-orange color to items soaked with it. The honey with hay-like, green/grassy, and metallic notes is depicted by cooking experts and saffronologists as the descriptors of this unique spice. The taste of saffron is similar that of hay and is bitter [1]. Based on these properties, saffron is extensively applied in the food industry such as baked crops, meat, fish, soups, bread, confectionary and pastry, dairy products, cheese, butter, ice cream, dressings, puddings, sausages, curries, liquors, and alcoholic and nonalcoholic beverages [1]. It is also applied as a good condiment for rice in Iran, India, Spain, and other territories. The abovementioned pleasant interests have been attributed to the diverse chemical compounds with various contents existing in the stigmas of the flower [2].

Overall, saffron can be divided from the point of view of the chemical composition into major and minor fractions. Indeed, along with the present primary metabolites (e.g., fats, carbohydrates, vitamins, and minerals) [10], the saffron plant includes a large number of compounds ascribing to various groups of secondary metabolites such as monoterpenoids, carotenoids, anthocyanins, and flavonoids [7]. Crocetin (a natural carotenoid dicarboxylic acid as a precursor of crocin), crocin (mono-glycosyl or di-glycosyl polyene esters), picrocrocin (monoterpene glycoside precursor of safranal and a product of zeaxanthin degradation), and safranal (Fig. 1) [7] are the four main bioactive compounds in saffron which contribute both organoleptic profile of saffron (pigment, pigment, taste, and odor, respectively) and health-progressing features [11]. There are several literature reviews on diverse aspects of

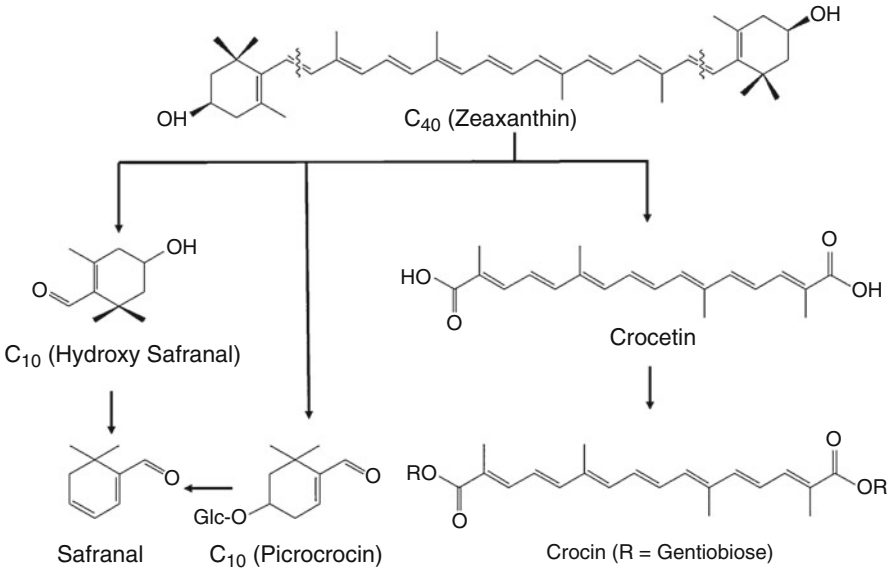

Fig. 1 Commonly admitted hypothesis for the formation of the secondary metabolites in saffron from the zeaxanthin precursor

C. sativus comprising its chemical composition [12, 13]; traditional and modern uses; pharmacology and clinical uses [14]; usefulness in medicine, cosmetics, and coloring industries [14]; reproductive biology [12]; production and distribution [15]; and cultivation, harvesting, processing, and yield [1].

Isolation, identification, and quantification of bioactive compounds from complex and natural matrix of foodstuffs are a primary challenge of initial interest in food quality measurement and characterization. The perception of the composition in saffron matrix has received more attention in last decades. Therefore, due to the complicated structure of saffron matrix, there are challenges for the extraction, isolation, identification, and quantification of its chemical profile. Chromatography is a set of constituents' separation techniques in a complex mixture. Recently, chromatographic methods were widely used for the isolation, identification, quantification, and analysis of saffron components. However, this chapter principally focuses on the gas chromatography (GC) and high-performance liquid chromatography (HPLC) techniques conducted to analysis of saffron compounds.

2 Saffron Chemistry

The proximate analyses of the chemical composition in saffron regarding dried and red stigmas of the flower have been disclosed by weight (% w/w), including 10% moisture, 12% protein (N*6.25), 6% inorganic matter (ash), 6% nonvolatile oils, 1% volatile oils, 5% crude fiber, and 53% water-soluble matters comprising 14% sugars, 10% gums, 8% pentosans, 6% pectin, 6% starch, 2% α-crocin, and 1% other carotenoids [10, 16, 17]. Additionally, trace elements of thiamine and riboflavin vitamins have been found in saffron [11]. The amounts of all chemical compounds in saffron may alter considerably because of growing situations and geographical origin [9].

The quality of saffron is determined by its common combination of intense red color, aromatic smell, and bitter taste [14]. The literature data shows the red stigmas of the saffron flower involve three major metabolites: (1) crocins being saffron-colored compounds (uncommon water-soluble carotenoids because of their elevated glycosyl extents), (2) picrocrocins being the principle constituents responsible for bitter taste of saffron, and (3) safranal being a volatile compound responsible for the unique aroma of saffron [4, 11, 13]. High-quality saffron is composed of approximately 30% of crocins, from 5% to 15% of picrocrocin, and generally up to 2.5% of volatile compounds involving safranal [14].

The word saffron probably originates from the Persian word sahafaran derived from asfar which means yellow or white to redden [7]. This name mentioning the elevated concentration of carotenoid pigments existing in the stigmas of the flowers contributes mostly to the profile of color in this unique spice [2]. Both lipophilic and hydrophilic carotenoids were reported in saffron [18]. A number of lipophilic carotenoids have been reported comprising trace extents of lycopene, α- and β-carotene, zeaxanthin, phytoene, and phytofluene, being the oil-soluble color pigments in saffron [10, 19]. From the hydrophilic carotenoids, crocins are either

mono- or di-lycosyl polyene esters of crocetin in which D-glucose and/or D-gentiobiose happen as carbohydrate residues [20, 21].

α-Crocin (crocin 1), a digentiobioside, is the most predominant crocin with an elevated solubility which is ascribed to these sugar moieties. Crocin with deep red pigment promptly dissolves in water to generate a solution with an orange color, thereby introducing crocin extensively applied as a natural food colorant. Apart from this feature, crocin also has an antioxidant properties such as free radical quenching and cells and tissues protecting against oxidation [22–24].

The bitter taste of saffron comes from picrocrocin, the β-D-glucoside of hydroxysafranal (4-hydroxy-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde), being the second most predominant compound (by weight), altering between 1% and 13% in dry matter of saffron [13, 18]. Its structure was first reported by Kuhn and Winterstein [25]. The stereochemistry at the chiral center of the aglycone moiety was identified to be (4*R*) [26] being in relationship with the chirality of its assumed precursor, the carotenoid zeaxanthin. The hypothesized bio-oxidative cleavage of zeaxanthin gave rise to picrocrocin and crocin, the intensively water-soluble pigment of saffron [19]. During the drying process, high temperature and/or the action of glycosidases willingly changes picrocrocin into the aroma-active safranal [19].

Saffron's aroma profile is relatively complicated, originating principally from safranal (2,6,6-trimethyl-1,3-cyclohexadiene-1-carboxaldehyde) [27]. The stigmas of saffron freshly picked are practically odorless, containing the ordinary saffron flavor being promoted during the drying process. Safranal is particularly generated throughout the bitter glycoside picrocrocin hydrolysis by the enzymatic activity, the reaction producing safranal, and D-glucose. Along with picrocrocin, there are several other glycosides that might undergo the dehydration to produce a mixture set of compounds, which includes the volatile profile of saffron. Safranal and these further dehydration products might undergo other degradation to produce other volatile compounds [28].

Apart from safranal, 2,6,6-trimethyl-1,4-cyclohexadiene-1-carboxaldehyde (an isomer of safranal), 3,5,5-trimethyl-2-cyclohexen-1-one (isophorone), 3,5,5-trimethyl-3-cyclohexen-1-one (an isomer of isophorone), 2,6,6-trimethyl-2-cyclohexene-1,4-dione (4-ketoisophorone), 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one, 4-hydroxy-2,6,6-trimethyl-1-cyclohexen-1-carboxaldehyde (HTCC), and 2,2,6-trimethyl-1,4-cyclohexanedione are also significant aroma compounds in saffron [29]. From these compounds, safranal contributes about 30–70% of volatile oil and 0.001 to 0.006% of dry matter [5, 30]. In addition to its common spicy aromatic features, safranal has also demonstrated an elevated antioxidant capacity [22, 31] as well as cytotoxicity toward certain cancer cells in vitro [32].

3 Chromatographic Methods

Chromatography is described as an array of techniques applying for the isolation of analytes in a structure. There are two phases in this technique, namely, the stationary and mobile phases. The isolation of analytes is due to the diversity between partition coefficients of the two phases. Chromatography is the most well-known and

extensively applied analytical technique. Nevertheless, the possibility of the isolation in every compound in a complicated instance when applying a one-dimensional (1-D) isolation procedure has been appraised as varying between 19% and 37%, in a random mix, belonging to the complication and compound purity demanded [33].

Though one dimension of isolation represents adequate resolution for a large number of instances and analytical issues, a considerable number of applications still necessitate that the promoted resolution potency be utilized more than that supplied via a single dimension. In these situations, the isolation potency could be increased by applying more than one mechanism or isolation technique. Multidimensional chromatography is an isolation technology that applies two orthogonal isolation mechanisms to enhance the resolution potency and peak capacity of an experiment by raising the experiment selectivity.

Multidimensional chromatography itself could be divided into two groups: (1) only certain parts from the first dimension are introduced into a second dimension for other isolation, named multidimensional chromatography, 2-D, [34], and (2) every part eluting from the first dimension is introduced into the second dimension for further isolation named comprehensive multidimensional chromatography [35]. The technology could be led not only in the gas phase, 2-D comprehensive GC (GC × GC) but also in the liquid phase, LC × LC. A third dimension of information could be coupled by applying the information-rich detection setups, including a mass spectrometer [36–38].

Application of these and other techniques is almost accompanied by an enhancing number of biological instances needing prompt quantitative analysis, along with a decrement in the eligible quantitation amounts, as the bioavailability of plenty of analysis is at a low level and thus objective concentrations are very low. Therefore, suitably designed, quick, useful, and sensitive bioanalytical techniques are required. Usually a reliable bioanalytical technique, which is convenient for an intended target, should accomplish the requirements of validity guidelines such as precision, accuracy, sensitivity, selectivity, stability, and reproducibility [39]. There are various kinds of chromatographic techniques, comprising paper chromatography, gas chromatography, thin-layer chromatography, ion-exchange chromatography, liquid chromatography, and high-performance liquid chromatography. More recently, reversed-phase high-performance liquid chromatography (RP-HPLC), equipped with a UV-Vis detector or, more often, a gas chromatography (GC), with a mass spectrometer (MS) detector for the volatile compounds [29, 40, 41] and UV-Vis-DAD for nonvolatile compounds [42], is the method of choice, allowing the separation on an analytical level and the identification and quantification of the metabolites of interest [7]. Therefore, this work principally focuses on the application of the GC and HPLC in saffron spice as a food ingredient.

3.1 Gas Chromatography (GC)

The types of analysis that could be performed by GC are extensive. GC has been utilized for the determination of cholesterol and other sterols, triglycerides, fatty acids, gases, alcohols, solvent analysis, water and simple sugars, as well as vitamins,

amino acids and peptides, oligosaccharides, herbicides, pesticides, food additives, nitrosamines, antioxidants, drugs, polychlorinated biphenyls (PCBs), volatile compounds, and so forth. The fact that GC has been employed for these diverse applications does not necessarily mean it is the most suitable technique as better selections are often present.

GC is commonly suitable for the analysis of thermally stable volatile compounds. Compounds that do not meet these requirements such as vitamins, peptides, amino acids, oligosaccharides, and sugars are more suitable for the analysis by a technique comprising supercritical fluid chromatography (SFC) or high-performance liquid chromatography (HPLC).

Saffron volatile compounds can be categorized into two groups. The first group includes compounds which have structures that bear an explicit similarity to that of safranal and are disclosed also as isophorone-related compounds (C9 and C10 group of compounds) [40, 43]. These compounds are 4-ketoisophorone, isophorone, 2,2,6-trimethyl-1,4-cyclohexanedione, 4-hydroxy-3,5,5-trimethyl-2-cyclohexen-1-one, 2-hydroxy-3,5,5-trimethylcyclohex-2-en-1,4-dione, 4-hydroxy-2,6,6-trimethyl-1-cyclohexen-1-carboxaldehyde, and 4-hydroxy-2,6,6-trimethyl-3-oxocyclohexa-1,4-diene-1-carboxaldehyde. The second group includes C_{13}-norisoprenoids. These compounds are formed from lipophilic carotenoids [40]. These compounds are 3-[(*E*)-but-1-enyl]-2,4,4-trimethylcyclohex-2-enol, *E*-4-(2,6,6-trimethylcyclohexyl)-but-3-en-2-one, (*E*)-4-(2,6,6-trimethyl-7-oxa-bicyclo-[4.1.0]-heptan-1-yl)-but-3-en-2-one, and 3-(but-1-enyl)-2,4,4-trimethylcyclohexan-1-ol.

Moreover, the profile of the volatile compounds that are acquired is highly related to the extraction techniques that are utilized for the separation [29, 30, 44]. The number of volatile compounds has been detected in saffron spice achieved over 160 [5, 30]. Nevertheless, it is known that only a trace part of the numerous volatile compounds occurring in food indeed contributes to the overall aroma. Hence, a significant function in flavor investigations is to isolate the powerfully aroma-active compounds from the less odorous or odorless compounds existing in food [45].

Separation of the volatile compounds in saffron could be obtained by numerous extraction methods prior to the gas chromatography analyses [46]. In order to specify which compounds contribute significantly to the aroma of a crop or which compounds are responsible for the variations between the aromas of two crops, it is essential to ensure that the extraction technique supplies an extract with an aroma that is representative of the main crop. The GC system could be equipped with three different detectors such as (i) a mass selective detector (MSD), (ii) flame ionization detector (FID), and (iii) sniffing port (olfactometric detection). This system can provide an opportunity to simultaneously achieve an MS signal for the identification, an FID signal for the quantification, and the odor characteristics of each compound discovered via the sniffing port [46].

3.1.1 Sample Preparation Techniques Prior to GC Analyses

Preparation of sample affects almost all the later trial stages and is therefore critical for unerring qualification, confirmation, and quantification of compounds. It consists

of both the separation and pre-concentration of compounds of interest from different matrices as well as making the compounds more appropriate for isolation and identification. As analytical chemistry flourishes, gentle preparation of the sample becomes a main section of analysis, generally consuming up to 80% of the total analytical analysis time, including five stages, which are sampling, preparation of sample, isolation, identification, and data analysis [47].

While chromatographic techniques are contributed in the organic molecules analysis, preparation of the sample in bioanalytical techniques usually utilizes solid-phase and liquid-liquid extractions. Despite ultra-prompt chromatographic analyses, prevalent sample preparation methods are still more laborious and time-consuming due to an abundant number of stages.

Subsequently, sample preparation has increasingly progressed over the last few years [39, 47]. Development in analysis methods has led to numerous volatile compounds detected in foods [48]. Over the last few decades, serious investigations have been performed based on the organoleptic activity of the individual odor compounds of foods and beverages and the affiliation between the odor and the composition of the volatile section of these products. Most of the achievements within this field could be ascribed to the coupling of GC with olfactometric detection [49].

Determination of aroma compounds applying instrumental techniques includes two steps. The first and most important step of the analysis is isolation of the constituents from the food matrices. The genesis of the olfactograms extensively links to the separation process, as several comparative investigations disclosed that the utilization of various sample preparation methods (even employing diverse solvents in the case of liquid-liquid isolation) may impact the composition and amounts of the separated compounds [50–52]. The extract separated should be representative; therefore, the selection of a suitable sample preparation process is very important [53, 54].

Separates acquired utilizing perfect extraction techniques, comprised of distillation and solvent extraction, do not always reverberate the composition of the aroma reaching the aroma and taste receptors through drinking and eating. It ought to be emphasized that only some of the volatiles measure up to the characteristic aroma of food and beverages. The volatile fraction composition of the food products could vary belonging to the solubility of the compounds and the features of the matrices such as the amount of sugar.

Subsequently, it is more advantageous to employ separation techniques which reverberate the volatile compounds' liberation from the matrix rather than ascertaining the overall amount of such compounds, as this facilitates the correlation with organoleptic analysis outcomes. Both dynamic and static headspace methods could be utilized for this target; nevertheless, due to the feasibility of compound enrichment, dynamic techniques are applied widely [55].

The prevalent condition and last developments in sample preparation techniques were completely reviewed by [47]. The current review discussed some of the aroma extraction techniques used in saffron sample studies up to now, simultaneous distillation/extraction (SDE) and solvent-assisted flavor evaporation (SAFE) [46],

steam distillation (SD) [29], stir bar sorptive extraction (SBSE) [56], hydrodistillation (HD), microsimultaneous hydrodistillation-extraction (MSDE) [40, 56], vacuum headspace (VHS) [29], liquid-liquid extraction (LLE) [58], supercritical fluid extraction (SFE) [57], ultrasonic solvent extraction (USE) [60], and solid-phase microextraction (SPME) [59], described below in details.

Steam Distillation (SD)

Steam distillation is a remarkable technique which allows for the separation of volatile compounds from plants comprised of some amines, organic acids, and volatile oils, as well as relatively volatiles, insoluble in water (Fig. 2). Furthermore, steam distillation has been utilized to separate the volatile oil fraction from both plant material and a previously provided extract in a solvent with low boiling points such as diethyl ether or petroleum ether [61]. This method contains shortcomings, as it requires considerable energy consumption. A high temperature (ca. 100 °C) might result in the thermal decomposition of compounds. This could also impact the volatile oil compounds, thus causing flavor alterations [62].

Tarantilis et al. [29] investigated the volatiles of the dried and dark-red stigmas of saffron. For the separation of the aroma, they applied three distillation techniques such as micro-steam distillation extraction (MSDE), steam distillation (SD), and vacuum head space method (VHS) for the output to the extraction of representative volatile composition of saffron, and their results presented some qualitative variations among the three extraction techniques which revealed 16, 13, and 8 compounds, respectively [29].

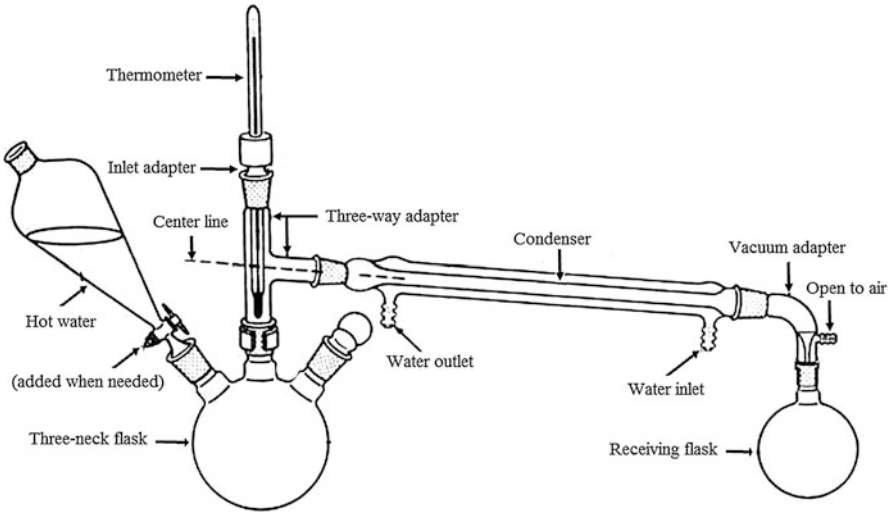

Fig. 2 A schematic exhibition of a steam distillation extractor

The abovementioned techniques disclosed the major characteristic compounds including 2,6,6-trimethyl-1,3-cyclohexadien-1-carboxaldehyde, namely, safranal (ca. 70% of the material in the extract); 3,5,5-trimethyl-2-cyclohexen-1-one, namely, isophorone (ca. 14%); 3,5,5-trimethyl-3-cyclohexen-1-one, isomer of isophorone (ca. 5%); 2,6,6-trimethyl-2-cyclohexene-1,4-dione (ca. 4%); and 2,6,6-trimethyl-1,4-cyclohexadiene-1-carboxaldehyde, isomer of safranal (ca. 3%). Plenty of volatile compounds (ca. 1–0%) were also available.

The intensive statuses of the SD technique formed substantially more elevated boiling point compounds than in the saffron main aroma. Numerous such compounds are presumably artifacts, including 2,6,6-trimethyl-1,3-cyclohexadien-1-carboxylic acid. This compound may have resulted from oxidation of safranal during the separation. Furthermore, this means that safranal as are all aldehydes is simply oxidized, especially when subjected to the elevated temperatures confronted through SD.

It is important to note that the steam distillation technique is sorely inappropriate for the determination of the volatile compounds in saffron due to the existence of carotenoids. Numerous volatiles in the concentrate were likely the degradation compounds of saffron carotenoids forming from the action of heat and oxygen on these ingredients [29, 63].

The MSDE technique formed both low and high boiling point compounds. This technique was less intensive than that of the SD technique. Therefore, odorants comprising 3,7-dimethyl-1,6-octadiene generated through the thermal degradation of carotenoids existed [29]. The eight compounds determined through the VHS technique were also discovered in the volatile oil formed by the two other techniques. Many of these compounds were the safranal and isophorone derivatives. Additionally, only the isomer of isophorone (3,5,5-trimethyl-3-cyclohexen-1-one) was not detected. It is hypothesized that the VHS extraction more resembled MSDE rather than SD [29].

Zareena et al. [64] investigated the effect of γ-irradiation at doses of 2.5 and 5 kGy, obligatory for the decontamination of microbes, in aroma features of saffron using the steam distillation extraction techniques. According to their outcomes, no significant qualitative alterations were detected in the aroma compounds upon the irradiation, though a trained panel in the sensory analysis can find slight quality deterioration at a dose of 5 kGy. They observed that the control samples, safranal, composed of the main compound detected, accounting for 30% of the oil, being far lower than the reported data values (60–70%). Ketoisophorone (3%), α-isophorone (5%), 2,4,4-trimethyl-3-carboxaldehyde-5-hydroxy-1-cyclohexanone-2,5-diene (3.4%), and dihydro-beta-ionone (3.71%) were the further main compounds determined in oil [64].

According to earlier reports [29], intensive situations are utilized in the SD and MSDE techniques terminated in the volatile oil over-enriched with elevated boiling point compounds due to the degradation of low boiling-sensitive compounds. Zareena et al. [64] reported that these kinds of impacts, besides the source or origin of instance, can account for the low amount of safranal. They reported that no

detectable qualitative variations in the volatile compounds can be detected between the irradiated and control samples.

Liquid-Liquid Extraction (LLE)

Solvent extraction technique utilizes nonpolar solvents being solvable with water to isolate the target compound from water by applying more solubility of the target compound in the solvent than water. Preferably, one selectively extracts the purpose compound by applying a solvent whose polarity is close to that of the purpose compound. Volatile solvents including benzene, hexane, ether, dichloromethane, and ethyl acetate are commonly employed for the separation of semi-volatile compounds from water. Hexane is appropriate for extraction of nonpolar compounds including aliphatic hydrocarbons; benzene is appropriate for aromatic compounds; and ether and ethyl acetate are appropriate for relatively polar compounds consisting of oxygen. Dichloromethane has high efficiency extracted for an extant range of nonpolar to polar compounds. It is appropriate for simultaneous analysis due to the following advantages: its boiling point is low and simple to reconcentrate after extraction, it is simple to isolate from water owing to its more elevated specific gravity, and it is nonflammable.

However, dichloromethane, like benzene, is carcinogenic, and the current consensus is to avoid utilizing these solvents in liquid-liquid extractions. Indeed, despite its simplicity, the modern trend is to replace LLE by other techniques because high-purity solvents are demanded for small analysis and due to the need to diminish the environmental and health risks associated with their manipulation. Furthermore, in the case of biological aroma, LLE cannot be applied to live samples [65]. Cadwallader et al. [66] used the LLE method for extracting aroma compounds of the Spanish "Mancha Superior" and compared it with the SDE method. The explanation of the comparison of these two methods was described in detail in Sect. 3.1.1.3. Additionally, Amanpour et al. [46] utilized the LLE method for the isolation of the aroma compounds in the Iranian saffron in a representative study.

Simultaneous Distillation-Extraction (SDE)

Simultaneous distillation-extraction (SDE) is a prevalent distillation-based sample preparation technique for aroma, which is well-known as the Likens-Nickerson technique (Fig. 3). An extent of the aroma-forming sample (e.g., sliced plant tissue, beverage, food), together with distilled water for dry samples, is subjected in flask II, and flask III attains an appropriate bulk of an extracting solvent more condensed than water (e.g., chloroform, dichloromethane). Flasks II and III are heated; then the water and solvent vapors are led to the extractor body, where they compress through the surface of cold tube IV [67]. In the procedure of this technique, aroma compounds are separated from the food matrices via the water vapor and transferred to the organic phase when the liquids condense together on the cold tube. Solvent and water are gathered together in the extractor body after their condensation and return to the corresponding functions, premising consecutive reflux. A modified apparatus provided an opportunity to use solvents lighter than water comprised of pentane or ethyl acetate as extractors [67].

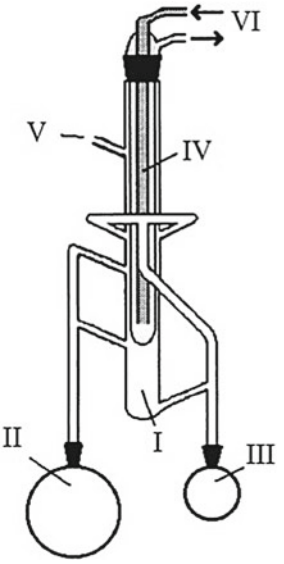

Fig. 3 A schematic shape of Likens-Nickerson apparatus/ simultaneous distillation-extraction extractor

This technique has been employed for separating the volatiles in saffron [40, 68]. Cadwallader et al. [66] separated volatile compounds from Spanish "Mancha Superior" saffron by two different methods such as SDE and LLE extraction. A total of 46 volatile compounds were determined. Among the detected volatiles, a total of 30 volatile compounds were common to both extracts, the LLE and SD. 2,6,6-Trimethyl-l,3-cyclohexadiene-l-carboxaldehyde (safranal) was the most prevailing volatile compound, followed by 3,5,5-trimethyl-2-cyclohexen-l-one (isophorone) and 2,6,6-trimethyl-2-cyclohexene-l,4-dione [68]. The concentrations of safranal were analogous to reported studies [69]. Moreover, the relative abundances (based on the safranal) for dominant volatile compounds were in proper agreement with former investigations [40, 43, 68]. Despite the agreement with reported data, volatile compounds of extracts using the SDE and DE techniques are altered from each other with regard to amounts of main volatile compounds as well as in the kinds of volatile compounds determined. LLE was released for the separation of acidic compounds (acetic acid, 2-methylpropanoic acid, and hexanoic acid), while no acids were found in the SDE extracts. Additionally, SDE extracts included higher amounts of main saffron volatile compounds such as 3,5,5-trimethyl-2-cyclohexen-1-one (isophorone), 2,6,6-trimethyl-1,3-cyclohexadiene-1-carboxaldehyde (safranal) and 2,6,6-trimethyl-2-cyclohexene-1,4-dione. Elevated amounts of these compounds might have been an outcome of thermally induced hydrolysis of their glucoside precursors over SDE [43].

Additionally, it is probable that further thermally formed compounds were generated over SDE. For instance, the sugar breakdown products such as

5-methyl-2-furancarboxaldehyde and 2-furancarboxaldehyde were only found in the extracts using SDE technique. SDE extracts also included four megastigmatriene isomers (megastigma-7,9,13-triene, megastigma-4,6,8-triene isomer, megastigma-4,6,8-triene isomer, and megastigma-4,6,8-triene isomer), which have been formerly disclosed as volatile compounds of star fruit [68]. In addition to this research, Amanpour et al. [46] studied the Iranian saffron volatile compounds, and they used four different extraction methods in a representative study which included SDE and LLE methods described in detail in Sect. 3.1.1.10.

Ultrasonic Solvent Extraction (USE)

Ultrasonic solvent extraction includes the application of elevated intensity, elevated frequency sound waves, varying between 16 kHz and 1 GHz, and their interaction with materials [9]. Indeed, ultrasonic vibrations are the energy facilitating source to liberate some compounds from the sample matrix [70]. USE is a common technology as it does not demand complicated instruments and is normally inexpensive (Fig. 4) [71]. It can be applied both in large and small scale [72]. USE comprises ultrasonic impacts of acoustic cavitation. As for the ultrasonic action, liquid and solid particles are vibrated and accelerated, and owing to that solute swiftly diffuses out from solid phase to solvent [68]. Numerous feasible mechanisms for ultrasonic increment of extraction, comprising cell disruption, developed penetration and increased swelling and capillary impact, and hydration procedure have been proposed [73]. If the severity of ultrasound is enhanced in a liquid, then it attains at a point at which the intramolecular powers are not able to hold the molecular structure intact, so it breaks down and bubbles are generated; this procedure is named

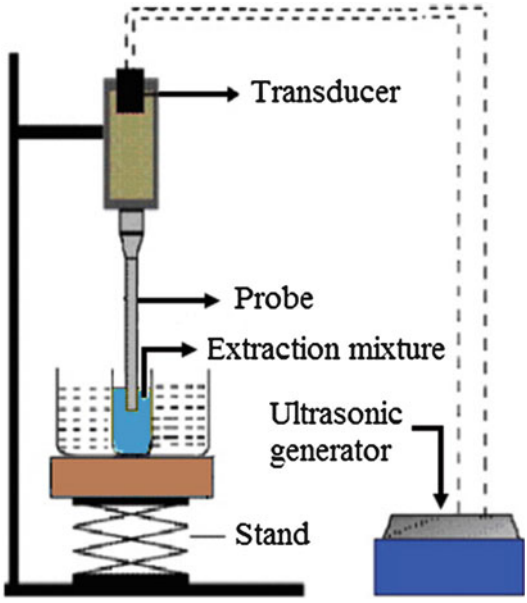

Fig. 4 A schematic exhibition of UAE setup

cavitation. Collapse of bubbles can generate physical, chemical, and mechanical impacts which terminate in the disruption of biological membranes to facilitate the liberation of extractable compounds and increase penetration of solvent into cellular materials and progress mass transfer [68, 74].

The useful impacts of sound waves on extraction are ascribed to the generation and asymmetrical collapse of micro-cavities near the cell walls leading to the formation of micro-jets rupturing the cells. The bubbles' pulsation is believed to result in acoustic streaming which develops a mass transfer rate by inhibiting the solvent layer surrounding the plant texture from attaining saturated and therefore development of convection [75]. The skin of external glands of the plant cell wall is very thin and could be readily ruined by sonication which liberates the volatile oil amounts into the extraction solvent, hence causing decreased extraction time and enhanced extraction output [76].

Jalali-Heravi et al. [60] studied the volatile compounds of Iranian saffron via the USE technique applying GC-MS. Variables impacting the extraction process were screened by applying a 25–1 fractional factorial scheme and between them; sample content, volume of solvent, solvent ratio (in binary mixture of solvents), and time of extraction were optimized by using a rotatable central composite scheme. The best levels of factors were 2.38 g instance, 29.04-mL solvent, 69.23% MeOH solvent ratio, and 71.8 min for the time of extraction. A total of 40 compounds were determined for Iranian saffron using GC-MS, accounting approximately 90% of the total peak area. The main compounds were safranal (26.29%); bicyclo[3,2,0] hept-2-ene-,4-ethoxy-,endo (5.69%); linoleic acid (4.77%); 4-hydroxy-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde, namely, HTCC (4.44%); and non-adecanol (3.32%) [60].

Maggi et al. [5] designed a comparative study to analyze the 418 commercial saffron instances depending on diverse ISO classes. UAE with an organic solvent and dynamic headspace desorption followed by gas chromatography/mass spectrometry were employed to characterize for the volatile profile of saffron. For both techniques, the saffron aromatic composition was specified by spicy aromatic features because of safranal, the most predominant volatile compound, by a flowery contribution imputable to 2,2,6-trimethyl-1,4-cyclohexanedione and isophorone, together with spicy and citrus aromatic features from 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one and 4-ketoisophorone, respectively. UAE permitted the discovery of a more number of volatiles, whereas the dynamic headspace technique was faster and a fewer amount of saffron was demanded. Compared with the ultrasound-assisted extraction technique, the dynamic headspace technique specified the instances as possessing a spicier and more floral aromatic contribution, hence corroborating that the isolation technique remarkably alters the aromatic fingerprint of saffron instances.

Maggi et al. [77] assayed the saffron quality control by using UAE of safranal optimizing on the basis of the solvent, diethyl ether, hexane, and chloroform, the extraction time, and the saffron concentration in each organic solvent. The most suitable extraction conditions were acquired when 20 g/L of saffron was extracted with chloroform for 15 min. The comparison of safranal content acquired from 40

saffron instances by applying the UV-Vis is based on the ISO 3632 (2003) and previously reported technique (Maggi et al., 2009). There was no correlation between the safranal content acquired by ISO 3632 (2003) and validated GC technique, because there are further compounds existing in saffron absorbing at 330 nm, comprising the isomers of *cis*-crocetin esters [77].

Supercritical Fluid Extraction (SFE)

The SFE technique penetrates plant materials approximately as well as gases, and this is caused from their low viscosity and elevated diffusion coefficients. SFE is employed at temperature close to ambient, hence inhibiting the material from causing in thermal denaturation [78]. SFE is a well-known method of solvent extraction; however, its commercial application occurred gently because of the sophisticated and expensive high pressure equipment and technology demanded [78]. Simultaneously, their dissolving potency is similar to that of liquids. However, the desired transport features of fluids near their critical points permit deeper infiltration into solid plant matrix and more efficient and faster extraction than with conventional organic solvents [9]. The most widely utilized isolating agent is carbon dioxide (CO_2), due to its low price, low toxicity, and desired critical parameters ($Tc = 31.1$ °C, $Pc = 74.8$ atm). CO_2 as a nonpolar material is able of dissolving nonpolar or mildly polar compounds. An admixture of CO_2 with modifiers (polar organic solvents) is applied for extracting the polar materials. The modifiers enhance the solubility of compounds, preventing them from adsorption on the active sites of sample matrix. The most substantial advantages of SFE involve the following: remarkable decrement in the bulk of solvent utilized, decreased the time of extraction, automation facility, the trace amount of instance demanded, feasibility of online coupling with the isolation and identification methods (SFE/HPLC, SFE/GC), elevated purity and trace bulk of the extract, and elevated selectivity [70]. SFE is moderately efficient even for compounds with compact and extremely available mixture. It is particularly well adjusted for the separation of materials of low and medium polarity and elevated volatility. As a rule, carbon dioxide or carbon dioxide with a volatile polar modifier, comprising methyl diethyl ether, acetate, methanol, ammonia, or formic acid, is applied as supercritical fluids [70]. A supercritical fluid extraction system is demonstrated in Fig. 5 [79].

Lozano et al. [80] have developed a supercritical carbon dioxide extraction technique to acquire selectively volatiles of saffron without sample destruction. The impact of both temperature and pressure was investigated, 100 °C and 20 MPa being the most appropriate situations to isolate the total safranal amount. A reduction in supercritical fluid density was demonstrated to be a crucial factor for increasing the extraction potency of carbon dioxide. For all the experiment circumstances, the extracts principally concluded HTCC and safranal, as indicated by GC and HPLC techniques. Both chromatographic techniques were appropriate for safranal quantification and exhibited perfect compromise.

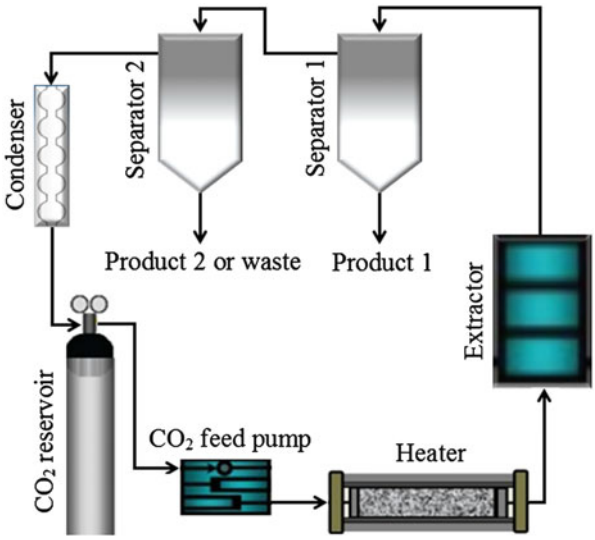

Fig. 5 Supercritical fluid extraction setup

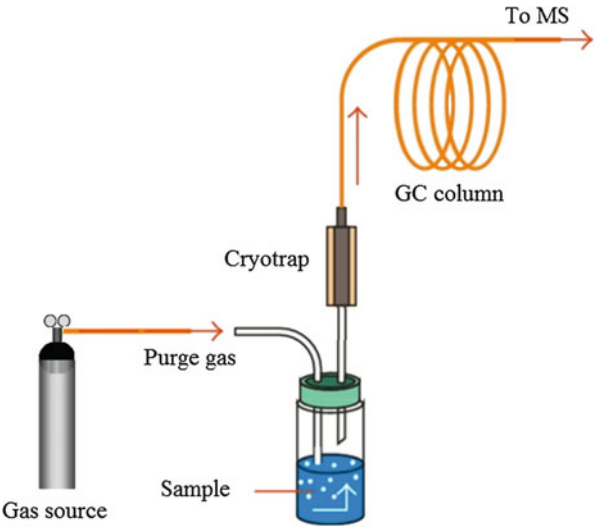

Fig. 6 Purge and trap extraction system

Purge and Trap Extraction (PTE) System

The purge and trap system is also referred to as the dynamic headspace method (Fig. 6) that diminishes matrix impacts and enhances sensibility, respective to static headspace methods. Instances including volatile compounds are subjected into a purge vessel, and a flow of inert gas such as nitrogen or helium is passed over the instance to remove the volatiles from the instance matrix at a steady flow rate for a determined time. Volatiles are desorbed from the instance into the headspace

(purged) above the instance and are then isolated from the stream of gas (trapped) by adsorbent filters.

After the process of purging is complete, the trap is quickly heated and back-flushed with carrier gas such as pure helium to desorb and transfer the compounds to the column of GC. Typical trapping (adsorbent) materials are activated charcoal, porous polymer beads, silica gel, further GC column packing materials, or combinations of such materials [65].

Cullere et al. [81] evaluated the aroma profile of a saffron instance from Valle de Jiloca (Teruel, Spain) by applying a purge and trap technique prior to GC-O. The LiChrolut EN cartridge (400 mg) was subjected on the top of a bubbler flask including 10 g of saffron. This instance was purged by a stream of nitrogen at ambient temperature for 4 h. Volatile compounds of saffron transferred in the headspace were trapped in the cartridge including the sorbent, and others were eluted with 3.2 mL of dichloromethane including 5% methanol.

Solid-Phase Microextraction (SPME)

Pawliszyn and Arthur [82] improved the SPME technique as a solvent-free technique concerning the sorption (adsorption-absorption) generality. Though it is a balance (non-comprehensive) technique, SPME was swiftly admitted as an easy, green, and miniaturized technique, which merges sampling, extraction, concentration, cleanup, and instance presentation in a solitary stage. Regarding its efficiencies, SPME rapidly became one of the 204 most extensively employed methods in different fields of analytical chemistry, involving environmental and biological applications [82]. Analyte enrichment by SPME has two stages. In the first stage, a fiber, coated with an adsorbent or stationary liquid, is exposed to a liquid sample, or the headspace above a sample and the analytes are sorbed on the fiber. In the second stage, the fiber is presented into the injection chamber of a gas chromatograph, where it is introduced to a high temperature or it is subjected into the injector of a liquid chromatograph. The liberated analytes are swept into the chromatographic column.

According to the position of the fiber coating in the extraction setup, the extraction techniques are categorized commonly into two modes: direct immersion (DI, the coating is completely immersed in the sample matrix) and headspace (HS, the coating is exposed to the gas phase above the sample matrix) modes. Solid-phase microextraction device is shown in Fig. 7. SPME is a sample preparation technique most suited for gas chromatography. Though SPME has been successfully mixed with HPLC, this needs moderately complex processes and supplementary devices. Hence, it could be anticipated that the method will be applied frequently with GC [9].

Auria et al. [59] analyzed the three saffron samples from various regions of Italy (Salerno, Sardinia, and Abruzzo) and one sample from Iran using SPME-GC/MS. They reported that the major compounds were those detected in ethereal extract of saffron in a study disclosed in 1971. Numerous compounds detected by applying further extraction-distillation methods were not detected. They detected 18 volatiles never found in saffron. In all the saffron samples, 3,5,5-trimethyl-2-cyclohexen-1,4-dione, 3,5,5-trimethyl-2-cyclohexen-1-one, 2,4,4-trimethyl-6-

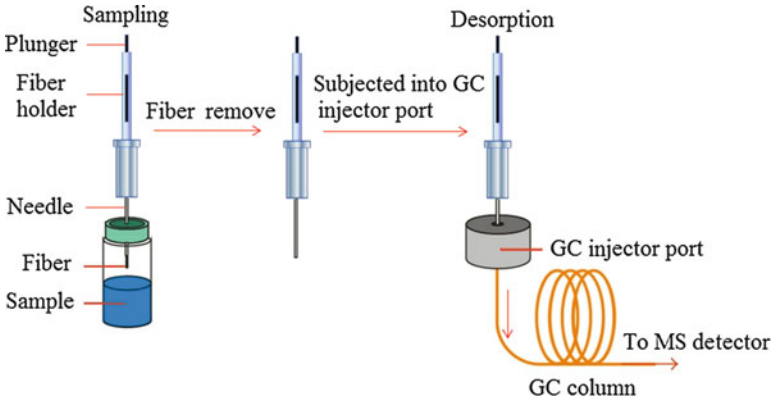

Fig. 7 Solid-phase microextraction setup

hydroxy-3-carboxaldehyde-2,5-cyclohexadien-1-one, and safranal were detected. 3,5,5-Trimethyl-1,4-cyclohexandione was detected in three samples. *β*-Ionone and 5,5-dimethyl-2-methylene-1-carboxaldehyde-3-cyclohexene were detected in six samples, and 2,6-di-t-butylphenol and nonanal were detected in two samples.

These volatiles demonstrate the compounds detected with the highest frequency. Concerning the relevant content of the compounds, safranal is the major compound in all the samples. The analyses indicate that saffron from various cultivation sites have some peculiarities because of the attendance of some uncommon compounds. The Iranian saffron sample indicated the attendance of 2,7,7-trimethyl-2,4-cycloheptadien-1-one, 3,5,5-trimethyl-2-hydroxy-2-cyclohexen-1-one, 1,3,3-trimethyl-2-(E-2-butenylidene)-3-cyclohexene, 1,1,3-trimethyl-2-(Z-2-butenylidene)-3-cyclohexene, 5,5-dimethyl-1,3-cyclohexadien-1-carbaldehyde, *β*-ionol, and 1-acetyl-5,5-dimethyl-bycyclo[3.1.0]hexane [59]. In another study, the influence of storage factor on the aroma profile of saffron was investigated [83].

Six samples of saffron from various regions of Italy are evaluated by SPME-GC/MS. Samples 1, 2, and 3 originated from cultivations of *C. sativus* in the zone of Salerno (Southern Italy) from 2000 to 2002. Samples 4, 5, and 6 are originated from cultivations in Sardinia, Italy (from 1998, 2000, and 2001, respectively). In all samples, 3,5,5-trimethyl-2-cyclohexen-1,4-dione, 3,5,5-trimethyl-2-cyclohexen-1-one, 2,4,4-trimethyl-6-hydroxy-3-carboxaldehyde-2,5-cyclohexadien-1-one, and safranal are detected. 3,5,5-Trimethyl-1,4-cyclohexanedione, 5,5-dimethyl-2-methylene-1-carboxaldehyde-3-cyclohexene, and β-ionone are discovered with 2,6-di-t-butylphenol, nonanal, and dihydro-β-ionone. Safranal is the principle compound in the all samples. The most significant variations are in the attendance of aldehydes and alcohols and oxidation products of the main terpenoid compounds. Moreover, the attendance of safranal, the most significant compound of the flavor, alters through the time, enhancing over 3 years and then declining after 5 years.

Du et al. [84] studied the quantitative structure-retention relationship (QSRR) investigations for the prediction of the retention times in 43 saffron aroma compounds being performed by using SPME-GC. The chemical descriptors were calculated from the molecular structures of the compounds of saffron aroma alone, and the linear and nonlinear QSRR models were constructed using the best multi-linear regression (BMLR) and projection pursuit regression (PPR) techniques. The foretell outcomes of the two approaches were in line with the data of experiment. The proposed models can also determine and supply some insights into structural properties that can play a role on the retention behaviors of the compounds of saffron aroma in the SPME-GC. The current investigation provides an easy but efficient approach for the investigation of the retention behaviors of further analogous herbs and plants [84].

To develop the stability of fibers, Sarafraz-Yazdi et al. [85] synthesized PEG/CNTs fiber, PDMS fiber, and PEG fiber by a sol-gel approach, for determining some polycyclic aromatic hydrocarbons (PAHs) such as fluorene, naphthalene, phenanthrene, and anthracene in aqueous saffron instance by direct immersion SPME and GC. A sol-gel method is employed for preparing the SPME fibers. Three types of sol-gel coatings on the fibers were examined and compared. They are consisted of poly(dimethyl siloxane) (PDMS), poly(ethylene glycol) (PEG), and a poly(ethylene glycol) modified with multiwalled carbon nanotubes (PEG/CNTs). The impacts of fiber coating, time of desorption, temperature of deorption, extraction time, rapid of stirring, and salting impact were optimized. Among the three kinds of the fibers, the sol-gel-derived PEG/CNT fiber has the best affinity for PAHs due to the particular features of multiwalled carbon nanotubes (MWCNTs).

Stir Bar Sorptive Extraction (SBSE)

SBSE was improved by Baltussen et al. [86] on the basis of the sorptive extraction. It is similar to SPME technique which prepared solventless sample. SBSE has the higher surface area and content of coating than the SPME fiber. Hence, SBSE in comparison with SPME was developed as extraction efficiency, and this could account for its major advantage [87]. Nevertheless, SBSE has typically longer extraction and desorption time (over 60 min) than the SPME because of the distribution of the volatiles in the large volume of coating. At the end of the extraction process, after rinsing with distilled water and drying the stir bar, sample can be straightly subjected to the thermal desorption (TD) setup in GC to analyze. From 70% to 130% is the recovery ranges of the compounds [9]. SBSE and TD coupled with GC-ion trap tandem mass spectrometry were first developed simultaneously as a technique for determining the 46 semi-volatile organic contaminants and pollutants of saffron sample. The designed analytical technique not only was easy, sensitive, and quick but also showed excellent repeatability, linearity, reproducibility, and accuracy through the limit of concentration examined. Additionally, target compounds exhibited greater correlation coefficients (>0.98), and detection ranges exhibited lower than 1 μg/kg except for simazine [27].

Maggi et al. [5] first applied saffron as an environmental biomarker to the characterization of the attendance of a complicated polycyclic aromatic

hydrocarbons (PAHs) admixture. To confirm the feasibility to utilize the saffron as an environmental bioindicator and to specify the bioaccumulation of compounds, current study was arranged to identify the quantitative information respecting to PAHs contamination in saffron. In this study, a total of 27 saffron samples obtained from various territories were applied for analysis using SBSE coupled with GC-ion trap tandem mass spectrometry. Consequently, the samples contained diverse values of contaminants, but some of them have greater concentrations than the maximum residue ranges of pollutants confirmed by the European Commission for spices.

Thermal Desorption (TD)

After adsorption, thermal desorption could introduce the whole trapped purpose compounds into GC-MS (Fig. 8). This technique is suited for volatiles' analyses and needed small amounts of sample which included low concentrations of purpose compounds. Heating the adsorbent materials desorbs the adsorbed compounds thermally. By altering the direction of GC carrier gas flow by applying a three-way valve, these compounds are introduced into the column of GC. All these procedures are automated and this equipment is available on the market. In this setup, cold trap is also equipped in order to trap the desorbed samples in a concentration tube cooled via liquid nitrogen and then subjected into the GC column through the heating. This kind of cold trapping system provides the faster sample preparation and makes sharper peaks. In fact, the advantages of TD are included in economy, swift, sensitivity, and facility of both liquid and solid sample analyses. Therefore, such

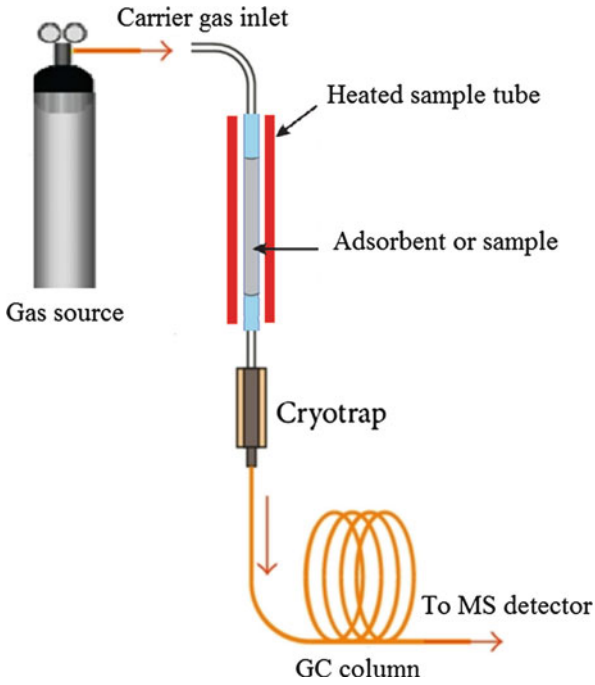

Fig. 8 Thermal desorption setup

system was improved to prepare solventless and easy sample to subject the volatile and semi-volatile compounds of foods into the GC or GC-MS [88].

Alonso et al. [27] utilized the TD-GC in saffron samples for the quantification of the safranal content. Seventy-two percent of the total volatile fraction of saffron is composed of safranal. β-cyclocitral was used as an internal standard, and samples were submitted to 70 °C for 8 min. Therefore, the determination percentages of the total volatiles for the first, first-second, and third desorption were 83, 95, and 100%, respectively.

Recently, Amini et al. [89] studied the impact of cold plasma on crocin esters and volatile oils of saffron using thermal desorption system. After the treatments (Ar, Ar/5% O_2 and Ar/10% O_2 at 8 and 12 kV of voltage), a decrement in crocin esters and saffranal and an enhancement in isophorone and 4-ketoisophorone were confirmed. After 4 min, the saffron samples treated with Ar/20% O_2 had blackened and the treatment was discontinued. The outcomes exhibit that raising the input voltage and enhancing the extent of added oxygen to argon gas promoted the variations in the safranal and crocin esters. There was no *trans*-2G, *cis*-4GG or *cis*-3Gg compounds observed after the Ar/10% O_2 cold plasma treatment at 12 kV.

Solvent-Assisted Flavor Evaporation (SAFE)

The SAFE technique was progressed as a well-set and versatile distillation setup for the swift and precise separation of volatile compounds from complicated food matrix by Engel et al. [90] (Fig. 9). The SAFE unit contained a high vacuum pump (5×10^{-3} Pa) and permits to separate the volatile fractions of either solvent extracts; aqueous materials comprising fruit pulps, beer, and milk; or even matrix containing an elevated oil amount. In comparison to formerly employed methods for either solvent extracts or fatty matrices (50% fat) like elevated vacuum transfer, the SAFE application exhibited greater outputs in model solutions of chosen aroma compounds.

Furthermore, distilling the aqueous foods directly including orange juice or beer resulted in flavorful aqueous distillates free from the matrix of nonvolatile compounds. The following problems of the equipment operated the scholars to develop this method better: (i) aroma compounds with higher boiling points may partially condense inside the tubings before reaching the traps; (ii) only dichloromethane and diethyl ether extracts could be utilized; otherwise, frozen solvent might block the tubes and traps; (iii) extracts including elevated concentrations of saturated fat such as butter might plug up the stopcock of the dropping funnel; and (iv) the SAFE unit takes a lot of bench space and at least 1 h is demanded to get the distillation begun. Additionally, this unit is brittle [90]. This method, due to low pressure used, extracts volatile compounds at low temperatures (40 °C), preventing the artifacts' formation, and has already shown its reliability for the volatile compounds' extraction in saffron [46], dill, savory [91], and golpar [92] spices from Iran, orange juice [93], and coffee [94].

Amanpour et al. [46] evaluated the aroma profile and aroma-active compounds of saffron obtained from Iran using GC-MS-olfactometry. For selecting a suitable and

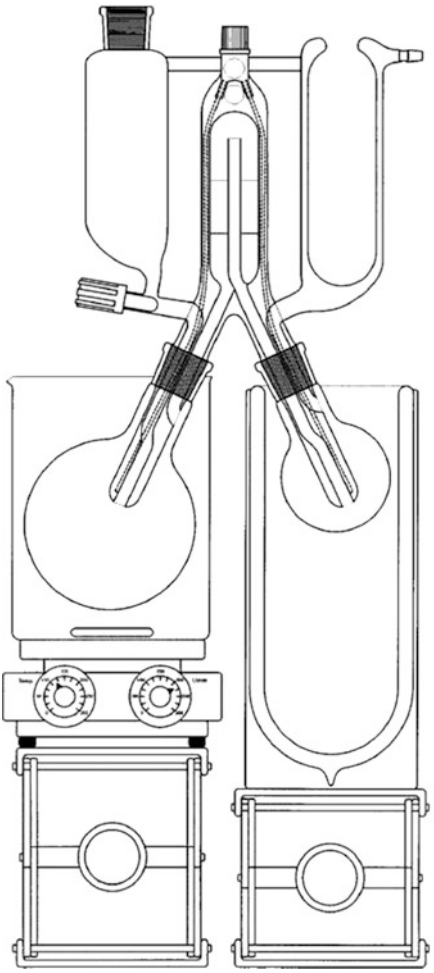

Fig. 9 Solvent-assisted flavor evaporation (SAFE) apparatus

representative aromatic extract from saffron, they used four diverse extraction methods such as the liquid-liquid extraction (LLE), simultaneous distillation-extraction (SDE), solid-phase extraction (SPE), and solvent-assisted flavor evaporation (SAFE). Based on the organoleptic evaluation results, SAFE aromatic extract gave the most representative aroma of saffron. A total of 28 compounds were detected in the saffron sample. The ketone group contained the most prevailing volatile compounds in the sample, followed by aldehydes and acids. Aroma extract dilution analysis (AEDA) was applied for determining the odor-active compounds in studied saffron. Nine odor-active compounds, in total, were discovered in the extract. According to the flavor dilution (FD) factor, the most potent odor-active compounds were safranal with 512 FD, 4-ketoisophorone with 256 FD, and dihydrooxophorone 128 FD values [46].

3.1.2 Selecting the Suitable Extraction Technique/Representativeness Test of the Aromatic Extract

There are different extraction techniques used in saffron aroma characterization as explained some of them above. Remarkably, the extraction technique employed ought to supply an extract containing the organoleptic properties as close as feasible to the source product. The efficiency of a selected extraction method and the representativeness of the sample are often evaluated via primary conventional organoleptic analysis and a comparison of the aroma features of the samples and their corresponding extracts [95, 96]. When one considers that the number of aroma-active compounds discovered by GC-O belongs to the extraction technique, involving variables are often arbitrarily chosen, comprising content of sample, factor of concentration, and volume of the injected sample. Therefore, it is clear that the technique for extraction of volatiles as well as all the variables must be carefully selected [48]. Various techniques could be applied to assess the representativeness of the aroma of aromatic extracts belonging to the kind of the study such as duo-trio, triangular, notation, similarity, and intensity tests. Recently, Amanpour et al. [46] used the similarity and intensity tests to choose the representativeness extraction technique for the GC-MS-olfactometric characterization of the Iranian saffron. The procedure of this suitable sensory analysis which they used in their investigation is explained in detail below:

Panel. The panel consisted of seven assessors (five males and two females from 27 to 48 years old) from the Food Biotechnology Laboratory, Food Engineering Department, Cukurova University. The assessors had good experiences in GC-MS-O analyses, and formerly trained in aroma diagnosis and organoleptic assessment methods, and become familiar with the aroma of saffron.

Sample preparation and presentation. In the investigation, they applied a cardboard smelling strip (reference 7140 BPSI, Granger-Veyron, Lyas, France) to evaluate the representativeness of the aromatic extracts acquired by four various separation methods. Smelling strips have already given excellent outcomes for the representativeness of aroma extract in cherry tomato extracts [97] and orange juice [93]. First, a 10-mL bulk of aqueous solution of saffron was subjected in a 25-mL brown-coded flask as an original sample (reference) for the tests of representativeness. Aromatic extracts of saffron acquired by four various solation methods were adsorbed onto a cardboard smelling strip. After 1 min (the required time for the evaporation of solvent), the strips' extremities were cut off, and then they were subjected in four various dark-coded flasks (25 mL) and introduced to the panel after 15 min. As dichloromethane is a very volatile solvent, it evaporates very quickly; therefore no panelists discovered the aroma of the solvent. Evaluation of samples was carried out at temperature of 20 °C (close to room temperature).

Similarity test. A similarity test was performed to evaluate the closeness between the odor of extracts and the saffron (reference sample). The panelists were instructed to sniff and memorize the aroma of the reference sample and, for the extracts, to sniff the smelling strip and determine the similarity of their odors. A 100-mm unstructured scale was used, anchored with "far from the reference" on the left and "near to

Fig. 10 A 100-mm unstructured scale for evaluating the similarity test

Fig. 11 A 100-mm unstructured scale for evaluating the intensity test

the reference" on the right (Fig. 10). The position of the sample on the unstructured scale was read as the distance in millimeters from the left anchor.

Intensity test. The evaluation of the odor intensity of the extract was requested from panelists. A 100-mm unstructured scale was utilized, anchored with "no odor" on the left and "very strong odor" on the right (Fig. 11). The sample position on the unstructured scale was read as the distance in millimeters from the left anchor. Outcomes were assessment by analysis of variance using Statgraphics Plus program (Manugistic, Inc., Rockville, MD).

The median intensities and similarities of aroma in Iranian saffron observed by the panelists for the aromatic extracts acquired by four different extraction methods are indicated in Fig. 12. The goal of the intensity and similarity assessment tests was to the comparison of the representativeness of the aroma of the extract with that of original sample (reference). Between these methods, the SAFE technique was first used on saffron, and perfect outcomes were attained. The aromatic extracts of SAFE, SPE, LLE, and SDE techniques exhibited 71.8, 61.1, 55.4, and 37.8 mm on a 100-mm unstructured scale, respectively, for the similarity scores. The median similarity scores acquired from four various extractions were detected to be statistically diverse from each other ($p < 0.05$).

The SAFE technique demonstrated an acceptable value for the similarity score. In comparison with further investigations, 70.4 mm in a cherry tomato extract by Selli et al. [97], 64.2 and 63.5 mm in extracts of oils obtained from Turkish olives using pentane/dichloromethane and dichloromethane solvents by Kesen et al. [98], 66.7 mm in banana by Selli et al. [99], and 60.6 mm in blood orange juice extract by Selli and Kelebek [93] were detected for similarity scores. The aromatic extracts of SAFE, SPE, LLE, and SDE techniques indicated 63.9, 69.1, 53.5, and 58.7 mm on a 100-mm unstructured scale, respectively, for the intensity scores.

3.1.3 GC-Olfactometric Characterization of Saffron Key Odorants

GC coupled with MS and FID has been applied for identification and quantification of volatiles. Nevertheless, GC-MS-O or GC-O techniques are a potent approach to specify powerful odor-active compounds of food aroma. The identified volatiles in saffron have been reached over 160 compounds [5, 100]. Nevertheless, it is well-

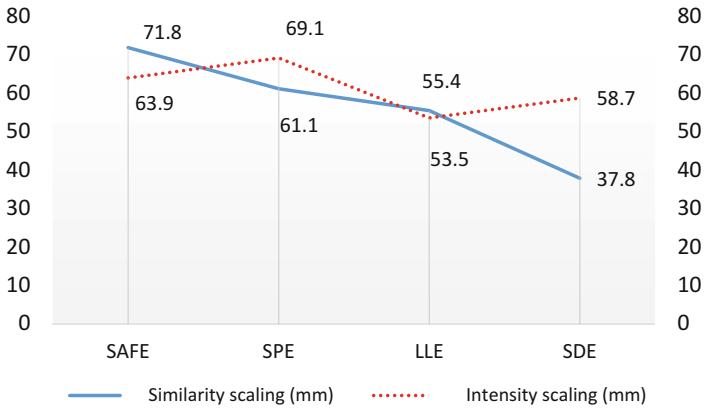

Fig. 12 Similarity and intensity scores of the different extraction techniques [46]

accepted that only a small fraction of the large number of volatile compounds occurring in food actually contributes to the overall aroma. Therefore, a major task in flavor studies is to separate the strongly odor-active compounds from the less odorous or odorless compounds present in food [45]. An interesting way is sniffing the gas chromatographic effluent of a representative separate of volatiles of a food in order to associate odor activity with the eluting compounds. Plenty of the "chemical" detectors are not as sensitive as the human nose for many aroma-active compounds. Experience indicates that plenty aroma-active compounds happen at very low concentrations; their organoleptic relevance is because of low odor thresholds.

Hence, the profile of peak acquired by any "chemical" detector does not presently reflect the profile of aroma in a food. GC-O was designed by Fuller et al. as early as 1964 and has demonstrated to be a valuable technique for the chosen of aroma-active compounds from a complicated structure [45]. Olfactory detection, a variant of organoleptic evaluation, places the nose of a trained expert at the outlet of a column in GC. The expert prompts a slide rheostat with settings altering from no odor to moderate odor to extreme odor, and the attached time versus intensity recorder forms a trace looking like a chromatogram [101].

Numerous ways have been extended to gather and provide GC-O data and to evaluate the organoleptic contribution of single potent aroma-active compounds, which could be categorized in the following four classes [48]:

1. **Dilution analysis techniques** for generating vigor amounts according to stepwise dilution to the threshold, e.g., mixed aroma extraction dilution analysis (AEDA) and hedonic response measurement (Charm analysis).
2. **Detection frequency techniques** for registering discovered aromas by a class of assessors. The number of panelists discovering an aroma (detection frequency) is applied as an assessment of intensity of aroma.
3. **Posterior intensity techniques** for generating assessments of comprehended intensity, being registered after a peak has eluted.

4. **Time-intensity techniques** for generating assessments of comprehended intensity registered at the same time with the elution of the chromatographic peak, e.g., [48].

Among these methods, AEDA technique, which is one of the detection concentration methods, is the most frequently used method in olfactometric analysis. The greatest advantage of this method, which is simple to fulfil, is that the number of panelists participating in the olfactometric analysis is low compared to other methods [102].

Although GC-MS-olfactometry, a very sensitive instrumental device, is used to identify aroma-active compounds, from this point of view, there are limited studies. Indeed, four papers have undertaken olfactometric investigations of saffron samples so far and their olfactometric results are summarized in Table 1 [40, 46, 68, 81]. Rodel and Petrzika [40] were the first to employ GC-O to characterize saffron aroma obtained from Absheron Peninsula, Baku, Azerbaijan. They observed the highly intense and characteristic odor related with the peak produced by safranal, considered to be the main volatile compound in saffron, the key aroma compounds. Although as is typical of such characteristic impact compounds, safranal provides the main impact of the flavor of saffron; however, they also detected several unidentified aroma-active components. In fact, it is apparent that many other compounds contribute to the complete flavor of the material [40].

Cadwallader et al. [66] determined the odor-active compounds in Spanish "Mancha Superior" saffron via direct solvent extraction (DE) and simultaneous steam distillation solvent extraction (SDE) applying AEDA. They confirmed that 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one (saffron, dried hay-like) has much more significant contribution to the aroma of the Spanish saffron than safranal. Furthermore, other several volatiles also contribute to the aroma of saffron based on the GC-O and AEDA results. Although extracts of both DE and SDE techniques had characteristic saffron-like aroma, they showed gentle differences between each other. Floral, spicy, and sweet aroma notes were found in the extracts of DE, and these features were similar to the dried saffron; whereas nutty, cooked, and hay- and rice-like aroma notes were found in the extracts of SDE but sustained certain saffron-like attributes. A mixed total of 25 odor-active compounds were discovered in the extracts of DE and SDE by using GC-O and AEDA techniques. Eighteen of them existed in both of the extracts in common. The majority of the 25 odor-active compounds could be nearly classified applying the organoleptic characteristic terms such as floral, sweet, spicy, herbal, barky, fatty, and harsh/acrid [41]. It is clear that plenty of compounds can be classified in more than one term, while some of them cannot fall under any of these ones. The highest FD factor was found in 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-l-one, followed by safranal. However, previous studies showed reverse results, and safranal was regarded as the most potent aroma-active compound in saffron. This may be depicted by the fact that the amount of 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-l-one has been commonly detected in a far lower values (nearly 10–20-fold less) than safranal [68].

Table 1 Identified aroma-active compounds in saffron by different authors

No.	Aroma-active compounds	Aroma descriptions		
		Cadwallader et al. [68]	Cullere et al. [81]	Amanpour et al. [46]
1	2,3-Butanedione	Buttery, cream cheese	Butter, cream	
2	4-Hydroxy-2,5-dimethyl-3(2H)-furanone	Cotton candy, strawberries		
3	3,5,5-Trimethyl-3-cyclohexen-1-one	Saffron, floral, hay		
4	Linalool	Floral, honeysuckle		Floral
5	2-Phenylethanol	Floral, rose		
6	2,6,6-Trimethyl-1,3-cyclohexadien-1-carboxaldehyde (safranal)	Saffron, tea	Saffron	Saffron
7	2-Hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one	Saffron, stale, dried hay		
8	(E,Z)-2,6-Nonadienal	Sweet, cucumber		
9	(E,E)-2,4-Decadienal	Fatty, fried fat		
10	l-Octen-3-one	Mushroom earthy	Mushroom	
11	3-Methylbutanoic acid	Rotten, sour, dried fruit		
12	Acetic acid	Vinegar, acidic	Vinegar	
13	2-Acetyl-1-pyrroline	Nutty, popcorn		
14	3-(Methylthio)propanal	Baked potato		
15	Hexanal		Grass	
16	3-Hexen-2-one		Grass, geranium	
17	Octanal		Lemon	
18	6-Methyl-5-hepten-2-one		Clove, spicy	
19	Isophorone		Saffron	Saffron, herbal
20	(Z)-2-Nonenal		Green, metallic	
21	(E)-2-Nonenal		Melon, aldehydic	
22	(E,Z)-2,6-Nonadienal		Cucumber	
23	Butyric acid		Cheese	
24	Isovalerianic acid		Cheese	
25	(E,E)-2,4-Nonadienal		Rancid oil	
26	(E,E)-2,4-Decadienal		Fatty, deep-fried	
27	b-Phenylethanol		Roses	
28	Furaneol		Cotton candy	
29	Homofuraneol		Cotton candy	
30	4-Ketoisophorone			Saffron

(*continued*)

Table 1 (continued)

No.	Aroma-active compounds	Aroma descriptions		
		Cadwallader et al. [68]	Cullere et al. [81]	Amanpour et al. [46]
31	Dihydrooxophorone			Saffron
32	Phenylethyl alcohol			Floral, rose
33	4-Hydroxy-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde			Green

Along with these compounds, 3,5,5-trimethyl-3-cyclohexen-l-one and numerous unknown compounds derived from carotenoid compounds had also slightly elevated FD factors and the contribution in the saffron-like aroma properties. Plenty of other volatile compounds were formed through (i) lipid oxidation such as (*E,Z*)-2,6-nonadienal, l-octen-3-one, and (*E,E*)-2,4-decadienal; (ii) Strecker degradation/Maillard reaction such as 2-acetyl-l-pyrroline, 2,3-butanedione, 3-methylbutanoic acid, and 3-(methylthio)propanal; and (iii) hydrolysis of non-carotenoid glycoside precursors such as 2-phenylethanol, benzenemethanol, and linalool, which contributes to the overall saffron aroma. The attendance of 4-hydroxy-2,5-dimethyl-3(2H)-furanone in saffron can be described by either Maillard reaction or possibly by its liberate from a glycoside precursor. Concerning the above results, it could be summarized that together with the carotenoid-derived compounds, plenty further non-carotenoid compounds influence the saffron aroma [28].

Cullere et al. [81] investigated the extract of aroma in a Spanish "Teruel" saffron sample applying a purge and trap setup to isolate volatiles of saffron prior to GC-O. Via an olfactometric method employing the mixed evaluations of intensity and frequency of detection, they demonstrated 20 different aroma-active compounds in the GC-O analysis. The specificity of all the chemicals responsible for these compounds could be established with various classes of certainty. Only two of them were unknown. The elevated modified frequency level of safranal (93%) was considerable. (*E*)-2-Nonenal, hexanal, 2,3-butanedione, and a fourth unidentified compound with a distinctive aroma note of burnt curry also released elevated modified frequencies. Majority of the sustaining aromas had modified frequency levels that were quite elevated (50–70%). Additionally, carbonyl compounds had an important role in the aroma of saffron. Only 6 of the 20 compounds were not included in carbonyl compounds. The odor-active compounds involved an alcohol (β-phenylethanol), two furans (furaneol and homofuraneol), and three acids (acetic, butyric, and isovaleric). The carbonyl compounds composed of three five alkenals, ketones, two aliphatic aldehydes (octanal and hexanal), and two carbonyls with a cyclohexane base (isophorone and safranal). Thirteen of the compounds were formerly considered related [68]. Three of these odor-active compounds were unknown then but were detected to be (*Z*)-2-nonenal, (*E*)-2-nonenal, and hexanal in the current examine. Seven of these compounds such as butyric acid, octanal, (*E,E*)-2,4-nonadienal, 6-methyl-5-hepten-2-one, homofuraneol, and two unidentified

compounds were first determined as related to odor-active compounds in a GC-O analysis in the aroma of saffron. 6-Methyl-5-hepten-2-one and octanal have been discovered formerly by GC-MS experiment in saffron [83, 84]. The majority of these compounds (except homofuraneol and butyric acid) had modified frequency levels greater than 55%. This might demonstrate that some of these newly determined compounds of saffron may be substantial volatiles in its aroma. Additionally, some odor-active compounds found in a former GC-O analysis [68], including 2-acetylpyrroline and three unidentified volatiles with RI (DB-Wax) 1682, 1734, and 1980, respectively, were unknown in the present assay in the profile of aroma. The odor-active compound with RI (DB-Wax) 1734 is specified as 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one [68]. This compound in the La Mancha (Spain) saffron was reported as the most odor-active compound, even greater than safranal.

Nevertheless, 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one was found in the current investigation containing a MF of less than 30% (exactly 19%) in saffron and is hence not included as an odor-active compound. Thus, it can be concluded that in spite of the attendance of this odor-active compound in both types of saffron, its concentration was only elevated enough to be related in one of the saffron varieties [81].

Recently, Amanpour et al. [46] characterized the odor-active compounds in Iranian saffron by GC-MS-O. They used the SAFE technique for the isolation of aroma extracts, which showed a most representative extraction technique close to saffron aroma. The powerful aromas were specified employing AEDA for the evaluation of flavor dilution factors (FD factor). Therefore, the AEDA application on the SAFE extract of saffron liberated nine odor-active compounds such as two three ketones, alcohols, two aldehydes, and two unknown compounds discovered by GC-O but were unknown by GC-MS. The range of FD factors of odor-active compounds was altered between 16 and 512.

Two odor-active aldehyde compounds were found in the sample, namely, safranal and HTCC; safranal with 512 FD showed the most potent odor-active compound, supplying distinct saffron aroma note. HTCC was first discovered as an odor-active compound in the Iranian saffron. According to the aroma chemistry of saffron, safranal is an important volatile compound in the volatile oil and is generated from picrocrocin and HTCC over the drying process of fresh saffron [80, 103]. 4-Ketoisophorone with 256 FD, dihydrooxophorone 128 FD, and isophorone 32 FD factors were found as odor-active ketone compounds in the examined sample. Among these compounds, isophorone was detected in the most elevated concentration (845 μg/g) in Iranian saffron. This ketone is remarkable in saffron to the formation of the saffron aroma note [81].

Dihydrooxophorone and 4-ketoisophorone were first discovered as odor-active compounds generating saffron aroma note in the assayed sample. In addition, these compounds were determined in Spanish “Mancha Superior” [68] and in Iranian saffron [60]. Derivatives of isophorone are the major volatile compounds of the volatile oil and are responsible for the distinct aroma of saffron [103].

On the basis of the β-isophorone biosynthesis, it was disclosed that its generation happened via a mechanism including the zeaxanthin degradation, with

the concomitant generation of both (1R)-3,5,5-trimethyl-3-cyclohexen-1-ol *O*-*β*-D-glucopyranoside and (4R)- and (4S)-4-hydroxy-3,5,5-trimethyl-2-cyclohexen-1-one *O*-*β*-D-glucopyranoside [13]. These two glycosides are feasible precursors of *β*-isophorone and *α*-isophorone. Additionally, alcohols are considerable as odor-active compounds in the saffron sample. Phenylethyl alcohol and linalool were found in Iranian saffron with the identical aroma note (floral) and flavor dilution factor (FD = 32). Linalool was found in Spanish "Mancha Superior" as an odor-active compound with honeysuckle and floral aroma attributes [68]. Nonetheless, phenylethyl alcohol was first found as an odor-active compound generating floral aroma note in this investigation. Moreover, two unidentified compounds might chip up to the overall aroma in saffron. Unidentified 1 (LRI = 1044) was found in saffron providing a buttery odor (FD = 64). Unidentified 2 (LRI = 1221) formed buttery and burnt odor features (FD = 16) [46].

3.2 High-Performance Liquid Chromatography (HPLC)

HPLC device is a widely used chromatographic method that could isolate compounds' structure and is applied in analytical chemistry for identifying, quantifying, and purifying the individual compounds of the structure [104]. This method is well-known between numerous analytical methods in order to fingerprint, control quality, and determine the saffron adulteration [105]. This method is preferably suitable for the swift processing of such multi-compound instances on both an analytical and preparative scale [106]. The majority of researchers pronounce the utilization of HPLC in order to characterize and quantify the secondary metabolites in the extracts of plant such as steroids, flavonoids, alkaloids, and phenolic compounds [107]. Reversed-phase chromatography is the most generally employed isolation method in HPLC because of its wide application limit. Consequently, its advantages comprise the versatility, simplicity, and scope of the reversed-phase technique as it is capable of handling compounds of a different polarity and molecular mass.

Chromatographic setup must be able to resolve from the peak of interest all other compounds that give a detector signal. The success of method validation depends mainly on the correct determination of the peak purity and selectivity of given HPLC system. It is clear that acceptable selectivity and specificity can result in pure peak. Therefore, the appropriate determination of the purity of a chromatographic peak is of primary interest. One of the most important steps in HPLC studies is the detector selection. After the detector is selected, a chromatographic separation assessed must be developed. The UV, VIS, and PDA (photodiode array) detectors are classified as absorbance detectors. They supply excellent sensitivity for light-absorbing compounds at small value. They are simple to prompt and supply excellent stability. UV detector is a very generally employed detector for HPLC analyses. A standard UV detector permits user to select wavelength from 195 to 370 nm. In comparison with a UV detector, a Vis detector applies longer wavelength between 400 and 700 nm. There are detectors that supply more extensive wavelength choice, which cover both UV and Vis ranges (between 195 and 700 nm) named UV/Vis detector. PDA detects

a complete spectrum simultaneously. UV and Vis detectors conceive the acquired outcome in two dimensions (light intensity and time), but PDA adds the third dimension (wavelength). This is proper to specify the most appropriate wavelength without repeating analyses. Phenolic compounds are often specified utilizing UV-Vis and photodiode array (PDA) detectors at wavelengths between 190 and 380 nm [108].

Further detection techniques are also being used to find phytochemicals among which is the diode array detector (DAD) coupled with mass spectrometer (MS) [106]. Liquid chromatography coupled with mass spectrometry (LC-MS) is an intensive method for the analysis of complicated botanical extracts [109]. HPLC is impressive in isolating chemical compounds in an admixture, and MS supplies numerous knowledge for structural elucidation of the compounds when tandem mass spectrometry (MS) is employed. Therefore, the blend of HPLC and MS comforts swift and accurate specification of chemical compounds in medicinal herbs, particularly when a pure standard is not accessible. Newly, LC-MS has been vastly utilized for phenolic compounds' analysis [106]. Electrospray ionization (ESI) is a preferred source because of its elevated ionization efficiency for phenolic compounds.

The extraction of bioactive compounds from the saffron and their quantitative and qualitative analysis is important for exploration of new biomolecules for use in pharmaceutical and agrochemical industry. These biomolecules are used directly or can be used as a lead molecule to synthesize more potent molecules. Saffron includes a vast limit of constituents that could be applied to treat chronic as well as infectious illnesses [110]. In the literature, more than hundreds of phytochemicals in saffron were disclosed as a safe and widely impressive alternative spice containing less adverse impact. Plenty useful biological activities comprising anti-inflammatory, antioxidant, antimicrobial, anticancer, wound healing, and analgesic activity were disclosed.

However, clinical experiments are essential for the demonstration of the effectiveness of a bioactive compound to confirm this traditional claim. Owing to the fact that saffron extracts commonly happen as a blend of different kinds of bioactive compounds or phytochemicals with various polarities, their isolation still sustains as large challenge for the process in order to identify and characterize them [111].

More than 150 compounds were reported in saffron stigmas [14]. Numerous analytical investigations have been led to specify the big number of possible biologically active compounds detected in saffron. The compounds generating saffron features are crocins ($C_{44}H_{64}O_{24}$), picrocrocin ($C_{16}H_{26}O_7$), and safranal ($C_{10}H_{14}O$) [112].

The first reference to crocin [crocetin di(β-gentiobiosyl) ester] was disclosed in 1818 by Aschoff [113] who gave it its name. Pfander et al. [19] were the first to separate six glycosides of crocetin in saffron sample. In 1984, Speranza et al. [114] characterize their *cis* and *trans*-isomers via HPLC-UV-Vis. Tarantilis et al. [115] characterize a more number of crocetin esters and their *cis* and *trans* isomers using high-performance liquid chromatography with diode array detection and mass spectrometry (HPLC-DAD-MS), and Carmona et al. [116] identified four more

by HPLC-DAD-MS. Thus far, the quantification of crocetin esters by HPLC has been carried out without high precision [117–119], and the use of commercial standards in calibration curves gives low correlation coefficients, owing to the phenomenon of aggregation that some authors have demonstrated that happens in highly concentrated aqueous solutions of crocetin esters [120, 121]. The kinetics of individual crocetin ester degradation in aqueous extracts of saffron were studied to determine their stability [117]. Different methodologies and analytical devices have been employed to recover bioactive compounds of saffron preparative high-performance liquid chromatographic purification of saffron secondary metabolites [69, 103, 115, 122].

Analysis of saffron chemicals coming from different geographical zones demonstrates that the content of compounds belongs highly to processing, drying, extraction techniques and quantification. Saffron metabolites' extraction is optimized by testing different parameters such as the temperature, solvent, light, and stirring time utilized in the procedure. Diverse solvents such as diethyl ether, ethanol, and water are applied for crocin extraction [103, 123]. Last investigations show that a solution of methanol-water (50%, v/v) with magnetic stirring during 1 h in darkness at 25 C is optimal for acquiring all the saffron compounds, comprising crocin [58, 122, 124].

Picrocrocin [4-(*β*-D-glucopyranosyloxy)-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde] has been identified only in the genus *Crocus*, of which the only edible species is *Crocus sativus* L. Therefore, picrocrocin is a molecular marker of this spice that is able to give a unique taste that cannot be imitated from other spices or seasonings. This compound was isolated for the first time in the stigmas of *C. sativus* by Winterstein et al. [125]. Its molecular structure was defined in 1934 by Kuhn et al. [25]. Glycosidic compounds that are structurally related to picrocrocin have been identified. Tarantilis et al. [115] identified three glycosidic compounds in 1995; the Winterhalter research team [126, 127] recognized eight other glycosidic compounds between 1997 and 1998; and Carmona et al. [128] identified four more by HPLC-DAD-MS in 2006, which were found in considerably lower amounts than picrocrocin. The picrocrocin stability was determined by Sanchez et al. [129], and picrocrocin is more stable than the crocetin esters. The principled usage of the identifications recommended by the ISO 3632 has managed to categorize saffron in world trade by its coloring strength, supplied that the sustaining necessities are accomplished. Subsequently, this categorization has been conducted to the being of a spectrophotometer in approximately all saffron companies. The coloring strength is representative of the crocetin ester amount.

Nevertheless, the specification of picrocrocin over the parameter at 257 nm indicates a trouble of selectivity since further compounds of saffron extract, primarily crocetin esters, also have absorbance at this wavelength because of the glycoside bonds, which cause interferences in assessment [58, 116, 117, 130]. Until now, further methods comprising thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC) have been employed for the quantification of picrocrocin, with this last method remarked as being the most impressive [69, 115, 131].

Safranal is a nonpolar compound, but its solubility in water has not been studied. Different analytical techniques have been developed for its quantification, such as GC-O [40, 46, 68, 81], GC-MS [5], HPLC [58], or ultrasound-assisted extraction/ultraviolet-visible spectroscopy (USAE/UV-Vis) [77]. The results obtained are quite different between these various methods.

Numerous investigations previously disclosed have explained their biological activities: crocins, safranal, and picrocrocin possess a cytotoxic impact on human tumor cells [130]; crocins indicate antioxidant potency [132] and memory-promoting influence [133]; and safranal possesses a relaxant impact [134]. Crocins compose approximately 6–16% of saffron's total dry matter belonging to the growing circumstances, variety, and processing techniques [20]. Picrocrocin, which is the second most prevailing compound (by weight), accounts for nearly 1–13% of saffron's dry matter [18]. Another important chemical compound is safranal which contains nearly 30–70% of volatile oil and 0.001–0.006% of dry matter vastness [5]. Quality of saffron belongs to the amount of these three principle metabolites generating the incomparable color, taste, and aroma to the saffron stigmas [80].

Saffron stigmas are identified by the attendance of vitamins, fats, minerals, sugars, and secondary metabolites including carotenoids, anthocyanins, flavonoids, and terpenes. Among the secondary metabolites, carotenoids are the most substantial compounds since they characterize the spice color and taste [135]. Of these compounds, lycopene, α- and β-carotene, zeaxanthin, crocetin (liposoluble), and crocins (hydrosoluble) derived by crocetin esterification with sugars could be mentioned. Crocins are *trans*-crocetin di-(*β-D*-gentiobiosyl) ester (named *trans*-4-GG), *trans*-crocetin (*β-D*-glucosyl)-(β-D-gentiobiosyl) ester (named *trans*-3-Gg), *trans*-crocetin (β-D-gentiobiosyl) ester (named *trans*-2-G), *cis*-crocetin di-(β-D-gentiobiosyl) ester (named *cis*-4-GG), *trans*-crocetin di-(β-D-glucosyl) ester (named *trans*-2-gg), and *cis*-crocetin (*β-D*-glucosyl)-(β-D-gentiobiosyl) ester (named *cis*-3-Gg) [135]. Crocetin is classified as a natural carotenoid dicarboxylic acid that generates brick red crystals with a melting point of 285 °C. Its chemical structure is the central core of crocins [136].

The saffron-colored compounds are crocins, a family of uncommon water-soluble carotenoid mono- and di-glycosyl esters of a polyene dicarboxylic acid, called crocetin, where D-glucose and D-gentobiose happen as carbohydrate residues. The digentiobiosyl ester of crocetin, named α-crocin, is the main compound [19, 58]. Picrocrocin is the major compound responsible of the bitter taste in saffron, it is a colorless glycoside, the sugar moiety of which is D-glucose, and HTCC the aglycone. Safranal is the volatile oil responsible of the distinct saffron aroma note. This compound originated from HTCC and picrocrocin over the drying process of saffron [10, 43, 137]. Techniques used to detect and quantify saffron metabolites are not integrated. In the last few years, there has been increasing attention to guarantee and to defend the quality of saffron historically produced in specific regions. Among the methods used for saffron characterization, currently recommended by the International Standardisation Organisation (ISO/TS 3632, 2003), is UV-Vis spectrophotometry [138]. The absorbance measurements in saffron at 250 nm (λ_{max} of both HTCC and picrocrocin), 310 nm (λ_{max} of safranal), and 440 nm (λ_{max} of crocins) are

considered to be proper for the identification of the taste, aroma, and color, respectively [131]. Unfortunately, this technique is not specific and able to adequately distinguish between original saffron and adulterated one and hence incapable of providing a quality class on the international market [139].

For the quantitative analysis of picrocrocin and crocetin, a new high-performance thin-layer chromatographic method was developed [140]. A rapid and nondestructive technique to determine safranal and HTCC contents was performed using supercritical carbon dioxide extraction combined with high-resolution gas chromatography (HRGC) and reversed-phase high-performance liquid chromatography (RP-HPLC) [80]. For HPLC analysis, a DAD (diode array detector) was commonly used [112], sometimes in combination with electrospray ionization (ESI) mass spectrometry (MS) [141]. Sánchez et al. [61] developed a solid-phase extraction procedure coupled with RP-HPLC-DAD analysis.

According to the isolation and purification of bioactive compounds in saffron, an aqueous water, ethanol, or methanol is usually utilized for the extraction of numerous bioactive compounds [2]. An easy, susceptible, and peculiar HPLC-UV technique has been first improved for simultaneous quantification of the five main biologically active compounds in saffron such as crocin 1, crocin 2, crocin 3, crocin 4, and crocetin. Calibration curves were provided by spiking authentic compounds and internal standard, 13-*cis*-retinoic acid, into herbal samples prior to extraction. Extraction was led easily by stirring dried herb (20 mg) with 80% aqueous methanol (5 ml) at room temperature in the dark for 2 h. The HPLC technique was carried out on a reversed-phase C_{18} column with linear gradient elution employing methanol and 1% aqueous acetic acid. Calibrations were linear ($r^2 = 50.999$) for all five analytes, with global intra- and interday RSDs of less than 11%.

The technique was successfully used to determine the four crocins and crocetin in three saffron samples and two Zhizi, another crocin-containing herb. Findings show that the progressed HPLC technique could be readily employed as a quality control technique for crocin-containing medicinal herbs [124]. In addition, crocins' extraction and purification are well depicted in the published literatures [64, 142, 143]. After defatting with diethyl ether, stigmas are usually extracted 2 or 3 times utilizing 70–90% methanol or ethanol (~10-mL solvent/g saffron). Solvents involving extract are pooled, evaporated to dryness, and then purified applying silica gel column chromatography with ethanol-ethyl acetate-water (~6:3:1) as the mobile phase. Crocin and crocetin esters are eluted singly [143]. Picrocrocin could be effectively separated from saffron stigma by successive, exhaustive Soxhlet extraction applying light petroleum, methanol, and diethyl ether to acquire three fractions [58].

The diethyl ether phase involving picrocrocin and lipids is evaporated to dryness, defatted applying Soxhlet for picrocrocin purification, and then dissolved in methanol for filtration. The filtrate is then analyzed applying HPLC device. Tarantilis et al. [58] effectively analyzed picrocrocin applying an HPLC LiChroCART 125-4 Superspher 100 RP-18 column and 20–100% ACN in water linear gradient mobile phase. Several studies reported in the literature about the bioactive compounds in saffron using HPLC.

Eleven authenticated saffron samples obtained from Iran, Spain, Greece, India, Italy, Azerbaijan, Turkey, New Zealand, France, China, and the Sigma Chemical Company were used for analyzing by applying an HPLC photodiode array detection technique. Also, for determination of chemical composition of 11 saffron samples, the reversed-phase C18 HPLC was applied. Ten main compounds in each sample were identified, and a well-resolved baseline isolation was attained. Each compound was specified in comparison with its retention time as formerly explained in the published papers [115, 124, 131] as well as by LRFAB-MS analysis through the detection (m/z) of its corresponding pseudomolecular ion $[M + H]^+$ [115, 144]. The peak specification is as permits: picrocrocin, HTCC, and 3-gentiobiosyl-kaempferol were discovered at 250 nm, safranal at 310 nm, and *trans*-crocin 4, *trans*-crocin 3, *trans*-crocin 20, *cis*-crocin 4, *trans*-crocin 2, and *cis*-crocin 2 at 440 nm. With respect to this study, various saffron samples did not alter in their chemical composition but did alter in the amount of each compound. Findings demonstrated that the Indian, Greek, Spanish, and New Zealand saffron extracts had the highest amounts of water-soluble glycosidic carotenoids.

Cossignani et al. [138] evaluated the quality of saffron belongs to the amount of secondary metabolites such as crocins, picrocrocin, and safranal. The purpose of the current study was to assess the impact of drying circumstances on the secondary metabolite amounts of saffron obtained from Cascia region, in the center of Italy. Diverse aliquots of the identical saffron sample were submitted to different dehydration conditions and analyzed by UV-Vis spectrophotometry for the determination of crocins, picrocrocin, and safranal. Safranal was also analyzed by elevated resolution gas chromatography, while the crocins and picrocrocin were identified by HPLC-MS-DAD. The chromatographic analyses resulted in that the samples dried in the milder conditions possessed the lowest amounts of secondary metabolites. Furthermore, the sample dried at 60 C for 55 min had the highest amounts of *trans*-crocin-4 and picrocrocin, while safranal was the most represented in saffron dried at 55 C for 95 min [138].

A research was to perform saffron as a supportable replacement product with elevated added level in some Moroccan agricultural zones with low and erratic rainfalls, for their socioeconomical improvement. The saffron quality must be determined prior to recommendation for commercial production. For the sake of this target, saffron was first cultivated in experimental plots in 11 various experimental areas with a disparity of the different climates, soils, and altitudes. HPLC was utilized for the quantification of the most significant saffron compounds, namely, crocins, picrocrocin, and safranal. The related mean levels, in % dry matter, across all sites altogether are 29.01 ± 5.6, 14.04 ± 7.1, and 0.22 ± 0.11, respectively. The analysis statistically indicates that crocins are stable under each specific environment examined ($p > 5\%$) for 3 years of investigation. Simultaneously, there was a large alteration in the safranal amount for the identical stage ($p < 0.05$). Results showed that the post-harvest processing of saffron produced under various environment conditions might need to be developed. Analysis of environmental influence on the quality of saffron indicated that just the altitude impacts crocins ($R2 = 0.84$, $p < 0.05$) [112].

García-Rodríguez et al. [145] carried out a comparative assessment of the ISO 3632 (2011) technique and an HPLC-DAD technique for determining the safranal amount in saffron. Analyses of samples from various areas were performed by UV-Vis based on the ISO 3632 (2011) and by HPLC-DAD technique. Both techniques were compared with each other, and there was no correlation between the safranal amount acquired by UV-Vis and HPLC-DAD. An overestimation in the UV-Vis test was confirmed, being linked to the *cis*-crocetin esters amount, as well as further compounds. The findings illustrated there was no relationship between ISO quality classified and safranal amount applying HPLC-DAD device. Hence, HPLC-DAD may be preferred to UV-Vis to the determination of the safranal amount and the categorization of saffron for commercial targets. Additionally, HPLC-DAD was enough to the determination of the three foremost factors that describe the saffron quality such as crocetin esters, picrocrocin, and safranal; thus, this assay can be contained in the ISO 3632 technique (2011) [145].

D'Archivo et al. [146] used HPLC-DAD for analyzing the 144 Italian saffron samples obtained from five distinct zones placed in four diverse districts comprising Sardinia, Umbria (Cascia and Città della Pieve), Tuscany (Florence), and Abruzzo (L'Aquila) cultivated in the years from 2009 to 2015. In order to attempt geographical discrimination of saffron samples, intensities of the chromatographic peaks ascribed to crocins, safranal, picrocrocin and its derivatives, and flavonoids were remarked as variations in linear discriminant analysis. The findings exhibited that samples produced at various regions of Italy could discriminate with excellent accuracy from each other. The discrimination of the saffron sample obtained from Sardinia from those obtained from Central Italy was principally ascribed to diverse amounts of the most dominant crocins. Also, excellent discrimination of samples obtained from close regions of Central Italy was confirmed, 88% of validation saffron samples being correctly categorized; some minor crocins are responsible for this differentiation [146].

The impact of various cooking times at 100 °C (in boiling water) in "La Mancha" saffron samples on the bioactive compounds such as safranal, picrocrocin, *trans*-crocin 3, *trans*-crocin 4, and *cis*-crocin 4 was studied. HPLC-photo diode array-mass spectrometry was applied as a confirmatory method in crocin specification. When the samples are introduced to various cooking times, they exhibited diverse behaviors, belonging to the bioactive compound. Moreover, no alterations were confirmed in the amount of picrocrocin, while heat culinary treatment adversely impacts the crocins and safranal amounts [147].

García-Rodríguez et al. [148] proposed an HPLC-DAD technique to determine the three principal compounds responsible for the determination of the saffron quality such as crocetin esters, picrocrocin, and safranal by providing an aqueous extract with regard to the ISO 3632 standard to solve the difficulty that this standard has for aroma and taste specification by ultraviolet−visible spectroscopy. According to this target, laboratory-isolated picrocrocin; a safranal standard with a purity of ≥88%; *trans*-crocetin di(β-D-gentiobiosyl) ester (*trans*-4-GG) and *trans*-crocetin (β-D-glucosyl)-(β-D-gentiobiosyl) ester (*trans*-3-Gg) standards, both with a purity

of ≥99%; and 50 different saffron spice samples from Italy, Iran, Greece, and Spain were applied in the intralaboratory validation of the HPLC technique.

The analytical technique proposed was enough in terms of selectivity, linearity, accuracy, and sensitivity for the determination of the three foremost factors that describe the saffron quality employing only a saffron solution provided based on the ISO 3632 standard.

Sujata et al. [69] have applied gas chromatography (GC), high-performance liquid chromatography (HPLC), and thin-layer chromatography (TLC) techniques to determine the saffron quality. HPLC and TLC liberated comparable outcomes for crocin and crocetins (color principles), picrocrocin (bitter substance), and safranal (aroma). In a similar manner, the specification of safranal by GC was in line with analysis by HPLC and TLC. Isolation of the compounds was performed by silica gel G TLC applying an n-butanol-acetic acid-water (4:l:l) system. The resolution of crocin, crocetins, and picrocrocin by HPLC was acquired applying a Shimadzu 15-cm CLC-ODS column with 20–80% acetonitrile in water as the eluent; for safranal an isocratic run with 76% acetonitrile in water was proper. GC was adopted only for the determination of safranal applying a Shimadzu 5% SE-30 column. HPLC was most appropriate for the adulterants' detection and was easier and more effective for saffron quality analysis. The TLC technique was time-consuming and also released an overestimation of the color sources.

Numerous authors have indicated that spices involving flavonoid and phenolic compounds showed antioxidant potencies, so they are often utilized as antioxidant food supplements [149, 150]. The antioxidant potency of the saffron stigma can be due to its phenolic amount as well as to its active compounds comprising safranal, crocin, crocetin, and carotene, all of which have been disclosed to possess antioxidant potencies [149]. Picrocrocin could be impressively separated from stigma of saffron by successive, exhaustive Soxhlet extraction applying light methanol, diethyl ether, and petroleum to attain three fractions [58]. The diethyl ether phase involving picrocrocin and lipids is evaporated to dryness, defatted applying Soxhlet for picrocrocin purification, and then dissolved in methanol for filtration. The filtrate is then analyzed applying HPLC devise. Tarantilis et al. [58] effectively analyzed picrocrocin applying an HPLC LiChroCART 125-4 Superspher 100 RP-18 column and 20–100% ACN in water linear gradient mobile phase [58].

The antioxidant potencies of spices are principally ascribed to their flavonoid and phenolic compounds. Flavonoid in saffron was first identified in saffron using mass spectrometry by Tarantilis et al. [115], proposing a kaempferol structure with a disaccharide moiety. Straubinger et al. [126] specified kaempferol 7-O-glucopyranosyl-3-O-sophoroside and kaempferol 7-O-sophoroside by NMR and MS after countercurrent preparative chromatography. According to this determination, the authors similarly remarked that the specification of a new flavonoid called kaempferol 3-O-gentiobioside fulfilled by Lozano et al. [131] was not correct [13]. Additionally, further flavonoids might be detected in saffron, as they have already been explained in further *Crocus* species [151]. Saffron is one of the spices believed to have antioxidant potencies, but knowledge on its antioxidant potency, flavonoids, and phenolic compound are rather limited; hence a study was accomplished to assess

the antioxidant potency of saffron stigmas isolated with various solvents. The flavonoid and phenolic compounds in saffron were also tested applying reversed-phase (RP)-HPLC.

Outcomes illustrated that stigma of saffron has antioxidant potency. The free radical-scavenging and ferric diminishing power activities were greater for the methanolic extract of saffron stigma at a concentration of 300 μg/mL, with levels of 68.2% and 78.9%, respectively, as compared to the corresponding boiling water and ethanolic extracts, but the activities were lower than those of antioxidant standards such as BHT and α-tocopherol. The acquired total phenolic compounds' level for methanolic saffron extract was 6.54-mg gallic acid equivalent (GAE)/g dry weight (DW) and for total flavonoids, 5.88-mg rutin equivalent/g DW, which were also greater than levels acquired from the ethanolic and boiling water extracts. Furthermore, the RP-HPLC analyses showed the presence of gallic acid and pyrogallol as two bioactive compounds. Briefly, stigmas of saffron demonstrated antioxidant potency and methanol appeared to be the best solvent to extract the active compounds, among which the presence of gallic acid and pyrogallol might contribute toward the antioxidant activities of stigma. Therefore, stigma of saffron can be utilized as a source of natural antioxidant for industrial aims [100].

Makhlouf et al. [152] reported that the total amount of polyphenols in saffron (16-mg gallic acid/l) showed greater than that in white grape juice (6.285-mg gallic acid/l). Their experiment indicated that saffron extract attained from the saffron flower possessed elevated contents of polyphenol compounds, which could impressively decline activity of free radicals and could supply an intensive protection for the various organs such as the heart, lung, kidneys, and liver against some oxidative damages under a dose-dependent behavior. Therefore, saffron exhibited a good and natural antioxidant in comparison with the antioxidant capacity of white grape source.

The elevated content of saffron was detected to be more in counteracting the manifestation of hyperlipidemia than elevated content of crocin. These propose that together with crocin of saffron, there are further compounds responsible for synergistic antihyperlipidemic and antioxidant potential of saffron. The potent hyperlipidemic activities could be straightly connected to the presence of flavonoids in saffron as it is known that flavonoids have potent hypolipidemic features [153].

The compounds considered to be pharmacologically active in saffron are the bitter principles and the pigment derivatives from the carotenoid crocetin [11]. In addition to picrocrocin, that is to say 4-(β-D-glucopyranosyl)-2,6,6-trimethyl-1-cyclohexene-1-carboxaldehyde, the main compound responsible for saffron bitterness, further compounds with this sensory feature have been identified in saffron. These are linked to picrocrocin and flavonoids [127, 154]. Flavonoids have several functions in the ecology, physiology, and biochemistry of plants, and they are significant in the nutrition of both animal and human [155]. The antioxidant potency of flavonoids toward free radicals and reactive oxygen species, plus their potential estrogenic and anticancer activity, draws attention to their health-protecting role in human and animal foods [156]. Some of these health features might be because of

the flavonoid amount, as has been disclosed for anti-inflammatory and anti-conceptive influences [157].

There is also an important interest in accurate techniques for the characterization of saffron that can be employed to prevent adulteration and to categorize saffron from various geographical areas or territories [124, 131]. The differentiation and discrimination of saffron from diverse territories could be achieved by screening of color compounds present in the saffron matrix [18]. Since this time, various analytical methods such as ultraviolet-visible (UV-Vis) spectrophotometry [130, 158, 159], spectrofluorometry [160, 161], TLC [103, 159], GC [5, 69], LC [124, 140, 162, 163], HPLC [64, 80, 115, 131, 140, 164], capillary electrophoresis (CE), infrared spectroscopy (IR) [119, 144, 165], Fourier transform near-infrared (FT-NIR) spectroscopy [165], LC-MS [115], liquid chromatography-tandem mass spectrometry (LC-MS/MS) [166], liquid chromatography-diode array detection-tandem mass spectrometry (LC-DAD-MS/MS) [100], hydrogen-1 nuclear magnetic resonance (1H-NMR) [166], Raman spectroscopy [167], and chemometrics [139, 168] are widely used.

Among these methods, HPLC with DAD has been indicated to be the most efficient method for analyzing the sensitive compounds in complicated extracts of natural products [112, 115]. However, HPLC and most of the other methods can hardly be used for routine analysis since they require equipment that are hardly ever detected in small- or medium-sized companies that process and package saffron spice [58].

Abstract

Enzyme immobilization is defined as artificially restriction of enzyme mobility that leads to change of its structurer, properties, and activity. Since enzymes are very sensitive, their classical immobilization methods are still limited mostly as a result of reduction of enzyme activity. Because of unique and tunable properties of nanomaterials, they have been increasingly applied as carrier for enzyme immobi-

1 Introduction

Enzymes are biological catalysts which accelerate chemical reactions by lowering activation energy [1]. Nowadays enzymes have a wide range of applications in food productions such as cheese, bread, yoghurt, and fermented beverages [2]. These biological compounds have excellent properties such as high activity, selectivity, and specificity that may permit to implement the most complex chemical processes [3, 4]. But use of enzymes, purely in food, will be associated with problems such as (1) the need of a lot of enzymes, (2) high costs, (3) increased residual enzyme left in the product, (4) low stability of the enzyme, (5) higher labor costs, (6) incompatible of the continuous process, and (7) low activity [5]. Therefore a new method called immobilization emerged to overcome these limitations which is the powerful tool to improve almost all enzyme properties [3]. During immobilization, enzymes are attached to an inert and insoluble material such as porous glass, polystyrene, agarose beads, and zeolites by physical (hydrophobic and van der Waals), ionic, or covalent binding [4]. The structures of supports have important effect on performance of immobilized enzymes. Thus, the characteristics and reactive groups of material and immobilization conditions are almost considered in development of new supports [3]. Commonly used methods of enzyme immobilization can be classified into (i) physical methods like adsorption, encapsulation, and entrapment and (ii) chemical methods including electrostatic interactions, chelating with a metal, and covalent coupling. Encapsulation and entrapment techniques are commonly used, but the main problem with these methods is the enzyme leakage and slow diffusional mass transfer of substrates and products within the support material. Immobilization using physical adsorption and electrostatic interactions is easy to run, but there are risks regarding non-specific protein binding and loss of enzymes during operation [6]. The main advantage of using physical immobilization methods is their compatibility with mass production. Chemical coupling methods, on the other hand, are more efficient than physical adsorption and entrapment methods with regard to retention of enzyme activity, while they are more complex [7]. Additionally, these methods suffer from the drawback of potential denaturation and deactivation caused by the distortion of the three-dimensional conformation of the protein as a result of multipoint binding [6]. Altogether, the practical applications of the classic immobilization methods are

still limited mostly as a result of the reduction of enzyme activity after immobilization [8]. The reason for that is the change of enzyme conformational integrity which in turn leads to the loss of dynamic properties of enzyme [9].

Application of nanotechnology as a new method leads to some improvement in material properties such as multifunctionality, remote addressability, stability, and multi-compartmentalization [10]. Size reduction of enzyme carrier materials to nanoscale can ameliorate the enzyme features, because this particle size provides minimum diffusional limitation, maximum surface area per unit mass, and high enzyme loading [11]. Enhancement of enzyme stability and activity in some nanostructures such as nanoparticles, nanoflower, nanofibers, mesoporous materials, solgel silica, cross-linked enzyme aggregates (CLEAs)/crystals (CLECs), and single-enzyme nanoparticles have recently been reported [12, 13]. Several studies on the enzyme immobilization on nanosized material of polysulfone nanofibers for extracellular lipase from *Penicillium notatum* [14], PEGylated poly(urea-urethane) nanoparticles for *Candida antarctica* lipase [15], carrageenan hydrogel beads for b-galactosidase [16] and lactase [17], single-enzyme nanoparticles (SENs) for α-chymotrypsin and trypsin [18], nanogel for phenoxazinone synthase [19], and silica gel for laccase [20] have been reported.

2 Enzyme Immobilization

Enzyme immobilization is defined as artificial restriction of enzyme mobility [21]. During immobilization, enzymes are attached to an inert and insoluble material such as porous glass, polystyrene, agarose beads, and zeolites [22]. As shown in Fig. 1, enzymes can be immobilized on the support by different methods, namely, physical adsorption, covalent bonding, entrapment or encapsulation, and cross-linking [4, 23].

2.1 Physical Adsorption

During physical adsorption, enzyme is attached to the support by the interaction of reversible or noncovalent bonding (Fig. 1a) which included ionic, hydrogen bonding, hydrophobic, and van der Waals interactions. Ionic and hydrogen bonding are stronger than hydrophobic and van der Waals interactions. Physical adsorption has several advantages such as simplicity in process that is not affected by the enzyme structure and inexpensive process. Because it is composed of reversible bonding, enzyme can be easily leached [21].

2.2 Covalent Bonding

This immobilization method is composed of covalent attachment between amino acid groups such as histidine, thiol, threonine, and glutamic acid and active groups of solid carrier such as indolyl and imidazole [20] (Fig. 1b). Properties of immobilized

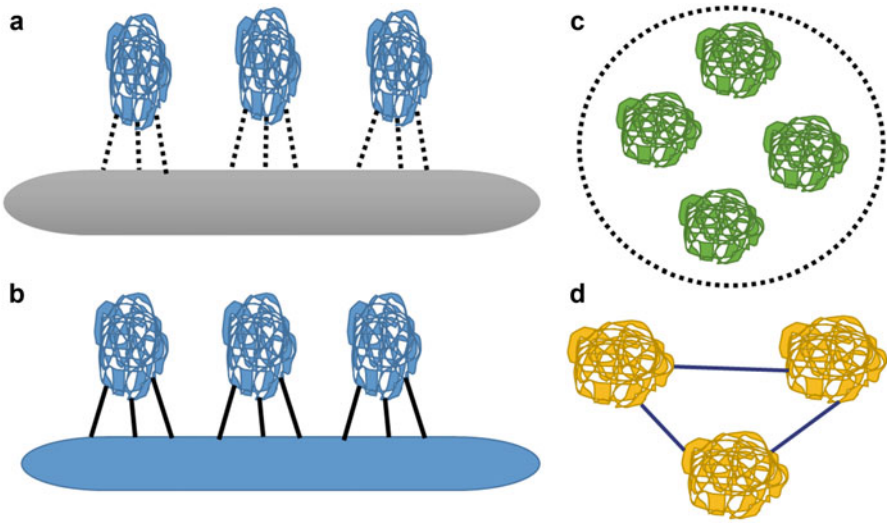

Fig. 1 Physical adsorption (**a**), covalent bonding (**b**), entrapment or encapsulation (**c**), cross-linking (**d**)

enzyme is dependent on the type of active groups and their distribution over the solid carrier [21]. Enzyme leaching in this method is low but structure of enzyme can be changed [4].

2.3 Entrapment and Encapsulation

In this method enzymes are physically confined in the limited space (Fig. 1c) by polymeric matrices, cross-linked arrays, hollow fibers, ultrafilter membranes, and liposomes. Entrapment method has advantages, such as its simplicity in process and reduction of chemical changes of enzymes, while low stability of enzymes, being sensitive to environmental changes which can disrupt capsule, and enzyme leaching are its disadvantages [21].

2.4 Cross-Linking

Because selection of support or carrier and designing immobilization process conditions are time-consuming and more than 50% enzyme activity is lost when it is immobilized on the support, the use of cross-linking is increased. Cross-linking is a carrier-free method in which enzymes are chemically cross-linked together without a solid carrier; therefore its volumetric activity is not decreased [4, 21] (Fig. 1d). Direct cross-linking of enzymes resulted in low activity and weak mechanical stability; therefore this method usually is not used [21]. But recently two methods of

cross-linking (cross-linked enzyme crystals and cross-linked enzyme aggregates) emerged to overcome these deficiencies [4, 24].

2.5 Limitations of Enzyme Immobilization

It is necessary to mention that enzyme immobilization has practical limitations such as the cost of support which in some cases is more expensive than enzyme, the amount of loaded enzyme on the support being low, and structural changes of enzyme [21].

2.6 Selection of Support

The structure and morphology of supports have a large effect on the performance of immobilized enzymes. Thus, the characteristics of the support, functional groups, and immobilization conditions are important [3]. Different nanostructures such as nanofibers, nanoflowers, nanoparticles, nanoliposome, and solgel were used successfully as support because they have high surface to volume ratio [25]. One of the important supports or carriers for enzymes is nanofibers. Nanofibers are defined as long fibers with fine diameters which range from several micrometer to 10 nm and are fabricated by electrospinning process [26].

3 Enzyme Immobilization on Nanofibers

The term electrospinning is derived from "electrostatic spinning" [27] and is an electrohydrodynamic process which converts a polymeric solution to fibrous material. Electrospinning process is composed of different parts such as power supply, syringe pump, and grounded collector. Polymer solution is ejected from needle syringe with constant rate, and then the polymer is stretched by electrostatic force which exists between the needle (as positive pole) and collector (as negative pole). This phenomenon causes decrease in fiber diameter and solvent evaporation. Figure 2 shows schematic of electrospinning instruments [22, 28].

Electrospinning has powerful ability to produce fibers in the range of micrometers to 10 nm. Fibers produced by this method have unique properties such as high surface area, alterable surface properties, and high porosity which directly correlate with solvent vapor pressure. On the other hand, when vapor pressure of solvent is high, the solvent vigorously evaporate from fibers and create many holes or pores on the surface of fibers [23, 29]. Moreover some studies prepared nanofibers with specific secondary structure, which contained core-shell (fabricated by two polymers and specific needle), hollow (fibers with hollow interior), and porous (fibers having a porous surface which is created by two methods: selective removal of a component and application of phase separation) forms [28]. The unique properties of nanofibers

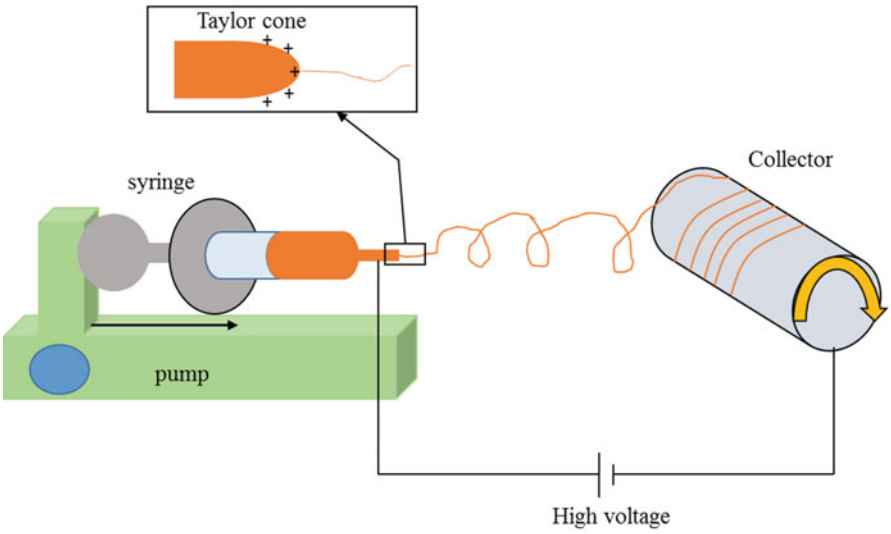

Fig. 2 Schematic electrospinning process

enable them to utilize in a wide range of applications such as tissue engineering applications, dressings for wound healing, energy generation applications, drug delivery, filtration, and enzyme immobilization [27]. Many studies have immobilized enzymes on nanofibers; investigated their properties such as stability, activity, and enzyme loading; and optimized conditions by modifying surface of fibers or selecting the best fibers with special enzyme to improve these properties. Activity of enzymes is calculated by dividing micromole of substrate to minute per gram of catalyst in defined condition [21]. Quantity of loaded enzyme is obtained by subtracting the final concentration (after washing fibers) from the initial concentration [30]. Table 1 shows the results of some studies which worked on the immobilization of enzyme using nanofibers.

Generally, enzyme activity in immobilized state is lower than in free state because immobilization process has limited mass transfer. On the other hand immobilization reduces connection of enzyme and substrate. Moreover when enzymes are immobilized by covalent bonding, it is possible that its structure changed, and therefore its activity decreases [30, 35, 40]. Several factors have influence on activity, stability, and quantity of loaded enzyme.

(i) Mass transfer is an effective factor on the immobilized enzyme activity which is classified in two categories, namely, external mass transfer that is defined as transportation of substrate from environment to the surface of immobilized enzyme and internal mass transfer which is expressed as diffusion of substrate into the support or carrier media [21]. Nanofibers caused higher mass transfer and higher enzyme activity by increasing surface to volume ratio [30, 35, 36].

Table 1 The result of some studies on the enzyme immobilization by nanofibers

Nanofibers	Immobilized enzyme	Fiber diameter	Enzyme loaded (mg/g fibers)	Activity retention %	Immobilization method	Reference

(ii) Diameter of fibers, by decreasing fiber diameter, and surface of fibers increased, so the amount of loaded enzyme increased which leads to higher activity of nanofibers [30–32, 36, 42].
(iii) Type of enzyme interaction with nanofibers is another factor affecting its activity and stability. Lee et al. [34] find that stability and activity of immobilized β-glucosidase by aggregation method is more than the immobilized enzyme by covalent method because loaded enzyme in aggregation is higher than covalent method [34].
(iv) Autolysis of enzyme during the immobilization resulted in production of amino acids, and then these compounds compete on the active sites of nanofibers therefore decreasing enzyme loading, stability, and activity.
(v) Availability of active group on the nanofibers. Sometimes active groups are covered by other nanofibers and so are not available for enzyme, reducing enzyme loading [31].
(vi) Fibers' compatibility with immobilization conditions.

There are some limitations with immobilized enzyme which can be solved by some modifications of nanofibers' surface. The modification methods can be mentioned:

(i) Modification of surface by biomimetics methodology which creates a condition for immobilized enzyme same as living cells. For example, nanofibers with carboxyl groups were modified by chitosan or gelatin [25].
(ii) Modification of surface in order to increase enzyme mobility. In this method, spacer arms (such as poly(ethylene glycol)) are added to the nanofibers to increase enzyme mobility (Fig. 3a) [25].
(iii) Modification of surface in order to increase electrical conductivity. This method is applied to redox enzymes which can be used for polymers with high electrical conductivity.
(iv) Modification of surface by adding or grafting polymers on the nanofibers. As shown in Fig. 4b, c, some polymers, for example, poly acrylic acid, can be grafted on cellulose nanofibers by different methods which included gel-like or brushlike structure. Gel-like structures have high enzyme loading capacity but low mass transfer, and brushlike structures have low enzyme loading capacity [25].

4 Immobilization Using Magnetic Nanoparticles

By enzyme immobilization, its structure, properties, and activity can be changed. Since enzymes are very sensitive, their immobilization needs a proper methodology for maintaining or finally improving their properties such as stability and activity. Immobilization can be reversible and irreversible. Irreversible immobilizations (covalent attachment of the enzyme to the surface or entrapment in a matrix or encapsulation) prevent enzyme from leaching, but reactions happen. This system

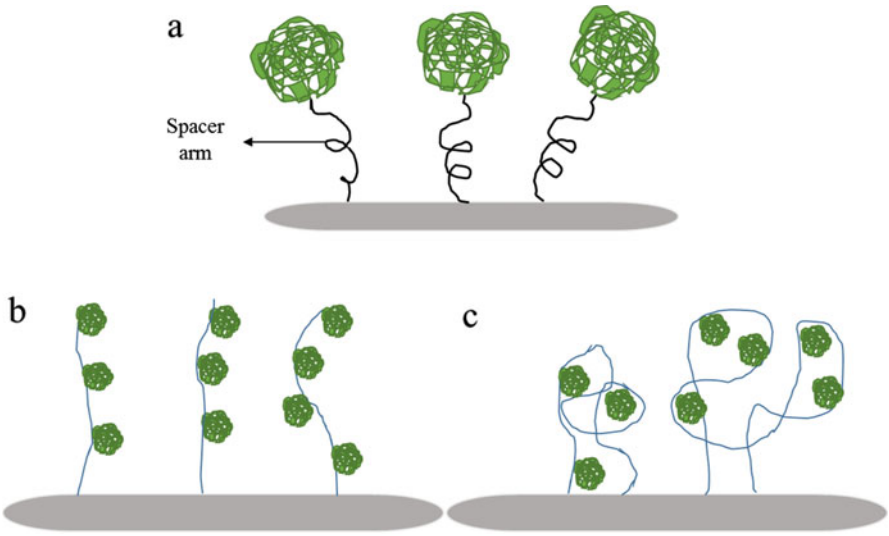

Fig. 3 Schematic representation of spacer arm (**a**), brushlike (**b**), and gel-like (**c**) structures

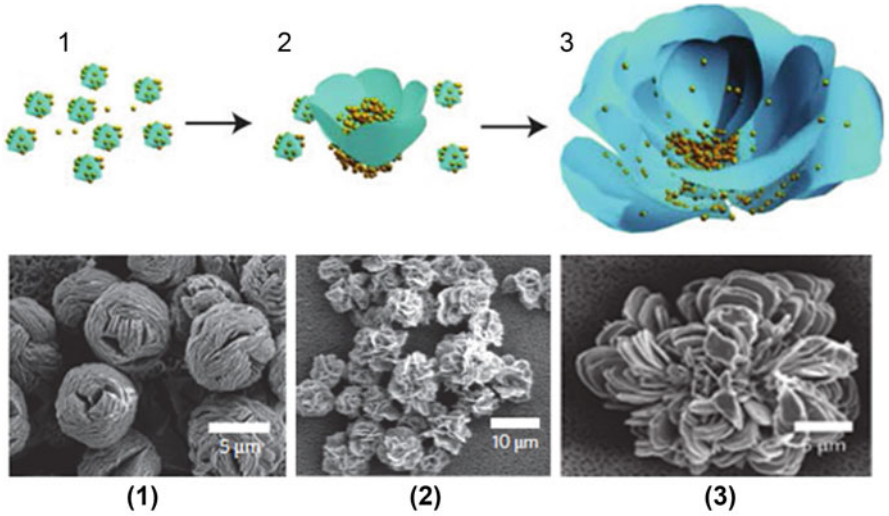

Fig. 4 Up, proposed mechanism, comprising three steps: (*1*) nucleation and formation of primary crystals, (*2*) growth of crystals, and (*3*) formation of nanoflowers. Down: SEM images of carbonic anhydrase hybrid nanoflowers at protein concentrations of (*1*) 0.5 mg ml^{-1}, (*2*) 0.1 mg ml^{-1}, and (*3*) 0.02 mg ml^{-1} [83] (with permission)

permits recovery of support after enzyme inactivation. In reversible immobilization (e.g., in immobilization using magnetic nanoparticles), the simplest method is direct adsorption over the surface, and the interactions between nanoparticle surface and

enzyme surface can be hydrogen bonding, van der Waals forces, and hydrophobic interactions. This system can be affected by pH, ionic strength, temperature, or polarity of the solvent [44].

In recent years, nanoparticles as solid carriers are employed in various immobilization methods [45]. While their limitation is removing them from solution and environment. For this reason, researchers introduced magnetic nanoparticles that would be easily recovered for reuse [46]. Magnetic nanoparticles among the rest of nanomaterials are suitable carriers for bioactive materials such as peptides, enzymes, antibodies, and nucleic acids [47]. Their benefits are tailored surface chemistry, low toxicity, low cost, improved enzyme activity and stability, high surface area, easy separation, and recyclability [46]. Various magnetic particles and magnetic supports have been applied [48]. Among different types of iron oxide, the most popular magnetic nanoparticles are nanoscale zerovalent iron, Fe_3O_4, and Fe_2O_3, with the former being used more frequently since Fe^{+2} state has good potential for acting as an electron donor [49].

Various studies have been performed on magnetic nanoparticle application for immobilization of enzymes like cholesterol oxidase by Fe_3O_4 nanoparticles for analysis of total cholesterol in serum [50]; laccase on chitosan-magnetic nanoparticle for bioremediation of environmental pollutants [51]; α-amylase on cellulose-coated magnetite nanoparticles for starch degradation [52]; pectinase over the silica-coated magnetic (Fe_3O_4-SiO_2) nanoparticles for apple juice clarification [53]; peroxidase on gold-chitosan nanoparticle for rapid deterioration of H_2O_2, water treatment, and pharmaceutical and biomedical applications [54]; cyclodextrin glycosyl transferase on cellulose-silver nanoparticle for biosensors [55]; alcohol oxidase on cellulose-silver nanoparticle for determination of methanol and methyl ester content of pectin [56]; co-immobilized alpha amylase and glucoamylase on magnetic chitosan beads for complete hydrolysis of starch into glucose [57]; and multiple immobilized enzymes of maltodextrin phosphorylase, glucose-1-phosphate thymidylytransferase, and pyrophosphatase on amino-functionalized magnetic nanoparticles for production of uridine diphosphate glucose [58].

There are three methods to prepare magnetic nanoparticles [59]:

(i) Physical methods such as (a) size reduction to the nanometer scale and dispersing in an aqueous solution and (b) condensation of precursors from a liquid and gaseous phase [60]. The difficulty of producing the desired particle size and shape is the main drawback of these methods [61]. However, magnetic nanoparticles with an average particle size of 20–50 nm and narrow particle size distribution can be produced by a new laser ablation or evaporation synthesis method [62].

(ii) Wet chemical preparation methods such as chemical coprecipitation, hydrothermal, solgel reactions, flow injection syntheses, electrochemical, aerosol/vapor methods [63], sonolysis [64], and thermal decomposition [65].

(iii) Microbial methods that magnetic nanoparticles are produced by a biomineralization process [66]. The advantages of this method are high efficiency, good reproducibility, scalability, and control over the particle size [67].

During enzyme immobilization, cross-linking agent has an important role in enzyme activity, recovery, and stability [68]. Among cross-linking agents for protein, glutaraldehyde is the best choice. It is inexpensive and readily available and has ability to make covalent bonds with most of enzymes [69]. While due to some drawbacks, glutaraldehyde cannot be commonly used as a cross-linker in all cases. Small size of glutaraldehyde causes to be placed in enzyme active sites, resulting in inactivation of enzyme in some cases [70]. In addition, its toxic nature has harmful effect on human and aquatic life, if leaching of glutaraldehyde from prepared materials occurred [71]. For this reason, recently, cross-linker agents based on polysaccharides for proteins have been noticed [72]. Newly, pectin-based cross-linker has been used to immobilize glucoamylase onto 3-aminopropyl triethoxysilane-modified magnetic nanoparticles. Results show that pectin is more effective than traditional glutaraldehyde [73].

When magnetic nanoparticles covered with chitosan are employed as support for β-galactosidase, the same or even higher activity in a wider range of temperature and pH, than the free form of enzyme, was observed, and 92% of its activity after 15 successive cycles was maintained. Immobilization of protease on magnetic nanoparticle for reducing autolysis of products showed significant resistance to thermal inactivation, and about 59% of its initial activity after 2 h at 65 °C was retained [44]. Sojitra and Nadar [74] reported that when pectinase was immobilized on chitosan-magnetic nanoparticles by dextran polyaldehyde as a macromolecular cross-linking agent, its V_{max} and K_m values were nearly similar to native form. The residual activity of immobilized pectinase was 85% after seven successive cycles of reuse, and it maintained up to 89% of residual activity on storage of 15 days which displayed great stability and durability. Eventually, magnetic pectinase was applied for apple juice clarification and showed turbidity reduction up to 74% after 150 min of treatment. The effect of particle size on activity and recycling capabilities of glucose oxidase immobilized onto magnetic nanoparticles had been studied by Park and McConnell [75]. Three different sizes of magnetic nanoparticles (5 nm, 26 nm, and 51 nm) had been used, and the results showed about 20% of activity was lost for the large-sized (51 nm) and medium-sized (26 nm) glucose oxidase-magnetic nanoparticle and approximately 96% activity was lost for the smallest one (5 nm) after ten cycles. Table 2 showed enzyme-recovered activities (the activity of the immobilized enzyme comparing to the activity of its free form). Apparently most of them are less than the activity of free enzymes. Magnetic silica nanocomposite materials due to coating of the surface of magnetite nanoparticles with functionalized silica will not be aggregated in liquid, and their chemical stability and biocompatibility will be improved. The binding of enzymes on the hydrophilic surface of silica nanoparticles in aqueous solution will be performed better [44].

5 Immobilization on Organic-Inorganic Hybrid Nanoflowers

Organic-inorganic hybrid nanoflowers (HNFs) are novel promising materials for immobilization of enzymes that demonstrate mostly much greater activities and stabilities than free and conventionally immobilized enzymes. They attracted

Table 2 Examples of enzymes immobilized on magnetic nanoparticles and their recovered activity

Enzyme	Coupling agent	Magnetic carrier	Recovered activity (%)	Reference
Cellulase	Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride	Fe_3O_4	30.2	[76]
Glucose oxidase	Glutaraldehyde	$CoFe_2O_4$, SiO_2	80	[77]
Cholesterol oxidase	Glutaraldehyde	eFe_2O_3, SiO_2	60	[78]
Candida rugosa lipase	Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride	Fe_3O_4, lauric acid	180	[79]
Esterase	Glutaraldehyde	Fe_3O_4	63	[80]
Alkaline phosphatase	Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride	Fe_3O_4	44	[81]

growing attention in recent years due to their simple, eco-friendly, and low energy-intensive synthesis procedure [82]. The production method was discovered for the first time by accidental addition of $CuSO_4$ solution to phosphate-buffered saline (PBS) containing protein (bovine serum albumin (BSA)) [83]. The typical BSA-$Cu_3(PO_4)_2 \cdot 3H_2O$ HNFs was synthesized as follows: 3 mL of 10 mM phosphate-buffered saline (pH = 7.4) containing 0.1 mg of BSA and 20 μL of $CuSO_4$ aqueous solution were added at room temperature (25 °C). After incubating for 3 days at room temperature, a blue color precipitate was formed at the bottom of test tube. Analyzing the precipitate with scanning electron microscopy (SEM) revealed a porous and flowerlike structure for HNFs, shown schematically in Fig. 4 [83].

The enhanced activity of HNFs was thought to be due to (1) greater surface area of nanopetals and as a result less limitations against mass transfer (2) cooperative effects of immobilized enzyme molecules on each other and (3) better confinement of enzymes inside the nanoflowers [84]. Following Zare group, many other researchers utilized this novel immobilization technique for the synthesis of various new HNFs using several other enzymes and metal ions. As examples, laccase [85], lipase [86], horseradish peroxidase [87], soybean peroxidase [88], lactoperoxidase [89], glucose oxidase [90], urease [91], trypsin [87], chymotrypsin [92], papain [93], his-tagged enzymes [94], and α-acetolactate decarboxylase [95] have already been immobilized in the form of HNFs. In most cases, literature data shows that enzyme-incorporated HNFs have higher activities compared to free or conventionally immobilized enzymes.

These enzyme-based HNFs have been used as biosensors, bioanalytical devices, biofuel cells, and biocatalysts. For example, colorimetric sensors for detection of hydrogen peroxide and phenol were developed by Sun et al. [90]. Wang et al. synthesized α-amylase-$CaHPO_4$ HNFs for digestion of protein [96]. Recent reviews by Altinkaynak and Tavlasoglu [84] discussed in more detail the types, structural characteristics, potential mechanism of formation, and futuristic bio-based applications of some enzyme-inorganic hybrid nanoflowers. Co-immobilization of two or more different proteins or enzymes simultaneously in a single unit is an interesting idea for extending functionality, and applications of hybrid nanoflowers attracted

much attention recently. Co-immobilized glucose oxidase and horseradish peroxidase hybrid nanoflowers (GOx-HRP-$CU_3(PO_4)_2$) enabled the two-step reaction in only one-step cascade catalytic reaction [90]. Ye and Zhu [97] developed concanavalin A-GOx-$CaHPO_4$ (CGC) hybrid nanoflowers with a facile and eco-friendly method which was used as probes for on-site detection of *E. coli* O157:H7. They reported that the enzymatic activity of GOx decreased by 27% probably due to the limited mass transfer in CGC configuration. By contrast, GOx immobilized in CGC nanoflowers showed more storage stability with more than 90% residual activity after 30 days at room temperature. Table 3 shows some recent works concerning with enzyme immobilization using (HNFs) technique. Cui et al. developed a new strategy to increase further the activity and stability of lipase-embedded hybrid nanoflowers. Normally, lipases have a concealing polypeptide chain named "lid" on their surface, blocking the access of substrate to active site of enzyme which in this case enzyme is in its inactive form [98]. But, surfactants cause the dislocation of lid and as a result lipase change to its open and active form [98].

6 Enzyme Entrapment in Nanoliposomes

Encapsulation of enzyme in a polymeric network by covalent or noncovalent bonds is named entrapment. Liposomes are spherically aggregated amphiphilic molecules in water and can be produced by natural ingredients. Liposome sizes are in the range of 10–100 nm for monolayer liposomes to several micrometers for multilayer liposomes. Nanoliposomes are liposomes in nanosize and used in encapsulation and controlled release systems. Compared to liposomes, nanoliposomes have more surface area and potential to increase solubility, improve bioavailability, and meliorate controlled release [106]. They can be applied to encapsulate protein such as enzymes owing to their ability to contain water-soluble enzymes within [106]. Liposomes and nanoliposomes separate encapsulated enzymes from the surroundings and maintain them in conditions that would hinder their activity or cause denaturation. In addition, they can be applied as a means of controlled release. Enzymes can deliver their content in specific parts of the food system or in an appropriate time [107]. When amphiphilic molecules such as phospholipids are put in an aqueous environment and sufficient amount of energy is supplied, phospholipids aggregate; they can arrange themselves in the form of liposomes. During this process, hydrophilic materials in solution can be entrapped in liposomes, and lipid-soluble molecules can be entrapped in liposomal bilayers by dissolving them with the lipids [107]. During liposome preparation, enzyme can be entrapped in the aqueous interlaminar spaces [108]. Preparation method and its condition (such as lipid concentration, enzyme purity, and phospholipid type) have important effects on enzyme encapsulation efficiency [108].

There are several methods to produce nanosized liposomes such as mechanical (extrusion, sonification, high-pressure homogenization, microfluidization, and colloid mill) and nonmechanical (reversed-phase evaporation and depletion of mixed detergent-lipid micelles). Also, many methods for liposome stabilization

Table 3 Enzyme immobilization with hybrid organic-inorganic nanoflowers

Enzyme	Hybrid nanoflower	Application	Relative activity (%)	Storage stability (days)	Reusability (cycles)	Specific advantage	Reference
α-Acetolactate decarboxylase (ALDC)	Alginate coated ALDC-$Ca_3(PO_4)_2$	Prevention of diacetyl (off-flavor compound) formation in beer	98	–	80% (6)	Improved stability against broad range of pH and temperature, improved recyclability	[95]
Peroxidase from Turkish black radish (TBR)	TBR-$Cu_3(PO_4)_2$	Decolorization of Victoria blue dye	450	–	–	Excellent stability and reusability	[99]
Peroxidase from horseradish (HRP)	Streptavidin-HRP-$Cu_3(PO4)_2$	Combined with ELISA, used as colorimetric sensor for detection of disease-related biomarker	–	>80% (30, RT)	75% (6)	Improved catalytic activity	[100]
Lipase from *Candida rugosa*	Glutaraldehyde-treated lipase-$CuSO_4$	–	95	–	>70% (4)	Improved reusability	[101]
Glucose oxidase (GOx) from *Aspergillus niger*	Concanavalin A-GOx-$CaHPO_4$	On-site detection of *Escherichia coli* O157:H7	73	>90% (30, RT)	–	A simple but potentially powerful amplification biosensing technology with excellent simplicity, portability, sensitivity, and adaptability	[97]
Horseradish peroxidase (HRP)	Antibody-HRP-$Cu_3(PO_4)_2$ three-in-one nanoflower	As a novel enzyme-labeled antibody (ELISA) for *Escherichia coli* O157:H7 detection	–	93% (10, RT)	–	Easier preparation, high antigen capture capability, enhanced enzymatic activity, potential alternative to conventional ELISA	[102]

(*continued*)

Table 3 (continued)

Enzyme	Hybrid nanoflower	Application	Relative activity (%)	Storage stability (days)	Reusability (cycles)	Specific advantage	Reference
Lipase from porcine pancreas	Lipase-$Cu_3(PO4)_2{\cdot}3H_2O$	–	878	–	–	–	[82]
Papain	Papain-$Cu_3(PO4)_2{\cdot}3H_2O$		7260	–	–	–	
Lipase from bovine pancreas	Surfactant-activated lipase-$CuSO_4{\cdot}5H_2O$	–	460	95% (20, 25 °C)	>90% (8)	Improved kinetic parameters, higher temperature and pH resistance, good mechanical stability	[98]
Lipase from *Burkholderia cepacia* (BCL)	BCL-$Ca_3(PO_4)_2{\cdot}nH_2O$	–	308	>75% (15,	80% (5)	–	[103]
Glucoamylase	Glucoamylase-$Cu_3(PO_4)_2{\cdot}3H_2O$	Liquefaction of oligosaccharides and starch	204	91% (25, RT)	70% (8)	Improved thermostability	[104]
L-arabinose isomerase from *Paenibacillus polymyxa*	PPAI-$Ca_3(PO_4)_2$	Production of L-ribulose and D-tagatose	–	–	–	Improved thermal and acid stability	[105]
Papain	Papain-$Zn_3(PO_4)_2{\cdot}4H_2O$	–	–	82.3% (36, 4 °C)	88.8% (10)	Improved operational stability, improved thermostability, long storage life	[93]
Urease from bovine serum	Lipase-$Cu_3(PO_4)_2{\cdot}3H_2O$	–	2000	96.3% (30, 4 °C)	–	–	[91]
Soybean peroxidase (SBP)	SBP-$Cu_3(PO_4)_2{\cdot}3H_2O$	Simultaneously purification and immobilization of SBP	446	–	–	Excellent reusability	[88]

such as lyophilization, freezing, spray-drying, and supercritical fluid (SCF) technology have been studied. Lyophilization is the preferred method to prolongate the liposome shelf life, especially for liposomes containing thermosensitive materials like enzyme [109].

Most common methods for nanoliposome production and their advantages and disadvantages are listed in Table 4. Large-scale production of liposome and nanoliposome for food application is always easy.

Physical stability of nanoliposomes depends on their size, number of layers, phospholipid structure, and manufacturing method. Temperature, ionic concentration, pH, and presence of phospholipase enzymes affect the release of the encapsulated enzyme. When the enzymes are put into the bilayer position of nanoliposomes, their release became faster than when they are located in the center [110]. It should be noted that leaking of entrapped enzymes from liposomes may occur during storage. Nanoliposomes are thermodynamically unstable and during their storage they aggregate, precipitate, and flocculate. Increasing interparticle repulsion by coating the vesicle surfaces with special polymers, like polyethylene glycol or chitosan and using stabilizing agents like cholesterol or glycerol, can improve their stability [107].

Application of entrapped enzyme using nanoliposome has been reported for proteolysis enhancement of cheese for better texture and flavor in half normal time and lower amount of enzyme. Some advantages of lipid vesicles applied for cheese production are as follows: (1) they can be produced from naturally present ingredients in cheese, (2) can protect casein from early hydrolysis during cheese manufacturing, (3) and can properly separate in curd milk [106]. Encapsulations of β-galactosidase to induce the slow digestion of lactose for lactose intolerants and various cheese-ripening enzymes like lipase, nutrease, chymotrypsin, chymosin, neutral protease, cyprosine, flavourzyme, and palatase in liposomes and

Table 4 Most common methods for nanoliposome production: advantages and disadvantages

Method	Advantages	Disadvantages	Reference
Probe sonication	Rapid method	Possible degradation of active material because of high-energy sonication	[110]
Homogenization	Efficient in producing dispersed nanoparticles	Possible degradation of active material because of high-energy input	[110]
Microfluidization	No organic solvent needed	Possible degradation of active material because of high energy and pressure input	[108]
Heating method	No organic solvent needed	Multistep technique; possibility of enzyme denaturing	[108]
Mozafari's method	Very simple and rapid method; no organic solvent needed	Possibility of enzyme denaturing	[109]

nanoliposomes have been reported earlier and were reviewed by Mohammadi and Mahmoudzade [110].

7 Enzyme Entrapment in Solgel

Solgels are inorganic gel in the form of films, fibers, or nanospheres that are stable in chemical, thermal, and photochemical properties. Oxide mixtures of silica, alumina, alumnosilica, titanium, or zirconium are generally used for solgel preparation. For encapsulation of biomaterials like enzymes, silica solgels are often good choice. Because of using relatively mild conditions in their production, activity of the entrapped enzymes is almost retained [111]. Silicon dioxide (SiO_2) and silicon tetroxide (SiO_4) are commonly used for enzyme immobilization. The former is flexible and the latter is rigid, while both of them are in 3D polymers. They have adsorptive properties because of hydrophilic and hydrophobic sites [112]. Silica (or silica gel) is nontoxic and biocompatible and does not swell very much, and its porosity remains unchanged [113]. Since silica carriers are chemically inert, their modification is required for activation. Commonly for introducing amino group, they are modified by treating aminoalkyl triethoxysilanes and a variety of methods for enzyme immobilization [112]. Their functionalities can be changed by decorating the surface of the silica with free silanols through chemical derivatization (silanization reactions), electrostatic interactions (adsorption of polycations), and hydrogen bonding [113]. In a typical manufacturing, tetramethyl orthosilicate or tetraethyl orthosilicate is hydrolyzed into "sol" and then enzyme solution added to the "sol." It initiates condensation reaction and makes "gel," and encapsulation of enzyme in silicate matrices is performed. Various pores and channels in the final silicate matrices in the range of 0.1–500 nm are formed [12]. If obtained solgels are dried before use, gels with different pore sizes (xerogels, aerogels, or ambigels) are obtained. When hydrophilic solgel at room temperature is dried, xerogels with pores of 1–10 nm in diameter are obtained. Aerogels can be made by drying the solgel with supercritical CO_2 and have near unaltered porosity. By gelation at pH 7 and drying with supercritical CO_2, aerogels with large distribution in pore diameters (2–80 nm), mostly between 12 and 40 nm, are formed. When hydrophobic gels are dried at room temperature, ambigels with the same size and porosity as wet gels are produced. If hydrophobic gels are dried with supercritical CO_2, aerogels with hydrophobic properties are obtained [111].

Recently aerogels have been applied for encapsulation of several enzymes, like tyrosinase for phenol removal from aqueous solution and cellulase for hydrolysis of carboxymethyl cellulose [111]. Entrapped enzymes in solgel can be used in electrochemical and optical biosensors to determine the concentration of various analytes. Solgel-encapsulated creatine kinase was resistant to heat and has maintained 50% of its activity ten times longer than the free enzyme. Phosphatases in silica solgel matrices are resistant to harsh pH conditions. For example, alkaline phosphatase with optimum activity at pH 9.5 can be active at a pH as low as 0.9. Probably, this was due to space limitation in the pores [114]. For preventing the leaching of

encapsulated enzymes during storage, careful optimization process is required. However, if leaching is prevented, solgel method leads to a relatively stable form of enzyme immobilization and prevents from unfolding and denaturation of encapsulated enzymes [12]. The nature of the encapsulated protein and the gel are the most major factors in enzyme retention. If molecular mass of protein is as low as 8000 Da, it can be efficiently retained, while larger molecules with molecular mass over 100,000 Da, like polylysine, can diffuse inside the same gel [115]. It should be noted that solgel-immobilized enzymes generally have lower activity than the free enzymes because of small pore size and non-open pore obstacle. Moreover, the dissimilar pore sizes of most silica gel made less reproducible processes. Unlike solgel silica, mesoporous silica materials supply tunable and similar pore system, functionalizable surfaces, and closed nanospaces for enzyme immobilization [116].

8 Conclusions

Over the last few years, some interesting new developments in enzyme immobilization have entered an exciting new phase. Apart from retention, recovery, and stabilization, other advantages to enzyme immobilization such as enhanced enzyme activity, modification of substrate selectivity, and multienzyme reactions have emerged. In this chapter, some enzyme stabilization methods and their properties were discussed. Application of magnetic nanoparticles can improve the stability of the immobilized enzymes as well as reduce the need for downstream separation processes to recover the biocatalyst. Nanofibers with hollow and porous structure have unique properties to be utilized in a wide range of applications for enzyme encapsulation. Immobilized enzymes in solgel retain their bioactivity and are even protected by the silica cage. Such inorganic matrices offer several advantages compared with organic polymers such as mechanical strength or chemical inertia. Moreover, they do not swell in water and can be easily shaped into microcapsules, films, or fibers. The enhanced activity of nanoflowers was due to greater surface area of nanopetals, cooperative effects of immobilized enzyme molecules on each other, and better confinement of enzymes inside their structure. These technologies were initially developed in the pharmaceutical world and now expanding in other fields like food processing. Cost and scale-up are the main issues which are limiting the application of these types of technologies. It is clear that these areas of researches still have a very big opportunity for researchers in order to develop new ideas concerning modeling and scale-up of immobilized enzymes.

Abstract

Seafood authenticity is a key parameter for seafood quality, particularly in Europe where regulations provide a strict framework for seafood labeling. A wide variety of methods are commonly used in control laboratories (private or public) to identify seafood species, but emergent approaches for the development of new and fast DNA- and protein-based methods for species differentiation are also considered. To address the challenges in controlling further labeling requirements in the latest European legislation on seafood product traceability and labeling (Regulation (EU) 1379/2013), a review of the development of methods to identify fishing areas and to distinguish between wild and farmed fish, as well as an overview of the advanced methods that could be used for differentiation of fresh and frozen-thawed fish, is given. These methods will become increasingly important in the near future as the risk-based control of food authenticity is prescribed by the new EU control regulation (Regulation (EU) 2017/625).

Keywords

Seafood identification · Traceability · Seafood geographical discrimination · Seafood authentication

1 Introduction

The consumption of fish and seafood products has increased considerably worldwide, from an average of 9.9 kg per capita in the 1960s to 19.7 kg in 2013 (26.8 kg per capita in industrialized countries) [1]. Fish and seafood products are among the most traded food commodities in the world and represent about 9% of total agricultural exports and 1% of world merchandise trade in value [1]. Trade in fish and seafood products has expanded considerably in recent decades, rising by more than 245% in terms of quantity (live weight equivalent) from 1976 to 2014 and by 515% if trade in fish for human consumption alone is taken into consideration. This trade is driven by high demand and is fueled by growing complexity in commodity flows, with the fisheries sector operating in an increasingly globalized environment. In addition, there is significant trade in fisheries services, with some products crossing multiple national borders during the seafood supply chain. The European Union is a

net importer of fisheries and aquaculture products, importing 5,947,708 tons and exporting 2,145,169 tons in 2014 [2].

Fisheries and aquaculture production are very heterogeneous in terms of species and food products. Fifty percent of the catches traded are processed (i.e., fillets, portions, elaborated products) because of their high perishability and also so as to prepare convenient products. In this way, by losing the morphological characteristics, they generate more opportunities for fraudulent operations [1].

Mislabeling has been identified by numerous studies for different species and types of seafood [3, 4]. In addition to being an economic problem, it is thought to contribute to fish decline because it frequently hides illegal, unreported, and unregulated (IUU) fishing, accounting for approximately one fifth of the global catch and, thus, posing a major threat to sustainable fisheries [5].

For fishery or aquaculture products sold to the final consumer, the European EU 1379/2013 regulation requires that commercial designation and scientific names are shown on the labels. It is also established that different member states can legally (i) designate official commercial names for fish species which can be different from one country to another, (ii) give a common commercial name for a specific genus, and/or (iii) group some fish species together for commercial purposes (e.g., the European regulation stipulates that canned products labeled as tuna should be prepared either from the *Thunnus* genus species or from skipjack tuna (*Katsuwonus pelamis*)).

International trade generates an increased need for international harmonization of the conventions for naming fish species and requires standardized species identification tools, methods for the easy identification of fishing grounds or farming areas, and production methods. These measures will contribute to improving controls by customs officers, fishery inspectors, and fish industries, ultimately preventing fraud and increasing consumers' trust in seafood labeling and traceability. Validated and harmonized methods are the prerequisite for realizing the new EU control regulation (Regulation (EU) 2017/625) which dictates the risk-based control of food authenticity.

This chapter first reviews the methods commonly used for seafood authentication which are mainly based on DNA. Second, different approaches to the development of quick DNA-based methods and new identification procedures are presented. Finally, there is a review of the development of methods for identifying fishing areas and distinguishing between wild and farmed fish. An overview of the advanced methods that could be used for differentiating fresh and frozen-thawed fish addresses some of the challenges for controlling new labeling requirements in the latest European legislation on seafood product traceability and labeling.

2 Common Methods Used for Seafood Surveillance

2.1 Protein-Based Methods: Isoelectric Focusing (IEF) and Other Electrophoresis Techniques

Although many different DNA methods have been developed and successfully implemented in the last 25 years, isoelectric focusing (IEF) technology has not yet disappeared because users appreciate its benefits in terms of simplicity and cost and

time efficiency. For that reason, official laboratories still continue to use IEF to identify certain fish species [6]. Recent publications by Kappel and Schröder (2016) [7] and Wang and Hsieh (2016) [8] have demonstrated how reliable this technology is as a screening method for proving labeling compliance in the case of common sole, cod, and striped catfish.

While self-drawn gels were used in the early days, commercial gels facilitated and accelerated the task, making it possible to standardize a method indicated in national legislations for many years [9, 10].

The principle of the method is based on the separating water-soluble sarcoplasmic proteins, predominantly found in the white muscle tissue of fish, in a polyacrylamide precast gel with a pH gradient (mostly used in a wide range of pH 3–10 and 0.3 mm thick) connected to an electric field with specific settings [11]. Proteins are electrically charged macromolecules whose total charge is dependent on the negative and positive charges of the amino acid side chains and therefore on the pH of the environment. During the IEF separation procedure, proteins migrate within the gel with a pH gradient depending on their charge until they reach the position where their total charge is neutral. These protein-specific positions are called isoelectric points (pI), and the resulting protein patterns are comparable with a barcode, forming important parameters for identifying species in unknown samples.

After the protein bands have been visualized, for instance, with a Coomassie dye SERVA Violet and fixed with acid, the samples must be verified by comparing the banding patterns with those of reference individuals that were run in the same gel. Only intense protein bands are used for evaluation. The pI values of the characteristic bands are calculated by comparing the positions of the marker proteins (commercial calibration pI kit, adjusted to the pH gradient applied) with the sample bands using a visualization system and analysis software [12]. Piñeiro et al. (2000) [13] demonstrated the high reproducibility of characteristic protein profiles because the IEF technique seems to be less affected by polymorphism factors such as intraspecies variability.

Many fish species and products have been identified using IEF technology, for example, catfish, tilapia, and snapper [14]; Sparidae species [15]; barramundi and tilapia [16]; different Aegean and Atlantic species [12, 17]; swordfish and spearfish [18]; puffer fish [19]; red snapper [20]; tunas, bonitos, and mackerels [21]; perch species and flat fish species in combination with two-dimensional electrophoresis [22, 23]; or gadoid species using auxiliary detection of specific enzymes [24] to detect food fraud practices. In particular, the acidic proteins in proximity to the anode (pI values from 3.5 to 5.5) can be applied for species identification. These characteristic, small-sized Ca^{2+}-binding proteins (<14 kDa) are identified as parvalbumins [25], which are heat stable and give species-specific patterns, not only in raw but also in processed fish such as cooked [26] or smoked fish fillets [27]. Kappel and Schröder (2016) [7] and Wang and Hsieh (2016) [8] were also able to show that prepared restaurant samples of common sole and striped catfish were easy to differentiate by means of acidic protein patterns.

Different application modalities were developed and standardized to extend the scope of IEF. Processing methods such as cooking, frying, and smoking lead to more

or less pronounced denaturation as well as degradation of the proteins and result in loss of characteristic protein bands in IEF [28]. Due to specific heat stable parvalbumins, applying native IEF to heated products is still possible with a few fish species [28]. Nevertheless, other electrophoresis techniques as denaturing urea IEF or sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) have shown better results for species identification in high pressure-treated products [29] and may be alternative approaches in cooked fish species depending on the type of product [30, 31]. A collaborative study revealed that urea IEF has a greater species-discriminating power than SDS-PAGE for smoked and gravad salmonid products, as well as smoked eels [32]. In general, the research group responsible recommended using native IEF, urea IEF, and SDS-PAGE in combination depending on the product and species.

In some cases, closely related species could not be differentiated by IEF alone, because of nearly identical protein band patterns.

Overall, the different examples of applications for IEF, urea IEF, and SDS-PAGE highlight their broad range of applications and show their possibilities for saving time and costs in case of species identification.

2.2 Immunological Methods

Immunological methods are based on the specificity of the antigen-antibody (Ag-Ab) reaction. Generally, studies on the use of these methods for fish species identification are rare, partly because of the high number of commercialized fish species [33]. Muscle proteins are generally used as antigens, and polyclonal antibodies (pAbs) or monoclonal antibodies (mAbs) are generated specially.

pAbs directed against muscle proteins have thus been developed to distinguish fish species such as halibut, sole, cod, eel, sardine, salmon, trout, haddock, grouper, and Nile perch mainly using the enzyme-linked immunosorbent assay (ELISA)-based methodology [34–37] or tuna and less-valued scombrid species [38]. Fish-specific polyclonal antisera have also been generated against a 36 kDa thermostable protein from a mix of different fish species (Atlantic salmon, yellowfin tuna, swordfish, black grouper, tilapia, red snapper, amberjack, basa, catfish, and perch) to detect the presence of fish muscle in food products for the protection of fish-allergic children or adults [39]. To specifically detect possible adulteration of surimi-based products, ELISA and dot-blot methods have also been used to check for the presence of crab meat using pAbs raised against crustacean arginine kinase [40]. A competitive ELISA was also developed to quantify Alaska pollock surimi in crabsticks using pAbs generated against a 15-amino-acid peptide from the myosin light chain 1 [41]. Likewise, a polyclonal anti-mackerel myosin light chain 1 antiserum was used to detect different fish species in boiled and dried fish products by immunoblotting partially purified fractions of myosin light chains [42]. Even though the production of pAbs is simple, their use is very limited in routine analysis because of their low specificity, resulting in cross-reactivity problems and the need to continuously require new immunizations in animals.

Monoclonal antibodies have thus been used because of their high specificity and absence of cross-reactivity against other species, as well as their unlimited production. These mAbs have been used to identify red snapper [43], grouper [44–46], catfish [47–49], wreck fish [46], and three species of clam [50].

Although immunoassays, once developed, are easy to use and have high sensitivity and throughput, their use is limited because of a number of disadvantages: (i) they require analysis in parallel reference samples to verify their cross-reactivity with other or similar species, and (ii) they are not suitable for forensic purposes in the analysis of processed food products given that processing may alter the three-dimensional structure of proteins, thus losing and/or modifying the targeted protein recognition site(s).

2.3 Main DNA-Based Methods

2.3.1 DNA Sequencing: BLAST and FINS

DNA sequencing makes it possible to directly retrieve genetic information from the DNA molecule: the order of nucleotidic bases is fundamental to genetics, evolution, and molecular taxonomy, and a great deal of scientific effort has thus been devoted to finding suitable methods for achieving this goal. In 1977, Frederick Sanger [51] proposed the chain termination method, and it has been the basis for all sequencing methods for the last 40 years. This methodology requires the use of DNA polymerases and chemically modified deoxynucleotides, so-called dideoxynucleotides. Briefly, the method consists of using a DNA template, often a PCR amplicon, which, after denaturation and reaction with a matching primer, is exposed to a mixture of deoxynucleotides (dATP, dCTP, dGTP, dTTP), dideoxynucleotides (ddATP, ddCTP, ddGTP, ddTTP), and a polymerase. For several cycles, the DNA polymerase synthesizes the complementary strand by incorporating dNTPs and stopping when a ddNTP is randomly incorporated. This strategy generates a series of overlapping DNA fragments in which the last NTP of each newly synthesized oligonucleotide is known because it is a ddNTP (earlier these ddNTP were radioactively labeled, and four simultaneous reactions were prepared with each of them). These fragments, which differ in size by one nucleotide, could be separated by electrophoresis, and the sequence can easily be retrieved by putting the size of the fragments in order [52].

Using DNA sequencing to identify fish species was first reported by Bartlett and Davidson [53]. They combined the capacity provided by PCR to produce a substantial amount of a specific DNA fragment, mitochondrial cytochrome b (*cytb*), with the relative easiness of DNA sequencing, thanks to the early sequencing kits and the capacity to analyze DNA sequences with a phylogenetic approach named FINS: forensically informative nucleotide sequencing [54].

Therefore, one important aspect to be considered when applying this technique is the target DNA marker to be used. Early developments (1990s) considered *cytb* to be an adequate marker for species identification as it codes for a fully functional monomer protein, a component of the electron transport chain, whose structure was well-known for having both conserved and variable regions. These features

made it possible to design universal primers for amplifying fragments which contained species-specific nucleotides [55]. Although some *cytb* DNA sequences for certain fish species were available at that time in public databases such as the NCBI (National Center for Biotechnology Information), it was still necessary to collect most commercial ones to sequence their *cytb* gene. It was nevertheless a very useful starting point and is still used nowadays as a reliable marker [56–62].

In 2009, Rasmussen and Morrisey [63] reviewed the use of DNA markers in seafood products from 1995 until 2008, in particular in each of the main seafood species groups. Their compilation showed that mitochondrial *cytb* was used in 39% of the studies, whereas other mitochondrial markers altogether were used in 30% of the cases. At that time, COI was used in only 4% of studies (Fig. 1).

In 2014, Griffith et al. [6], on the basis of a survey of authenticity testing laboratories across six European countries, reported that most laboratories were using *cytb* (73%), COI (28%), and *16S* rRNA (18%).

However, the use of a universal barcode such as one fragment of the COI gene has gained much attention in recent years. This approach was proposed by Herbert et al. in 2003 [64, 65], and it is based in a relatively long fragment of 650 bp of the COI gene with universal primers. Although it is an interesting approach for standardization of fish species identification, it presents a certain number of problems for the identification of some fish species groups (i.e., tunas [66]), as some degeneration of the primers is needed in order to make possible the amplification of certain fish species [67], and the target amplicon has to be reduced if thermally processed seafood products are to be analyzed (minibarcodes [68, 69]). In addition, for other major seafood groups, such as crustaceans and mollusks, *16S* rRNA markers are usually preferred [63, 70].

Another important aspect that should be considered when working with DNA sequences is the DNA sequence reference database, necessary for comparing the sequence obtained from the sample. There are two main approaches: having a proprietary database or relying on public databases. Although some laboratories

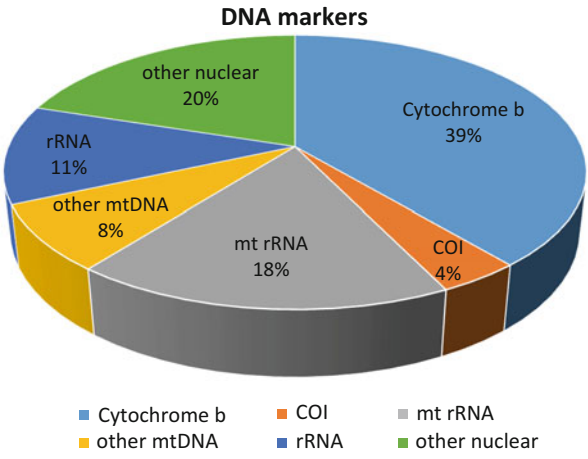

Fig. 1 Analysis of the use of DNA markers for seafood identification in research publications for the period 1995–2008 compiled by Rasmussen and Morrisey [63]

can afford to have proprietary databases, these usually involve considerable efforts in sampling and sequencing. Public databases are a perfect solution, as the effort is divided between many different laboratories, both private and public, around the world, and a large number of sequences of species and specimens can be collected. Probably the largest of all of them, hosting 260,000 formally described species, is the NCBI DNA sequence database GenBank [71], where it is possible to retrieve sequence from many different fish DNA fragments from around the world. Some authors have reported that GenBank is not specifically designed for species identification, and inconsistencies have been found in the terminology and sequence data for particular species, reflecting taxonomical issues in particular groups or taxons. There is also no guarantee that only authenticated voucher specimens are used [72]. The other major public database containing reference sequences is the Fish Barcode of Life Initiative (FISH-BOL; http://www.fishbol.org). In this case, the main objective of the database is to identify fish species around the world using genetic information from voucher specimens with taxonomic identifications and specifically a 650 bp COI marker. This initiative was launched in 2005, and since then many publications have shown the importance and convenience of having a standard barcode [73, 74] for fish identification.

Finally, once the sample DNA sequences have been obtained and the appropriate sequence database is available, in order to identify the species present in the sample, the use of a robust method is needed to analyze the level of similarity between the sample and reference sequences. The most commonly used approach is forensically informative nucleotide sequencing, which involves genetic distance methods for estimating the similarity and a phylogenetic tree to represent the distances obtained. Several genetic distance methods have been used for species identification, including Kimura-2 (takes into account nucleotide substitution and type, transitions, and transversions), Tamura-Nei (takes into account nucleotide substitution and type and also nucleotide frequencies), and Jukes-Cantor (equal rate of nucleotide substitution) [72]. However, models which take into account the complexity of type of nucleotide substitution and frequency might be more appropriate for species identification than simpler models [70]. Once the genetic distance matrix has been calculated, the topography can be visualized either with Neighbor-Joining or Unweighted Pair Group Method with Arithmetic Mean (UPGMA) methods, and in both cases a phylogenetic tree is produced (Fig. 2).

Another approach for species identification is to use particular nucleotides in a DNA fragment to identify the species in a sample. This has been referred to as character-based identification and requires prior identification of diagnostic nucleotides [75]. This approach is similar to PCR-RFLP, where the presence of certain diagnostic characters is evaluated by means of a restriction enzyme [76], and will be needed for the future development of microarray-based identification systems, where only particular nucleotide positions will be interrogated [75].

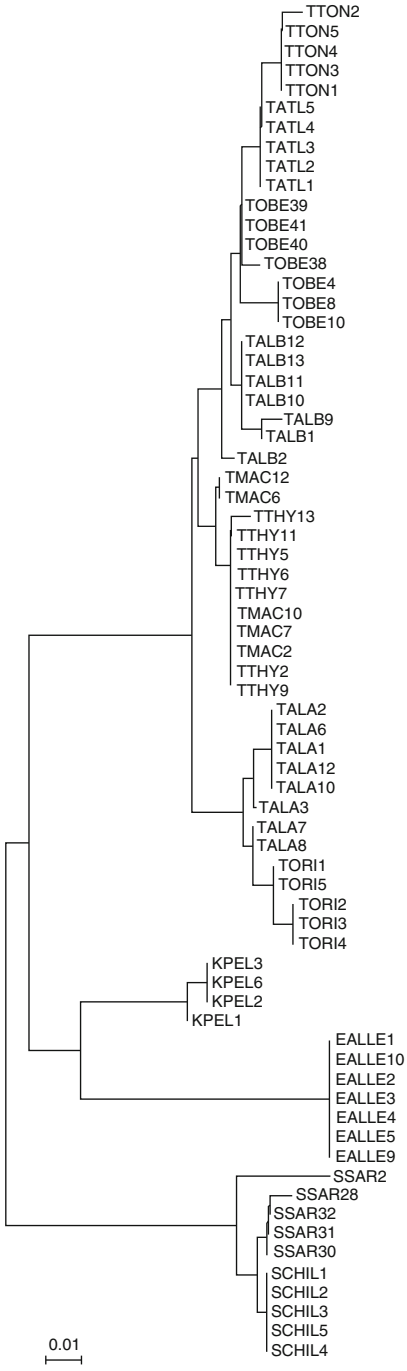

Fig. 2 Phylogenetic tree based on the cytochrome b DNA sequences of different species in the Scombridae family

2.3.2 Real-Time PCR (qPCR)

The first real-time or qPCR systems were introduced into the market in the middle of the 1990s, and the success of this technology could be seen in the increasing number of publications at the beginning of 2000. In contrast to the endpoint PCR, qPCR systems benefit from amplification progress that is recorded in real time using special fluorescent technology without any further analysis. Furthermore, qPCR enables the user to quantify the target DNA of interest in the exponential amplification phase. The fact that post-PCR proceedings, such as gel electrophoresis, enzyme digestion, or sequencing, are no longer necessary shortens the reaction time enormously and prevents any "carryover" with foreign DNA. Therefore, qPCR is suitable as a high-throughput method using specific primers and different fluorophores and probes for detecting and quantifying specific target DNA in a simple or multiplex approach in approximately 1 h. In terms of different fluorescent technologies, the simplest choice is SYBR® green I which binds to the minor groove of dsDNA. Much higher specificity is achieved by working with specifically designed hydrolysis probes (5′nuclease probes) that hybridize with one target DNA strand if there is complementarity. The most commonly used probes are TaqMan® probes, which rely on the fluorescence resonance energy transfer (FRET) mechanism. Numerous reporter dyes, such as FAM™, HEX™, ROX™, or Cy5, and reporters such as TAMRA are used, for example. Besides TaqMan® probes, other approaches with hybridization probes based on FRET, like molecular beacons and Scorpion® probes, can also be used [77]. In order to improve the affinity of probes for the target DNA, incorporating minor groove binder (MGB) groups or locked nucleic acids (LNA) has led to an increase in the melting temperature, thus making it possible to shorten the probes with a simultaneous increase in sequence specificity, especially when there are only one or two mismatches, for instance, in allele genotyping assays or identification of closely related species [78, 79]. In addition, great attention should be paid to optimizing and validating during the development of a qPCR method [80, 81] because very frequently key essentials such as positive controls or testing of robustness are missing in many applications.

Although qPCR has been widely used in numerous fields, in this chapter only works related to species identification in questions of seafood and allergens will be discussed. One of the first research works on fish species differentiation using qPCR was published in 2002 by Taylor et al. [82]. In this work, a simultaneous identification method using specific primers (ATPase6 gene) and species-specific MGB TaqMan® probes was developed to identify fish or fish eggs in three gadoid species (cod, haddock, and whiting) providing a tool for stock assessment, spawning site mapping, and detection of commercial fraud. Further examples clearly show that only certain questions justify the considerable effort required to develop a qPCR method for species identification of fishery products.

Justified by the increasing mislabeling of specific fish products in certain markets, research groups have presented qPCR methods for species authentication that mainly target mitochondrial genes. Although *16S* rDNA is known to have highly conserved regions, some research groups have used it for fish species or genus differentiation. Using the *16S* rDNA gene, qPCR methods were developed to

differentiate Nile perch and wreck fish from grouper species [83] or to identify the European eel [84] and species such as gilthead sea bream, among others [85]. Particularly worthy of mentioning is that Lopez and Pardo (2005) tried to develop a semi-quantitative qPCR method to identify albacore and yellowfin tuna on the basis of *cytb* and by performing relative quantification of these species by estimating their Cq values in relation to the Cq value of the unspecific PCR products of a scombroid species [86].

More often than *16S* rDNA, the mitochondrial gene COI is used for fish species identification by means of qPCR: cod [87], swordfish [88], two anglerfish species [89], seven commercially important salmon and trout species [90], grouper species of four genera [91], as well as escolar and oil fish [92].

Depending on the species of fish and the experiences of certain research groups, the mitochondrial gene *cytb* is also used in qPCR approaches for species identification. Examples of applications are tunas. They are a highly valued fish species and in some cases overexploited. Methods were therefore developed to identify yellowfin tuna, Atlantic bluefin tuna, and albacore in cans [93] as well as yellowfin tuna, bigeye tuna, southern bluefin tuna, and Pacific bluefin tuna [94] in separate simplex qPCR systems. The applicability of qPCR to tuna cans has only recently been demonstrated by Bojolly et al. (2017) [95] for identifying and quantifying (absolute as well as relative) of bigeye tuna and yellowfin tuna. Due in particular to the fact that qPCR is based on the amplification of short fragments (approx. from 60 to 180 bp), it is best suited to determining species in highly processed products such as sterilized tuna cans.

Although qPCR technology makes possible multiplex approaches, few users have taken this advantage. In this respect, Giusti et al. (2015) was one of the few research groups to develop a multiplex approach to identifying the gemfish species *R. pretiosus* alongside *L. flavobrunneum* and differentiating them from potentially replaced species such as cod, tunas, and sablefish using all three of the mitochondrial genes mentioned: *16S* rDNA, COI, and *cytb* [96].

Also suitable for fish species differentiation is the nuclear and ribosomal gene region *ITS* (internal transcribed spacer) which is applied to simplex qPCR of Atlantic salmon [97] and European sole [98].

Only a few qPCR studies address the problem of quantifying fish species by means of nuclear genes, as in the work on haddock in commercial products using transferrin [99] or the study on Atlantic cod, Atlantic salmon, and European plaice on the basis of nuclear sequences such as pantophysin, growth hormone, and parvalbumin [100].

In addition to fish identification, a few qPCR methods concerning mollusks have been presented in the last 10 years. In terms of gastropods and bivalves, management or ecological studies were the reasons for developing such high-throughput assays. Target bivalve species such as abalone [101], the *Mytilus* species [102], oysters [103], octopus and the main substitute species [104], and squid [105, 106] have been the focus of research groups using mitochondrial and nuclear gene regions.

As qPCR technology is highly versatile in terms of its applications, a variety of methods that were submitted in the framework of food safety, especially for

detecting food allergens related to fish, shrimps, and mussels, need to be mentioned. The challenge of these methods is that detecting allergens requires high sensitivity in order to detect trace amounts of the special allergen against an abundance of different food ingredients. In contrast to protein-based methods like enzyme-linked immunosorbent assays (ELISA), qPCR analysis is not usually affected to any extent by high temperatures. In addition, gene targets for qPCR applications are not limited to the genes coded for allergenic proteins. They can be chosen on the basis of other characteristics, such as sensitivity or species specificity, for instance. A specific gene sequence for parvalbumin identified as the main allergenic protein in fish [107] was the target of Sun et al. (2009) when developing a potential tool for detecting and labeling management of fish in food [108]. Other target gene sequences of *18S* rDNA [109] or *Hoxc13* [110] were selected to determine allergenic fish proteins in foods. In the case of crustaceans, one of the main allergenic proteins is tropomyosin. However, the qPCR assays for detecting crustacean allergens were developed on *12S* rDNA, *16S* rDNA, and *cytb* or COI [111–113]. Commercial test kits for allergen detection of crustaceans, fish, and mollusks are already available, for example, from R-Biopharm®, Germany.

Finally, universal qPCR methods for detecting a broad spectrum of fish in highly processed matrices such as animal feed should also be mentioned. Only a few research groups have published fish-related issues in this context. In particular, Martin et al. (2010, 2013) [114, 115] and Benedetto et al. (2011) [116] described qPCR applications using conserved gene regions of mitochondrial *12S* rDNA for detecting fish in feed.

All these qPCR applications show more or less potential for seafood authenticity issues, but to the best of our knowledge, no qPCR has been standardized for any official method so far.

3 Emergent Methods for Species Identification

3.1 Microarrays

PCR products can be analyzed by hybridization to species-specific oligonucleotide probes arrayed on so-called ‘DNA chips’ or ‘DNA microarrays’. These DNA microarrays can contain hundreds to several thousand or even millions of DNA probes attached like small spots on the array surface. Upon hybridization of labeled PCR products, species can be identified directly, based on the pattern of positive probes.

DNA microarrays are mainly used for gene expression profiling today, but there are various other applications. However, species authentication using DNA microarrays is still a niche application, and only a few studies targeting marine species have been published so far. One of the pioneer works on DNA microarrays for identifying marine species was the EU-funded Fish & Chips project [117], carried out from 2004 to 2007. This project aimed to move “Towards DNA chip technology as a standard analytical tool for the identification of marine organisms in biodiversity

and ecosystem science." Two DNA microarrays were developed capable of identifying 30 European marine fish species [118] and 15 marine invertebrates, respectively, with oligonucleotide probes binding to fluorescently labeled PCR products of mitochondrial DNA markers [119]. Another DNA microarray targeting 30 fish species among 79 different vertebrates was developed in France [120] to analyze food and forensic samples. Several studies on DNA microarrays for detecting various fish (or even whale) species have also been published by a South Korean group [121–126]. In addition, a DNA microarray to authenticate American catfish products was developed by the American Food and Drug Administration (FDA) in order to protect domestic aquaculture against adulteration by imported species [127].

A commercial DNA chip for species differentiation of food products was launched in France in 2004. The "FoodExpert-ID" (bioMérieux, France) could identify 33 vertebrate species including 15 fish species with an Affymetrix high-density DNA chip comprising 80,000 *16S* rDNA oligonucleotide probes [128]. However, the product line was discontinued, probably because it did not find a strong market [129]. In contrast to this, two commercial DNA microarray systems targeting exclusively land vertebrate species in food products, the "CarnoCheck DNA-chip" (Greiner Bio-One, Austria) and the "LCD Array Kit MEAT 5.0" (Chipron, Germany) [130], seem to have achieved market success with fast and easy-to-handle formats and are already used by some official food surveillance laboratories in Germany.

DNA microarray technology with its early nature requires extensive technical equipment such as microarray spotting robots and fluorescence laser scanners. This has hampered implementation of DNA microarrays in routine applications for species differentiation. Recent developments, like the CarnoCheck DNA-chip and the LCD Array, have led to smaller and cheaper devices and may introduce the technique into official food surveillance laboratories with wider distribution. Furthermore, a current research project in Germany is working on developing a DNA microarray for seafood species which is more suited to small laboratories or even on-site applications in the fish-processing industry [131].

3.2 High-Resolution Melting (HRM)

High-resolution melting (HRM) is based on the fact that double-stranded DNA will dissociate at different temperatures (Tm, melting temperature) [132] when the size and/or the DNA sequence is different, especially when there is different GC content. This approach has been used in qPCR to differentiate between amplicons and primer dimers; however it did not make possible fine differentiation among amplicons with only small sequence differences [133], and therefore a number of improvements in the dyes and equipment were made to make it possible to detect SNPs or just a few differences.

It is thus necessary that the appropriate chemistry be used to detect dissociation (saturation dyes which strongly emit fluorescence only with double-stranded DNA), thermocyclers with the capacity to perform temperature ramps

precisely and reproducibly and with a system for collecting fluorescence data, and that the appropriate analysis software be used. The technique involves three steps: (1) amplification of the DNA in the presence of fluorophores, considering that HRM performs better if amplicons are shorter than 300 bp; (2) melting of the amplicons by increasing the temperature; and (3) data analysis requiring registering the changes in fluorescence (F) with temperature (T) in order to obtain graphs where, after normalization, it is possible to observe shape and Tm differences [133].

This approach has been used to successfully identify a variety of vegetables [134], milk [135], GMOs [136], meat animal species [137], species of gadoids [138, 139], and mussels [140]. One of the main advantages of HRM compared with other techniques such as RFLP is the higher accuracy, lower price, and reduced analysis time (only 1.5 h). The cost is also lower compared with similar techniques such as TaqMan® assays [141], so it is becoming an emergent technique for identification of seafood species.

3.3 Digital PCR

Digital PCR (dPCR) is another emerging technique which was developed in the 90s, with the first reported application in 1999 [142]. Quantification of target DNA molecules by qPCR presented some issues, such as amplification efficiency, the requirement of standard curves, and nonspecific amplification, among others. Digital PCR overcomes some of these, and it is claimed to be a better approach for absolute quantification of specific DNA molecules. The principle underlying the technique is to amplify individually template DNA molecules so that after amplification the resulting products can also be individually identified. In fact, in dPCR, target DNA molecules are randomly partitioned in individual PCR reactions, some of these reactions will not contain any target DNA molecules, and others will contain one or more. These individual PCR will be performed until endpoint and positive reactions are recorded versus negative ones, and a concentration of target DNA molecules is calculated as the ratio of positive reactions and number of reactions analyzed [143].

Different platforms have been developed and are commercialized nowadays. Roughly speaking, they can be divided grosso modo in those using microfluidic chip technology [144] (Biomark HD dPCR system by Fluidigm) and those using droplet generators coupled with chips (QuantStudio® family by Life Technologies, RainDrop™ instrument by RainDance Technologies) or microfluidic approaches [145, 146] (BioRad QX200TM Droplet Digital™ PCR system). Although no publications have been found for quantification of fish species in seafood, they are expected to appear soon, as in other food categories, some applications have been published using this technique, especially when issues regarding the presence of particular species, such as the horse meat scandal [145], need a reliable species identification and quantification methodology.

3.4 Next-Generation Sequencing (NGS)

Classic Sanger sequencing of PCR products is not suited to analyzing products with mixed species content and can easily overlook admixtures of species in low concentrations. "next-generation sequencing" (NGS) techniques, also known as "high-throughput sequencing" (HTS), can overcome this problem by massively parallel sequencing of different target sequences in one reaction. "Metabarcoding", the targeted parallel sequencing of preamplified genetic markers, has already been used in many marine ecological studies such as eDNA surveys, in which the presence of fish or invertebrate species is recorded indirectly via the DNA shed by the organisms into the water column [147, 148]. However, few studies have been published on metabarcoding for species detection in food (e.g., meat [149, 150], candy [151]), traditional Chinese medicine [152, 153], herbal supplements [154], or seafood products.

In an early study, the suitability of pyrosequencing was explored for detecting species in fish cakes [155] and was compared to microarray-based species differentiation. However, few details are given about the nature of the target DNA or the outcome of the comparison. Another pyrosequencing study was carried out to identify the species of individual fish samples targeting *16S* rDNA. In cases of ambiguous results, segments of the NADH dehydrogenase subunit II gene (ND2) or *cytb* gene, respectively, also had to be sequenced for exact species assignment [156]. A similar pyrosequencing approach targeting short stretches of *16S* rDNA, as well as the COI gene, was used to identify individual bivalve mollusks as a "simple, rapid, and cost-effective alternative" for species differentiation [157].

Identification of species in mixed seafood samples or products by means of metabarcoding has been published recently by two groups. The first study analyzed the reliability of metabarcoding two short *cytb* segments on the MiSeq platform (Illumina, USA) with prepared mixtures of different tuna species as a prerequisite for metabarcoding-based species authentication in tinned tuna [158]. Although all the species from the mixtures could be detected with this approach, substantial bias was identified in read recovery, i.e., skipjack tuna sequences were always much more prominent than those of *Thunnus* species. In the second publication, the application of a commercially available metabarcoding system (Biopremier, Portugal) with the Ion Torrent Personal Genome Machine (Life Technologies, USA) was described to authenticate Brazilian cod products [159]. Despite the small amount of scientific literature on metabarcoding for food products and still unresolved problems such as PCR bias or incomplete primer universality, targeted metabarcoding is already being offered by European service providers at ever lower costs.

As PCR-based bias in sequence read recovery is a common phenomenon of NGS [160] and considerably hampers quantification of species ingredients in complex food products, the development of a PCR-independent NGS approach is very promising as described in two publications [161, 162]. The "All-Food-Seq" (AFS) software pipeline for quantification of species composition in food uses metagenomics shotgun sequencing and sequence read counting to infer species

proportions. However, reference genomes are needed to map sequences and species assignment. In view of the vast diversity of fish and seafood species, this approach remains a significant challenge for seafood authentication. In light of this, another approach for targeted NGS may gain significant importance: combining droplet PCR with NGS techniques [163, 164] might be able to overcome the problem of PCR bias and lead to more reliable or even quantitative metabarcoding results.

3.5 Isothermal Amplification

Thanks to the existence of reference DNA sequence databases, and in addition to metabarcoding using NGS technologies, development of "handheld" systems based on DNA identification would facilitate the authentication processes and reduce the time needed to identify species [165]. This type of "handheld" device is mainly based on isothermal amplifications, but so far very few systems have been developed.

Nucleic acid sequence-based amplification (NASBA) was first developed by Compton in 1991 [166]. This is primer-dependent technology to amplify nucleic acids in a single mixture at constant temperature. Immediately after its first development, NASBA was used for the rapid diagnosis and quantification of HIV-1 in patient sera [167]. Nevertheless, this technique was only used for the first time for fish authenticity purposes in 2013. Ulrich et al. [168] developed a 90-min multiplex RT-NASBA assay targeting a portion of the *16S* rRNA gene for accurate identification of most commercially important grouper species present on the FDA seafood list. The same authors have further developed a handheld device based on RT-NASBA assays [169]. They have demonstrated that the field sensor (80 min for assay completion) is only slightly less sensitive than the benchtop instrument and could discern 49 of the 61 FDA allowable species (80.3% of groupers – no target sequence available for 3 species).

Loop-mediated isothermal amplification (LAMP), a method based on isothermal amplification of DNA, was first developed by Notomi et al. (2000) [170]. The method requires a DNA polymerase and a set of four specially designed primers that recognize a total of six distinct sequences on the target DNA.

The first report of an application for LAMP in fish authentication was recently published by Saull et al. [171]. They designed a LAMP assay based on the *cytb* gene as targeted DNA to discriminate Atlantic cod (*Gadus morhua*) from two closely related species, Pacific cod (*Gadus macrocephalus*) and Greenland cod (*Gadus ogac*). Reactions were obtained in a heating block at 63 °C for 60 min and were concluded by heating up to 80 °C for 1 min in order to denature the Bst polymerase. The method they developed was able to detect 0.1% w/w *Gadus morhua* in a homogenized raw fish mix. The LAMP assay showed a higher tolerance of amplification inhibitors than PCR and was shown to be highly specific as it did not generate positive results when challenged with a range of nontarget species, including *Gadus macrocephalus* and *Gadus chalcogrammus.* Nevertheless, validation of this method is required, involving greater numbers of samples (in particular

processed products) and fish species, before the LAMP assay can be used as a routine test.

Ye et al. [172] have also recently developed LAMP-based assays for identification of jumbo flying squid (*Dosidicus gigas*) using the COI gene to design species-specific primers. Only *D. gigas* DNA was detected by real-time fluorescence detection (RealAmp) or by visual detection using SYBR® Green I staining (Visual-LAMP), after incubation at 65 °C for 30 min. The authors reported that the detection limits were 10 pg for purified *D. gigas* DNA and 0.01% w/w *D. gigas* in homogenized cephalopod mixtures. They also specified that these methods can be applied to all kinds of processed squid and squid-containing products.

A third isothermal nucleic acid amplification technique, recombinase polymerase amplification (RPA), was developed by Piepenburg et al. [173]. Their innovative approach coupled isothermal recombinase-driven primer targeting of template material with strand-displacement DNA synthesis. It achieved exponential amplification with no need for pretreatment of the DNA sample. Reactions were sensitive, specific, fast, and operated at a constant low temperature. RPA reaction products can be detected in a simple sandwich assay, thereby establishing an instrument-free DNA testing system. This was the technology used by TwistDx Ltd. (a biotechnology company based in Cambridge, UK) to identify red snapper (*Lutjanus campechanus*) (a highly prized fish species) in 20 min using a dedicated analysis kit (TwistFlow® Red Snapper not currently available).

Helicase-dependent amplification (HDA) is another DNA amplification method at a constant temperature, but, although the simplicity of the reaction procedure makes HDA a very interesting alternative [174], to our knowledge it is not yet used in seafood identification.

3.6 PCR-ELISA and Dipstick

DNA methods for species identification based on DNA probes have gained attention in the last decade as they are a convenient alternative to sequencing methods. One example of these approaches is the immunodetection of DNA [175] by an ELISA (enzyme-linked immunosorbent assay) to probe the presence of a specific DNA fragment in PCR products [176]. The method involves three main steps: (i) amplification and labeling of the sample DNA digoxigenin (DIG-dUTP), (ii) hybridization of the labeled and amplified DNA with a specific probe which is attached to a microplate well, and (iii) detection of hybridization with an antibody conjugated with an enzyme (Fig. 3) [177].

Some publications have shown this technique in applications to detect allergenic components in food [178] and detect and quantify viruses [179, 180].

PCR-ELISA has also been used to identify fish species, such as Nile perch [181], tunas [182], and gadoids [183]. One of the advantages of using PCR-ELISA is that there is now wider access to conventional PCR and extended use of ELISA equipment and reagents in many food control laboratories for different applications (such as detecting allergenic substances, pathogens, etc.) making this approach available to

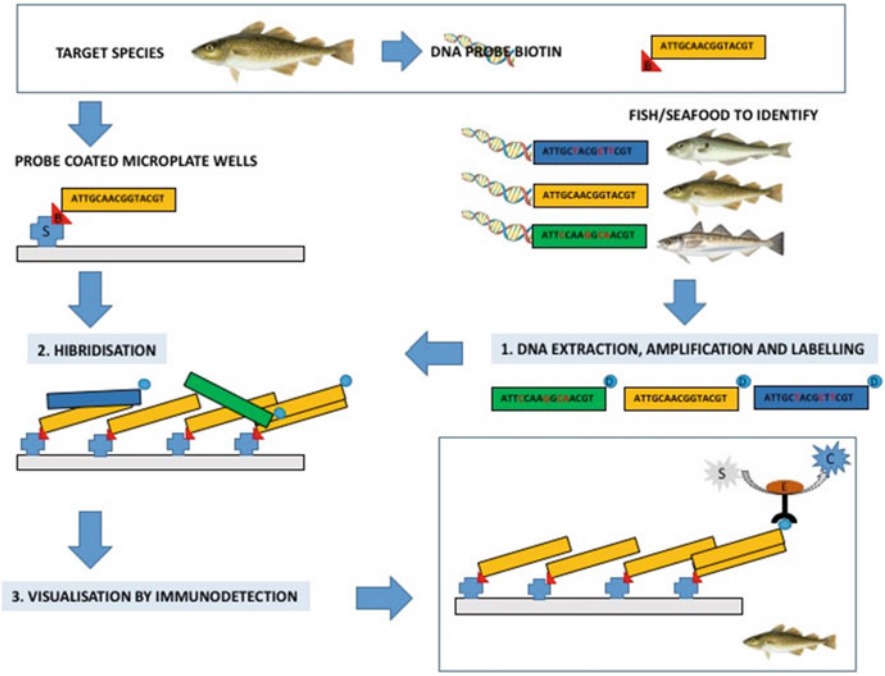

Fig. 3 Schematic representation of a PCR-ELISA design for species identification

many laboratories. In addition, it simplifies and reduces the analysis time as it makes possible a quick and visual inspection of both positives and negatives (Fig. 4). Another advantage is that it also makes it possible to detect mixed species present in a food product [183].

Another type of DNA visualization technique is known as lateral flow dipstick assay (LFDA). This methodology can be applied to a number of the assays mentioned above for obtaining DNA, such as PCR or isothermal amplification. The aim of this technique is to simplify as much as possible the process of probing the presence of a specific genotype in a sample, involving only visual inspection of the result [184]. Only two steps are needed to perform the assay: (1) PCR amplification of a specific DNA fragment and (2) detection of PCR products with the naked eye using the dipstick [185].

The universal dipsticks are available commercially to design different tests (http://milenia-biotec.de). Basically, these kits are composed of a membrane dipstick with three zones, the sample application zone, the test zone, and the control zone [185], and reagents to perform the visualization experiment.

DNA should be labeled beforehand by PCR with, for example, biotin and 6-FAM as this will be required for the visualization step. In the sample application zone of the dipstick, gold nanoparticles linked to an antibody which recognizes 6-FAM will react with DNA labeled with this molecule. When the complex labeled DNA-gold

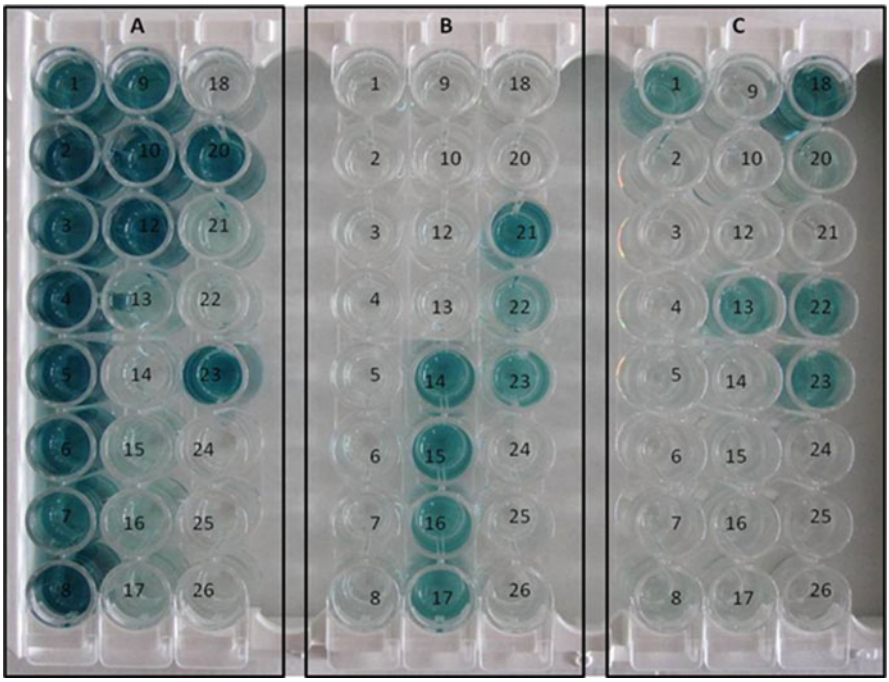

Fig. 4 PCR-ELISA plate results for three species probes tested with commercial samples: (**a**) *Gadus morhua* probe, (**b**) *G. chalcogrammus* probe, (**c**) *Molva molva* probe. Blue-colored wells correspond to positive signals, in some samples a mixture of species was detected (1 and 18), while sample 23 is a deliberate mixture of the three species [183]. Adapted with permission from Taboada et al. (2014) [183]. Copyright (2014) American Chemical Society

nanoparticles reaches the test zone, it is captured by the biotin ligand. Finally, the control zone has antibodies attached that recognize the anti-6-FAM present in the nanoparticle; therefore it makes it possible to test the correct flow of reagents through the dipstick [185] (see Fig. 5). Positive and negative results are easily seen within 5 min after loading the labeled PCR. Figure 5 shows the resulting dipsticks for positive and negative results. This technique has been applied to the detection of viruses [186], bacteria [187], GMOs [188], coffee [185], and seafood [185].

3.7 Mass Spectrometry Methods (MALDI-TOF, LC/MS/MS)

Progress in recent years in proteomic tools and particularly in new techniques based on mass spectrometry (MS), mainly matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) and electrospray ionization-ion trap (ESI-IT) MS, brings potential for developing new methods in the particular case of seafood authentication. Proteomic tools were first developed to investigate the proteome which is defined as the large-scale analysis of proteins present in a particular biological

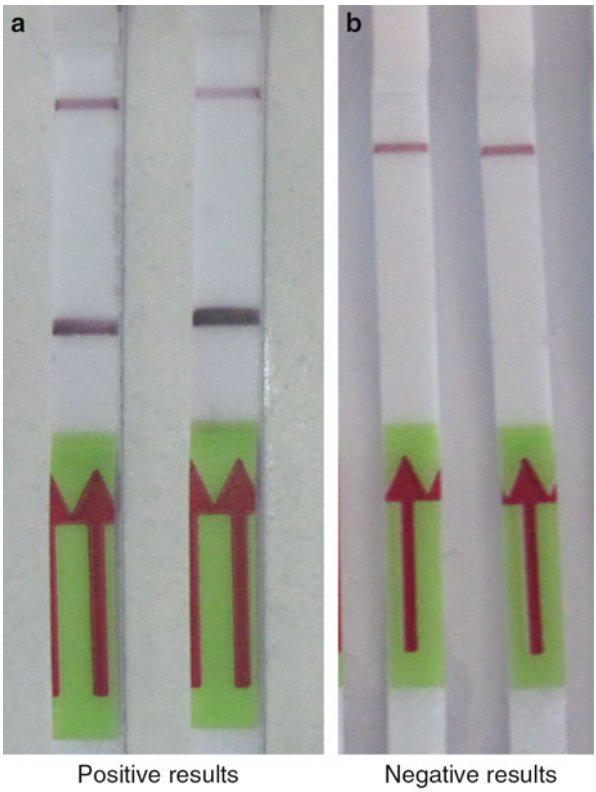

Fig. 5 Dipsticks showing positive results (species identification, in this case the positive shows the presence of *Gadus morhua*; negative shows the absence of *G. morhua*)

system at a given moment. Nowadays, automated data acquisition and powerful bioinformatics processing have made possible high-throughput protein and peptide identification and quantification. In this context, using proteomic tools to investigate seafood products (authentication, food quality, and safety) is steadily increasing. These "molecular profiling" approaches in food science and particularly in seafood products based on MS methodologies have been thoroughly reviewed in recent papers [189–196]).

As pointed out by Ortea et al. (2016) [194], proteomics methodologies can be applied to both global (whole protein) and specific (peptide-based) approaches or top-down and bottom-up workflows for food authentication.

In the bottom-up approach [197], peptides were generated after protein digestion, most commonly using trypsin. The bottom-up approaches are divided into two groups depending on whether the fractionation step, for reducing sample complexity, is performed at the protein level (before enzymatic digestion) or at the peptide level (after enzymatic digestion). In the first strategy, proteins were first isolated based on their isoelectric point and their molecular weight using a two-dimensional electrophoresis (2-DE) gel-based approach. After excision from the gel and digestion into peptides, the peptides are analyzed by MS for protein identification. In the second

strategy (called "shotgun" proteomics), the resulting mixtures of peptides are generally separated by high-performance liquid chromatography (HPLC) or ultrahigh-performance liquid chromatography (UHPLC) before being analyzed using MS.

The top-down approach [198] characterizes the fragments produced by dissociating the proteins directly inside the spectrometer. Ortea et al. (2016) [194] pointed out that even if this analysis is currently available thanks to new dissociation mechanisms and new high-resolution MS equipment, instrumental constraints limit its use.

3.7.1 Application to Shellfish Identification

The first application of a complete bottom-up proteomic approach to species identification was made by López et al. [199] on three species of European marine mussel. They characterized species-specific peptides by comparing MALDI-TOF maps generated from prominent protein spots (after 2-DE protein isolation). These species-specific peptides were found to be tropomyosin peptides.

Arginine kinase (a sarcoplasmic protein) was also used as a biomarker to identify shrimp species thanks to its variability found in 2-DE profiles. The peptide mass fingerprinting (PMF) spectra of arginine kinase were firstly used to differentiate six commercially important shrimps [200]. This study describes the first application of MS-based proteomics in species authentication. Two subsequent studies [201, 202], based on 2-DE, tryptic in-gel digestion, MALDI-TOF, and electrospray ionization-ion trap (ESI-IT) mass spectrometry, were carried out to identify species-specific arginine kinase peptides in the identification of the seven most commercially important species of shrimps and prawns. Using these characterized peptides, a shotgun proteomic approach [203] proved to be useful for penaeid shrimps. The approach was based on using high-intensity focused ultrasound-assisted trypsin digestion for ultrafast sample preparation, peptide separation, and identification by reversed-phase capillary LC (RP-HPLC) coupled with an ion trap working in the ion monitoring scanning mode (SIM) and applied to commercial shrimp samples.

A final study [204] on shrimp identification based on MALDI-TOF mass spectrometry used commercial mass spectral fingerprint matching software (Bruker BioTyper). A mass spectrum reference database was first constructed from the analysis of six shrimp species of commercial importance. This in-house generated database was further tested using 74 unknown shrimp samples from the 6 reference species. Seventy-two samples were identified at the species level and two samples were identified at the genus level.

3.7.2 Applications in Fish Species Authentication

Before the development of proteomic tools including MS analysis, differences in 1-D electrophoresis (SDS-PAGE and IEF) and 2-DE sarcoplasmic protein profiles were used to distinguish between fish species. Combining 2-DE and peptide mass fingerprinting (PMF) spectra, analyzing parvalbumin fractions from nine commercial, closely related species from the genus *Merluccius* and one grenadier species, demonstrated that the isoform patterns were species-specific [205]. MALDI-TOF

mass fingerprints of the peptides produced by tryptic digestion made genus differentiation possible, and some specific masses made it possible to identify certain hake to the species level. This work was completed with the development of a new proteomics workflow using a particular combination of 11 peptides, resulting from the use of accelerated in-solution trypsin digestion of thermostable protein parvalbumins under an ultrasonic field provided by high-intensity focused ultrasound (HIFU) and the monitoring of several peptides by selected MS/MS ion monitoring in a linear ion trap mass spectrometer [206]. This strategy made it unequivocally possible to identify all commercial fish species from the Merlucciidae family. Using the classical proteomic approach, the same authors also used fragmentation spectra to characterize by de novo peptide sequencing the different isoforms of nucleoside diphosphate kinase B (NDK B) from all the commercial hake from the family Merlucciidae and grenadiers [207]. Nevertheless, even though the authors showed that specific NDK tryptic peptides can be useful for differentiating between the two genera and classifying the hake according to their geographical origin (European-African or American), the strategy clearly identified only one species of hake (*M. bilinearis*) from the others.

Using a similar approach (a combination of 2-DE and PMF), differences in sarcoplasmic proteins from two closely related fish species, *Sperata seenghala* and *Sperata aor*, were also investigated [208]. One of the proteins identified by MALDI-TOF and liquid chromatography-tandem mass spectrometry (LC-MS), triosephosphate isomerase (TPI), was found to have three isoforms, of which two were specific to *S. aor* and one was specific to *S. seenghala*.

Mazzeo et al. [209] have developed an innovative method based on MALDI-TOF mass spectrometry on muscular protein extracts from 25 different fish species. Highly specific mass spectrometric profiles were obtained, and signals generated from about 11 kDa proteins, later identified as parvalbumins, were selected as specific biomarkers for unambiguous discrimination of species subjected to fraudulent substitutions, such as those belonging to Gadidae and Pleuronectiformes. In 2016, the author's group also published [210] their previously published data and other data that clearly demonstrated the reliability of MALDI-TOF MS, showing that it can be upgraded by making use of modern mass spectrometers, thus guaranteeing faster analysis and performing completely automated data acquisition and processing.

Wulff et al. [211, 212] demonstrated the suitability of a new proteomics method based on large-scale pairwise comparison of tandem mass spectra (proteome-wide comparison without peptide or protein identification) of fresh samples of different fish species. They established an automated and standardized workflow using existing, well-tested software for species identification and comparing raw and differentially processed samples using a database of spectral libraries of individual species. They showed that it was possible to identify the unknown origin of unknown species, even in processed products [213]. Furthermore, in a recent study [214] in the context of an interlaboratory comparison using data from different types of mass spectrometer and in an attempt to distinguish closely related flatfish by analyzing heavily contaminated samples, they clearly demonstrated that when using

untargeted data acquisition and spectral library matching, 94–97% of the samples were correctly identified.

In the same approach, Ulrich et al. [215] used a MALDI-TOF MS-based method on the vitreous fluid of fish eyes, and all the mass spectra obtained were processed by means of MALDI Biotyper OC 3.1 and ClinProTools 3.0 software. This methodology clearly distinguished between the two closely related species brown and rainbow trout. But further studies are needed to validate this approach for identifying other fish species and establishing a database with reference mass spectra. In Germany, some groups (competent authorities and private companies) are establishing reference databases for MALDI-TOF profiles for fish species identification [216, 217]. In addition, this approach showed limited applicability in the identification of time of storage.

4 Advanced Methods for Determining Geographic Origin in Seafood

Rapid identification techniques for species and geographical origin are a current requirement for the purposes of fraudulent labeling prevention and food regulation control [218]. In many countries (i.e., EU and US regulations), place of origin labeling for processed foods is required for imported marine seafood products as well as for products sold to the final consumer. In addition, there is growing awareness and concern among consumers regarding what they are buying, a need to know where their seafood was harvested and/or produced [219], and the sustainability of the products they purchase. Fraud concerning fish origin can also reduce the effectiveness of conservation and management programs that help to protect overexploited and endangered species [220]. According to El Sheikha and Montet (2016) [221], methods for determining geographical origin depend on the substrate studied and can be categorized into physicochemical and biological techniques. The former test components such as fatty acids [222], trace elements [223], or chemical constituents (i.e., antioxidants) and assume that these components characterize that particular origin of fish. However, modifications in diet or environment may change their actual profiles [224]. The biological techniques use analysis of isoenzymes and different molecular-based techniques [225, 226]. Each method has a number of advantages or disadvantages depending on the state of the product, as summarized in Leal et al. (2015) [219]. Trace element analysis is a simple methodology, but it is not applicable to processed products or those with no mineral structures such as fillets. Fatty acid analysis is also a fast, inexpensive, and simple methodology but cannot be applied to all processed products. Also, lipids are susceptible to oxidation. Finally, analyzing DNA is used in an increasing number of fishery products, because it is species-specific, highly sensitive, and accurate, but includes a number of complex and time-consuming methodologies. In addition, it cannot be applied to all processed products or to geographically close populations. Depending on whether or not there are sound baseline databases and quality reference material of known origin, many authors prefer to use a

combined analysis, such as trace elements and DNA markers or even the shape of the otoliths and molecular markers [227].

4.1 Analyzing Trace Elements

Trace element fingerprints (TEF) of fish and shellfish mineral structures (shells, otoliths, and bones) have been successfully used to distinguish specimens of different geographical origin [228]. In hard, inert mineral structures, trace elements depend on their availability in seawater, which varies in each ecosystem and reflects the geographical surroundings of a given specimen throughout its life. TEF can be analyzed by means of inductively coupled plasma-mass spectrometry (ICP-MS) or laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). A wide range of element ratios can be measured in these calcified structures, although the most common are Ba/Ca, Cd/Ca, Cu/Ca, Cr/Ca, Mg/Ca, Mn/Ca, Pb/Ca, Sr/Ca, U/Ca, and Zn/Ca. Distinguishing cockles from geographically close populations – only one km apart – was carried out successfully in the work of Ricardo et al. (2015) [229] using ratios of Ba and Mn as the most important for differentiating locations. Yamashita et al. (2008) [218] used multivariate analysis of trace elements in muscle and bone to distinguish tuna species and skipjack tuna meat in canned products; Japanese eel from Japan, Taiwan, and China from fish bone; littleneck clam from Japan, Korea, and China using shells; and chinook salmon from Japan, Canada, Chile, and Russia with fresh and frozen muscle. Tanner et al. (2012) [230] used the ratios Mg/Ca, Cu/Ca, and Ba/Ca on the otoliths of *Solea solea* and found that these correlated well with different water salinities. They later used otolith chemistry to delineate different stocks for this species [231]. Wells, Thorrold, and Jones (2000) [232] used scales to distinguish weakfish from five estuarine locations and found high correlations between Mn/Ca, Sr/Ca, and Ba/Ca ratios, in both scales and otoliths. Their study favored the use of scales as they are a nonlethal alternative to otoliths and are easier to collect and prepare. To succeed in using trace elements on the geographic identification of fish and shellfish, it is generally agreed that there is a need to define reference ranges of trace elements in foods from animals, along with information on geographic origin, genetic background, production time, and type of production system. Danezis et al. (2016) [233] stressed that these reference ranges are critical both for defining the quality control standards for measurements and for identifying signatures that characterize food origin be it geographic, production system, or any other indicator of interest together with new algorithms for analyzing all the data.

4.2 Stable Isotope Analysis

Stable isotopes are different forms of the same element, differing only in the number of neutrons in the nucleus of the atom resulting in different weight atoms and diverse distribution in the environment. These atoms are incorporated into animal tissues

through ingestion of water and feed and their ratio can vary according to environmental conditions [234]. The most commonly used isotope ratios are $^{2}H/^{1}H$ (or D/H), $^{13}C/^{12}C$, $^{18}O/^{16}O$, $^{15}N/^{14}N$, $^{34}S/^{32}S$, and $^{87}Sr/^{86}Sr$ of the elements H, C, N, O, S, and Sr. They can differentiate foods based on their geographical origin and are measured reliably in routine work in different matrices, with their results comparable between different laboratories [235]. Stable isotope analysis is thus a promising approach for authenticating the origin of different organisms. Krivachy et al. (2015) [236] stated that C, N, H, O, S, B, and Sr isotopes are adequate for determining the geographic origin of several plants, as related to the soil and their fixation in the plant. Li et al. (2016) [237] indicated that stable isotope and multielement analysis were two of the most widely used methods in traceability of aquaculture products and related fish to production methods (wild or farmed, organic or intensive), due to their distinctively different food sources. Nevertheless, in fish and shellfish, stable isotopes are affected by more complicated factors: isotope fractionation in animals, geographical origin of the sample, physiological and anatomic properties, and even their positions in the food chains.

Stable isotopes are usually analyzed in an isotope ratio mass spectrometry (IRMS) instrument, and the ratio is obtained by comparing the value of the isotopes with its natural form. Generally, the analysis in fish is made using otoliths [238–240], which provide a record of fish life. Tissues such as fillets, which integrate diet over months and within the same species, can be very different from site to site [241]. Evaporation, condensation, and precipitation of water in nature affect the $^{2}H/^{1}H$ and $^{18}O/^{16}O$ ratios [234]. Changes in diet can also affect $\delta^{15}N$ in the organs and muscles of fish, and those changes need a certain period of time to remain steady, as Olsen et al. (2015) [242] showed in cod after only 40 days of a dietary shift. Isotopes also vary between tissues within the same fish, so many authors use scales and otoliths, which reflect the events that occurred during the fish's growth [243]. Curtis et al. (2014) [244] suggest using both stable isotope and trace element analysis depending on the situation, because the first is more accurate, for instance, for distinguishing hatchery-reared and wild spotted trout, while the latter seems to have greater discriminatory capacities for studies over a period of time. This has also been confirmed by Moreno-Rojas et al. (2008) [245].

Morrison et al. (2007) [246] used isotopes to authenticate the production origin of gilthead sea bream (*Sparus aurata*) and $\delta^{18}O$ as a discriminatory factor. Wolff et al. (2012) [247] used the strontium isotope ratio ($^{87}Sr/^{86}Sr$) of otoliths as markers for reservoir fish and for tracking the movements of invasive fish in river-reservoir systems. They found that these markers are site-specific and temporally stable over time. Recently, Carrera and Gallardo (2017) [248] succeeded in using the stable isotope ratio (SIR) to determine the geographical origin of all commercial fish species in the Merlucciidae family using SIR analysis of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$). It is rare for a single element to provide full information for food authenticity, and usually several stable isotopes need to be combined to determine the geographic origin of aquaculture products [249]. Other isotope ratios, such as $\delta^{13}C$ and $\delta^{15}N$, do not offer a consensus on their use. Some authors, like Kim et al. (2015) [250], find the former to be discriminatory for geographic origins, and others,

like Chaguri et al. (2015) [251], suggest that $\delta^{15}N$ is a better indicator for wild versus farmed fish. Menard et al. (2007) also used $\delta^{15}N$ and found that latitude affected this ratio in yellowfin tuna and swordfish [252].

As stated above, isotope ratio analysis has been used with success to verify geographical origin in various cases in relation to legal or other enforcement activities. However, to determine the geographical origin of a certain food item, the stable isotopic data of the test samples must be compared with a reliable database or databank containing some information about the basic element profile and multivariate data evaluation [235]. In 2009, after a major case of fraud, the first European caviar database appeared based on the isotopes of C, O, H, N, and S in the water and the roe protein fractions of 29 authentic caviar samples.

When using isotope ratios, a sound database should be used with representative samples, different tissues, and structures, with previous isotope values to be compared with the intended organisms especially if the items were subjected to any kind of processing, such as freezing or ice storage [253].

4.3 DNA-Based Techniques

Molecular-based analysis has greatly improved in the last few years thanks to technological progress in equipment. Its performances have also increased in terms of speed. Markers such as allozymes, AFLP, whole mitochondrial genomes, RAPD and RFLP on mitochondrial DNA (mtDNA), and nuclear DNA have frequently been used in fishery research. Generically, many studies reveal that it is possible to differentiate fish populations using microsatellites, highly variable genetic markers. Mitochondrial DNA has also been used to detect the causes of population divergence by means of historical isolation in certain marine fish.

Microsatellites are a set of short repeated DNA sequences (2–13 base pairs) at a particular locus on a chromosome, which vary in number in different individuals and have been used for genetic fingerprinting since the early 1980s [254]. They are analyzed by conventional PCR amplification and amplicon size determination, followed by Sanger DNA sequencing, and are a cheap and easy methodology, with several applications in population genetics. In the field of fisheries and aquaculture, microsatellites are useful for characterizing genetic stocks and dense linkage maps [255]. Lane, Symonds, and Ritchie (2016) [256] used nine polymorphic microsatellite DNA loci to investigate the phylogeography of hapuku wreckfish around New Zealand and to distinguish its populations. Sanchez et al. (2016) [257] divided jumbo squid into two population groups using an innovative nuclear microsatellite locus and a fragment of 675 bp from the mtDNA ND2. In another study on the distribution of *Octopus vulgaris* in the NE Atlantic and Mediterranean, Cabranes et al. (2008) [258] found significant differences in samples separated by up to 200 km using five polymorphic microsatellite DNA markers. A similar work by De Luca et al. (2016) [259] using 13 microsatellite loci was carried out to study genetic variations and population structures in *Octopus vulgaris* in seven sampling sites in the Mediterranean and southern Portugal. The results showed some distinct

populations but no clear separation of all of them. The authors also used the DNA barcoding approach, analyzing COI gene fragments to understand the phylogenetic relationships within populations. They concluded, however, that it is not a good marker for detecting genetic structure. Some authors have used a combination of microsatellites, allozymes, and mtDNA [260] microsatellites and mtDNA markers to separate the effect of migration, genetic drift, and local adaptation of populations [261]. Zhigileva et al. (2013) [262] used nuclear DNA inter-simple sequence repeat (ISSR) markers and compared them with allozymes, having found that these provide more precise geographical differences in population groups of fish. A different hypothesis for tracing the source of a product involves analyzing the microbial communities of the food and statistically linking this analysis to their origin. Le Nguyen et al. (2008) [263] tested the bacterial community structures of *Pangasius* fish from South Vietnam and found that the band pattern of the bacterial communities isolated from the fish, obtained by PCR-DGGE, was linked to the microbial environment of the fish. The *16S* and *26S* rDNA profiles generated by PCR-DGGE (PCR-denaturing gradient gel electrophoresis analysis) were used by Montet et al. (2008) [264] to detect variations in the structures of bacteria and yeast communities in fish and fruit.

In a recent review, Cuellar-Pinzon et al. (2016) [265] suggest that microsatellite and mitochondrial DNA-based markers, though rarely used in recent years, will probably be replaced in fishery research by increasingly accessible techniques such as gene sequencing and next-generation sequencing (NGS)-derived markers. Davey and Blaxter (2010) [266] proposed the use of restriction site-associated DNA sequencing (RADSeq) that can identify and score thousands of genetic markers, randomly distributed across the target genome, from a group of individuals. This has the advantage that it can be used on species with no, or limited, existing sequence data. Within the FishPopTrace European-funded project, forensically validated panels of SNP (single nucleotide polymorphism) markers were proposed for geographic origin assignment of four commercially important fish species, cod (*Gadus morhua*), hake (*Merluccius merluccius*), herring (*Clupea harengus*), and common sole (*Solea solea*) [267–269].

Whether using TEF, stable isotopes, or any of the molecular biology techniques, determining the geographic origin of fish and other fishery products needs multivariate analysis methods and specific genetic software to support the processing of the results.

5 Methods for Distinguishing Wild Seafood from Farmed

Different approaches have been used over the years in the methods proposed for differentiating wild/farmed fish. The studies published have compared genetics, chemical characteristics, fatty acid composition, concentration of certain trace elements, levels of certain pollutants, stable isotope concentrations, morphology, and organoleptic characteristics [270]. A recent comprehensive review of tools for differentiating the wild and farmed origins of Mediterranean fish [270] showed that analyzing fatty acids and/or lipids includes the most frequently used method

(63% of all the reviewed works). Other, less studied, methods involved the morphological differences between wild and farmed fish (37%) and differences in the proximate composition (27%). The techniques using stable isotopes and pollutants were the least frequently used methods (12% each). SNP-assays have also been developed by Bylemans et al. (2016) [271] to trace farmed fish. At present, there are no known official standardized methods. Nonetheless, on account of the accuracy of the results, stable isotope fingerprinting and fatty acid analysis seem to be the most promising and suitable methods for differentiating wild and farmed fish and are discussed below.

5.1 Analyzing Stable Isotopes

Of all the isotopes, carbon (^{13}C), nitrogen (^{15}N), and oxygen (^{18}O), being major constituents of organic matter, transfer from one organism to another through the food cycle and increase the isotope fingerprint as a result of assimilation and growth. On account of this, determining stable isotope ratios is an important analytical tool in trophic studies, as they show the relative levels of different isotopes in a particular atom determined by isotope ratio mass spectrometry (IRMS). Depending on the atom selected, the isotope ratios may reflect, in the case of animals, the isotopic makeup of the diet or feed which has been used [272–274].

Food availability and origin in wild fish differ significantly from that of farmed fish. Farmed fish feed is poorer in raw materials of marine origin and has an increasingly large component of vegetable meals and oils, characterized by a higher terrestrial carbon input and a lighter isotope content. This can be exploited to determine seafood authenticity, and most research has investigated the use of these isotopes, namely, $^{13}C/^{12}C$ and $^{15}N/^{14}N$ [275], to distinguish farmed from wild fish or organic from conventionally farmed fish.

Several studies have shown the existence of distinct differences in the isotope ratios between wild and farmed fish [242, 246, 276–281] and among wild, conventionally and organically farmed fish [282]. Farmed fish could be distinguished from wild fish mostly because of a constantly lighter isotopic composition of $\delta^{13}C$, thus revealing the land-based origin of some of the feed raw materials and their lower ^{13}C content. The higher lipid content of farmed fish seems to induce greater isotopic fractionation of ^{13}C than in wild fish on account of the higher metabolic turnover and a lower fat content, both resulting from food shortage [270].

For $\delta^{15}N$, significant differences were also found between wild and farmed sea bass [276, 277] and seabream [246] with the wild fish muscle characterized by a higher ^{15}N isotopic content than the farmed fish. These differences were attributed to the higher trophic level of wild fish marine feed and also to the different inputs of terrestrial N sources in the farmed feed mixtures.

Most works published on fish authenticity and stable isotopes have a relatively reduced sample size. Nevertheless, using stable isotope ratios or any other marker for authenticity needs to address all the variables affecting the marker with comprehensive sampling and sufficient data. A study of this nature performed in a large sample

(171 fish) of wild and farmed Atlantic salmon (*Salmo salar*) of 32 different origins within Europe, North America, and Tasmania was presented by Thomas et al. [283]. In order to maximize the range of variation present, sampling was extended to all seasons over two consecutive years and included fish raised using different practices. The results showed that $\delta^{15}N$ measured on choline and $\delta^{18}O$ measured on total oil could be used to successfully distinguish between fish of authentic wild and farmed origin. However, the authors also added that to strengthen the certainty of identifying mislabeling in market-derived fish, analyzing the percentage of linoleic acid (LA, 18:2n-6) in the lipidic fraction should be included.

Published data has shown however that though isotope analysis can be accurate standardization of methodologies is necessary in order to be able to obtain responses over an entire range of farmed and wild species. Although a cost- and time-effective alternative to other analytical techniques for identifying wild and farmed fish, comparison with databases of known isotope values or ranges of wild fish species is also necessary to determine authenticity, and, as different factors (e.g., food source, availability) affect isotope ratios, these need to be comprehensive and frequently updated.

5.2 Analyzing Fatty Acids and/or Lipids

Farmed fish has been shown to have in general a higher lipid content than wild fish [284–287] mostly as an expression of the high fat content of their diet and intensive feeding regime. As finfish and crustacean farming depends on scarce marine resources that provide key dietary nutrients, such as fish meal and fish oil, aquaculture diets are diversified to contain a wide variety of alternative plant-based ingredients such as legume seeds, oilseed cakes, leaf meals, and an increasing proportion of vegetable oils [288]. As the fatty acid (FA) profile of the fish tissue is the expression of the incorporation and accumulation of the FAs present in the diet [289], differences in the lipid composition and dietary FA profiles of the feed have been used to distinguish between wild and farmed fish. The presence of high levels of FAs of terrestrial origin such as oleic acid (OA, 18:1n-9), α-linolenic acid (LNA, 18:3n-3), or LA, which are usually found at low levels in marine fish, is generally evidence of these differences [277, 290]. The prevalence of LA, augmented LNA, and the generally increased n-6/n-3 ratio in the flesh of farmed fish therefore seems to be the result of incorporating increased levels of plant oils as an alternative raw material for fish feeds [291]. Contrary to what happens in freshwater fish, the deficiency in marine fish of the enzymes (δ-5-6-desaturase) needed to elongate the carbonic chain of LA and LNA from the fish feed and transform them into n-6 and n-3 FAs [292] may justify the increased levels of these FAs.

The vast majority of studies report significant differences between wild and farmed fish mostly in terms of LA, arachidonic acid (ARA, 20:4n-6), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) [286, 293–296]. For example, LA and ARA were generally found in higher and lower levels, respectively, in farmed sea bass and sea bream [277, 297, 298].

Nevertheless diverse patterns of FA distribution (e.g., EPA and DHA) and FA indexes (e.g., n-3/n-6) were determined between wild and farmed fish in other fish species. Major factors affecting this heterogeneity are dietary related and include high variability in terms of the FAs in the feeds available on the market, which is a consequence of the fish oil used as a source of long-chain n-3 polyunsaturated fatty acids [299, 300]. Likewise, wild fish also show considerable FA profile variation depending on season, food availability, and fishing ground [301, 302] all of which affect the usability of FAs for authenticity purposes. Nevertheless, in some cases, this variation – and in particular the distinctive FAs accumulated in farmed fish from feed produced with raw materials from different marine environments – has been used as biomarkers. A clear example is the monounsaturated fatty acid, 22:1n-11, which originates in dietary fish oils produced from Northern Atlantic fish and is not a normal constituent of the body lipids of warm water fish such as sea bream. It is nonetheless found in farmed fish of this species but is almost absent in wild specimens [303].

Though terrestrial fatty acids in fish feeds are considered to be strong biomarkers and distinct FA signatures and different stable isotope ratios may characterize wild and farmed fish species, using multivariate analysis has been proposed as a method for analyzing in a more robust way the effects of all the variables analyzed [277, 304]. This technique was used successfully in the farmed/wild differentiation of several species, namely, bogue [222], saithe and cod [305], Mediterranean horse mackerel [306], sea bass [277], salmon [307], and turbot [304].

In terms of analytical methods, the most common testing protocols involve gas chromatography (GC) to determine the origin of fish using fatty acid profiles [308], although other fat-related analytical methods such as near-infrared spectroscopy [296] and nuclear magnetic resonance [309, 310] have also been used. Comprehensive two-dimensional gas chromatography-mass spectrometry (GC × GC–MS) was also used to determine fatty acid fingerprints in fish (*Sparus aurata* and *Dicentrarchus labrax*) from Southern Italy [311] in order to highlight differences in the fatty acid profiles of farmed and wild fish samples. GC × GC-MS analysis showed that omega-3 fatty acids were naturally more concentrated in wild fish, whereas their presence in cultivated fish was lower and in favor of n-6 and oleic acids, as a distinct consequence of food supplementation. In this study, some fatty acids were detected only in one type of fish (wild or farm-raised) or were determined at very different levels, such as the biological mediator ARA, which was almost 50 times more concentrated in wild-caught fish.

Despite the reported usability of these methodologies for farmed/wild fish differentiation, problems with procedure standardization have hindered wider use in seafood authentication [312]. Variability in laboratory results has mostly been attributed to equipment characteristics, differences arising from lipid extraction and diverse methodologies of fatty acid esterification. To ensure the consistency and accuracy of these methods and ultimately convert them into regulations, not only continuous monitoring of fatty acid/stable isotopic composition of both cultivated and wild fish is recommended but also necessary standardization of the methodologies through collaborative work.

6 Advanced Methods for Determining Previously Frozen Seafood

Fresh fish and seafood are highly perishable foodstuffs that deteriorate rapidly at high storage temperatures, and this limits their shelf life and safety. Even though numerous preservation methods have been used to extend the shelf life of fish, freezing is still the most frequently used preservation technology. The aim of freezing is to decrease microbiological growth and the activity of deteriorating enzymes by converting the available water into ice crystals [313]. Nevertheless, extended textural and functional changes can occur on account of cell rupture by enlarged ice crystals and also due to inadequate freezing procedures, post-freezing, and thawing processes [314]. As a result, frozen fish usually has a much lower price than fresh fish, and the substitution of frozen-thawed for fresh fish is a significant authenticity issue [315]. In fact, even though changes occur during freezing, consumers do not have the ability to differentiate between fresh and frozen-thawed fish because of the similarity of the sensorial characteristics of the two products.

The ability to differentiate between fresh and frozen-thawed fish is all the most important for preventing fraudulent practices as (i) freezing-thawing has been a management process for fresh fish and expedites supplies of "fresh products" to consumers based on demand; (ii) fish that is consumed raw, such as sushi and sashimi, is obligatorily a frozen-thawed product and needs to be checked, on account of special regulations that include compulsory freezing at −20 °C for at least 24 h for parasite control (Regulations (EC) No. 178/2002, 853/2004, and 2074/20 05); and also (iii) safety issues can arise, as thawed meat is more susceptible to microbial growth.

Different analytical methods have been proposed, and these can be classified into three main categories: enzymatic, physiological, and physical. Enzymatic methods are based on determining increases in the enzymatic activity of specific enzymes that leak into tissue exudate following cellular disruption that occurs during the freezing/thawing process. These methods can involve assays of enzymes originally bound to (i) mitochondria (β-hydroxyacyl-CoA-dehydrogenase [316, 317], glutamate oxaloacetate transaminase [318], lipoamide reductase and 5' AMP deaminase [319], cytochrome C oxidase [320, 321], aspartate aminotransferase [322], lactate dehydrogenase [319, 323], succinate dehydrogenase [324], fumarase and glutamate dehydrogenase [323], L-malate dehydrogenase [325], L-malate-NADP oxidoreductase [326]), (ii) red blood cells (β-N-acetylglucosaminidase [327, 328]), and (iii) lysosomes (α-glucosidase, β-galactosidase, and β-N-acetylglucosaminidase [329–331], acid phosphatase [330, 331], β-galactosidase and β-glucuronidase [323]). The disadvantages of using enzymes as freezing indicators have however been reported, namely, in relation to the existence of corresponding mitochondrial isoenzymes in the cytoplasm and also because the activity of differentiating enzymes can be highly sensitive to other stresses imposed on the product (e.g., previous ice storage) [332]. Which type of enzyme (mitochondrial, lysosomal, or extracted from blood cells) is the most suitable for authentication purposes depends also to some extent on the fish species [315, 331] and is also a limiting factor.

Physiological methods may involve examining the opacity of the fish eye lens, namely, change in the transparency of the medulla (central part) of the eye which becomes turbid or opaque after freezing [315, 333, 334]. The robustness of this method must, however, be checked as differences have been reported as not being evident in species like plaice and eel [335, 336]. Determining the hematocrit value as an index of blood cell destruction or as judgment of the integrity of red blood cells by microscopy has also been proposed for differentiating freeze-thawed fish from fresh fish [329, 337, 338].

In an attempt to overcome the tedious and destructive nature of physiological methods, which are also time-consuming and require highly trained operators, attention has recently been focused on the development of advanced noninvasive and nondestructive instrumental techniques such as front-face fluorescence spectroscopy (FFFS). Limitations in some methods because of fish or fillet samples with no blood, eye lens, or skin are also overcome with these new methods. A study of the potential of FFFS combined with chemometric tools to differentiate frozen-thawed from fresh whiting fillets (*Merlangius merlangus*) showed that nicotinamide adenine dinucleotide (NADH) fluorescence spectra recorded directly on fillets have the potential to differentiate frozen-thawed from fresh fish and may dramatically reduce analytical time and costs when looking at enzymatic and biochemical measurements [339]. The NADH emission spectra (excitation 340 nm) of fresh fish showed a maximum at 455 nm, while frozen-thawed fish was characterized by a maximum at 379 nm. Similarly, FFFS made possible reliable discrimination between fresh and frozen/thawed sea bass (*Dicentrarchus labrax*) fillets (72 out of 78 samples) and was therefore considered a promising tool in routine inspections [340]. NADH fluorescence spectra and Fisher linear discriminant analysis was also considered a potential method for reliable differentiation between frozen-thawed and fresh fish, as a 100% correct classification of large yellow croaker (*Larimichthys crocea*) fresh/frozen-thawed samples was achieved using this technique [341].

Physical methods can be based on changes in the electric resistance of tissues, as used by the FISCHTESTER, the RT Fish Freshness Tester, or the Torrymeter [315, 342–345] to account for the loss of impedance in fish induced by the freezing/thawing cycle [346]. As membranes are destroyed by freezing and thawing, the electrical resistance of thawed fish is also significantly reduced [315]. In view of the limitations of these initial technologies, which examined only optimum frequencies to make the measurements, other bioelectrical impedance spectroscopy methods that analyze the electrical response over an entire frequency region from 1 Hz to 1 MHz have been developed [347–350].

In addition to these technologies, other physical methods rely on measurement of dielectric properties in the microwave region as a function of frequency (100 MHz to 10 GHz) and multivariate analysis of the spectra obtained using principal component analysis [351]. Differentiation of fresh/frozen-thawed octopus (*Octopus vulgaris*) was successfully reported with the use of the Sequid RFQ-Scan® system (Sequid GmbH, Bremen, Germany), which is based on the principle of dielectric spectroscopy combined with time domain reflectometry (TDR) and applying an ultrawide band step signal to the material being tested [352]. The release of water and ions

during octopus thawing was suggested as an explanation of the differences found between fresh and frozen-thawed samples.

Taking into account that a nuclear magnetic resonance (NMR) signal is usually sensitive to water mobility and its interaction with other molecules, this technique has also been considered appropriate for determining freezing and thawing changes in fish flesh in a noninvasive and nondestructive way [353]. The effect of freezing and thawing on NMR signals (e.g., relaxation time and spin densities) was studied using magnetic resonance imaging (MRI) techniques in cod (*Gadus morhua*) and mackerel (*Scomber scombrus*) [354, 355], trout (*Salmo gairdneri*) [356, 357], salmon (*Salmo salar*) [358], and haddock (*Melanogrammus aeglefinus*) [355, 359]. Despite the acceptable results obtained and the potential of NMR/MRI analysis for fresh/frozen-thawed fish differentiation, the high investment costs, the still-significant size of the equipment, and the associated infrastructures needed for operation strongly limit its use at present as a standard analytical tool.

In addition to existing methods, volatile profiles measured by solid phase micro-extraction/gas chromatography/mass spectrometry analysis (SPME/GC/MS) were also used for authenticity purposes [360]. Analysis of fish samples of European sea bass (*Dicentrarchus labrax*), gilthead seabream (*Sparus aurata*), and fillets of cod *(Gadus morhua*) and salmon (*Salmo salar*) using SPME/GC/MS showed four volatile compounds common to all species, dimethyl sulfide, 3-methylbutanal, ethyl acetate, and 2-methylbutanal, most likely derived from free amino acids, which are part of the soluble substance in the aqueous extract of the muscle tissue. Taking into account that the selected volatiles were shown in larger quantities after thawing but also increased with the duration of storage at −20 °C, they were considered as differentiation potential markers between fresh products and those that have been frozen.

New methods based on the electromagnetic absorption of organic compounds, such as near-infrared (NIR) spectroscopy, are gaining attention because of the major advantages they have over traditional chemical methods [315, 361–366]. As NIR is a physical and very fast method, it requires minimal or no sample preparation and its precision can be high [367]. Furthermore, and in contrast with traditional chemical analyses, no reagents are required and no waste is produced. The results from application of dry extract spectroscopy by infrared reflection (DESIR) on the meat juices of horse mackerel (*Trachurus japonicus*), bigeye tuna (*Thunnus obesus*), and amberjack (*Seriola purpurascens*) samples showed after differentiation by means of principal component analysis and multiple linear regressions that this technique could categorize fresh and frozen-thawed samples with 100% accuracy [367]. Likewise, a fiber-optic measurement surface probe using visible/NIR spectroscopy analysis was used on the skin of 108 fresh and frozen-thawed red sea bream samples (*Pagrus major*) in order to differentiate the origin of fresh or thawed samples [368]. After multivariate data analysis, the results showed that on account of the changes in light scatter, possibly arising from alterations in the physical structure of at least the surface layer of the fish, all the samples were correctly categorized according to their origin. The good results obtained, along with the fast data throughput and eco-friendly nature of the device, all supported the suggested application of this type of measurement in online or at-line processing control.

The effectiveness of near-infrared spectra used as a species-independent screening method for foodstuff classification in terms of fresh/frozen-thawed differentiation has also been validated in a database of more than 1200 samples of different fish species [361]. Analytical strategies based on partial least squares discriminant analysis of data from spectra of two NIR instruments exploring different spectral regions, respectively, from 680 to 1100 nm and from 1100 to 2500 nm, were developed using samples of species not included in the calibration data. The results showed the best validation classification accuracies with values between 91% and 88.4%. Besides being effective in fish differentiation, Vis/NIR spectroscopy combined with Savitzky-Golay 19-point smoothing of spectra and chemometrics methods (discriminant analysis and discriminant partial least squares) was also shown to correctly identify all 55 fresh shrimp and 50 frozen-thawed shrimp [369]. Given the advantages of NIR spectroscopy, this technology has been referred to as having high potential for performing efficiently in enforcing conformity with regulations [370]. Applying increasingly powerful and sophisticated chemometric tools to NIR databases improves calibration robustness and accuracy, whereas developing an extended range of algorithms in commercially available software packages is facilitating implementation.

Methods that distinguish fresh and frozen-thawed meats should not require reagents and should be fast, nondestructive, quantitative, and relatively inexpensive. Thus, as an emerging technique, hyperspectral imaging has also been suggested as being able to differentiate between fresh and frozen-thawed meat. Recent studies have demonstrated that hyperspectral imaging detects freshness in fish [363, 365, 371]. To assess the automatic freshness of cod fillets at an industrial speed of 400 $mm.s^{-1}$ or 1 $fillet.s^{-1}$, a hyperspectral imaging system with a handheld interactance probe was developed [363]. The results indicated that fresh cod (*Gadus morhua*) fillets could be fully separated from frozen-thawed fillets by using a small subset of wavelengths in the visible region (487, 557, 606, and 646 nm). In another application, fresh halibut (*Psetta maxima*) fillets were successfully separated from frozen-thawed fillets with a correct classification rate of 97%, based on both spectral and textural features that were extracted from hyperspectral images in the spectral region from 380 to 1030 nm [365].

Other new technologies such as Fourier transform infrared (FTIR) spectroscopy [372], and more recently Raman spectroscopy [373], are gaining wide attention because of their advantages, such as rapidity, on-site usability, and high accuracy. A patent has been filed for a rapid control method suitable for rapid differentiation of fresh and frozen/thawed meat or fish using FTIR spectroscopy and subsequent data processing based on hierarchical cluster analysis and artificial neuronal network analysis [374]. Raman spectroscopy and fatty acid profile analysis were combined to analyze 64 fish fat samples from 6 different species, namely, horse mackerel (*Trachurus trachurus*), European anchovy (*Engraulis encrasicolus*), red mullet (*Mullus surmuletus*), bluefish (*Pomatomus saltatrix*), Atlantic salmon (*Salmo salar*), and flying gurnard (*Trigla lucerna*) [373]. The Raman data collected were used as inputs for chemometric analysis and made it possible to develop a PCA model that successfully differentiated fresh and frozen-thawed fish samples.

Fresh and frozen-thawed fish can be differentiated by a wide range of methods, although until now the lack of standardization has deterred wider use in seafood authentication. In view of the need for food control, the authorities' methods should preferably be fast, nondestructive, and relatively inexpensive and not require reagents. Most of the present-day methods proposed need to be improved to match these requirements. For this, research needs to continue, not only in terms of the equipment but also on chemometrics in order to fully validate the best performing methodologies and standardization among laboratories.

7 Conclusion

This chapter has given an extensive overview of the most common methods used in seafood authenticity surveillance. Most are DNA-based methods, but some protein-based methods such as IEF or mass spectrometry have also been included because they are used as simple and cheap screening methods. For the emerging methods for seafood species identification, NGS is a method with great potential for species authentication in mixed products like surimi, cans of tuna, or wild shrimp. Nevertheless, at present, it is not yet possible to quantify the presence of seafood species with this method. Isothermal amplification methods, coupled with easy-to-handle detection devices such as dipsticks, are promising approaches for fast and on-site species detection and would be a valuable tool for official food surveillance, as well as companies' self-monitoring systems. In addition to DNA-based methods, promising methods in seafood species identification are those that use mass spectrometry – methods such as the very fast MALDI-TOF MS, for which some European laboratories (official and private) have already established fish species reference databases.

The methods reviewed for determining geographic origin and previously frozen seafood, and to distinguish wild from farmed seafood, are still under development. They are a very challenging field of research, in terms of their need to address all the traceability requirements and to tackle new questions such as how to distinguish double-freezing or super (or sub)-chilling. Nevertheless, reliable and standardized methods will be needed in the near future in order to fulfill the requirements of the new EU control regulation (Regulation (EU) 2017/625) which regulates the risk-based control of food authenticity. With regard to this, Germany is already in the process of establishing a national center for the authenticity and integrity of the agri-food chain. The development and standardization of new food authentication methods will be one of the priorities of this institution.

Some Statistical Considerations Regarding the Occurrence and Analysis of Bioactive Materials in Foods

71

Basil Jarvis

Contents

Abstract

Bioactive materials (BMs) include a diversity of reactive chemicals that occur in foods and feeds. Some are natural constituents of specific foods, while others may be developed as a consequence of processing or microbial growth, as environmental contaminants, or as additives and adulterants. Many BMs have potential health-giving benefits, but those that are potentially harmful to the consumer are

of equal, or possibly, greater importance. Examples of BMs that occur in foods are discussed briefly and some examples of the statistical methods used in planning and/or analysis of experimental work are described. Of critical importance is the manner in which the distribution of specific compounds within a food material may impact the outputs of statistical procedures.

1 Introduction

Bioactive materials (BMs) have been defined as "... extra-nutritional constituents that typically occur in small quantities in foods." Many such materials are being intensively studied to evaluate their effects on health [1] since BMs that occur in both plant and animal products have pharmacological effects on living organisms. The range of beneficial BMs include fatty acids, flavonoids, caffeine, carnitine, choline, polysaccharides, polyphenols, and anthocyanins. In-depth study of such compounds has shown that many are able to promote good health by acting as antitumor, immunological, anti-inflammatory, hypoglycemic, or antiviral agents. One consequence is that BMs may play a vital role in the development of new drugs. However, it should not be overlooked that while a compound may be beneficial at low concentration, it may also be harmful at higher concentrations. Paracelsus (1493–1541) noted, "Everything is poison; it is just the concentration that will decide if something is nontoxic."

But this is only one aspect of the occurrence and role of BMs in relation to health and well-being [2]. Although many raw foods, especially plant materials, contain a diversity of BMs that have a potential beneficial effect on health [3], many foods are not eaten raw – most are cooked or are processed commercially using thermal and other process conditions that affect the composition of the food. Such processes may reduce, or increase, the nature and the availability of BMs. Many processed foods also contain food additives that have bioactive effects – although such materials may

not be harmful (to some a matter of debate), deliberate adulteration of foods can result in the addition of harmful substances. The growth of microorganisms in the field or during storage of raw and processed food materials can also result in the formation of harmful materials, including bacterial toxins, such as staphylococcal enterotoxin and botulinum toxin. But possibly the most important microbial products are mycotoxins, such as aflatoxin and ochratoxin, which contaminate a wide range of food commodities. Finally, it is important not to overlook the potential impact of food contaminants such as agrochemical residues at levels in excess of those permitted by legislation in most countries. Examples of some beneficial and harmful BMs are shown in Tables 1 and 2.

Table 1 Some beneficial bioactive materials that occur in foods

Chemical group	Examples	Source
Glycosides	Glucosinolates Anthraquinone glycosides	*Brassica* spp.
		Rhubarb
Flavonoids and proanthocyanidins	Phytoestrogens	Fruits, nuts, beans, cereals
Terpenoids	Diterpenoids	Coffee beans
Lignans	Phytoestrogens	Oil seeds
Alkaloids	Methylxanthines	Coffee and cocoa beans
Proteins and peptides	Lectins[a]	Most foods including beans and cereals

[a]See also Table 2

Table 2 Some harmful bioactive materials that occur in foods

Group	Examples	Foods
Plant toxins	Ricin and other lectins	Castor beans
	Furocoumarins	Citrus peel and oils
	Muscarine; psilocybin	Wild mushrooms (toadstools)
Microbial toxins	*Staphylococcus* enterotoxin	Cheese, cured meats
	Botulinum toxin	Cured meats and sausage
	Mycotoxins, e.g., aflatoxins, ochratoxins	Cereals, nuts, milk
Agrochemicals	Pesticides, e.g., chlorpyrifos, captan	Plant foods
	Herbicides, e.g., glyphosate	
Food adulterants	Melamine, urea, formalin, arsenic	Dried and fresh milk
	Diethylene glycol	Wine
	"Denatured" rapeseed oil containing derivatives of OOPAP[a]	Olive oil
	Metanilic acid	Spices, e.g., turmeric
	Methylmercury	Grain

[a]OOPAP = 1,2 dioleoyl-3-(*N*-phenylamino)-1,2-propanediol

2 Distribution of Bioactive Materials in Food Materials

2.1 Natural Occurrence

Levels of naturally occurring BMs in raw foods vary considerably, depending on the species, the cultivar, and the environmental conditions under which they are grown. Even for crops grown under "ideal" conditions, the range of concentrations can vary tenfold or more between different cultivars. For instance, the glucosinolate content of broccoli genotypes grown under controlled conditions was reported to vary, on average, from about 0.2 to 1.8 μmol/g dry weight [4]. The concentration of glucoraphanin in the commercial broccoli variety "Marathon" is about five times higher than that in the variety "Everest" [4]; it is not possible for the commercial user or the consumer to differentiate between varieties in order to select for enhanced levels of glucoraphanin.

The presence of specific nutrients in the soil influences the pattern and levels of glucosinolates in broccoli [5]. In field experiments, fertilization with increased sulfur levels generally gave a higher glucosinolates concentration in *Brassica* species [6]. However, the levels of the alkyl glucosinolates, glucoraphanin and glucoiberin, were reduced by 70% in broccoli supplied with enhanced nitrogen levels in comparison with plants receiving no added nitrogen [7]. Nitrogen fertilization also lowers the anthocyanin content in Merlot grapes [8]. Anthocyanin levels in red cabbage are reported to be reduced by high nitrogen levels, but potassium and phosphorous have little effect [9]. The highest lycopene concentrations, and the best color, in tomatoes were reached under low nitrogen levels, but the yield was increased by higher nitrogen levels; however, the lycopene concentration increased with increasing phosphorous and potassium [10]. In carrots, the carotene content seems to increase with increasing nitrogen supply [11].

Similarly, the concentrations of BMs in many plants are affected by the levels of solar radiation, temperature, and moisture content. Generally, levels of BMs are increased significantly when grown in conditions where the soil moisture content is low, while levels were increased by exposure to sunlight and low mean temperatures [12].

The importance of BMs in relation to the quality of foods and feeds has created interest in their natural biosynthetic pathways and in the possibility of manipulating the levels to produce new and improved varieties. Breeding projects to develop F1 hybrids and genetic manipulation procedures have been used to improve agronomic and quality traits and to select for specific characteristics such as increased total phenols content and total antioxidant capacity [13].

A good example of deliberate breeding for high levels of health-promoting glucosinolates is the selection of broccoli cultivars for higher levels of glucoiberin and glucoraphanin, the precursors of the isothiocyanates iberin and sulforaphane, respectively [14]. This was achieved by crossing a standard broccoli cultivar with *B. villosa*, a wild relative of *B. oleracea* from Sicily, which accumulates high levels of glucoiberin in the flower buds. The F1 hybrids had high levels of both glucosinolates. By using a series of backcrosses, two regions of the *B. villosa* genome for high glucosinolate content were introduced into a commercial broccoli. These high glucosinolate broccoli cultivars have subsequently been used in human

intervention trials in the UK and shown to deliver about four times the amount of sulforaphane to the systemic circulation than standard cultivars [15]. It is important to note that the isothiocyanates derived from these glucosinolates contribute little to flavor so that it is possible to enhance their levels. However, increasing the levels of certain other glucosinolates may result in more pungent isothiocyanates, such as 2-propenyl or 3-butenyl, which are commercially undesirable.

2.2 Contaminants in Foods

This diverse category of BCs includes both agrochemical residues and microbial toxins. Generally, the levels of pesticide and herbicide residues in plants are below the limits set by law in most countries. However, the most recent (2016) results of pesticide residue monitoring in the UK shows that residues were detected in about 48% of all commodities tested and levels exceeded the legislative limits in some 3.2% of all samples tested, mainly in imported foods [16]. Similar levels of incidence are found in most developed countries although recent US studies suggest a much higher incidence of residues. But in the third world, residue levels are often much higher, and the adverse consequences for health of consumers, especially children, are significant [17].

However, the situation is different for microbial toxins, both those produced within an agrochemical commodity and, potentially, as a consequence of microbial growth in a manufactured food product. Growth of fungi within a primary product may occur in the field or during postharvest storage of crops; fungi and their metabolites are perpetuated along the food chain as a consequence of blending of primary raw materials prior to, or as part of, a manufacturing process. Possibly the best-known example of such contaminants is the occurrence of the potentially carcinogenic aflatoxins in nuts, cereals, and other food crops. Growth of the producer organisms, *Aspergillus flavus* and *A. parasiticus* strains, occurs within individual nuts. While widespread infection by the fungi may occasionally affect entire batches of a crop, it is widely recognized that often there is only a small number of infected nuts within a consignment that is otherwise largely unaffected. In certain instances, aflatoxins may occur at levels of 1000 μg g-1 in peanut kernels and up to 5000 μg g-1 in cottonseed [18, 19]. Good Manufacturing Practices use color, UV fluorescence, or other forms of automated detection to screen out damaged and highly contaminated nuts, [20] but in rural communities in Africa, South America, and elsewhere, such screening is not possible. As a consequence, a population that consumes the nuts as a primary food source is exposed to high levels of dietary aflatoxin and/or other mycotoxins [21–23]. The presence of aflatoxin B_1 in the feed of dairy animals results in the excretion of aflatoxin M_1 in the milk.

2.3 Distribution of BMs in Food Materials

The distribution of naturally occurring BMs in food plants generally conforms reasonably to a normal distribution (ND), as do those BMs developed as a

consequence of food processing operations, such as heating, for instance, the development of furans in pasteurized fruit juices and acrylamide in high temperature-cooked products. Similarly, BMs added as food supplements, food ingredients, or food additives will generally be well mixed during the food preparation stages so that the distribution in the food conforms reasonably to the expectation of a ND. Generally, the distribution of agrochemical residues in crops also conforms reasonably to the ND.

However, the variability in the levels of contamination by mycotoxins is considerable, even within a "lot," and the distribution in primary food materials does not conform to a ND. The most usual conformation is to a negative binomial (Gamma-Poisson) distribution (NBD) [24–27]. By contrast, aflatoxin M_1 in "lots" of milk and in products such as cheese and yogurt is normally distributed [28] although there may be significant differences between "lots" depending on the level of contamination of the animal feed.

Toxins derived following growth of bacteria, such as staphylococcal enterotoxin and botulinum toxin, will normally occur in the vicinity of microcolonies of the producer organisms but will diffuse into the product over time. The initial bacterial contamination will usually be distributed randomly, although sometimes high-level microbial contamination occurs in localized areas, such that distribution of the cells conforms to a Beta- or Gamma-Poisson NBD [29]. If the initially contaminated product is subsequently processed by blending, then the organisms, and their toxins, will more usually be distributed more randomly in accordance with the expectation of a Poisson distribution [27].

3 Statistical Aspects of Sampling for Analysis

3.1 Sampling Protocols for Surveillance and Monitoring

The underlying principles of sampling are "dependent on purpose," but the primary objective is to obtain a series of samples that is "representative of the batch of material under investigation." Regulators may seek more samples than a producer may wish to have tested so that the question "how many samples do I need to take?" has often been answered with the general advice "more than you can afford to test." By contrast, the analyst generally sees a sample purely as "a quantity of material selected for analysis from a larger quantity of material" – but this misses the point: the selected sample(s) may not be truly "representative" of the whole [30].

In many countries, regulations concerned with control of contaminants often set a level of compliance as a limit value (e.g., a maximum or average value depending on the nature of the test). Demonstrating compliance against a limit requires a sampling and analytical plan (SAP) that often specifies the need for "representative" samples and analysis by an accredited laboratory. The SAP rarely requires measurement uncertainty to be reported nor does it require that the samples were truly representative of the "lot" which provides evidence regarding

the variability of the analyte concentration in the material. Merely replicating the sampling and analysis may provide some evidence that sampling is representative but ignores the possibility of a common sampling bias affecting a series of tests. It is relevant, therefore, that ISO 3534-4 [31] states that "the notion of a representative sample is fraught with controversy with some practitioners rejecting the term altogether." Even changing the concept to one of "appropriate" sampling [30] may not solve this dilemma especially when investigating the levels of a specific constituent, such as a contaminant in a food material. Part of the dilemma lies in the difference of understanding between the analyst and the statistician. To the analyst, the term "representative sample" usually refers to the material that arrives for laboratory analysis, whereas the survey statistician considers the sample as "one for which the observed values have the same distribution as that in the population sampled."

Wherein lies the problems of sampling? A generally homogeneous material, such as a nonviscous liquid, can be mixed relatively easily; but, even then, there will be variation between results on replicate samples that reflect both the distribution of the analyte within the bulk material, inaccuracies in the preparation of the sample for analysis (e.g., compounding of bulk materials and extraction of the analyte), the imprecision of the method, and the way that it is used by the analyst. Sampling of solid materials (e.g., plant materials) requires homogenization of the target material in order to draw a uniform sample for analysis. But which target material is to be used? If a BM (or other analyte) is present only in the flower bud, should the "buds" be separated before analysis, or should the buds and stalks be analyzed together? If the latter, how does the analyst ensure that a similar admixture of plant materials is always analyzed?

Bulk granular materials are even more variable! A "lot" of, e.g., corn or peanuts will contain different quantities of the analyte throughout the bulk such that very large samples of the target material require effective grinding and mixing to give a relatively homogeneous primary target sample that can be further ground, mixed, and subjected to extraction. While such procedures can be carried out for chemical analysis, they can rarely be done for microbiological analysis [27].

3.2 Sampling Plans and Analytical Methods

For monitoring and control purposes, a SAP is generally based on a specification relating to the number of individual samples to be examined for a given bulk of material using defined sample preparation and analytical methods. The results of the analyses are then compared against criteria that define an acceptable upper or lower limit for the analyte.

By contrast, surveillance studies aim to determine the frequency and levels of occurrence of the analyte. If the analyte is known to be a constituent of the material under investigation, then only quantitative tests will usually be undertaken, but if one is concerned with ascertaining whether a contaminant might be present in a product, both qualitative and quantitative methods may be required. For instance, surveys of

the incidence of aflatoxin in a commodity or processed food are usually predicated on the use of semiquantitative methods that provide both a measure of frequency and an indication of the level of contamination in a proportion of samples. The choice of method should therefore be determined by the precision and accuracy required for the result. For analytes which are known to be highly variable, the number and size of primary samples for analysis should always be much greater than for a more homogeneous target.

Figure 1, using data reported by Whitaker et al [24], shows the distribution of the mean levels of detection of aflatoxins in a total of 290 samples of shelled peanuts, being 10 sub-samples taken from each of 29 lots. Whilst some 57% of the samples contained less than 20 μg kg-1, including no detectable aflatoxin, 43% contained aflatoxins at levels up to almost 300 μg kg-1. The range of mean aflatoxin levels within individual lots ranged from 0 to 14 μg kg-1 through to 0 to 285 μg kg-1 in another lot. The 'box and whisker' plot (Fig. 2) shows a selection of the results for individual lots. Lot 16 is particularly interesting because although nine of the ten samples contained aflatoxin at < 20 μg kg-1 one sample contained an average level of 285 μg kg-1. Although not unusual, such an observation illustrates the diversity of contamination levels that may result from only a small number of contaminated peanuts within a lot. Other surveys for mycotoxin contamination of food and feed materials have shown similar distribution patterns, reflecting the nature of microbial activity.

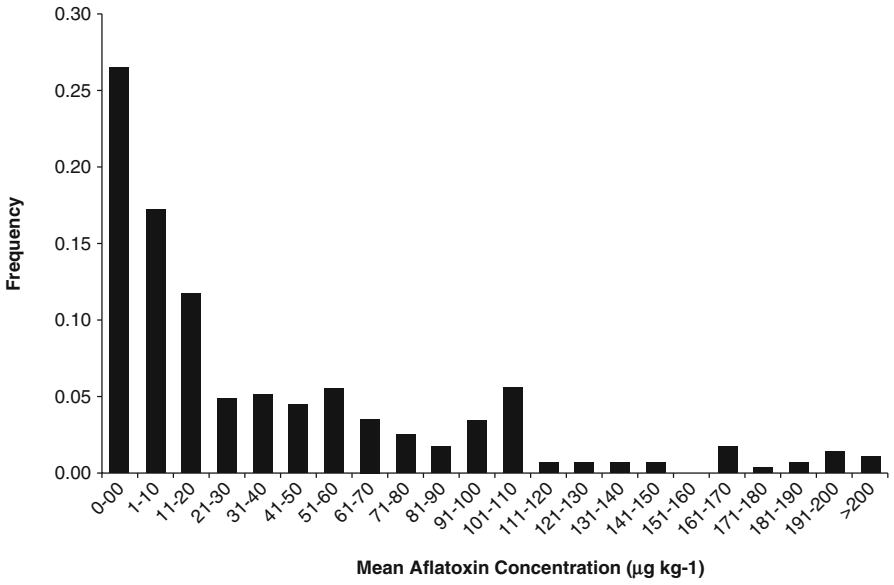

Fig. 1 Frequency distribution plot of the mean aflatoxin levels in each of 10 replicate subsamples taken from primary samples of 29 lots of shelled peanuts. The data, reported by Whitaker et al [24], were used originally to demonstrate that aflatoxin contamination follows a NBD

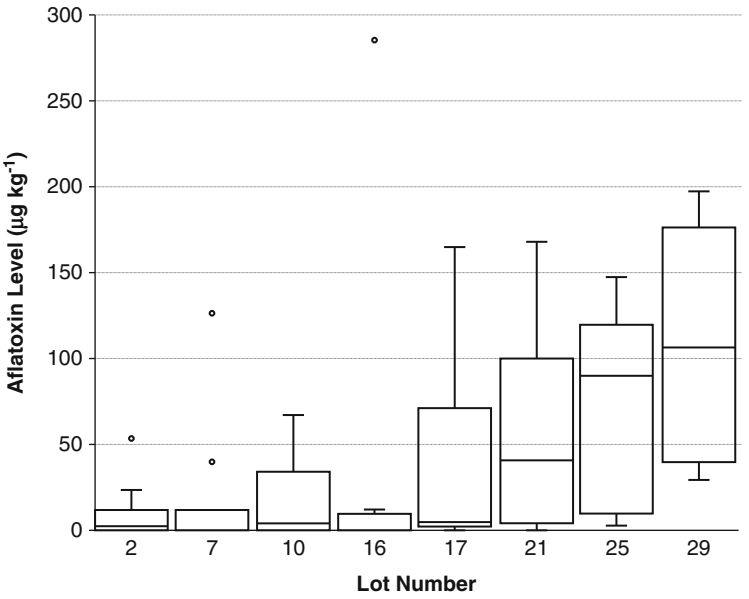

Fig. 2 'Box and Whisker' plots to illustrate the diversity of aflatoxin contamination levels on 8 of the 29 lots of peanuts reported by Whitaker et al [24]. Whilst a general low level of contamination was found in lots 2, 7 and 16 individual test samples from these lots contained higher levels in one or more samples. By contrast a more widespread contamination occurred in lots 17, 21, 25 and 29

The choice of method should be determined by the precision and accuracy required for the result. For analytes which are known to be highly variable, the number and size of primary samples for analysis should always be much greater than for a more homogeneous target.

3.3 Analytical Uncertainty

For any SAP, there will always be a level of uncertainty in the results. In this context, uncertainty takes into account both the precision of the method and the accuracy of the result [32]. Three kinds of uncertainty occur: sampling uncertainty, sample preparation uncertainty, and measurement uncertainty.

Sampling uncertainty is a measure of the variability of the analyte in a "lot" of the target material and, even with relatively homogeneous materials, is usually much greater than measurement uncertainty for both chemical [32, 33] and microbiological procedures [34].

Sample preparation uncertainty relates to the variability associated with the production of individual test samples taken from a primary target sample. Techniques such as grinding and mixing of a relatively large quantity of primary sample may be needed to reduce the bulk of material to provide a more

homogeneous matrix that will be sampled again in order to provide a "test sample" for analysis.

Analytical (measurement) uncertainty is an estimate of the variability of the results of an analysis that is related to the analytical method and its use in an individual laboratory and/or in a number of collaborating laboratories [35, 36]. Usually the statistical error (variability) of sample preparation is included as part of analytical uncertainty, but some workers may treat it separately.

The overall estimate of uncertainty is determined from the square root of the combined variances of the individual stages (Eq. 1):

$$U = \sqrt{s_{\text{sam}}^2 + s_{\text{prep}}^2 + s_{\text{an}}^2} \tag{1}$$

where $U =$ the estimate of overall uncertainty measured as a standard deviation; s_{sam}^2 = the estimate of sampling variance, i.e., the "between sample" variance; s_{prep}^2 = "within" sample (preparation) variance; and s_{an}^2 = the analytical variance. Statistical analysis of variance (ANOVA) is usually applied to derive the individual variances, but reliable results for the variances require that estimates conform to a ND. If this is not so, then the original data need to be "normalized" before an analysis of variance is undertaken. If, for instance, the distribution of the analyte in the product is believed to conform to a negative binomial distribution (as in the case of many mycotoxins), it is necessary to transform the original data before determining the estimates of variance. In the case of the negative binomial, the usual transformation is $\sinh^{-1}\sqrt{\frac{x+0.375}{k-2(0.375)}}$, where x is the analytical result and k is the negative binomial exponent. In the case of the distribution of aflatoxins in peanuts, Whittaker et al. [24] determined the value to be $k = (2.0866 + 2.3898\,\text{m}) \times 10^{-6}$ (in terms of the μg kg-1 contamination levels), where m was the mean concentration of aflatoxin.

The overall uncertainty (U) is multiplied by a "coverage factor" (K) to give an expanded standard deviation that is an approximate estimate of the confidence limits of the analysis. The coverage factor used is normally a value of 2, so that the approximate 95% expanded uncertainty is given (Eq. 2) by

$$U_{\text{exp}} = K\text{U} = 2U \tag{2}$$

By way of example, let us assume that analysis of ten samples of a product for a natural constituent gives a mean concentration of 6.8 μgkg^{-1} product and a test for "normality" is not rejected. ANOVA gives a between sample variance of 0.80 μgkg^{-1}, a within sample variance of 0.15 μgkg^{-1}, and an analytical variance (reproducibility) of 0.22 μgkg^{-1}. Then the uncertainty estimate is given by $U = \sqrt{0.80 + 0.15 + 0.2} = \sqrt{1.05} = 1.0724$. Expanded uncertainty is $2U = 2 \times 1.0724 \approx 2.145$ μgkg^{-1}, so the overall test result is 6.8 ± 2.145 μgkg^{-1} and the bounds of the lower and upper 95% confidence limits are 4.655–8.945 μgkg^{-1}, respectively.

4 Sampling for Special Purposes

4.1 Planning and Analysis of Trials

Trials can take many forms depending on the overall objectives. The requirements for growth trials of new cultivars and trials of cultivation conditions (soil type, moisture, solar effects, temperature, etc.) are all well described in scientific literature, yet in so many cases, one finds that proper randomly controlled trials are not undertaken. There are three key elements: replication of each test factor (e.g., soil) for each test subject (e.g., a cultivar), replication of each test subject between each test factor, and a consistent approach to analysis for the defined analyte between subjects and test factors [37].

The original examples using the Latin Square approach to controlled replication of experiments, were described almost 250 years ago by Leonhard Euler (1707–1783). More recently, Williams [38], Laywine and Mullen [39], and Fisher [40] have provided working tools to enable the researcher to apply the concept of Latin Squares in the design of experiments. The primary objective of Latin Squares is to ensure randomization and replication under controlled conditions, as illustrated in Fig. 3 for a series of 25 "plots" of land used to trial four new cultivars and to provide a comparison to a "standard" cultivar.

As shown in the figure, each cultivar is replicated five times to make allowance for variations in the soil. Of course, replication of plants within a "plot" permits estimation

a

D	B	E	C	A
B	A	D	E	C
C	D	B	A	E

Fig. 3 Two forms (**a**, **b**) of Latin Squares. Note that each letter (from A to E) occurs once in each row and each column. Form (**a**) is a cyclic orthogonal Latin Square, where letters in succeeding rows move to the left one row at a time; by contrast, form (**b**) shows a random orthogonal allocation. The control (or reference) trial and the four test trials (cultivars or treatments) would each be allocated randomly to a letter location. For a field trial, unless testing for effects of soil type, the underlying assumption is that the composition and type of soil are essentially uniform across all test plots

of variation between plants of each cultivar so that the "within plot" and "between plots" variance can be determined. The Latin Square approach is not restricted to just a few cultivars or treatments; Latin Square designs allowing 20 or more sets can be produced, but the level of statistical analysis is increased proportionately to the increased number of parameters. For larger numbers of parameters, an alternative approach is the use of a Quasi-Latin Square where twice the number of factors can be tested but on half the number of replicate occasions but with slightly reduced precision [41].

4.2 Example

Suppose that in a simple experimental trial, we wish to assess and compare the levels of a metabolite X in four new plant cultivars against an existing commercial cultivar. We plant three replicates of each cultivar in each of five trial plots (25 plots in total). Throughout the trial, we monitor and record the condition of each plant (in terms of size, conformation, appearance, etc.), and at harvest time we again record condition and take the materials for analysis. Table 3 illustrates the sort of results that might be found using a categorical scoring system of 0 = no growth, 3 = good growth, and 5 = luxuriant growth. From the scores, it is clear that plants of cultivar C grew poorly and that cultivar D grew more strongly than did the control plants (A); cultivars B and E grew at a rate comparable to A. Table 3 also demonstrates that overall growth in row 1 was slightly less than in the other four rows. The question now arises as to whether the differences are of statistical significance. The null hypothesis is that all cultivars grow equally well; the alternative hypothesis is that they do not.

Since the data are categorical (i.e., scored by reference to preset criteria), it is necessary to use a nonparametric analysis of variance, such as the Kruskal-Wallis (KW), test to assess whether the results differ significantly. The total score from each plot in Table 3 is ranked across all plots (Table 4), where if two or more results have the same value, the average rank is used. Then for each set of data, the ranked values are summated to give a value (*Tc*), which is squared and divided by the number of replicates to determine a value, *H*, using Eq. (3):

Table 3 Categorical results for cultivar growth over an 8-week period. The control (reference) cultivar was allocated to A and the other four cultivars to B, C, D, or E. The results are based on growth of three replicates in each plot scored a five-point scale with 0 representing no growth, 3 good growth, and 5 excessive growth

Cultivar	Growth in row					Total
	1	2	3	4	5	
A	3,3,4 = 10	4,4,3 = 11	3,3,3 = 9	3,2,3 = 8	3,3,3 = 9	47
B	3,2,3 = 8	3,3,3 = 9	4,3,3 = 10	3,3,2 = 8	4,3,3 = 10	45
C	0,1,1 = 2	1,1,1 = 3	1,2,1 = 4	1,2,2 = 5	1,1,1 = 3	17
D	5,4,4 = 13	5,5,3 = 13	5,5,4 = 14	5,5,5 = 15	4,5,5 = 14	69
E	3,3,3 = 9	3,4,4 = 11	3,4,3 = 10	3,3,4 = 10	3,3,4 = 10	50
Total	42	47	47	46	46	228

$$H = \left[\frac{12}{N(N+1)} \times \sum \frac{\mathrm{Tc}^2}{n_c}\right] - 3 \times (N+1) \quad (3)$$

where H is the KW value, N is the total number of tests in all groups, n_c is the number of tests in a specific group (in this case it equals 5), Tc^2 is the square of the sum of the ranked values for each group (c), and $\sum$ means "sum of" for all groups. Critical value tables for the H can be found in Meyer and Seaman [42], but the value of χ^2, available in statistical tables, provides an approximation for H. For the ranked data shown in Table 4, $H = 19.298$ with four degrees of freedom (five test series – 1). From tables of χ^2 for 4 df, the value of H is greater than the critical value (18.467) for $p = 0.01$, so the differences in the results are highly significant. However, a word of caution: if many values are of equal rank, the result of this nonparametric form of ANOVA may be misleading – theory suggests that ideally there should be few tied ranks.

For this example, it was not really necessary to carry out a statistical analysis because, just by inspection, we could rate cultivar C as poor while cultivar D obviously grew much better than the control (A) or the two other cultivars (B and E). But for other data, it could be important to have the statistical confirmation.

Suppose also that the mature plants have been analyzed for a hypothetical constituent X and, since these are actual values, it is appropriate to compare them using a parametric ANOVA. As before we have three replicate plants from five cultivars each grown in five different plots of land. We can assess the mean and variance for the level of X in all three plants from each plot, but, for the sake of simplicity, I will assume that we analyze only the mean level of X in the plants in any one plot. Preliminary tests for ND [43] showed that for cultivar C both the mean value and the variance of the results were low compared to the other cultivars (Table 5). The results for cultivar C were therefore removed from the dataset, and a test for homoscedasticity (equality of variances) was performed on the four remaining cultivars using Levene's test [43] which did not reject the hypothesis that the variances of the remaining four populations were equal ($F = 0.16$ with 3 and 16 df and $p = 0.9203$). ANOVA was then carried out on the data for the four cultivars (Table 6), and the results demonstrate a highly significant difference ($p < 0.001$) that requires rejection of the null hypothesis that the mean values of all the results are equal. A post hoc test, using pair-wise

Table 4 Ranking of cultivar growth in a Latin Square trial of four new cultivars (B to E) against a control cultivar (A). Note that if two, or more, results are the same, then each is given the average rank

	Ranked values for each plot					
Cultivar	1	2	3	4	5	Tc sum
A	15.5	19	10.5	7	10.5	63.0
B	7	10.5	15.5	7	15.5	55.5
C	1	2.5	4	5	2.5	15.0
D	21.5	21.5	23.5	25	23.5	115.0
E	10.5	20	15.5	15.5	15.5	76.5
Sum	55.5	73.5	69	59.5	67.5	325

Table 5 Hypothetical results for a compound (X) determined on cultivars grown in a 5 × 5 Latin Square trial

Cultivar	Mean level of X (μg/g) in plot					Mean	Variance
	A	B	C	D	E		
A	37.6	37.1	35.9	35.6	36.1	36.46	0.723
B	31.6	33.5	33.6	33.2	33.4	33.06	0.688
C	2.6	3.6	2.1	2.8	2.3	2.68	0.337
D	40.2	39.4	41.6	40.2	39.8	40.24	0.688
E	36.5	38.1	37.2	36.3	38.1	37.24	0.728

Table 6 Results of ANOVA of the data from Table 5 after removal of data for Cultivar C

Source	SS	DF	MS	F	*p*-value
Cultivar	130.60	3	43.53	61.60	<0.0001
Error	11.31	16	0.71		
Total	141.91	19			

comparisons of the four sets of data using Tukey's "least significant difference" test [42] showed that the level of compound X in cultivar E did not differ from that in the reference cultivar (A), that B was significantly lower, and that D was significantly higher than the reference value (both at $p < 0.01$).

By comparison with the results for the reference cultivar, we can conclude that cultivar B grew at a similar rate but produced a lower level of compound (X); that cultivar C did not grow well or produce much X; that cultivar E was not different in terms of growth or production of X; but that cultivar D was more prolific in its growth and also produced significantly higher levels of X. It is important to recognize that differences in growth and metabolic output between cultivars need not only to be observed but also to be demonstrated as being of statistical significance.

5 Chemometric Methods

Surveillance work for trace compounds in foods, and for investigation of food adulteration, often produces a database with results from many tests; some of which may be purely categorical, while others are analytical data [43]. Categorical (observational) data may be of three types: nominal (e.g., three or more types of foods, etc.), dichotomous (e.g., authentic or adulterated), and ordinal (data ordered by criteria, e.g., three levels of sensorial evaluation such as 1 = unacceptable, 2 = marginally acceptable, or 3 = acceptable). On the other hand, quantitative variables include continuous scales (temperature, pressure, time, concentration, mass, etc.), intervals, and ratios. In recent times, many investigations use multivariate statistical procedures such as principle components analysis (PCA), cluster analysis, and other more complex procedures, to associate the level of BMs with in vivo or in vitro functional properties.

PCA is a statistical procedure that uses an orthogonal transformation to convert a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables called "principal components." The number of distinct principal components is equal to the smaller of the number of original variables minus one. The transformation is defined in such a way that the first principal component has the largest possible variance (i.e., accounts for as much of the variability in the data as possible); each succeeding component in turn has the highest variance possible under the constraint that it is orthogonal to the preceding components. The resulting vectors form an uncorrelated orthogonal base set. PCA is sensitive to the relative scaling of the original variables and is mostly used as a tool in exploratory data analysis and for making predictive models. It is also used in canonical correlation analysis to define coordinate systems that optimally describe the cross-covariance between two datasets so that the PCA defines a new orthogonal coordinate system that optimally describes variance in a single dataset.

"Cluster analysis" is a procedure for grouping a set of objects in such a way that objects in the same group (a cluster) are more similar to each other than to those in other groups (clusters). Its main task is for exploratory data mining.

A recent paper [43] describes and reviews the use of these, and many other forms of, chemometric analysis that have been used in food-related studies. For instance, chemometrics based on appropriate analytical techniques have been used to confirm adulteration of wines, honey, essential oils, and many other high-value food products. Aside from food adulterations, chemometrics have been used to analyze data on soil toxicity, influences of climate change on the nutritional value of foods, and changes in functional properties consequent on processing.

6 Clinical Trials

Validation of beneficial or harmful effects in experimental animals requires careful planning and ethical approval. Is the target species appropriate and how will the effects be recognized? Even if beneficial effects are observed in, e.g., rats, mice, or hamsters, will the effects also be seen in humans? Clinical trials on humans require both careful practical and statistical planning and ethical review before the trials commence. It is not possible to summarize all the planning and statistical issues that must be reviewed, but guidance is available in publications such as the US FDA regulations [44] and the European Commission Guidelines [45].

7 Validation and Verification of Methods

Whenever possible analytical methods that have been collaboratively tested under AOAC [46], ISO [47], or other recognized national schemes should be used for detection and estimation of levels of occurrence. The primary objective of validation and verification of methods is to ensure that the results are obtained using the most reproducible procedures, rather than by an ad hoc procedure developed in a specific

laboratory. Unfortunately, in many cases workers tend to use their own methods of analysis. Of course, new developments in analytical technology offer opportunities to improve sensitivity, precision, and accuracy of methods – but, such developments should always be validated against reference methods that have been internationally approved as standard methods. Observation of a new potentially beneficial or toxic constituent requires validation using approved methods.

A similar stricture applies also to the choice and use of statistical methods of analysis. An experimental or surveillance program needs to be reviewed and approved by a statistician before the work is undertaken to ensure that the work plan is appropriate. All too often one finds that results given in papers submitted for publication have been obtained using nonstandard methods or that the statistical methods used to substantiate the findings are not appropriate. It is then difficult to assess whether a reported finding is genuine or merely a consequence of the analytical or statistical procedure used by the authors of the paper. Even relatively minor changes to methodology can affect the validity of the results!

8 Conclusions

The occurrence of BMs in raw and processed foods may offer benefits or risks to the health of consumers, be they human or animal. Surveys for presence and levels of BMs need to be undertaken using statistically sound experimental sampling plans with adequate levels of control and to use appropriate analytical and statistical methods. Key among these is the need to develop an appropriate statistical approach before practical work is undertaken.

Acknowledgments I am grateful to Dr Alan Hedges of the University of Bristol for his inciteful and helpful comments on the draft of this chapter.

LC-MS/MS Determination of Pesticide Residues in Fruits and Vegetables

72

Anna Stachniuk

Contents

Abstract

A proper diet is commonly regarded as one of the most important factors determining one's health. A key role in such a diet is played by unprocessed food of plant origin, mainly fruits and vegetables, as they contain many important dietary bioactive compounds such as polyphenols, carotenoids, fiber, antioxidants, several important vitamins, and minerals. Despite the nutritional benefit, they may also contain substances that adversely affect human health. Pesticides constitute a special group of contaminants as even small amounts of these substances can result in acute poisoning, lead to cancer, and have an adverse impact on the endocrine, immune, and nervous system. A considerable number of pesticides have a harmful effect already in low concentrations, within the range of μg kg^{-1} and below μg kg^{-1}; hence, there is a great need for identifying and determining them by means of highly selective and sensitive methods. In the analysis of pesticide residue, similarly to the analysis of other food contaminants,

there is a clear tendency to prepare multiresidue methods that enable monitoring a large number of compounds in a great number and variety of samples. Most multiresidue methods reported for fruits and vegetables in the last decade are based mostly on the use of liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS), which is the technique of choice for the majority of pesticides and their metabolites nowadays.

1 Introduction

Recent years have seen a clear trend encouraging people to consume unprocessed food. An active lifestyle and a balanced diet have a decisive impact on protecting human health. Fresh fruits and vegetables hold a prominent place in this diet as they are a rich source of fiber and several vitamins and minerals important for health. According to the World Health Organization (WHO), consumption of fruits and vegetables in Europe constituted over 30% of consumer diet [1]. In unprocessed food, including raw fruits and vegetables, a considerable number of healthy bioactive compounds can be accompanied by contaminants occurring in atmospheric air, soil, and water. Unfortunately, almost all of the agricultural commodities currently cultivated and distributed are exposed to contaminants. Three main groups of contaminants are distinguished based on the impact of environmental factors: physical, chemical, and biological [2]. Chemical contamination, mainly caused by the increasing use of agrochemicals in the agricultural and food industry, constitutes a special group of contaminants. Unlike dangerous biological contamination of food immediately resulting in poisoning, chemical contaminants usually emerge with a delay because they can accumulate in human tissue over a long time and cause symptoms of disease only after reaching a critical level. The presence of chemical contaminants in food is one of the basic criteria for assessing the safety and quality of foodstuffs [2]. Plant protection products, i.e., pesticides, constitute the most varied source of food contaminants. Owing to their long-term persistence and long-term effects in living organisms, they are ranked among the most toxic chemical substances in the environment. Their presence in food poses a serious threat to the health and life of consumers. One of the protection measures against pesticide residues in food is to determine the maximum residue levels permitted in a food product, and to carry out an obligatory and systematic analytical testing of food for pesticide residue. For each pesticide used in food production, legislators specify the definition of residue, which enables the assessment of the health hazard. In Europe, maximum residue levels (MRL) of pesticides permitted in food and feed, including fruits and vegetables,

intended for human consumption were established by Regulation (EC) No 396/2005 of the European Parliament and Council on pesticide residues [3].

Recently we have seen growing public concern and scientific investigations related to the presence and control of pesticide residues in plant products to assess the potential health hazards more thoroughly. Before food products can enter a particular market, requirements for MRL must be met for a variety of pesticides [4]. Therefore, there is a need for reliable and sensitive analytical methods that are able to quantify a large number of compounds at the low limits set out in legislation [3]. With over a thousand compounds to monitor [5] in various matrices, multiresidue methods using gas and liquid chromatography coupled with tandem mass spectrometry have become the Gold Standard methodology for both quantification and semiquantitative screening of food contaminants, such as pesticides [6, 7]. Nowadays, both liquid and gas chromatography are complementary techniques covering the full range of pesticides [6, 8–12]. However, gas chromatography has the drawback of being unsuitable for a number of pesticides because of their instability and polarity [13]. Compounds which are thermally labile, not volatile, and have not been derivatized, can be separated by liquid chromatography [13]. Liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) can analyze a much wider range of contaminants than gas chromatography coupled with tandem mass spectrometry (GC-MS, GC-MS/MS). A general discussion of the application of GC-MS/MS and LC-MS/MS for the analysis of different chemical classes of pesticides can be found in the book chapter by Raina [14]. Liquid chromatography coupled with mass spectrometry provides a large amount of information about complex mixtures and the structure of the analyte without the need to derivatize the analyte. It also enables the screening, confirmation, and quantification of hundreds of components with one analysis. Its sample purity requirements are not stringent, and it enables a simultaneous analysis of contaminations with considerable variations of polarity [13]. Indeed, to achieve a wide scope and better sensitivity for a wide range of new generation pesticides and their metabolites, which are more polar compounds [6], it is not surprising that LC-MS/MS has become the method of choice for routine pesticides multi-residue analysis in vegetables and fruits.

This chapter presents general information about pesticides and modern methods of their identification by means of LC-MS/MS. A review and assessment was carried out of the existing techniques and methods of sample preparation, separation of multicomponent mixtures, as well as kinds of detection used in the analysis of pesticides in fruits and vegetables by means of LC-MS/MS. Special attention is paid to the QuEChERS technique and the triple quadrupole analyzer (QQQ) most frequently used in MS detection. Furthermore, pesticide residues most frequently occurring in fruits and vegetables are presented.

2 Pesticides: General Information

Pesticides have been widely used around the world since the middle of the twentieth century [8]. About 1000 active ingredients have been employed and are currently formulated in thousands of different commercial products [5]. They are part of a

large group of compounds with extremely diverse physicochemical properties and large differences with regard to polarity, volatility, and persistence [15]. They are widely used in the control or prevention plant crop diseases. Their extensive applications go beyond agriculture. Pesticides are used to reduce the number of plant and animal parasites, combat plant diseases, regulate the growth and development of plants, remove weeds, and reduce losses in food during storage and transport. Furthermore, they help increase personal hygiene by destroying domestic insects (fleas, lice, and cockroaches) and insects bearing diseases hazardous to humans such as malaria, the plague, or spotted fever [16]. Their introduction contributed significantly to increased productivity in agriculture through the stabilization of agricultural crop volume and quality. Alongside unquestionable benefits, the common use of pesticides also has an adverse impact on the natural environment, including human and animal's health and life, mainly because of the varying persistence, toxicity, bioaccumulation capacity, and mobility of pesticides [17–21]. Pesticides are classified as chemicals with a high level of toxicological hazard. They have a carcinogenic, teratogenic, and embryotoxic effects [20]. Several studies have found that human exposure to pesticides underlies many disorders such as Alzheimer's disease [22], infant mortality [23], carcinogenicity [24], neurotoxicity [25], reproductive toxicity [26], and metabolic toxicity [27]. Pesticides have an effect on both harmful and useful organisms. Their benefits and hazards are summarized in Fig. 1. The influence of pesticides on the natural environment and food quality was described extensively in studies by Aktar [28] and Fenik [15].

The great diversity of compound structure and broad spectrum of effects and applications makes a clear classification of pesticides difficult. The following criteria are used most frequently: purpose of application, chemical structure, toxicity, environmental stability, and pathways along which they penetrate target organisms [15, 16]. The classification by purpose of application is presented in Table 1. In terms of

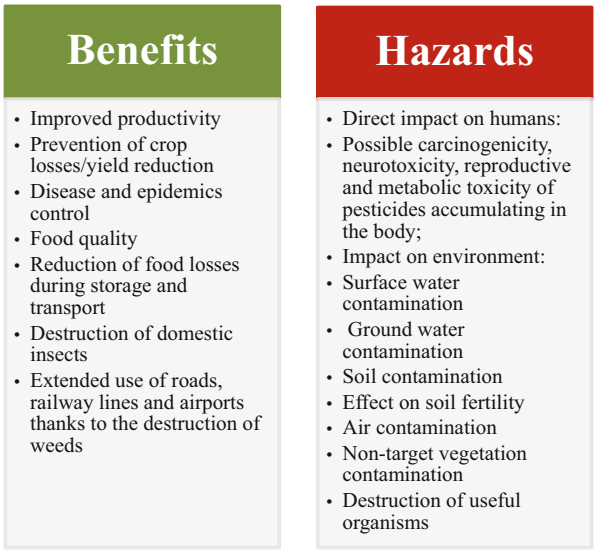

Fig. 1 The effects of using pesticides: their benefits and hazards

Table 1 Classification of pesticides based on their application [16]

Type	Purpose of application	Type	Purpose of application
Zoocides	Used to exterminate harmful vertebrates	Fungicides	Control or kill fungi
Insecticides	Control or kill insects	Herbicides	Kill or inhibit the growth of unwanted plants
Rodenticides	Control mice and other rodents		
Molluscicides	Control slugs, snails and other mollusks	Plant growth regulatory	Alter the growth of plants
Disinfectants	Control germs and microorganisms		
Bactericides	Control or kill bacteria	Defoliants	Cause plants to drop their leaves
Algicides	Control or kill algae	Desiccants	Are used to dry up living plant tissues
Virucides	Control or kill viruses	Fumigants	Produce gas or vapor intended to destroy pests
Acaricides	Control or kill mites	Repellents	Repel unwanted pests
Nematocides	Kill roundworms	Pheromones	Used to attract insects or disrupt their mating behavior
Ovicides	Control eggs of insects and mites	Synergists	Make certain pesticides more effective

chemical structure, pesticides are divided into organic and inorganic. Inorganic pesticides are used very rarely nowadays. Arsenic insecticides, fluoride insecticides, inorganic fungicides, and inorganic herbicides are examples of typical inorganic pesticides [15]. Organic pesticides are an extremely numerous group of chemical compounds, among which the following pesticides occur most often in fruits and vegetables: organophosphorus pesticides (OPPs), organochlorine pesticides, carbamate pesticides, synthetic pyrethroids, triazoles, triazines, imidazoles, strobilurin, and neonicotinoid pesticides [15, 29–31]. The most widespread food contaminants include organophosphorus pesticides (OPPs) (e.g., dichlorvos, methamidofos, malathion, methyl parathion, chlorpyrifos, diazinon, phosalone, and monocrotophos). They include all organic compounds containing phosphorus [15]. They are used mainly as insecticides but also as herbicides, fungicides, and acaricides. Their presence has been confirmed in a wide variety of fruits and vegetables such as oranges [31], apples and pears [30], bananas [30], peaches [32], grapes [10], olives [9], cauliflowers [11], cabbages [33], celeries and peppers [34], eggplants [35], potatoes and tomatoes [11].

The overview above mentions only the most frequently encountered groups of chemical compounds contaminating food, and encompasses just a fragment of the list of all pesticides permitted for use. In the literature on the subject, one can find many extensive monographic studies containing the basic definitions, bases for classification, ranges of toxicity, and persistence in the environment [16–20, 28, 36]. It should be remembered that, along with the progress of science and technology, each year encounters more and more active compounds belonging to various chemical groups permitted for use as pesticides.

3 Pesticide Legislation

In the European Union (EU), there are a number of pieces of legislation which regulate the presence of pesticide residues in food, including fruits and vegetables. The most important ones include Regulation EC/396/2005 that came into force on 1 September 2008 and defines a fully harmonized set of rules for pesticide residues for all EU countries [3]. The European Commission sets the maximum permitted levels of pesticide residues to ensure that they do not pose an unacceptable health risk for consumers. This regulation simplifies the previously existing legislation by setting European Maximum Residue Levels (MRLs). Until 5 January 2018, 120 amendments were made to the regulation (the first one on 22 February 2006 and the last one of 4 January 2018) [3]. The list of the MRLs for all the various commodities is easily accessible in the EU Pesticides database [37]. Commission Decision 2002/657/EC implementing Council Directive 96/23/EC concerning the performance of analytical methods and the interpretation of results [38] is another extremely important piece of legislation that must be observed by laboratories where food is analyzed by means of LC-MS/MS. This document includes definitions and descriptions of how to assess trueness, recovery, repeatability, ruggedness, as well as detailed requirements for MS detection and identification of targeted substances. This piece of legislation is critical in the context of the required number of identification points corresponding to the accurate number of precursor ion–product ion transitions, guaranteeing the reliability of the analytical method based on MS detection. Nowadays, many laboratories all over the world develop and validate their own methods for pesticide residue analysis because, depending on the analytical technique chosen, different approaches for sample treatment can be considered. Therefore, it is extremely important for the newly developed methods to be reliable. The European Commission's Directorate for Health and Food Safety (DG SANTE) provides a guidance document [39] on analytical quality control (SANCO) to laboratories for the validation of methods for pesticide residue analysis in food and feed. Laboratories performing pesticide residue analyses should meet the performance requirements detailed in the SANCO Guidance [39]. An overview of the identification criteria for LC-MS/MS in various application areas are summarized by Mol et al. [40].

The regulatory frameworks require each chemist analyst dealing with the analysis of pesticides in food to have an excellent knowledge of the current law and to apply it while carrying out LC-MS/MS analyses in the laboratory, particularly when new detection methods are being developed.

4 Approach to Pesticide Identification by Means of LC-MS/MS

In pesticide residue analysis, similarly to the analysis of other food contaminants, there is a clear tendency to prepare multiresidue methods that enable the determination of hundreds of analytes in single analysis [5, 13, 41, 42]. This approach has become a necessity because of the use of diverse active substances in agricultural

pesticides, which can lead to the cooccurrence of a wide range of pesticides with different chemical properties in food. A growing need for such analyses is also a natural consequence of introducing low maximum pesticide residue levels in the European Union and their obligatory control. The increased awareness of consumers who demand products that are safe and free from chemical contaminants is also significant.

Multiresidue methods follow the basic analytical steps including sample preparation (homogenization, extraction, and cleanup) and determination (separation and detection).

4.1 Sample Preparation

Sample preparation is the cornerstone of any effective multiresidue method. The correct extraction and preparation of the sample are of fundamental importance because they determine the quality and reliability of the determination result. The choice of the sample preparation procedure is determined by the kind of foodstuff and the chemical structure of the determined contaminants. Many different extraction procedures are used in laboratories [41, 43–45]. So far, to purify and extract organic compounds from fruits and vegetable samples, various preparation techniques have been employed, such as liquid–liquid extraction (LLE) [46], microwave-assisted extraction (MAE) [47], accelerated solvent extraction (ASE) [48], matrix solid-phase dispersion (MSPD) [49], solid-phase extraction (SPE) [50], solid-phase microextraction (SPME) [51], supercritical fluid extraction (SFE) [52], and membrane extraction techniques [53]. Advantages and disadvantages of these techniques have been discussed extensively in many papers [43–45]. The majority of the aforementioned methods are rather time-consuming, labor-intensive, complicated, and expensive, and they consume a large volume of solvent. Therefore, they fail to meet the standards of a multiresidue application [30]. Nowadays, there is a marked trend to have simple, fast, easy-to-perform procedures [54]. One example of such a procedure is the so-called Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) method of pesticide analysis. This technique involves liquid–liquid partitioning using acetonitrile and purifying the extracts using dispersive solid-phase extractions. Since its development and publication [55], the QuEChERS method has been gaining significant popularity. According to Web of Science (January 2018), over 1200 papers on using the QuEChERS method for pesticide analysis in food have been already published. Now, it is the method of choice for food analysis because it combines several steps and extends the range of pesticides recovered in comparison with older, more difficult, and laborious extraction techniques (Fig. 2).

The QuEChERS procedure was developed in the years 2000–2002, and for the first time it was presented at the 4th European Pesticide Residue Workshop in Rome in 2002 by Anastassiades et al. [56]; it was published a year later [55]. It was used as a method to prepare samples for the determination of pesticide residues in fruits and

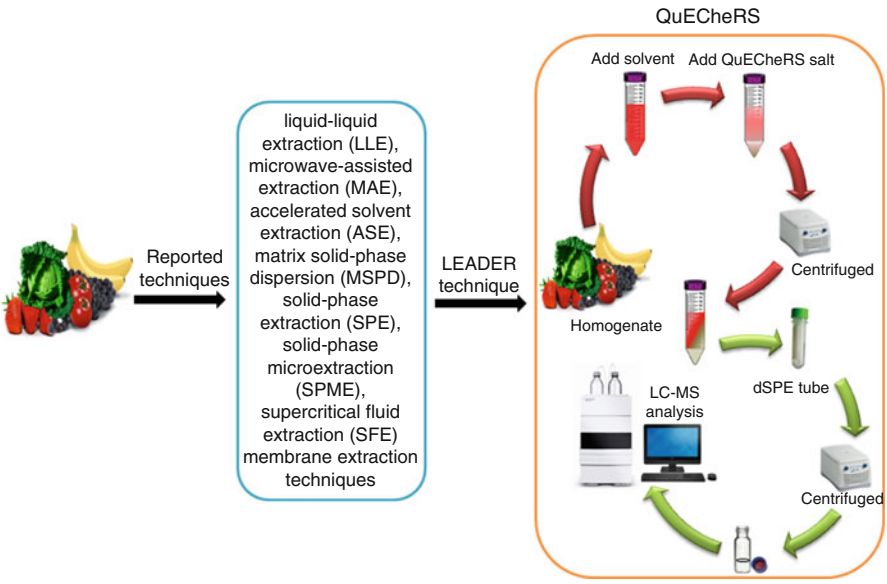

Fig. 2 Extraction techniques used to isolate pesticides from food by means of the LC-MS/MS method

vegetables by means of GC-MS [55]. Its first application in conjunction with LC-MS methods was recorded in 2005 as a continuation of research conducted by Anastassiades in 2003 [57]. The results obtained then from the validation method for over 200 different pesticides in a dozen or so fruits and vegetable samples with a varied matrix composition attracted an enormous interest in the procedure and led to its very fast growth. The basic concept of QuEChERS [55], which was developed to determine pesticide residues in fruits and vegetable samples with a high water content, is based on extraction by centrifugation of the food matrix with acetonitrile. Water is separated from acetonitrile through the addition of adequately mixed salts (anhydrous magnesium sulfate and sodium chloride). The extract is then cleaned up using dispersive solid-phase extractions (d-SPE) with anhydrous magnesium sulfate and primary-secondary amine (PSA), which efficiently removes many polar interfering substances present in the matrix.

The QuEChERS procedure [55] consists of several steps [54]. The first step is to weigh 10 g of the homogenized sample into a 50 mL polypropylene tube, then add 10 ml of acetonitrile and shake the sample vigorously for 1 min. After that, an internal standard (ISTD) is added and the tube is shaken intensively for another 1 min by hand. Next, an addition of salt mixture (4 g anhydrous magnesium sulfate and 1 g sodium chloride) is followed by intense agitation. The whole sample is again shaken vigorously for 1 min and centrifuged. Afterwards, 1 mL of organic supernatant (upper acetonitrile layer) is transferred into dispersive solid phase extraction (d-SPE) tubes containing 150 mg of anhydrous magnesium and 50 mg of PSA. Then the sample is shaken vigorously for 1 min and centrifuged. The obtained supernatant

is transferred to an autosampler vial for LC-MS/MS analysis. The schematic flow chart for the main steps is presented in Fig. 2.

Depending on the objective of the analysis, the type of analysed compounds, kind and composition of the matrix, the original procedure [55] is subjected to various modifications. To apply the QuEChERS method to a wide range of pesticides, including pH-sensitive pesticides, the original procedure was modified with buffers. Lehotay et al. modified the method to use a relatively strong acetate as a buffer and the method became the AOAC Official Method 2007.01 [58]. Annastassiades et al. chose citrate as the buffer and this version was named by the European Committee for Standardization (CEN) as Standard Method EN 15662 [59]. Other frequent modifications include: changes in the composition and/or proportion of the salts used in extraction [60], changes in the composition and/or proportion of the sorbents used [10, 12, 61], using various proportions of buffers: citrate [12, 32, 62, 63] or acetate [12, 32, 63] and (in order to maintain the optimum pH of the sample within the 5–5.5 range) using appropriate acids [29, 60] or bases [29]. One should also note other variants of the method that are based on omitting the cleanup step completely [40], using the sorbent deposit in the form of a column [64], replacing acetonitrile with ethyl acetate as the organic solvent [65], or introducing an additional step where the analytes are concentrated in the cleaned up extract by evaporating and/or replacing the solvent [61, 66, 67]. Lee et al. proposed an interesting modification of the method [68]. To improve the recovery of some problematic highly polar pesticides in pepper (*Capsicum*), they introduced the dry ice-partitioning QuEChERS method. This approach uses dry ice to separate a sample extract into the acetonitrile layer and aqueous layer without the need for salting out and centrifugation [68]. The protocol developed involves two extraction methods. The first detects the acetonitrile layer for general pesticides, and the second combines the acetonitrile and the aqueous layer for propamocarb, pymetrozine, and flonicamid metabolites [68].

The selection of the right sorbent in sample cleanup is a key stage of the QuEChERS procedure. In dispersive solid-phase extractions (d-SPE) used in QuEChERS, the traditional sorbent deposit was replaced with loose sorbent, added directly to the sample solution. The method involves the d-SPE cleanup procedure whereby the extract is shaken with a small amount of sorbents and $MgSO_4$ [45]. Among the different kinds of d-SPE sorbents, primary secondary amine (PSA) is the most commonly used in the QuEChERS method; it is used to remove polar organic acid, fatty acids, polar pigments, and some sugar [69]. In some modified QuEChERS methods, graphitized carbon black (GCB) and octadecyl silica (C_{18}) are applied to remove sterols, pigments, and nonpolar interfering substances [69]. GCB is useful for the purification of carotinoids, chlorophyll, and sterols with the disadvantage of losses of planar analytes [54]. C_{18} provides good results in the purification of samples with significant fat and wax content but recoveries of the more lipophilic pesticides may suffer [54]. One of the new sorbents recently used in the QuEChERS method are carbon nanotubes (CNTs). Based on the principle of carbon atom layers in the wall of nanotubes, the carbon nanotubes are classified as multiwalled carbon nanotubes (MWCNTs) and single-walled carbon nanotubes (SWCNTs) [69–72].

MWCNTs exhibit a good affinity for polycyclic compounds and could be used as effective d-SPE sorbents to adsorb the interfering substances in fruits and vegetable matrices owing to their unique structure and huge surface area [69]. They have been used for the cleanup of complex matrices such as grape, mango juice, wheat, spinach, carrot, apple, citrus, peanut, leek, and leaf lettuce [10, 50, 69, 71]. The application of different d-SPE sorbents for the QuEChERS cleanup step of various matrix types is extensively described by Rajczak and Tuzimski [54].

The QuEChERS extraction technique makes it possible to reduce the number of the necessary steps of analysis, reagents, and laboratory glassware. It also simplifies the step of analyte extraction and extract cleanup. In comparison with other extraction techniques, it is characterized by very good results in removing matrix ingredients and high recovery of the target compounds [45, 54, 69]. The QuEChERS approach is also in accordance with the principles of green chemistry due to low solvent consumption and absence of chlorinated solvents and very small generation of waste [54]. Since the introduction of the QuEChERS method, the literature on the subject has presented numerous examples of its use to determine pesticides in a whole range of food products [12, 73] as well as studies reviewing the method [44, 54, 73] and comparing it with other extraction techniques [12, 45].

4.2 Sample Determination

The accurate determination of pesticides in complex matrices such as fruits and vegetables is a challenge due to the complexity of the matrix and low mass fraction levels to be dealt with. The choice of appropriate separation and detection techniques is a step of fundamental importance.

Most multiresidue methods (MRMs) reported for fruits and vegetables are based on the use of liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS), which is a powerful technique that provides excellent selectivity and sensitivity, allowing a reliable identification and quantification of a wide range of pesticides and their metabolites [42]. The most important advantages of coupling LC with MS/MS include: a clear identification of sample components, very high sensitivity of the analytical system, possibility of identifying all or most of the sample components, high repeatability of measurements, possibility of quantitative analysis (generating real chromatographic peaks by the LC system), possibility of distinguishing substances with identical molecular mass but different retention times (isomers), and possibility of obtaining additional information about each sample component by means of fragmentation [42, 74, 75]. Using multiresidue methods in chromatographic determinations, the problem of the coelution of sample components occurs. Coupling liquid chromatography with mass spectrometry allows the identification of the studied compound based on the mass spectrum, enabling the quantification of substances even if they are not fully chromatographically separated [74]. This technique provides information regarding the characteristic ion of each analyte as well as two or more transitions of these ions, which is useful for

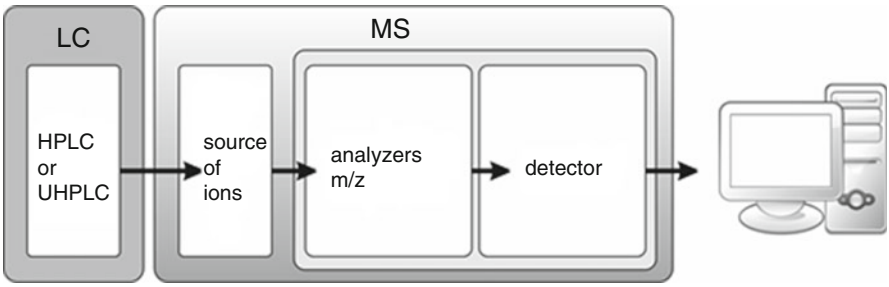

Fig. 3 Block diagram of the LC-MS/MS system

quantifying and confirming analytes at concentrations consistent with the maximum residue levels (MRLs) established [76].

In a typical LC-MS/MS system, the studied sample is first separated in the LC system and its consecutive fractions flowing out of the chromatographic column are subjected to ionization and introduced into the spectrometer. The typical LC-MS/MS system is shown in Fig. 3.

Liquid chromatography is one of the most widespread methods of separating complex samples. It is used for the analysis polar and/or nonvolatile and thermally labile pesticides for which GC conditions are not suitable. Most of the procedures used to determine pesticides in fruits and vegetables employ the HPLC technique in a reversed phase (RP) system, using gradient elution with a linear increase of the percentage of the organic solvent [69, 77]. The common stationary phases are based mainly on the nonpolar octadecylsilane phase (C_{18}) [69, 78, 79]; the medium-polar octylsilane (C_8) phase is used much more rarely [80]. The mobile phase consists of a mixture of acetonitrile, methanol, and water in various volume ratios [40, 60, 78]. In order to improve the ionization capacity, the use of different additives to the mobile phases has been described such as organic acid (formic [69, 78] and acetic [34]), ammonium salts (ammonium formate [60, 77, 78] or ammonium acetate [33, 67]) or a combination of an organic acid with its ammonium salt [77, 79]. One of the crucial technological revolutions in LC was the implementation of ultrahigh pressure liquid chromatography (UHPLC). The particle size of the solid phase was reduced from 5 μm to sub-2 μm resulting in an enhanced resolution in a shorter runtime [81]. The use of short columns with the particle diameter not larger than 2 μm was first proposed by Waters in 2004 [82]. The UHPLC system is currently the optimum solution for the separation of multicomponent mixtures.

Tandem mass spectrometry (MS/MS) is a key analytical technique enabling the identification of pesticides in different kinds of fruits and vegetables. The basic principle of MS/MS is the selection of the precursor ion, fragmentation of this ion, usually by collision-induced dissociation (CID), and measurement of the m/z ratio of the product ion formed [75]. Ionization in LC-MS/MS is mainly based on atmospheric pressure ionization (API), which enables the introduction of considerable

volumes of solutions flowing out of the chromatographic column into the mass spectrometer without the risk of losing a high vacuum [83]. The analyzers and detector of the mass spectrometer are kept in a high vacuum to avoid accidental collisions with air molecules [13]. The most frequently used ionization methods in pesticide determination include electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) [7, 13]. However, APCI appears to have been overshadowed by the extreme popularity of ESI [7]. A discussion about the application of both of these ionization methods in the LC-MS/MS analysis of pesticides can be found in our previous paper [13]. The analyzer is the most important part determining the parameters of a spectrometer. Tandem mass spectrometry (MS/MS) is a coupled system of two analyzers of the same type or different types, characterized by a high separation efficiency [13]. The current trend in food control is the use of tandem MS such as a triple quadrupole (QQQ) as well as high-resolution mass spectrometers (HRMS) such as quadrupole-time of flight (Q-TOF) and quadrupole-linear ion trap (Q-Trap). Among all of the above, the triple quadrupole (QQQ) is the most common MS analyzer in LC-based methods for multiresidue analysis in food nowadays. This is because of their excellent quantification and identification properties for a group of target compounds [7, 41]. As has been described previously by Stachniuk and Fornal [13], the conventional QQQ instrument is a serial connection of quadrupole analyzers, the middle of which performs the role of the collision cell. The first quadrupole only allows the so-called precursor ions (ions of a specific m/z value) to pass through. The precursor ions selected in the first analyzer are fragmented in the collision cell, filled with neutral gas and constituting the second quadrupole. The fragmentation spectrum, i.e., the m/z values of product ions, is recorded in the detector. When the third quadrupole allows only the selected product ions, the spectrometer works in the multiple reaction monitoring mode (MRM). When the third quadrupole allows all product irons, it works in the scan mode (full mass spectrum collection). Working in the scan mode, a tandem system of the QQQ type operates like a classic quadrupole analyzer. When measuring the full spectrum, the first two quadrupoles function as beam collimators, and the entire analysis is performed in the third quadrupole [13]. Thus, a mass spectrometer of the QQQ type can work with different settings for ion analysis parameters. First, MS can work in the positive or negative ion detection mode. Second, several ways of ion detection are possible. The first one is based on the monitoring of the total ion current (TIC) from the preset m/z range. The second one is based on monitoring only selected ions (SIM) characteristic of the compounds searched for. The third one, multiple reaction monitoring (MRM) (also called selected reaction monitoring (SRM)), enables the confirmation of the presence of fragmented ions formed from a specific precursor ion [13]. QQQ analyzers are used mainly for quantification and confirmation purposes. Typically, two or three MRM transitions are selected for a targeted analysis of pesticide residues: one for quantification and an additional one for confirmation purposes [62].

The use of the MRM mode in QQQ instruments for the determination of pesticide residue in food seems to have certain limitations: they require acquisition parameter

optimization for each compound analyzed, the number of the analyzed compounds is limited, only compounds from the target list can be detected, and retrospective data analysis is impossible [78]. Therefore, there has been a move to an alternative approach using HRMS capable of providing full spectrum data. Operating in a full scan mode, HRMS offer a significantly higher analysis selectivity and can detect an unlimited number of compounds. HRMS analyzers used for pesticide residue analysis in fruits and vegetables are the Q-TOF [84] and Q-Trap [78]. However, only few papers have described the use of HRMS for quantitative purpose [6, 11, 66, 78, 84]. The triple quadrupole remains the most common instrument in quantitative target analysis. Several reviews on the subject help to interpret the trends within the field [7, 13, 41, 42, 85]. The current LC-MS/MS strategies for multiresidue methods are summarized in Table 2.

One of the most limiting factors in LC-MS/MS pesticide residue analysis is the occurrence of the matrix effect. The ionization of target analytes can be affected when competition between the analyte and coeluting components for the available charge occurs. Exo- and endogenic substances present in the matrix can interfere with the analyte in the ion source [13]. This effect may cause the suppression or enhancement of ionization, leading to quantification errors. In various review articles, different approaches have been discussed to overcome this analytical problem [13, 41, 102, 103]. As reported by Ucles et al. [103], several approaches are used to eliminate or reduce matrix effects; they include optimizing sample preparation to remove interfering compounds from the samples [104], changing LC conditions to avoid the coelution of analytes and interfering compounds [105], changing MS conditions to reduce the occurrence of the matrix effect in the ion source [106], dilution of the sample [106] or using chemical treatment measures [107] or calibration techniques such as matrix-matched calibrations [29], and the standard addition method [13].

To reduce the matrix effect and increase the accuracy of determination during the sample preparation step in multiresidue analysis of pesticides in a wide range of food matrices, matrix-matched calibrations with the addition of a single internal standard are mainly used.

5 The Most Frequently Detected Pesticides in Fruits and Vegetables

Based on the review of the literature (Table 2), it was determined how frequently pesticide residues, determined by means of LC-MS/MS, occur in fruits and vegetables. The obtained results are presented in Fig. 4.

The most frequently detected pesticide residues in the fruit group included: carbendazim, azoxystrobin, chlorpyrifos, imazalil, imidacloprid, acephate, acetamiprid, cyprodinil, dimethoate, cypermethrin, metalaxyl, methomyl, and thiabendazole. As Fig. 4 indicates, carbendazim is one of the main detectable residues in fruit, and occurred in the concentration range of 0.0026–3.4 mg kg^{-1} as reported in eight different papers. The residues of carbendazim detected in

fruit samples are summarized in Table 3. The highest level of carbendazim (3.4 mg kg^{-1}) was recorded in a papaya sample [77].

The most frequently detected pesticide residues in the vegetables group included: acetamiprid, imidacloprid, carbendazim, azoxystrobin, chlorpyrifos, acephate, cypermethrin, dimethoate, metalaxyl, cyprodinil, imazalil, methomyl, and thiabendazole. The presence of the most frequently occurring acetamiprid was also confirmed by eight authors as was the case with fruits (Fig. 4). The results of the survey for acetamiprid are presented in Table 4. Monitoring data showed that the mean acetamiprid concentrations varied from 0.01 to 0.86 mg kg^{-1}. The highest acetamiprid level was found in a lettuce sample with the concentration of 0.86 mg kg^{-1} [89].

The results shown in Tables 3 and 4 were compared with the current maximum residue levels permitted by the European Union as of 5 January 2018 [3]. It should

Tomato	0.5	0.5	0.2	0.2	0.15	0.1	0.1

The differences of the results obtained in various papers suggest that further and continuous investigation of pesticide residues in fruits and vegetables is necessary to ensure consumer safety.

6 Conclusions

The analysis of pesticide residues in fruits and vegetables is a key issue that is strongly related to human health. For more than a decade, a lot of progress has been made in multiresidue LC-MS/MS methods for pesticide analysis in terms of the ease of preparation, analysis time, and number of targeted compounds with concomitant improvements of instruments performance. Today, high performance liquid chromatography coupled with triple quadrupole mass spectrometry in combination with QuEChERS extraction is the most used technique for pesticide residue analysis in fruits and vegetables. Operating in the multiple-reaction monitoring (MRM) mode provides a high degree of sensitivity and selectivity, and is highly suited for quantitative identification and determination of target analytes in samples. However, it does not allow the identification of nontarget compounds. Therefore, the use of nontargeted screenings employing high-resolution mass spectrometers (HRMS), e.g., quadruple-time-of-flight (QTOF) mass analyzers, is worth considering. Both (QQQ and QTOF) are complementary tools to develop large-scale screening methods. The conducted review of data provided in the literature reveals a considerable variation in the contamination of fruits and vegetables with pesticides. At the same time, it shows that monitoring and pesticide residue determination methods for various groups of fruits and vegetables should be continually developed and improved in order to fully protect the health of consumers.

Acknowledgments Author gratefully acknowledges the use of the facilities and services of the Center for Interdisciplinary Research at The John Paul II Catholic University of Lublin, Poland, co-funded by the European Union from the European Regional Development Fund in the frame of the Operational Programme Development of Eastern Poland 2007–2013 (POPW.01.03.00-06-003/09-00). This work was supported by the Polish National Science Centre via the research project DEC-2017/01/X/ST4/00722.I also acknowledge assistance in preparation of tables provided by Ms Agata Surma.

Abstract

Consumers' awareness of the relationship between diet and health is increasing the demand for nutraceuticals and functional food products. They usually involve the incorporation of bioactive compounds extracted from plant tissues, or, in some cases, beneficial microorganism species known as probiotics. Incorporation of these compounds as functional ingredients has to overcome various challenges related to their stability during food processing or gastrointestinal tract, in order to

guarantee that they exert health benefits after intake. An attractive strategy is the use of encapsulation technologies. Appropriate selection of encapsulation methods or core and carrier materials may influence most of the desired properties of the final food product. This chapter summarizes the main aspects to consider prior to developing nutraceutical or functional food products using encapsulated bioactive compounds.

1 Introduction

The design of functional foods and nutraceutical products is an active research area of the food industry. The addition of bioactive compounds to food products has increased in the last decades, as studies confirm their association with health-promoting benefits. It has also been shown that several bioactive compounds may be unstable under various environmental and processing conditions, which limits their industrial application [1]. Efforts have been made to facilitate their incorporation into food products, such as encapsulation, which is a useful technology that protects labile compounds by covering them in a resistant layer, such as polymeric matrix. This technology improves shelf life and masks undesirable taste, odor, and color [2]. Different encapsulation techniques can protect specific compounds, such as phenolic compounds (polyphenols) [3], carotenoids, phytosterols [4], and probiotics [5]. An adequate selection depends on the active compound to protect, as formation and rheological properties of most encapsulation systems strongly depend on interactions between carrier and core materials [6]. The most used encapsulation techniques are spray drying, freeze-drying, emulsions, nanoprecipitation, liposomes, and niosomes, while the main polymeric matrices are polysaccharides, proteins, and lipids. The objective of this chapter is to review the state-of-the-art encapsulation systems, focusing on the most common techniques and materials used to protect bioactive compounds from adverse conditions, such as food processing, storage, and physiological digestion conditions.

2 Overview of Encapsulation Methods and Matrices

Encapsulation is defined as entrapment of a core material (bioactive compound, inner phase, or payload phase) within another immiscible substance (carrier or wall), which can be solid or liquid [7]. The choice of the most suitable encapsulation method depends on the core material and desired characteristics of the final product [8]. It should be noted that carrier composition has a great influence on final properties, encapsulation efficiency, and release of the entrapped compounds. The

most relevant properties influenced by carrier composition are water solubility, shelf life, and bioavailability. As size and nature (hydrophilic or lipophilic) of an encapsulated particle are key factors to control these properties, nanoencapsulation provides further control by reducing particle size [9].

In spite of the benefits of nanoencapsulation, the most widely used methods are based on microencapsulation. This is achieved by physical methods like spray drying, fluid bed coating, extrusion, co-extrusion, molecular encapsulation, and emulsions, although chemical techniques are also employed. In terms of size, nanoparticles range from 1 nm–1 μm, whereas microparticles range from 1–800 μm. This makes nanoparticles more difficult to produce with common techniques used for microparticles; nanosize ranges are typically achieved through either bottom-up or top-down approaches (see Fig. 1).

A bottom-up approach refers to materials constructed through self-assembly and self-organization of molecules, by controlling factors like pH, temperature, concentration, and ionic strength. Common techniques for nanoencapsulation through a bottom-up approach are coacervation, nanoprecipitation, inclusion complexation, and supercritical fluid technique [9]. The opposite approach, top-down, involves the application of energy that allows size reduction and shaping of the material comprising the nanoencapsulation carrier. The most common top-down approach techniques are emulsification and emulsification-solvent evaporation [10]. Selecting the most adequate approach depends on the properties of the carrier and core materials, as well as their stability during encapsulation.

Current commercial nanoencapsulated products involve top-down approach, even if it usually requires increased temperature due to the high-energy shear rates applied during encapsulation. As bottom-up approach is becoming a promising

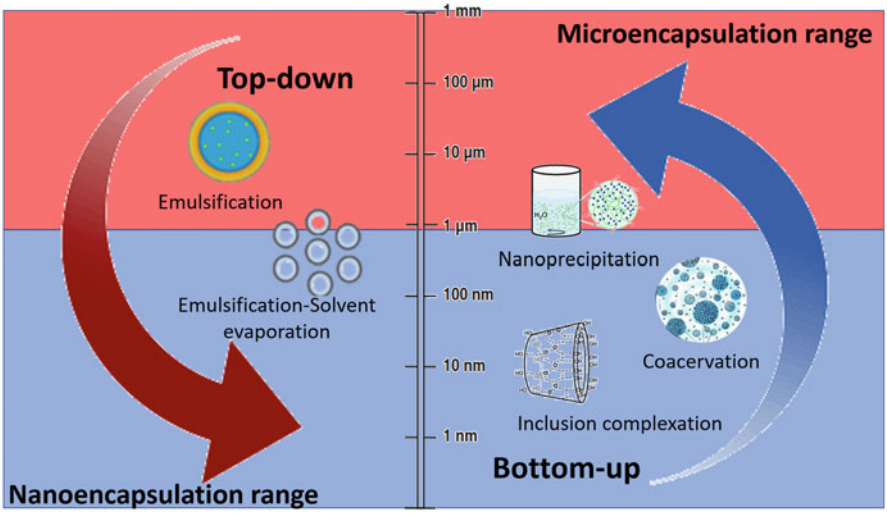

Fig. 1 Top-down and bottom-up approaches in nanoencapsulation technology (Adapted from [9])

option for nanoencapsulation, it is expected that future developments in nanotechnology lead to increased application.

2.1 Encapsulation Techniques

2.1.1 Spray Drying

High water content of food matrices, such as fruits and vegetables, is considered one of the main problems of preservation during packaging and storage. Spray drying allows the reduction of water content and microorganism proliferation because of conversion of liquids into solids. With the addition of carrier materials into the feed solution, labile compounds can be protected from light and oxygen, prolonging their shelf life. At the same time, smells and flavors are masked [6, 11]. This technique is based on atomizing a liquid/emulsion into a dryer chamber with a hot gas, that immediately removes water, producing a fine powder [12]. Carbohydrates and proteins are the main carrier materials used with this technology, and they noticeably prolong shelf life of bioactive compounds such as anthocyanins [13], carotenoids, and nut oils [14], among others. Spray drying has also been used to protect antigens [15], probiotics [5], and bacteriophages [16].

There are some processing parameters that can be optimized to obtain a final product with the highest quality; inlet/outlet temperature, flow rate, and wall-to-core ratio are the most important. Elez Garofulić and Zorić [6] found that maltodextrin with 13–17 dextrose equivalents (DE) in a 3:1 ratio and inlet temperature of 200 °C, got the highest retention of anthocyanins and phenolic acids, while anthocyanins from purple corncob were less affected when using 5% maltodextrin 16–19 DE and 150 °C [17]. Researchers can also use response surface methodology (RSM) to establish operational conditions that maximize the intended response, such as phenolic acid and anthocyanin retention from sour cherry juice by full factorial design [6], betalains from beetroot using Box-Behnken design [18], and total phenolic compounds from *Nigella sativa* oil with central composite design [19]. The main advantages of spray drying are its low cost, high reproducibility, low water content, high retention of bioactive compounds, and small and smooth particles; it is also one of the most used in food and pharmaceutical industries.

2.1.2 Freeze-Drying

Freeze-drying consists in drying the sample by sublimating its water content. This allows it to be widely used to dry thermosensitive compounds like essential oils, pigments, proteins, and microorganisms. Different authors report that freeze-drying prevents browning reactions and higher losses of vitamin C and polyphenols from grapefruit and kimchi (a Korean fermented food prepared from cabbage), in comparison with hot air drying, because this technique requires low temperature and absence of oxygen in the drying chamber [11, 20]. Ballesteros and Ramirez [2] observed higher retention of anthocyanins, phenolic compounds and antioxidant activity from spent coffee grounds, when encapsulating in maltodextrin through freeze-drying than using spray drying, similar results were obtained when bayberry

polyphenols were evaluated [3]. This behavior could be associated with low temperatures used during freeze-drying that minimize chemical changes of labile molecules.

Among the disadvantages of its use is that it requires crystallization of water, and mainly water-soluble materials can be used as core materials, such as maltodextrin, starch and gums [21]. Its high energy consumption and long processing time, also limits its industrial application. In order to reduce processing times and increase quality, some pretreatments have been evaluated, such as osmotic dehydration [22], or ultra-sonication [23].

2.1.3 Emulsions

Emulsification combines immiscible compounds in a mixture, through dispersions stabilized using surfactants. According to which solution is dispersed in a continuous phase, simple water-in-oil or oil-in-water (W/O, O/W) emulsions or even double water-in-oil-in-water and oil-in-water-in-oil ($W_1/O/W_2$, $O_1/W/O_2$) emulsions can be achieved. Ydjedd and Bouriche [24] found that encapsulation of phenolic compounds from carob (*Ceratonia siliqua* L.) pulp into $W_1/O/W_2$ emulsions protected them from chemical conditions of gastrointestinal tract, and released the bioactive compounds during intestinal phase, possibly enhancing their absorption into systemic circulation. Absorption of tea catechins was improved when they were incorporated into nanoemulsions; epigallocatechin gallate increased its plasma concentration, as compared to a non-encapsulated solution [25]. Encapsulation in coated emulsions could enhance the antimicrobial activity of essential oils, due to interactions between the positively charged surface coating and the negative surface potential of bacteria, by attractive electrostatic forces [26].

Some parameters directly affect the physicochemical properties of the emulsion, such as oil phase, emulsifier, and operational conditions. Addition of whey protein increases stability of O/W emulsions, while addition of calcium chloride promotes particle aggregation [27]. Concentrations of emulsifier and bioactive compounds were optimized to successfully produce stable emulsions with the incorporation of ascorbic acid and gallic acid. Addition of 4% Tween 20 and 1% bioactive compound produced emulsions with low polydispersity index <0.3, and emulsion stability index up to 98% [28]. Use of RSM can determine optimal process parameters that prevent coalescence, flocculation, and creaming of droplets [29].

2.1.4 Nanoprecipitation

Nanoprecipitation forms capsules and spheres by interfacial deposition of a polymeric matrix, with subsequent displacement of a polar organic solvent with a non-polar solvent. This technique is simple and reproducible, and yields small particles with unimodal size, in the range of 50–300 nm [30, 31]. High encapsulation efficiency (up to 80%) has been reported when using lipophilic or amphiphilic molecules, such as vitamin E [32], α-tocopherol [33], kaempferol [34], and lutein [35]. Release of bioactive compounds encapsulated by nanoprecipitation shows two steps, burst and prolonged release. Burst release is associated with adsorption of bioactive molecules onto the particles, while prolonged release is due to diffusion of

molecules trapped inside the polymeric matrix. Incorporation of quercetin into nanoparticles of polycaprolactone followed the Korsmeyer-Peppas kinetic release model, with burst release during the first 10 h and prolonged release until 48 h [36].

2.1.5 Liposomes

Liposomes are self-assembled bilayer vesicles of phospholipids with an aqueous core, which protect lipophilic and hydrophilic molecules. They can improve stability and bioavailability of bioactive compounds such as resveratrol, quercetin, lutein, β-carotene, and others. Addition of cholesterol during liposome formation is a key factor that directly affects the structural stability of the bilayer against environmental stress. Incorporation of cholesterol can maintain the bilayer's integrity under gastric conditions, but lipase and bile salts could change the phospholipids' assembly [37, 38]. Low stability, reproducibility, and encapsulation efficiency, as well as short shelf life and limited industrial scaling, are some of the main disadvantages of the implementation of liposomes in the food industry [39].

2.1.6 Niosomes

Niosomes are bilayer vesicles made from nonionic surfactants; they are a promising system due to their low cost, chemical stability, smaller size, and enhancement of bioavailability of lipophilic and hydrophilic molecules, among others [40]. There are many techniques to produce niosomes, such as film hydration, ethanol injection, microfluidization, and manual shaking. As with liposomes, cholesterol improves their stability, because it interacts with the surfactant's hydrophobic tail [41]. This system protected polyphenols under simulated gastrointestinal conditions, with a prolonged release for 24 h. The main problem during simulated digestion was an increase in size due to bile salts [42]. Niosome encapsulation enhances absorption and antiproliferative activity of curcumin and lycopene in cancer cell lines, with respect to free compound [43, 44]. It has been hypothesized that fusion, adsorption, or endocytosis could be the release mechanism from niosomes, making it suitable to deliver bioactive molecules through different routes (dermal, retinal, intravenous, and oral).

2.2 Encapsulating Matrices

Different matrices are available as options to protect bioactives, such as polysaccharides, proteins, and lipids. Selection of the adequate wall material is based on the desired properties and final application. Polysaccharides are the main polymeric matrix used; they are obtained from various sources, and are biodegradable, biocompatible, and nontoxic [45]. Some of the most used are maltodextrin, starch, pectin, chitosan, alginate, and gums. Bakowska-Barczak and Kolodziejczyk [46] found that maltodextrins with 11, 18, and 21 DE were more effective than inulin to protect anthocyanins, polyphenols, and antioxidant activity of blackcurrant extracts. At the same time, two or more combined carrier materials can improve physicochemical characteristics of particles, for example, maltodextrin/pectin particles of

herbal extracts maintained the antioxidant activity during 6 months of storage of various samples [47].

Proteins are also widely used as coating materials, mainly gelatin, zein (from maize), and whey protein. Bagheri and Madadlou [48] incorporated date palm pit extract (up to 70%) into whey protein particles. Quiroz-Reyes et al. (2014) evaluated gelatin nanoparticles as carrier for cocoa polyphenols, which resulted in narrow size distribution, spherical and uniform shape, with 77% encapsulation efficiency [49]. In both cases, infrared analyses showed that compounds extracted could be retained in protein particles through non-covalent interactions, such as hydrogen bonding between C=O groups of protein and OH groups of polyphenols, as well as van der Waals and hydrophobic interactions. Some polyphenols, such as epigallocatechin and quercetin, could covalently interact with zein, conferring thermal stability and higher antioxidant activity [50].

Different studies have focused on the use of lipid carriers to enhance transport and cellular absorption of lipophilic compounds. Because of their biocompatibility, low toxicity, and capability to entrap lipophilic and hydrophilic molecules, these systems have been widely studied. Phospholipids show good retention of quercetin and resveratrol, while a significantly reduced cytotoxicity against fibroblast cells, and higher efficacy against skin cancer cells was found when these molecules were incorporated into phospholipid vesicles, as compared to non-encapsulated molecules [51]. Incorporation of resveratrol into solid lipid nanoparticles improved oral bioavailability eightfold, with respect to free solution, with prolonged drug release up to 120 h [52].

As previously discussed, different matrices are available to encapsulate bioactive compounds, and an appropriate selection is crucial to obtain particles with desired qualities. It is important to also consider aspects like biodegradability, biocompatibility, and nontoxicity of coating materials to successfully use them in food applications.

3 Encapsulation of Polyphenols and Vitamins

Encapsulating a compound confers protection to it, so the most appropriate use of this methodology is on compounds whose chemical structure and/or biological activities are easily lost. Polyphenols and vitamins are thus excellent candidates to encapsulate, since they exert various health-promoting effects when consumed, but are highly sensitive to light, oxygen, pH, and temperature changes, which limits their shelflife when used as functional ingredients. The following paragraphs summarize the use of encapsulation on polyphenols and vitamins from different sources, in order to highlight their potential as nutraceutical products or functional ingredients.

Polyphenols have been considered as main contributors to the health effects of wine, and their incorporation into other edible products could allow them to exert the same effects. Sanchez and Baeza [53] used a maltodextrin matrix to encapsulate wine polyphenols by freeze-drying, a process that simultaneously eliminates the water and ethanol. Freeze-dried samples were milled to produce a powder, which

was then further studied. Polyphenols were concentrated in the dried samples (9.1 g L^{-1}), which only contained traces of ethanol (8.0 g L^{-1}, as compared to the initial 102.9 g L^{-1}). Furthermore, the stability of the polyphenols was well-preserved during storage, showing no degradation after 15 days of storage at 38 °C. This study suggests that wine polyphenols may be interesting functional ingredients that can be consumed in other products without an unnecessary alcohol intake.

Elez Garofulić and Zorić [6] used a spray drying method to encapsulate polyphenols from sour cherry juice, using maltodextrin (4–7 DE and 13–17 DE) or gum Arabic as wall material in varying concentrations. They determined that the ratio of carrier material to juice with the highest retention of polyphenols varied significantly. For example, a 2:1 ratio was optimal when the 4–7 DE maltodextrin was used, 3:1 was optimal with the 13–17 DE maltodextrin, and a ratio higher than 1:1 was optimal when gum Arabic was used. Furthermore, these particular ratios also varied when specific classes of polyphenols were analyzed, such as phenolic acids or anthocyanins. The authors of this study mention that selecting the proper wall material and its ratio is crucial to produce high-quality encapsulated sour cherry juice. This is likely to be the case for other polyphenol sources, since the concentration of sugars, proteins, and lipids may vary, along with physical characteristics such as viscosity, which suggests that working parameters should be optimized in order to use cherry polyphenols as functional ingredients.

Encapsulating specific polyphenols can be a useful approach when the most bioactive compounds from a particular source are known. For example, (+)-catechin and (−)-epigallocatechin-3-gallate (EGCG) have been intensely studied and have been recognized as highly bioactive compounds in teas and other sources. Song and Li [54] encapsulated both of these compounds in niosomes and analyzed their uptake in a Caco-2 cell model during 6 h. They determined that cellular uptake was 2.66-fold (catechin) and 2.13-fold (EGCG) higher when the compounds were encapsulated and administered in this form. The bioavailability of polyphenols is generally poor, which indicates that only a small fraction of the ingested amount will reach the systemic circulation and target organs. Interestingly, this study reveals that encapsulating certain polyphenolic compounds may increase their bioavailability, potentially requiring lower oral doses to reach pharmacologically-active concentrations in serum and in target organs. Similarly, Wang and Wang [55] encapsulated the polyphenolic compounds from *Cotinus coggygria* (a medicinal plant) in a polyvinylpyrrolidone K-30/sodium dodecyl sulfate and polyethylene glycol matrix. They administered free and encapsulated compounds to a brain glioblastoma cell line (DBTRG-05MG) and determined that the *C. coggygria* polyphenols exerted significantly stronger apoptosis-mediated antiproliferative effects when administered encapsulated. These results show that the encapsulation process played an important part in the treatments, by enhancing bioactivity of the compounds in this cell line model. Taken together, the results of Song and Li [54], and Wang and Wang [55] suggest that the encapsulation process may lower the dose necessary to exert a bioactive effect in a target organ by at least two mechanisms: first, increasing intestinal uptake, and second, enhancing their bioactivity.

Polyphenol encapsulation allows the use of different fruit by-products that would otherwise be discarded, as sources of bioactive polyphenols. For example, Saikia and Mahnot [56] extracted polyphenols from star fruit (*Averrhoa carambola*) pomace and compared freeze-drying or spray drying microencapsulation (using maltodextrin $\leq$20 DE). They showed that encapsulating efficiency varied according to the method used; it was higher when freeze-drying was used (78–97%), as compared to spray drying (63–79%). Other authors have used polyphenols from food by-product in various in vivo analyses, for example, Motilva and Macia [57] used grape pomace as a source of polyphenols, which were then encapsulated in a zein (protein) and L-lysine matrix. A randomized crossover study was performed (separated by 2 weeks of washout between treatments) to administer the polyphenols to healthy adult volunteers (six women, six men). The participants consumed either the vehicle (dealcoholized red wine), the vehicle with 1.3 g of non-encapsulated polyphenols, or the vehicle with 9 g of encapsulated polyphenols (equivalent to 1.3 g of free polyphenols). Subsequent analyses showed that different metabolites of phenolic acids, stilbenes, flavan-3-ols, phenyl alcohols, valerolactones, and anthocyanins were found in the urine of the volunteers, from which the authors were able to deduce the likely metabolic routes of these compounds after ingestion. In the experiments of Saikia and Mahnot [56], and Motilva and Macia [57], encapsulation was a valuable tool that allowed polyphenols from by-products to be thoroughly studied in different models, further highlighting the versatility of the methodology.

Vitamin encapsulation has the potential to increase their intestinal absorption, which can be used to prevent or treat deficiencies. Estevinho and Carlan [58] used chitosan, modified water-soluble chitosan, and alginate to encapsulate vitamin C and vitamin B12. They determined that the liberation of both vitamins was complete, but it varied according to the encapsulating matrix and with each vitamin. For example, liberation of vitamin C from the water-soluble chitosan and alginate matrices was complete in a short time (10 min for vitamin C, 20 min for vitamin B12), while complete liberation from the unmodified chitosan matrix required longer times (80 min for vitamin C and >140 min for vitamin B12). The significance of this study is emphasized by three facts: first, the encapsulation of vitamin B12 is of high interest because of its complex chemical structure that makes it highly susceptible to degradation; second, this form may be useful to patients with pernicious anemia (a potentially deadly vitamin B12 deficiency) by promoting its intestinal absorption; and third, the liberation of a vitamin can be tailored to be fast (< 10 min) or gradual (> 2 h), according to the encapsulating matrix.

Avinash and Purnima [59] used maltodextrin and modified starches to encapsulate (spray drying) vitamin A. They determined that inlet air temperature and concentration of solids were both critical factors that determine the quality of the resulting particles. These particles were then stored for up to 3 months under accelerated conditions (40 °C and 75% relative humidity, or 30 °C and 65% relative humidity), after which no significant changes were found, suggesting that vitamin A was well-preserved by the encapsulating matrix. These results suggest that vitamin A, encapsulated as described by the authors, may be incorporated into products with long shelf lives at room temperature.

Gamboa and Goncalves [60] used fully hydrogenated soybean oil and soybean oil (70:30%, w/w) to encapsulate α-tocopherol (vitamin E). They used a spray chilling methodology, varied the encapsulating material to α-tocopherol ratio (90:10, 80:20, 95:5, 85:15), and stored the microparticles at different temperatures (22 °C and −18 °C protected from light, and 25 °C exposed to light) for 180 days. Their findings showed very high encapsulation efficiency ≥90% and a near-complete retention (≥ 94.1%) after storage. Subsequent experiments showed that the physicochemical parameters of the capsules were unaltered by α-tocopherol, which was attributed in part to its solubility in the encapsulating matrix. Interestingly, the encapsulating matrix provided excellent protection even while storing the particles at room temperature and without shielding them from light. This particular methodology and encapsulating matrix could allow the use of vitamin E on edible products that can be stored at room temperature, without protection from light and for longer time.

Wagner and Spoth [61] encapsulated vitamin D_3 (also known as cholecalciferol) and ferrous sulfate ($FeSO_4$) within niosomes. The resulting particles had an average diameter of 1.4 μm and a 95.9% encapsulation efficiency for the vitamin. The particles were then stored at room (20 °C) or refrigerator (4 °C) temperature for 21 days, and interestingly, the particles retained their size and contents better at room temperature. Lower temperatures may have caused the Fe^{+2} to precipitate, oxidize, and crystalize, which may have then ruptured the niosomal membrane. According to these results, this system is useful to supplement edible products that are only stored at room temperature, in order to prevent rupture of the encapsulating matrix. Furthermore, the particles contained enough vitamin D_3 and Fe^{+2} ions to supply the recommended daily allowance (RDA) of both nutrients for men and women.

Ruiz-Rico and Perez-Esteve [62] encapsulated folic acid within silica particles (tetraethyl orthosilicate) that were then used to supplement commercial apple or orange juices. They showed that the low pH of the juices (approximately 3.5) and the various compounds they contain, did not promote liberation of the vitamin within the juice itself. This suggests that wall material would not dissolve during the juices' shelf life or in the acid environment of the stomach once ingested. At higher pH values (7.5), similar to those of the small intestine, the matrix does dissolve and allows complete liberation of the vitamin. Subsequent in vitro digestion studies confirmed complete liberation during the intestinal phase. Finally, encapsulated folic acid was resistant to temperatures and pressures of sterilization (121 °C, 100 kPa, up to 15 min), exposure to light (visible and UV, up to 24 h), and during refrigerated storage (4 °C, 28 days). Folic acid is an essential nutrient of particular importance for women of fertile age or pregnant, which is required for the synthesis of nucleic acids. This study shows that folic acid can be encapsulated and administered in a beverage (fruit juice), in order to prevent deficiencies.

In the case of polyphenols and vitamins, encapsulation is a suitable methodology to be applied to them. As summarized here, some of the benefits of encapsulating these compounds include protection during storage, protection during the digestive process against undesired interactions, controlled liberation, increased intestinal

uptake, enhanced bioactivity, and others. Encapsulation can therefore be used to incorporate polyphenols and vitamins in a stable form into various edible products, but choosing the most adequate encapsulating matrix, optimal core-to-carrier ratio, and operational parameters should be first performed in order to yield a high-quality product.

4 Nanoencapsulation

Encapsulation of bioactive compounds using a nanotechnological approach has been a goal of many scientists for the past decades [63]. Encapsulated particles can be classified into three different categories according to their size, macrocapsules (>500 μm), microcapsules (0.2–500 μm), and nanocapsules (<0.2 μm) [64]. Nanoparticles (NPs) are considered the most attractive delivery vehicles, product of nanoscience breakthroughs, which usually involve systems between 1–100 nm [65]. One of the most remarkable advantages of NPs, is that they have an induced homogeneity, which usually leads to improved physical and chemical properties, and, hence, a better encapsulation efficiency [64]. This section focuses on the state of art of nanoencapsulation of bioactive compounds, their possible application in food industry, and how it protects and enhances bioactive compound properties.

The encapsulation matrix must be suitable for food applications, and as previously mentioned, the most common carrier materials are carbohydrate-, protein-, and lipid-based systems. Carrier material will have a significant impact on its delivery and organoleptic properties it may confer to the food product. For example, carbohydrate-based carriers are suitable for most food applications, since they are biocompatible, biodegradable, and easy to incorporate within food products. In addition, carbohydrate-based systems are more resistant to high temperature processes, compared to lipid or protein systems, which is essential to consider in the development of certain food products.

Polyphenols are suitable to be nanoencapsulated, because their chemical structure allows them to exert various health effects (e.g., antioxidant, anti-inflammatory, or antibacterial) [66–69]. However, as mentioned by Fang and Bhandari [70], the effective concentration of polyphenols is higher on in vivo studies compared to those measured in vitro. In order to make bioactives, such as green tea catechins, as effective as they are on in vitro studies, researchers suggest increasing their stability and bioavailability [71]. The effectiveness of a bioactive compound strongly depends on preserving their chemical integrity and bioavailability.

One of the most studied and unstable polyphenolic molecules are anthocyanins. They are susceptible to pH changes, metal ions, exposure to light, temperature, oxygen, and enzymatic activities, which can modify their chemical structure, starting at the initial food product and continuing during digestion [72]. Ko and Lee [73] have suggested the use of nanoencapsulation in addition to copigmentation for anthocyanin protection. They found that copigmentated anthocyanin-loaded NPs, formed with chitosan and tripolyphosphate, had an increased half life and retention more than 2.6- and 7.4-fold greater than non-encapsulated anthocyanins stored at

high temperatures (25 and 50 °C). They also highlighted that the use of chitosan-based NPs is not affected at low pH, as has been observed with maltodextrins and other polymers.

In agreement, Han and Lee [74] showed that the antioxidant activity of chitosan NPs containing jujube phenolic extracts remains stable two-fold greater than non-encapsulated extract (3 days). In addition, the antioxidant decrease rate in chitosan NPs was slower than in non-encapsulated extract. As a stable antioxidant activity is related to the chemical stability of antioxidant molecules, it is essential to maintain it as long as possible at storage conditions, in order to be successfully applied in food products. Jeon and Lee [75] demonstrated that the use of chitosan NPs could increase the solubility of bioactive compounds, such as resveratrol, up to 4.2-fold compared to the non-encapsulated compound, while also preserving its antioxidant activity. Chitosan is one of the most suitable polymers to use in stable and effective NPs.

Protein-based nano-carriers confer desirable properties to nanoencapsulation systems, such as biodegradability. Some suggest that the use of proteins to encapsulate curcumin in nanoscale systems may improve its pharmacokinetic properties [76]. Zou and Zheng [77] found that protein-based nanosystems were able to incorporate the highest amounts of curcumin per unit mass of particles, which results in a lower amount required in food products in order to fortify them. In contrast to the economic advantages of this system, protein-based particles were not as effective to enhance curcumin potential absorption within micelles, as compared to lipid-based systems.

Bagheri and Madadlou [48] encapsulated an aqueous extract of date palm pit within whey protein NPs. They found that a heat treatment (60 °C, 30 min) decreased the mean size, and increased the monodispersity and particle yield of extract-free and extract-loaded particles. Combined nano-carriers can be made with protein-lipid mixtures. Sadeghi and Madadlou [78] nanoencapsulated date palm pit extract using microemulsification-cold gelation of whey proteins. They report a mean size of 23, 304, and 230 nm for heat-treated particles, extract-free particles, and extract-loaded capsules, respectively. They also suggest that a controlled release from extract-loaded NPs is achieved, based on the phenolic content of digestion experiments.

Belščak-Cvitanović and Bušić [79] report that combined carriers (alginate and whey proteins) are optimal delivery systems. They can promote NPs with regular spherical shape, high encapsulation efficiency of total polyphenols (77.35%), and very good retention of hydroxycinnamic acids (89.14%). The combination of alginate and hydroxypropyl methylcellulose enabled the best (prolonged) release profile of these compounds from the formulated microparticles in simulated digestion model. The use of combined systems (see Fig. 2) merges the advantages of individual nano-carriers, such as higher absorption rates of lipid carriers and health-related benefits of proteins. The addition of proteins to emulsion systems is the most common combination of these carriers, as whey peptides perform a dual-functional role in foods as both emulsifiers and bioactive compounds.

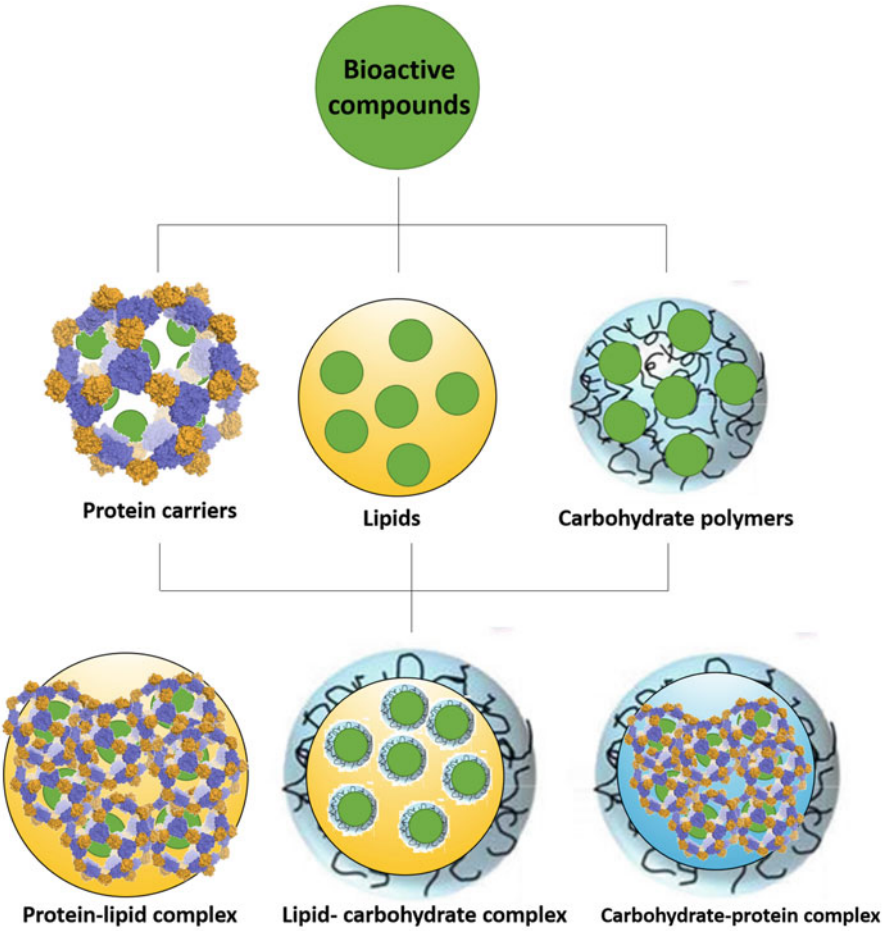

Fig. 2 Simple and combined encapsulation carrier materials

5 Encapsulation of Probiotics

Probiotics are living microorganisms that, when correctly administered, can have health benefits for the consumer [80]. One of the main advantages of probiotic consumption is its contribution to the restoration of intestinal homeostasis, as well as some anticancer, anti-bacterial properties and improvement of the nutritional status [81]. Most probiotics suffer rapid inactivation or degradation, because they are sensitive to environmental conditions, food processing, and storage. Once consumed, they are affected by physicochemical conditions of the gastrointestinal tract, such as pH bile salts [82]. In order to exert health benefits, several aspects must be considered, such as their survival rate, viability, and functionality [83].

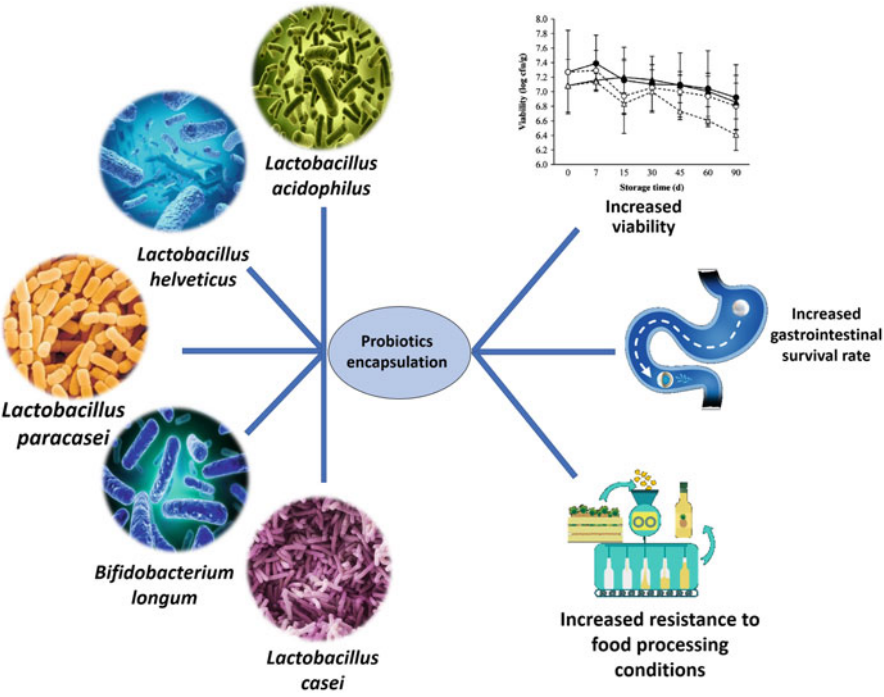

Fig. 3 Advantages of probiotic encapsulation

Encapsulation is a useful strategy to protect probiotics (see Fig. 3 [84]). This method stabilizes probiotic bacteria, improving their viability and stability and protecting them from adverse conditions [85]. Multiple methods are available to achieve this objective, such as spray drying, emulsions, and others [86].

Lactobacillus plantarum encapsulated in 3% alginate and coated with chitosan, showed lower viability loss (0.55 log) when added into yogurt and stored in refrigeration for 38 days, compared to free microorganisms incorporated in the same matrix [87]. González-Sánchez and Azaola [88] incorporated free and encapsulated *Bifidobacterium animalis* ssp. into kefir, and they observed that those encapsulated had higher survival rate than non-encapsulated. Addition of *Lactobacillus casei* and *Bifidobacterium lactis* encapsulated in calcium alginate beads into ice cream, significantly increases their survival rate. The increase of viability was 30% during 180 days of storage at −20 °C, and the addition of probiotics did not show significant changes in the sensory properties of the product [89].

Possemiers and Marzorati [90] incorporated *Lactobacillus helveticus* and *Bifidobacterium longum* as microencapsulated freeze-dried powder to different chocolate formulations, and evaluated the changes during digestion. Encapsulated probiotics showed 80% viability, which suggests that this technology is suitable to be used on probiotics as functional ingredients.

Probiotic encapsulation may increase their resistance to food processing conditions and other stressors. For example, viability of *L. casei*, *L. paracasei*, *L. acidophilus*, and *Bifidobacterium animalis*, encapsulated in alginate beads, were subjected to stress conditions (changes in pH, and temperature > 55 °C). *L. acidophilus* showed the highest survival rate, and showed greater tolerance to high temperatures, while free cells had low survival rates [91].

Sandoval-Castilla and Lobato-Calleros [92] encapsulated *L. casei* in pearls of sodium alginate and pectin, and the particles were incorporated into yogurt. Survival of *L. casei* under simulated digestion showed that they were better protected when encapsulated in a mixture of alginate and pectin. When encapsulating *L. plantarum* in alginate (2, 3, and 4%), the bacterium was protected from acidic conditions in the stomach, but were less resistant to in intestinal conditions [93]. Thantsha and Cloete [94] encapsulated *Bifidobacterium longum* in interpolymeric complexes formed with supercritical carbon dioxide. Once encapsulated, bacteria were subjected to simulated gastric and intestinal fluids, and with this, they obtained a limited reduction in the viability of the bacteria at the end of the exposure period. Encapsulation in the interpolymeric complex showed potential to protect probiotics.

L. acidophilus encapsulated in a W/O emulsion system with sodium alginate, showed that this microorganism survives at temperatures >70 °C and high salt concentrations (> 1%). Compared with free bacteria of the same strain, encapsulated ones were more stable, since they were reduced by 4.14 log, while the former were lost at 90 °C [95]. Papagianni and Anastasiadou [96] used W/O emulsions as an encapsulation system for *Pediococcus acidilactici*. They found that approximately 85% viability was conserved, while up to 92% of encapsulated bacteria could be released at the target site. This is in accordance with reports that state that emulsions can promote high survival rates [97]. Nag and Han [98] used a mixture of sodium caseinate and gellan gum to encapsulate *L. casei* in a W/O emulsion. Survival of encapsulated bacteria in simulated gastric fluid (30 min), was significantly higher than that of free bacteria, also protecting them from bile salts.

Sousa and Gomes [99] encapsulated four strains of probiotic bacteria (*L. paracasei*, *L. casei*, *L. acidophilus Ki*, and *Bifidobacterium animalis*) in alginate and alginate with L-cysteine. The capsules were stored at different temperatures (21, 4, −20, and −80 °C) for 6 months. Alginate encapsulation (−80 °C) protected all four strains, and L-cysteine improved protection of *B. animalis*. According to these results, encapsulation with alginate protects probiotics against freezing temperatures.

Encapsulating probiotics offers some advantages, but these depend on the materials and methods used. Encapsulation technologies allow probiotic bacteria to reach action sites and exert benefits along the digestive system. Commonly used encapsulation technologies have increased the number of food products in which probiotics could be incorporated without being affected by processing conditions. These methods still face various challenges, but consumer demand promotes continued work in the field.

6 Conclusion

Encapsulation technologies are viable options that can be used during development of functional food products. Nanoencapsulation is an improvement the basic method that allows precise and controlled release of bioactive compounds during digestion. It is essential to consider the desired properties of the final products, according to specific criteria like the nature of the core material and required release characteristics. Carrier materials are critical choices, and should be compatible with the method used and intended aplication.

Abstract

From *Myristica fragrans* L. (Myristicaceae) two spices, nutmeg and mace, were obtained. This plant is traditionally used in China, India, and African countries for the treatment of several diseases, such as decreased appetite, diarrhea, muscle spasm, rheumatism, etc. Recently, *M. fragrans* has been investigated for antioxidant, anticonvulsant, analgesic, anti-inflammatory, antidiabetic, hypolipidemic and hypocholesterolemic, antibacterial, and antifungal potential.

A perusal analysis of literature evidenced that *M. fragrans* deserves more attention by scientific community to explore its full range of bioactivity in the welfare of the society especially in emergent Countries.

Keywords

Myristica fragrans · Chemical profile · Bioactivity · Toxicity

List of Abbreviations

5-HT	Serotonin
AChE	Acetylcholinesterase
AMPK	AMP-activated protein kinase
BChE	Butyrylcholinesterase
DM	Diabetes mellitus
GABA	γ-Aminobutyric acid
IL	Interleukin
LDH-A	Lactate dehydrogenase
MCP	Monocyte chemotactic protein
MIP	Macrophage inflammatory protein
NO	Nitric oxide
PAS	Peripheral anionic site
THF	Tetrahydrofuran mixture

1 Introduction

Myristica fragrans L. (Myristicaceae) is an indigenous plant to India, Indonesia, and Sri Lanka. Now it is cultivated in many tropical countries of both hemispheres as well as in South Africa [1]. The tree is a small evergreen, not more than 40 feet in height, with smooth, greyish-brown bark, green on the younger branches. The alternate leaves are oblong-ovate, acute, entire, smooth, and dark-green. The flowers are very small and unisexual. The fruits, smooth and yellow, resemble a pear grooved by a longitudinal furrow and contain a single erect seed. The seed of the plant is known as “nutmeg” and the arillus of the seed is called “mace”.

Both kernel and arillus are rich in essential oil that imparts the characteristic aroma and taste to nutmeg as a unique culinary spice. Primary metabolites including carbohydrates, lipids/fatty acids, and proteins constitute up to 80% of the weight of dry nutmeg kernel while the remaining weight comprises secondary metabolites such as terpenes, phenolic acids, polyphenols, and pigments [2].

Since ancient times, *M. fragrans* nutmeg and its oil are used in Chinese and Indian traditional medicines for illnesses related to the digestive and nervous systems. Nutmeg is a rich source of essential oil, triterpenes, and various types of phenolic compounds that are responsible of the biological activities that may support its use in traditional medicine.

In this chapter, we reported and critically discussed data from literature published from 2000 to 2017 on the *M. fragrans* as source of bioactive compounds.

2 Bioactivity of Extract and Isolated Compounds

2.1 Effects on Metabolic Syndrome

Diabetes mellitus (DM) is a metabolic disorder characterized by hyperglycemia with impaired metabolism of carbohydrates, fat, and proteins due to defects in insulin secretion, insulin action, or both [3]. Spices are extensively used to enhance the taste and flavor of foods and are known to possess several medicinal properties including hypoglycemic effect. In this context, Somani and Singhai [4] reported that *M. fragrans* petroleum ether extract decreased blood glucose levels in normal, glucose fed, and alloxan induced diabetic rats by a mechanism of action involving a promotion of release of insulin from β-cells. Moreover, after oral administration a decrease in the rate of intestinal glucose absorption or potentiation of pancreatic secretions or increasing the glucose uptake was observed. The dose-dependent insulin secretion on isolated islets of Langerhans was confirmed by Patil et al. [5]. Moreover, this spice showed α-amylase inhibitory activity with an IC_{50} value of 0.85 mg/mL. A moderate hypoglycemic effect was confirmed for *M. fragrans* fruits ethanol extract in streptozotocin-induced diabetic rats [6]. Mace dried powered extract showed carbohydrate-hydrolyzing enzyme inhibitory activity with IC_{50} values of 62.1 and 75.7 μg/mL against α-amylase and α-glucosidase, respectively [7]. Among *M. fragrans* isolated constituents, macelignan (**1**) (Fig. 1) exerted a promising antidiabetic activity since it enhanced the insulin sensitivity and improved lipid metabolic disorders by activating peroxisome proliferator receptor-alpha/gamma and reducing endoplasmic reticulum stress [8].

In addition, macelignan (**1**) possess an inhibitory action against advanced glycation end products, an effect that adds to its potential role in the management of diabetes and metabolic syndrome [9].

Frequently DM is associated to an impaired metabolism of fat. Ram et al. [10] showed that oral administration of nutmeg extract (500 mg/kg body weight) for 60 days to hyperlipidemic albino rabbits significantly reduced the lipoprotein lipids level. Several research studies evidenced that AMP-activated protein kinase (AMPK) activators mimic or potentiate the exercise-related effects. Therefore, the activation of AMPK could be used as drug target for the prevention and treatment of obesity and diabetes by regulating the glucose and lipid homeostasis [11]. Tetrahydrofuroguaiacin B, and nectandrin B at 5 μM produced strong AMPK stimulation in differentiated C2C12 cells. In addition, the preventive

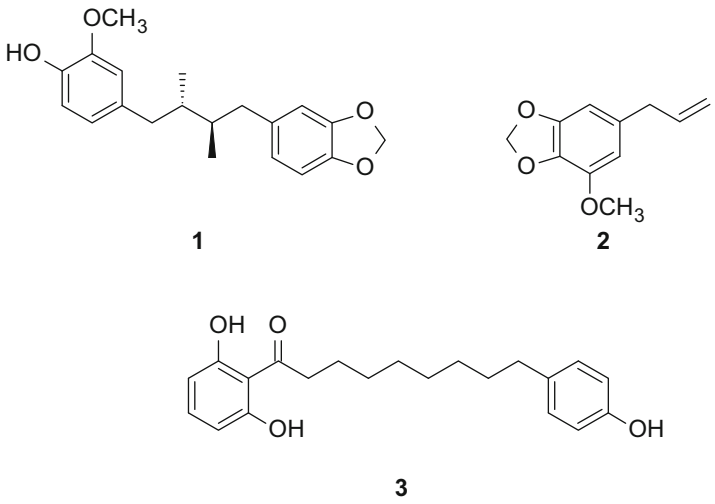

Fig. 1 Macelignan (1), myristicin (2) and malabaricone B (3)

effect of a tetrahydrofuran mixture (THF) containing tetrahydrofuroguaiacin B, saucernetindiol, verrucosin, nectandrin B, nectandrin A, fragransin C1, and galbacin on weight gain in a diet-induced animal model was examined. Results evidenced that final body weights and weight gain in the THF-treated mice were significantly lower than those of the control group. THF treatment prevented the increase in body weight and adipose tissue mass. However, increase in glucose and LDL levels in the THF-treated group was observed. These effects may be due partly by the AMPK activators in this extract [12].

2.2 Anti-Inflammatory and Analgesic Activity

Even though a number of steroidal or nonsteroidal anti-inflammatory drugs have been developed, the research of natural compounds as source of new anti-inflammatory agents with lower side effects is a topic of great interest. Nutmeg and mace essential oils are traditionally used to relief sprains and rheumatism. The oil exhibited an anti-inflammatory effect on acute inflammation. An analgesic effect was produced by the oil in the acetic acid-induced writhing model and in the late phase of the formalin-induced licking [13]. A similar effect was observed also with the chloroform extract in a model of inflammation such as carrageenan-induced edema in rats [14].

The anti-inflammatory effects of *M. fragrans* could be partially due to the presence of myristicin (**2**) (Fig. 1). This compound did not reduce the cell viability of mouse macrophages (RAW 264.7) but significantly inhibited the production of calcium, interleukin (IL)-6, IL-10, interferon inducible protein-10, monocyte chemotactic protein (MCP)-1, MCP-3, granulocyte-macrophage colony-stimulating

factor, macrophage inflammatory protein (MIP)-1α, MIP-1β, and nitric oxide (NO) [15]. Other promising anti-inflammatory agents from nutmeg are macelignans. These compounds suppressed lipopolysaccharide-induced activation of the Toll-like receptor 4 pathway. These actions are mediated by suppression of the nuclear factor NF-κB, reduction in cyclooxygenase type-2 (COX-2) expression, and inhibition of reactive oxygen species generation [16]. Moreover, macelignan (**1**) inhibited the calcium influx, degranulation, release of histamine, and other inflammatory mediators [17]. The anti-inflammatory activity was exerted also by malabaricone B (3) since it is able to attenuate the increased nitric oxide synthesis and enhancing the arginase pathway in mice [18]. Nutmeg is a traditional remedy for pain. Zhang et al. [19] demonstrated that nutmeg oil administration alleviate the induced joint swelling, mechanical allodynia, and heat hyperanalgesia in rats with a mechanism of action involving reduction of COX-2 expression and blood substance P level. An anti-pain action was demonstrated also for *M. fragrans* seed kernels alkaloids fraction [20]. At the dose of 1 g/kg this fraction significantly reduced the number of writhing responses in female but not male mice. However, a slightly toxic with LD_{50} value of 5.1 g/kg was found.

2.3 Antitumor

Several research articles evidenced the antitumor activity of *M. fragrans* with particular reference to its essential oil. Piras et al. [21] isolated volatile and fixed oils from nutmeg. Myristicin (**2**) (32.8%), sabinene (16.1%), α-pinene (9.8%), and β-pinene (9.4%) were identified as main compounds. In the fixed oil, the most represented fatty acids were myristic acid (14:0), oleic acid (18:1 n-9), and palmitic acid (16:0). Both oils and myristicin (**2**) displayed a significant growth inhibitory activity against the colon cancer cell line Caco-2.

A promising cytotoxic activity was observed with *M. fragrans* essential oil against human colorectal carcinoma (HCT-116) and human breast carcinoma (MCF-7) cell lines with IC_{50} values of 78.61 and 66.45 μg/mL, respectively [22]. *M. fragrans* essential oil showed antiangiogenic activity with IC_{50} of 77.64 μg/mL maybe due to the presence of some potential antiangiogenic compounds such as myristicin (**2**), limonene, eugenol, and terpinen-4-ol.

Myristicin (**2**) induced cytotoxicity in human neuroblastoma SK-N-SH with IC_{50} value $>$ or $=$ 0.5 mM at cells by an apoptotic mechanism since an accumulation of cytochrome-c and the activation of caspase-3 was displayed [23]. The apoptotic pathway with mitochondrial membrane potential alteration, cytochrome c release, caspase-3 activation, PARP-cleavage, and DNA fragmentation was observed, also, when myristicin (**2**) was applied to human leukemia K562 cell culture [24]. Previously, Chirathaworn et al. [25] observed that *M. fragrans* methanol extract at concentration of 10 μg/ml induces apoptosis in Jurkat leukemia T cell line through SIRT1 mRNA downregulation. Interestingly, *M. fragrans* antitumor activity could be mediated, also, by the inhibition of Lactate Dehydrogenase A (LDH-A). Tumor cells predominantly produce ATP by maintaining a high rate of lactate fermentation,

rather than by maintaining a comparatively low rate of tricarboxylic acid cycle. *M. fragrans* seeds extract suppressed cell growth and the overall Warburg effect in human colon cancer cells (HT29). Even though the expression of the enzyme was not changed, both lactate production and LDH-A activity were decreased [26].

Moreover recently, Li et al. [27] demonstrated that nutmeg-treated Apcmin/+ mice had decreased IL-6 levels and normalized dysregulated lipid metabolism, suggesting that uremic toxins are responsible, in part, for the metabolic disorders that occur during colon cancer tumorigenesis. Other *M. fragrans* essential oil representative compounds such as D-limonene, terpinen-4-ol, and eugenol showed cytotoxic activity through apoptosis-inducing effects on several cancer cells [28].

2.4 Antimicrobial and Antifungal Activity

The use of essential oils from spice is an attractive alternative method to control food/feed microorganisms as they should in principle not be toxic to man and could replace toxic synthetic compounds. The use of nontoxic natural compounds is attributed to growing problems encountered with microbial resistance towards conventional preservation with synthetic compounds and an increasing demand for minimal processed food along with "green" image policies of food industry. *M. fragrans* is known to exhibit strong antimicrobial activity against food poisoning and spoilage bacteria including *Bacillus subtilis*, *Escherichia coli, Saccharomyces cerevisiae*, and multi-drug resistant *Salmonella typhi* and *Helicobacter pylori* [29]. More recently, Firouzi et al. [30] reported the effect of nutmeg essential oil on growth and survival of *Yersinia enterocolitica* and *Listeria monocytogenes*. Nutmeg oil also had a significant effect on inhibiting the growth of *Escherichia coli* and *Staphyloccocus aureus* [31]. Several studies demonstrated also the antibacterial activity of nutmeg extracts. In particular, nutmeg acetone extract has shown the strongest antibacterial and antifungal activity with *Staphylococcus aureus* (13.8 mm) and *Aspergillus niger* (14.4 mm), respectively [32]. The nutmeg ethyl acetate extract showed a strong antibacterial activity against gram-positive and gram-negative bacteria with mean MIC value ranging from 0.625 to 1.25 mg/mL, and bactericidal effects at mean MBC value ranging from 0.625 to 20 mg/mL [33].

A good antibacterial activity was obtained also with seed and mace ethanol extracts. *M. fragrans* seed methanol extract had a strong MIC value of 12.5 μg/ml against the gram-negative bacterium *Helicobacter pylori* that is recognized as the primary etiological factor associated with the development of gastritis and peptic ulcer disease [34]. A promising activity against *H. pylori* was found also with dihydroguaiaretic acid (**4**) (Fig. 2) with MIC of 100 μg/ml and MBC of 125 μg/ml. This effect is comparable with that of clarithromycin [35]. Resorcinols, malabaricone B (**3**), and malabaricone C (**5**) from mace also showed strong antibacterial and antifungal activities while macelignan (**1**) is a potent natural antibiofilm agent against oral primary colonizers *Streptococcus sanguis* and *Actinomyces viscosus* [36, 37]. Nutmeg essential oil showed also antifungal activity against *Colletotrichum gloeosporoides, Colletotrichum musae, Fusarium*

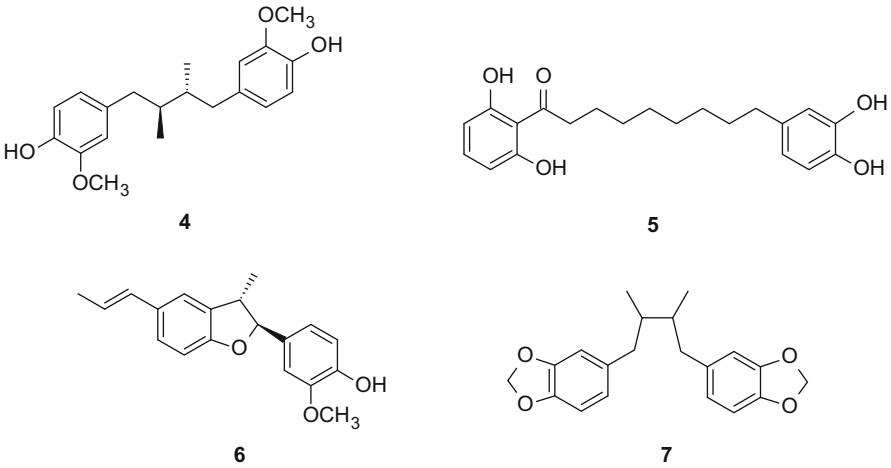

Fig. 2 Dihydroguaiaretic acid (4), malabaricone C (5), licarin A (6) and Machilin A (7)

oxysporum, Fusarium semitectum, Aspergillus niger, and *Aspergillus glaucus* [38]. Previously, Cho et al. [39] evidenced that erythro-austrobailignan-6, meso-dihydroguaiaretic acid and nectandrin-B isolated from the *M. fragrans* seeds methanol extract exhibited antifungal activities against *Alternaria alternata*, *Colletotrichum coccodes*, *Colletotrichum gloeosporioides*, *Magnaporthe grisea*, *Agrobacterium tumefaciens*, *Acidovorax konjaci*, and *Burkholderia glumae*. A significant antifungal activity was found also for mace methanol extract against *Candida albicans* and *A. niger* [40].

2.5 Effects on Central Nervous System

Several studies demonstrated different effects of *M. fragrans* in Central Nervous System (CNS).

Sonavane et al. [41] investigated the anxiogenic activity of the *M. fragrans* seed *n*-hexane extract seeds, acetone-insoluble part of the *n*-hexane extract, and trimyristin. Both extract and trimyristin reduced the number of head pock in the hole-board test. Authors suggests a nonspecific anxiogenic activity of TM and a mechanism, which involves serotonin (5-HT) and gamma-Aminobutyric acid (GABA). Successively, the same *n*-hexane extract at the dose of 10 mg/kg dose was found to have comparable potency to imipramine (15 mg/kg) and fluoxetine (20 mg/kg). The antidepressant-like effect of the *n*-hexane extract involved adrenergic, dopaminergic and serotonergic systems. The *n*-hexane extract inhibited both α1 and dopaminergic receptor antagonists as well as a serotonin synthesis inhibitor [42]. The memory enhancer activity of *M. fragrans* is confirmed by the in vitro and in vivo inhibition of acetylcholinesterase [43].

Cuong et al. [44] investigated the cholinesterase inhibitory activity of *M. fragrans* seeds MeOH extract and *n*-hexane, ethyl acetate, *n*-butanol, and water-soluble fractions. EtOAc showed the highest inhibitory potential was submitted to chromatographic purification led to the isolation of thirteen compounds. [(7S)-8′-(4′-hydroxy-3′-methoxyphenyl)-7-Hydroxypropyl]benzene-2,4-diol) exhibited the most effective activity with an IC_{50} value of 35.1 μM. Values of 42.1 and 44.0 μM were found for [(8R,8′S)-7′-(3′,4′-methylenedioxyphenyl)-8,8′-dimethyl-7-(3,4-dihydroxyphenyl)-butane] and malabaricone C (**5**), respectively.

More recently, Abdul Wahab et al. [45] evidenced that malabaricone B (**3**) (1.84 and 1.76 μM, respectively) and C (1.94 and 2.80 μM, respectively) are dual and mixed-type inhibitors of acetylcholinesterase (AChE) and butyrylcholinesterase (BChE). Molecular docking studies evidenced that both compounds interacts with the peripheral anionic site (PAS), the catalytic triad, and the oxyanion hole of the AChE. Differently Malabaricone B (**3**) interacted with the PAS, the catalytic triad, and the oxyanion hole of the BChE, while malabaricone C (**5**) interacted only with the catalytic triad and the oxyanion hole.

Anecdotal reports of *M. fragrans* use as a cheap marijuana substitute, coupled to previous studies reporting a cannabimimetic-like action, suggest that nutmeg may interact with the endocannabinoid system. *M. fragrans* seeds *n*-hexane extract administered orally in three doses 5–20 mg/kg p.o. enhanced learning and retention capacities of both young and aged mice. The effect of *M. fragrans* on endocannabinoid system was confirmed by El-Alfy et al. [46]. Dichloromethane and ethyl acetate fractions prepared from the methanol extract of powdered whole nutmeg interacts with the endocannabinoid system via inhibition of the endocannabinoid catabolizing enzymes fatty acid amide hydrolase and monoacylglycerol lipase. This mechanism provides insight into reported cannabis-like action as well as expands the potential therapeutic utility of nutmeg. Among nutmeg compounds, myristicin (**2**) demonstrated to possess anxiogenic effect and may antagonize the actions of benzodiazepine at the GABA A receptors level [47]. Moreover, trimyristin, the main triglyceride constituent of nutmeg, showed the depressant effect in mice [48]. On the other hand, Kiyofuji et al. [49] demonstrated that macelignan (**1**) treatment protected dopaminergic neurons against the interferon (IFN)-c and LP-induced degeneration by activation of the peroxisome proliferator activated receptor c, which in turns activated arginase 1 enzyme expression. For this reason, maceliganan can be used for the treatment of different neurodegenerative disorders. A neuroprotective effect was observed also for licarin A (**6**) against glutamate-induced toxicity of rat cortical cells [50]. The mechanism of action involves antioxidant effect, reduction of NO, and suppression of Ca^{2+} influx.

In order to clarify the potential central nervous system effects of nutmeg, Wu et al. [51] investigated the permeability of blood-brain barrier of twelve lignans and three phenolic malabaricones from the seeds of *M. fragrans*. Benzonfuran-type, dibenzylbutane-type, and arylnaphthalene-type lignans showed poor to moderate permeabilities; those of 8-O-4′-neolignan and tetrahydrofuran-lignan have moderate to high permeabilities, while the permeabilities of malabaricones were poor. Erythro-2-(4-allyl-2,6-dimethoxyphenoxy)-1-(3,4-dimethoxyphenyl)-propan-1-ol acetate,

verrucosin, and nectandrin B were transported by efflux way, while neolignans dehydrodiisoeugenol, myrislignan, and verrucosin permeabilities was passive diffusion.

2.6 Vascular Activity

In the treatment and prevention of cardiovascular disorders and strokes, the inhibition of platelet function plays a critical role. Erythro-(7S,8R)-7-acetoxy-3,4,3′,-5′-tetramethoxy-8-O-4′-neolignan (EATN), isolated from *M. fragrans*, inhibited thrombin- and platelet-activating factor (PAF)-induced platelet aggregation without affecting platelet damage with IC_{50} values of 3.2 and 3.4 μM, respectively. Moreover, this neolignan attenuated intracellular Ca^{2+} mobilization in thrombin-activated human platelets through increase cAMP levels [52]. A promising protective effect in vascular occlusive diseases was observed, also, with nectandrin B. This lignin activated AMPK in vascular smooth muscle cells (VSMC) and inhibited VSMC proliferation and neo-intima formation, events that are critical in the development of vascular occlusive diseases [53].

2.7 Other Activities

Nutmeg compounds showed other promising healthy effects. Machilin A (**7**) (Fig. 2) was able to stimulate, in a dose-dependent manner, osteoblast differentiation through activation of the p38 mitogen activated protein (MAP) kinase pathway [54]. The use of macelignan (**1**) as photo-aging protective agent is well documented. These compounds reduced the collagen synthesis and simultaneously upregulated the matrix metalloproteinases (MMPs) [55]. Moreover, these compounds act as natural depigmenting agent since at 10 μM inhibited melanosome transfer and dendrite formation in B16F10 melanoma cells [56]. Similarly acts licarin E that regulates the expression of MMP-1 and type-1 procollagen in UVB-irradiated human skin fibroblasts through MAPK and TGFβ signaling [57].

The hepatoprotective effect of nutmeg compounds was reported. Morita et al. [58] have reported that myristicin (**2**) showed a strong hepatoprotective effect with a mechanism of action that involves the inhibition of tumor necrosis factor-α release from macrophages while of macelignan (**1**) induced activation of the mitogen activated protein kinase (MAPK) signaling pathway, especially JNK and c-Jun [59]. The hepatoprotective effect demonstrated for nectandrin that protect hepatocytes against oxidative injury through the activation of Nrf2/ARE pathway mediated by ERK phosphorylation and AMPK-dependent inactivation of GSK-3β [60].

3 Conclusions

In traditional medicine, nutmeg has long been used as a remedy for several disease including gastrointestinal problems, cancer, infections, rheumatism, and psychological disorders.

Despite its traditional uses, the mechanisms underlying its effects remain unclear and further research studies are undoubtedly needed to properly assess the therapeutic potential of this plant and derived products. A perusal analysis of literature evidenced that myristicin (**2**), macelignan (**1**), nectandrin A and B, licarin A–E, and malabaricone B and C were well investigated especially for anxiolytic, anti-cancer, anti-inflammatory, and anti-infective effects. Although there is great interest in *M. fragrans* extract, oil and isolated constituents, limited preclinical studies on nutmeg not only for size but also for design and focus with no pure derived compounds included was observed. However, the evidence that nutmeg represent an in doubt font of secondary metabolites with significant potential as prototype agents for drug discovery, address the research interest on this plant. Further evaluation of bioactive constituents is warranted especially to determine in vivo pharmacokinetic parameters and to monitored nutmeg constituents toxicity. In fact, it is well documented that excessive doses have a narcotic effect, symptoms of delirium, and epileptic convulsions [61]. Moreover, one of the most promising compounds, myristicin (**2**) is hepatotoxic when ingested in large amounts [62].

Conflicts of Interest The authors declare no conflicts of interest.

Abstract

In recent times, the advancement in the knowledge regarding health perspectives of numerous micronutrients like carotenoids, anthocyanins, flavonoids, minerals, and vitamins at molecular level along with the findings of epidemiological studies has opened a new horizon in the field of nutrition. In this regard, various plant sources including herbs and spices exhibit high antioxidant activity owing to rich phytochemistry. Among herbs, coriander (locally known as "dhanya") is known for its therapeutic properties in the Indo-Pak subcontinent. It is one of the widely cultivated herbs and native to North Africa, Southern Europe, and southwestern Asia. Scientifically, coriander (*Coriandrum sativum* L.) belongs to the Umbelliferae (Apiaceae) family. The herb portion consists of leaves and stems. The herbs and seeds of coriander are being excessively used in the traditional culinary owing to its pleasant color and flavor. Coriander seeds are commonly used in spices, and its utilization is popular in the Mediterranean region. Furthermore, coriander seeds are added in the preparation of curry and traditional cuisines in south Asian region. Coriander leaves also possess unique aroma and commonly used to garnish the dish before serving. Leaves are also vastly utilized as a vital constituent in Vietnamese and Thai cuisine. Apart from appealing aroma, seeds and leaves are also known for their therapeutic potential in the Ayurvedic medicine since ages. Coriander has significant anti-inflammatory, hypoglycemic, and hypocholesterolemic potential. Alongside, it is also effective in mitigating gastrointestinal complications. Besides, essential oils extracted from coriander leaves and seeds are used in food applications, fish and meat products, pickles, beverages, and sweets owing to its pleasant aroma and high free radical scavenging activity. Coriander seeds and herbs also possess significant hepatoprotective and antioncogenic potential.

Keywords

Coriander · Flavonoids · Polyphenols · Hypoglycemia · Hepatoprotective · Hypocholesterolemic

Abbreviations

ALP	Alkaline phosphatase
ALT	Alanine transaminase
AST	Aspartate transaminase
BBD	Box-Behnken design
CAT	Catalase
CCl_4	Carbon tetrachloride
CE	Catechin equivalent
CS	*Coriandrum sativum*
DPPH	2,2-Diphenyl-1-picrylhydrazyl
DW	Dry weight
FRAP	Ferric reducing antioxidant power
GAE	Gallic acid equivalent

GI	Gastrointestinal
GSH	Reduced glutathione
GSH-Px	Glutathione peroxidase
HO	Heme oxygenase
IC_{50}	Half maximal inhibitory concentration
LO	Lipid peroxidation
MRQ	Maharasnadhi Quather
NADPH	Nicotinamide adenine dinucleotide phosphate
NO	Nitric oxide
PPM	Parts per million
Px	Peroxidase enzyme
ROS	Reactive oxygen species
RSM	Response surface methodology
SFE	Supercritical fluid extraction
SOD	Superoxide dismutase
SWE	Subcritical water extraction
TBARS	Thiobarbituric acid reactive substances
TE	Trolox equivalent
TEAC	Trolox equivalent antioxidant capacity
TLC	Thin-layer chromatography
TPC	Total phenolic content

1 Introduction

Indispensable link between nutrition and health has diverted the focus of masses toward plant-based natural herbs and spices as a remedy to alleviate numerous lifestyle-related dysfunctions. Cognizance of consumer toward health-promoting foods has forced the scientists, researchers, and food designers to develop functional foods. Functional foods are the foods which contain numerous health-promoting and protective bioactive compounds along with the traditional nutritional value. Functional foods may be similar in appearance to the indigenous foods but have functional properties. The market of functional foods has been increasing on a rapid rate in recent years throughout the globe [1]. Undoubtedly, the medicines are incomparable for treating several physiological disparities; however, medicines have allied side effects along with imposing economic issues in developing countries like Pakistan. For the purpose, there is a dire need to establish a novel method to combat the diseases. In this scenario, coriander being an ancient herb and spice is imperative owing to its accessibility, low cost, and allied therapeutic claims [2]. Numerous scientific explorations have suggested that consumption of coriander (seeds/herb) provides copious health benefits owing to their enriched phytochemistry and health-promoting essential oil [3]. Categorically, these bioactive components have potential to mitigate lifestyle-related disorders like hyperglycemia, hypercholesterolemia, and inflammations along with oncogenic, hepatic, and renal modulating perspectives.

Considering the aforementioned evidences, the current research was designed to explore the therapeutic role of locally grown coriander variety against oxidative stress-mediated dysfunctions.

1.1 Coriander (*Coriandrum sativum* L.): At a Glance

Herbs and spices are being used from prehistoric times for their health-enhancing and disease-preventing potential owing to the presence of bioactive components. The bioactive moieties majorly include polyphenols also known as phenolic compounds and constitute a vast and complex array of phytochemicals which have significant antioxidant potential and impart beneficial physiological effects. Phytochemicals have the ability to delay lipid oxidation and also exhibit prophylactic activity. Keeping in view the bioactivity of phytochemicals and their wide occurrence in vegetables, these are considered as natural antioxidants. Bioactive moieties with considerable antioxidant activity include phenolic acids and flavonoids that are being extracted from numerous sources like sage, rosemary, oregano, pepper, thyme, and coriander [4].

The World Health Organization (2002) reported that a significant population of the world depends on traditional medicines prepared from herbs. Herbs and spices possess enriched antioxidant status and known for their therapeutic role from centuries. In recent decades, various research investigations have been conducted to explore the antioxidant and health-enhancing potential of herbs and spices. Coriander is one of the oldest herbs that have been used over 3,000 years for both culinary and medicinal purposes. Coriander is native to the Mediterranean region, while it has also been widely cultivated all over the globe as in Central Europe, Russia, Asia, and North Africa [5, 6]. It is considered as an annual herb and spice because its leaves and seeds both are used as condiment. It belongs to carrot family Umbelliferae (Apiaceae). It is also known by its scientific name as *Coriandrum sativum* L., and its seeds and leaves both are used as a condiment. The whole plant of coriander including fruits, leaves, stem, and roots possess pleasant aromatic odor and flavor. The plant coriander can acquire a height of 20–120 cm, it flowers after 45–60 days of sowing, and flowers get fully ripe in about 4 months. Leaves of coriander are mostly used as flavoring agent in preparation of various curries and soups as well as for garnishing purposes in salads owing to its attractive green color and sweet aroma in all over the globe, especially, in the region of subcontinent [7].

On the other hand, fruit/seed of coriander is made up of dry cremocarp, possessing an almost globular shape with a diameter of about 1.5–5.0 mm. The color of mature seeds is tan to yellow brown. Coriander seeds are being mostly employed in the preparation of curry powder, sausages, pickling spices, and seasonings. It has also been used in the bakery industry for the preparation of flavored pastry, buns, biscuits, cakes, etc. [2]. Coriander seeds have also been known for their therapeutic perspectives and are considered diuretic, carminative, antibilious, aphrodisiac, and refrigerant. Coriander leaves and seeds have been utilized for the preparation of Ayurvedic medicines and as an indigenous home therapy for

numerous dysfunctions. Conventionally, coriander and its products have been in use to cure gastrointestinal ailments like diarrhea, anorexia, flatulence, dyspepsia, vomiting, and pain [8]. Instant research has revealed that coriander is effective in modulating serum cholesterol level, blood sugar, and free radical production. In the recent era, research investigations have explored that coriander seeds and leaves also help in maintaining the serum glucose and cholesterol levels along with controlling the production of free radicals in the body. Furthermore, volatile oil and oleoresins extracted from coriander seeds have high demand globally and being used in formulating flavorings and also to mask the unpleasant odor of medicines. Likewise, coriander seed oleoresins have found their extensive application in seasonings for preparing beverages, sweets, and pickles [9].

Early physicians utilized coriander for its therapeutic characteristics, which include aromatic stimulant. In the Indo-Pak subcontinent, coriander leaves were known since the Vedic period, but seeds were first introduced by Muslims when they arrived in subcontinent, and it is obvious from the copious use of coriander seeds in numerous Mughlai cuisines. According to United Nations COMTRADE Database (2008), in the present world, India is the largest exporter of coriander followed by Bulgaria and Morocco. Additionally the other countries cultivating coriander are Romania, Spain, France, Italy, Pakistan, the Netherlands, Mexico, Myanmar, Turkey, Australia, Canada, and Argentina, though to a minor level, the USA and the UK are also producing coriander [2].

Furthermore, coriander comprises of variable quantities of fats, proteins, carbohydrates, minerals, fibers, and vitamins. However, due to usage in small quantities in foods, they nonsignificantly contribute to the nutritional requirements, although the essential oils of coriander seeds have significant importance in establishing the quality of spices. Proximate analysis of leaves indicated that they are comprised of moisture (87.9%), carbohydrates (6.5%), protein (3.3%), ash content (1.7%), and fat (0.6%), while dried fully ripen seeds of coriander have 6.3–8.0% moisture content, 0.3–2.06% essential oil, 13–18% fatty oil, 11.5–21.3% crude protein, 17.81–19.15% fat, 28.4–29.1% crude fiber, and 4.9–6.0% ash content [10].

Moreover, glycolipids were also detected in the seeds of coriander. The glycolipids include acylated steryl glucoside, glucocerebroside, and steryl glucoside [11]. Selenium content of about 23.53 ppm was also measured in the seeds of coriander which is higher than any other spices [12]. Previously, the presence of other minerals like aluminum, magnesium, phosphorus, silicon, potassium, sulfur, tin, calcium, copper, iron, manganese, and zinc was also reported [13].

It was noticed that the pleasant odor and taste of coriander seeds are owing to their essential/volatile oil which is colorless to slightly yellow in shade. The basic flavor of oil is spicy, aromatic, fruity, and a bit sweet. It was observed in a scientific exploration that essential oil content is more in immature fruits as compared to matured ones [14]. The essential oil is mainly made up of monoterpene hydrocarbons along with oxygenated monoterpenes which are about 20% of volatile oil [15]. The major and the most important oxygenated compound is linalool which is also known as coriandrol. Its concentration in essential oil varies from about 19.80% to 82%. Studies showed the presence of other components majorly in essential oil

including pinene, terpinene, geranyl acetate, camphor, and geraniol, present as 10.5%, 9.0%, 4.0%, 3.0%, and 1.9%, respectively [2].

Multiple scientific studies have reported numerous compounds present in coriander essential oil in different concentrations like thin-layer chromatographic (TLC) analysis ensured the presence of limonene, α-pinene, β-phellandrene, linalool, linalyl acetate, geraniol, borneol, citronellol, β-caryophyllene, thymol, citronellol, geranyl acetate, elemol, caryophyllene oxide, and methyl heptenol [16]. The volatile oil mainly contains linalool and terpenes in considerable concentrations as 50–60% and 20%, correspondingly [14]. Another group of scientists indicated 53 different components in essential oil of coriander and depicted that linalool is about 38% of oil [17].

Different factors affect the composition of coriander seeds, leaves, and stems which includes location, fertilization, and other cultural habits along with the season of sowing [18]. It has also been observed that the composition of coriander seeds and leaves varies with the maturity stage of the commodity [19]. Composition of coriander volatile oil also differs among various varieties owing to differences in geographic locations as Indian coriander differs from European coriander in linalool concentration which is less in the former. Fresh herbage of coriander has completely different odor and flavor as compared to mature seed. In the fresh herb oil, aliphatic aldehydes are predominant, while in seeds linalool content is predominant which results in more pleasant and appealing sweet odor [2]. Furthermore, it was explored that both leaf and seed oils contain linalool, cymene, pinene, phellandrene, borneol, and geraniol, but the composition of leaf oil is entirely different from that of seed oil [20].

1.2 Local and Traditional Uses

Coriander is well known for its use as a vital constituent of culinary formulations along with a traditional cure for the prevention and treatment of various dysfunctions in indigenous medicine systems of diverse societies/communities [21]. Among various herbs and spices, coriander has a distinct property that its all parts (leaves, stem, and seeds) are edible and have unique flavor and significance [22]. Nonetheless, seeds of coriander are being used as a famous spice in the Mediterranean region, while in subcontinent it has been used in curry powder in ground form. Moreover, the green leaves of coriander also exhibit a pleasant aroma and flavor. The fresh leaves are being predominantly used in Vietnamese and Thai cuisines [23].

Likewise, roots of coriander plant have a much deeper and strong flavor than its leafy part. Root portion of the plant has been generally used in a range of Asian dishes and cuisines. Nevertheless, the stem portion of coriander is mostly utilized in the preparation of stews and soups in chopped form [24]. Along with splendid aroma and taste, coriander is well known as medicinal herb owing to its therapeutic perspectives. For the purpose, coriander has been widely employed in the preparation of numerous indigenous medicinal formulation to alleviate digestive ailments. Locally, in the northern region of Pakistan, the whole plant of coriander has been

utilized in folk medicinal interventions for the treatment of ailments like dysentery, flatulence, cough, diarrhea, jaundice, vomiting, and stomach complications [25]. In Indian indigenous remedies, coriander is employed to cure respiratory, digestive, and urinary systems with diuretic, diaphoretic, stimulant, and carminative activities. In the region of Turkey, brewed seeds of coriander have been used as carminative and digestive agent as well as appetite enhancer [26].

Numerous meta-analyses have authenticated the beneficial therapeutic perspectives of coriander. It has been depicted that the digestive stimulant role of coriander is owing to the stimulation of hepatic cells to secret bile acids enriched bile in more quantity. Likewise, it also enhances the activities and functionality of both intestinal and pancreatic aided digestive enzymes. These stimulations and activated actions elevated the rate of overall digestion and ultimately reduced the passage time of food via gastrointestinal (GI) tract [27].

Coriander has also been traditionally used for the treatment of enhanced glucose level in few countries like Jordan, Saudi Arabia, and Morocco [28–30]. Though the exact mechanism of limiting hyperglycemia has not been well defined, coriander has been used in Persian folk medicine to cure hyperglycemia. In this regard, a scientific investigation was conducted to evaluate the hypoglycemic potential of coriander in 20 diabetic rats by dividing them into four groups based on diet given to them. Three groups of them were fed on diet enriched with 15 g (60 g per kg body weight per day) of leaves for a period of 15 days, while the fourth diabetic and nondiabetic untreated group received a standard diet and served as positive and negative control, respectively. It was noticed that coriander leaves lower the serum glucose level nonsignificantly [31]. Ayurvedic literature has shown that continuous use of coriander seeds effectively lowers the serum lipid profile. Furthermore, the utilization of coriander as traditional treatment of urinary infections and as diuretic medicine has been traced back to pharmacopeia of Morocco and Palestine [32, 33]. Latterly, it was demonstrated that the administration of aqueous extract of coriander seeds via intravenous infusion for the period of 2 h at two selected doses of 40 and 10 mg/kg body weight, to anesthetized rats, can enhance the diuresis, rate of glomerular filtration, and excretion of electrolytes in a dose-dependent way [34].

Moreover, in traditional and Ayurvedic curative approaches, arthritis and inflammations have long been treated with coriander. For the treatment of arthritic condition, a traditional medicine has generally been recommended by the Ayurvedic practitioners, named as Maharasnadhi Quather (MRQ). MRQ is a polyherbal formulation having coriander seeds, one of the principle constituent. Study conducted to estimate the analgesic and anti-inflammatory perspectives of MRQ showed that it significantly prevents the rat paw edema induced by carrageenan and formulation also improves the pain tolerance by 57% after an hour of treatment. It was suggested that the MRQ has analgesic activity carried out by a supraspinal effect. It was also observed that treatment with MRQ for the period of 3 months significantly lowers the pain and inflammation along with improving the mobility of joints in the patients. The possible mechanisms of MRQ antiarthritic effects may include changes in the synthesis of leukotrienes and prostaglandins, antioxidant activity, and membrane stabilization [35].

Coriander has been used for a long time in traditional Iranian medicine for averting anxiety, convulsions, and insomnia. These primeval characteristics of aqueous coriander extracts have been validated by a number of pharmacological studies. It was observed that extracts possess sedative hypnotic and anticonvulsant activities [36, 37]. Traditionally, coriander has been used as an antimicrobial, antiseptic, and wound-healing agent in mouth, although coriander aqueous decoction has shown no antibacterial potential against almost 176 isolates of bacteria originated from 12 distinct genera of bacterial colonies obtained from the oral cavity of 200 individuals by means of disc diffusion technique [38].

Coriander has also been conventionally used as a curative measure against airborne ailments like bronchitis and cough; nonetheless scientific evidences supporting this specific character of coriander are not available. This showed that novel plant-based medicines can be made in the future depending on the knowledge obtained from the ethnobotanical studies [26].

2 Phytochemistry of Coriander

2.1 Coriander Seeds

The medicinal properties and nutritional significances of coriander seeds are owing to the presence of numerous bioactive moieties like fatty acids, tocols, sterol, and volatile components.

2.1.1 Polyphenols

The methanolic decoction of coriander seeds was evaluated for total phenolic content, articulated as mg gallic acid equivalents per gram of dry weight (mg GAE/g DW) of sample. Previously, it was reported that the coriander extract of Syrian variety had the maximum total phenolic content followed by Tunisian and Egyptian as 1.09, 1.00, and 0.94 (mg GAE/g, dry weight), respectively [39]. According to another study, the total phenolic content in the Canadian variety was found to be very much different which was about 15.16 mg GAE/g DW, while it was 12.10 mg GAE/g DW for the Tunisian variety [40, 41]. However, ethyl acetate extracts obtained from coriander seeds of Norwegian variety exhibited total phenolic contents to about 1.89 g GAE/100 g of extract [42]. Actually, the variations in the total phenolic content of coriander seeds could be the outcome of using diverse extraction solvents as highlighted by Wangensteen et al. [42]; they reported significant variations in the level of total phenolic contents of the same extract by varying the polarity of the solvent.

In literature, the total flavonoids and total tannin contents were estimated as catechin equivalents in mg per gram of dry weight (mg CE/g DW). Previously, total flavonoids were estimated in the methanolic extracts of coriander seeds, and they ranged from 2.03 to 2.51 mg CE/g DW. The total tannins were about 0.09–0.17 mg CE/g DW. It was noticed that the total flavonoids and total tannins were maximum in methanolic extract of Syrian variety [39].

Furthermore, the phenolic composition of coriander is still not completely understood and some data is conflicting. Overall, about 21 components were classified in various coriander varieties; these include about 11 phenolic acids named as chlorogenic, gallic, vanillic, caffeic, p-coumaric, rosmarinic, ferulic, o-coumaric, salicylic, trans-hydroxycinnamic, and trans-cinnamic acids, while almost 10 flavonoids were identified termed as quercetin-3-rhamnoside, luteolin, rutin trihydrate, resorcinol, quercetin dihydrate, kaempferol, apigenin, naringin, coumarin, and flavone. Furthermore, the researchers narrated that total phenolic acids were predominant in Tunisian variety (81.47%), while total flavonoids were maximum in Syrian variety (61.34%). Moreover, phenolic acids and flavonoids were about 49.17% and 50.83% in methanolic extracts of Egyptian variety of coriander [39]. In another scientific exploration, it was mentioned that coriander seeds only possess phenolic acids and its derivatives but lack flavonoids. Moreover, it was elucidated that among the derivatives, caffeoyl *N*-tryptophan hexoside was the most abundant phenolic derivative present at a concentration level of about 45.33 mg/kg, while caffeoyl *N*-tryptophan was among the least abundant derivatives as depicted from the concentration, i.e., 0.71 mg/kg, in the methanolic extracts of coriander seeds [43]. Additionally, the whole composition of polyphenol of seeds includes feruloyl *N*-tryptophan hexoside, p-coumaric acid, ferulic acid, feruloyl *N*-tryptophan, caffeic acid, di-*O*-caffeoylquinic acid, 3-*O*-caffeoylquinic acid, and ferulic acid derivatives [43]. In addition, coriander possesses an appreciable amount of β-carotene and carotenoid, 160 and 1,010 μg/100 g, correspondingly [44].

2.1.2 Essential Oil

Extraction Yield

Extraction yield of essential oil is defined as the actual amount of essential oil obtained from the coriander seeds after the implementation of various extraction methods. Generally, extraction yield is expressed in terms of percentage. Commonly the extraction of volatile oil from coriander seeds is carried out by means of steam and hydrodistillation. Literature has suggested that the quantity and yield of coriander essential oil vary with several factors like climatic conditions, origin of cultivar, and geographic location of growing region, so it is not uniform across the countries. In this regard, it was reported that the yield of essential oil was about 0.18–0.39% from Indian coriander variety [45], while the yield obtained from Tunisian coriander was about 0.35% [46]. Likewise, various accessions suggested that the essential oil content of Iranian coriander seeds was about 0.1–0.36% [47]. A scientific study conducted in Bangladesh narrated that the essential oil in the coriander seeds was about 0.42% on the fresh weight basis [48]. Moreover, another study reported that the essential oil concentration of different cultivars of coriander sowed and grown in Canada under cool wet conditions ranged from 0.8% to 2.2%. Furthermore, two coriander varieties from Turkey named as vulgare and microcarpum were compared, and it was established that the content of essential oil was about 0.15–0.25% in vulgare, while in microcarpum it was about 0.31–0.43% [14].

Composition of Essential Oil

Chemical composition of different varieties of coriander seed essential oil has been comprehensively studied around the globe. All the scientific conclusions agreed that the main bioactive compounds of coriander were alcoholic monoterpene, and among monoterpene, the most predominant moiety is the (S)-(+)-linalool. According to an estimation, about 35 distinct components have been identified in the essential oil of Bangladeshi, Tunisian [19], Indian [5], and Pakistani [49] coriander varieties, whereas only 17 compounds have been detected in the coriander essential oil of Algerian origin [50].

Normally, chemical composition of essential oil procured from different regions was proved to be an excellent source of oxygenated monoterpenes, predominantly (S)-(+)- linalool. Certainly, the essential/volatile oil obtained from the Tunisian variety was majorly made up of linalool which was found to be about 87.54%, while cis-dihydrocarvone was only 2.36% [19]. Moreover, the linalool content in the essential oil of Algerian variety was about 73.1%, and the other components found were p-mentha-1,4-dien-7-ol, neryl acetate, and α-pinene present in the concentration of about 6.51%, 3.22%, and 3.41%, respectively [50]. Furthermore, bioactive molecules found in the volatile oil of Iranian variety of coriander seeds were linalool, neryl acetate, γ-terpinene, and α-pinene, present in the concentration of 40.9–79.9%, 2.3–14.2%, 0.1–13.6%, and 1.2–7.1%, respectively [47], whereas, in essential oil of Bangladeshi origin, linalool was about 37.65% followed by geranyl acetate and γ-terpinene as 17.57% and 14.42%, correspondingly [48].

The content of linalool in the essential oil of the coriander seeds of Pakistani origin was about 69.60%; other bioactive components were geranyl acetate α-pinene, γ-terpinene, anethole, and p-cymene found in considerable quantities as 4.99%, 1.63%, 4.17%, 1.15%, and 1.12%, respectively [49]. Basically, the chemical composition of essential oil from Pakistani and Indian varieties was somewhat comparable as in Indian seeds; linalool was 75.30%, geranyl acetate 8.12%, and α-pinene 4.09% [5]. The proportions of different components were not identical. It was reported that the linalool was 83.21%, geranyl acetate 5.74%, and α-pinene about 4.47%. Additionally, the coriander seeds from Atlantic Canada exhibited normal to high percentage of linalool as 64–85%, while the other components identified in the essential oil were camphor, α-pinene, phellandrene, linalyl acetate, limonene, para-cymene, and geranyl acetate [18]. Besides, a study conducted in Brazil elaborated that the major moieties in coriander essential oil were linalool (77.48%), γ-terpinene (4.64%), and α-pinene (3.97%) [51]. Furthermore, linalool content was 63.5–71.0% and 42.1–52.7% in the essential oils of two Turkish varieties, i.e., microcarpum and vulgare, respectively. Some other vital components isolated were geraniol, geranyl acetate, (Z)-isoapiole dillapiole, γ-terpinene, and p-cymene [14].

Furthermore, essential oil of immature Tunisian seeds exhibited a bit different trend as it possesses more amount of geranyl acetate as compared to linalool, i.e., 46.27% and 10.96%, respectively, although with maturation the linalool content elevated to about 87.54%, suggesting that the variations may be associated with alterations in secondary metabolism [52]. Numerous other investigations aiming to

explore the chemical composition of essential oil of coriander seeds emphasized on several factors like developmental stage [53], sowing time [18], maturity stage [52] and interaction among growing areas along with abiotic stress conditions such as salinity [53, 54] and drought [55, 56]. Furthermore, other studies focus on the effect of various extraction technologies like hydrodistillation [57], microwave-assisted hydrodistillation [58], and supercritical fluid extraction technique [59] using carbon dioxide as solvent, on the compositional profile of essential oil of coriander.

The essential oil of coriander seeds is highly perishable and sensitive to harsh storage conditions. The changes that occur in the essential oil of coriander mostly include the transformations/oxidation of terpenes in the presence of sunlight. These alterations in the chemical profile of essential oil may result in the modifications of organoleptic characteristics of the oil, and it may also result in the accumulation of components which negatively affect the oil flavor and could be harmful to human health [24]. Subsequently, polymerization and oxidative processes could result in the loss of pharmacological characteristics along with quality of essential oil [60].

2.1.3 Water-Soluble Constituents

The water-soluble moieties of coriander seeds were not well reported unlike essential oil, although these components have been studied by a few groups of researchers, and it was reported that about 33 different compounds exist in the water-soluble part of methanolic extract of coriander seeds, which include four novel monoterpenoid glycosides, two monoterpenoid glucoside sulfates, and two novel aromatic compound glycosides. Further spectral explorations clarified their structure. Besides, two glycosides were sequestered from coriander seeds [61].

2.1.4 Lipids

Fatty Acids

Several recent scientific studies have elaborated the compositional analyses of fatty acid profile of coriander seeds. The oil yield of German and Tunisian varieties of coriander seeds ranged from 19.24% to 28.4% of dry weight [11, 52, 62–64]. The predominant fatty acids highlighted in most lipid classes were petroselinic acid trailed by linoleic acids present in the concentration of about 65.70–80.9% and 13.05–16.70%, respectively. Other noticeable fatty acids determined were oleic, palmitic, and stearic acids. Furthermore, palmitoleic (0.4–1.1%), α-linolenic (0.15–0.50%), and arachidic (0.10–0.25%) were also identified in lesser quantities. Likewise, the same fatty acid profile was observed in the Tunisian coriander fruits, although gadoleic, docosahexaenoic, and erucic acids were also observed at a lesser level of about 0.1% [52].

It was observed in a study that the neutral lipids in the seed oil were about 94.88% of the total lipids and majorly composed of triglycerides (95.50%), diacylglycerols (1.88%), free fatty acids (2.05%), and diacylglycerols (0.57%). Additionally, polar lipids were predominant counterpart of major phospholipid subclass, i.e., phosphatidylcholine (35.98%), trailed by 33.83% phosphatidylethanolamine and 15.40% phosphatidylinositol. However, phosphatidic acid (8.11%) and phosphatidylglycerol

(6.68%) were detected in lesser levels, while the most dominant galactolipid observed was digalactosyldiacylglycerol trailed by monogalactosyldiacylglycerol as 62.32% and 37.68%, respectively [64].

Sterols

Seed oil of coriander has been recognized as an essential source of sterols, exhibiting cholesterol-lowering effect by inhibiting the absorption of cholesterol. According to previous literature, the total content of sterol is in a range of 36.93–51.86 mg per gram of oil. The most common sterols in coriander are β-sitosterol and stigmasterol which are about 24.8–36.8% and 36.93–51.86 mg per gram oil, respectively. Other characteristic sterols are Δ5- and Δ7-stigmasterol, campesterol, and 24-stigmastadienol, although Δ5-avenasterol and Δ7-avenasterol exist in lower quantities. A small amount of cholesterol was identified in Tunisian variety of coriander seeds, i.e., 1.02–2.18% [62]. On the other hand, this moiety is not identified in seeds obtained from Germany; nonetheless two other sterols were detected named as lanosterol and ergosterol [11].

Tocols

Coriander seeds have also been proved to be an enriched source of tocols which are about 327.47 μg/g. The chief tocopherol is γ-tocopherol trailed by δ-tocopherol and α-tocopherol as depicted by their concentration, i.e., 26.40, 3.50 and 11.70 μg/g. Furthermore, coriander seed possesses higher quantities of total tocotrienols; among tocotrienols, γ-tocotrienol is the predominant component (238.40 μg/g), trailed by α-tocotrienol (24.90 μg/g) and δ-tocotrienol (12.57 μg/g) [63].

2.2 Coriander Herb

Herbal portion of coriander plant is not well studied as compared to seeds or fruit portion. Nonetheless, phenolic acids, polyphenols, flavonoids, and essential oil are among the major components detected in the leaf portion [65, 66].

2.2.1 Polyphenols

In a scientific study, the methanolic extracts of coriander green part have been investigated for total flavonoid contents along with phenolic contents; outcomes showed that they were 5,259.52 and 1,013.95 mg/kg, respectively. The polyphenol profile of coriander green portion consists of quercetin-3-*O*-rutinoside, quercetin-3-*O*-glucuronide, dimethoxycinnamoyl hexoside, quercetin-3-*O*-glucoside, and kaempferol-3-*O*-rutinoside present at about 3,296.16, 1,237.13, 406.39, 405.36, and 320.86 mg/kg, respectively. Among flavonoids, *p*-coumaroylquinic acid, 3-*O*-caffeoylquinic acid, ferulic acid glucoside, and caffeoylquinic acid were detected in the quantity of 303.83, 173.51, 122.29, and 7.92 mg/kg, correspondingly. It was also elucidated that the quercetin derivatives were the main bioactive commodities identified in the green part of coriander obtained from the Portugal [43].

Previously, about 21 phenolic components were recognized in the green part of coriander, and these were mainly the flavonoids, phenolcarboxylic acid, and coumarins. Some of the components were identified in the green part of coriander for the first time like luteolin, apigenin, hyperoside, vicenin, hesperidin, orientine, diosmin, dihydroquercetin, catechin, chrysoeriol, gallic acid, ferulic acid, dicoumarin, salicylic acid, esculin, 4-hydroxycoumarin, maleic acid, esculetin, arbutin, and tartaric acid [67].

Furthermore, it has also been described that the chief phenolic acids in coriander leaves of Indian variety were trans-ferulic, cis-ferulic, p-coumaric, and vanillic acids, while the flavonoids include acacetin, quercetin, 4′-OMe quercetin, 3′-OMe quercetin, and kaempferol. Furthermore, in green leaves of coriander, glycoflavones were not identified [66]. Nevertheless, aqueous extraction of Brazilian coriander leaves possesses phenolic acids like protocatechuic acid (6.43 μg/mL), caffeic acid (4.34 μg/mL), and glycitin (3.27 μg/mL) [4].

It has also been determined that the leaves of coriander possess anthocyanins. The biosynthesis of anthocyanins is increased by microelements and salicylic acid, particularly zinc application. On the contrary, anthocyanin content has a negative relation with nitrogen, phosphorous, and potassium [68]. Moreover, Barros et al. [43] performed a detailed analyses of phenolic components of coriander samples grown in vitro. It was reported that the samples possess more diverse polyphenolic profile and C-glycosylated apigenin as main component present in the concentration of 2,983 mg/kg. It was concluded that in vitro culture technique can be employed to explore new horizons of research in the field of industry, medicine, and pharmaceuticals along with synthesizing secondary metabolites like anthocyanins, flavonols, and flavones [43].

2.2.2 Essential Oil

Extraction Yield

It has been reported that coriander leaves possess lower amount of essential oil as compared to seeds [48]. It was observed that the air-dried leaves of Tunisian variety coriander contain 0.12% of essential oil, although the essential oil in root portion at the vegetative stage was about 0.06% [53].

Composition of Essential Oil

The studies revealed that the composition of essential oil of coriander leaves varies significantly in contrast to essential oil profile of seeds. Though the quantities differ, all the research investigations agreed that the major components of essential oil extracted from coriander leaf are aldehydes and alcohols. Essential oil from the leaves of Bangladeshi coriander variety exhibited the existence of about 44 moieties, which are mostly aromatic acids like 2-decenoic acid, E-11-tetradecenoic acid, and capric acid present about 30.8%, 13.4%, and 12.7%, respectively. Likewise, Kenyan coriander leaf essential oil encompasses chiefly aldehydes followed by alcohols, i.e., 56.1% and 46.3%, correspondingly. The main components were decanal (14.3%), (E)-2-decenal (15.9%), n-decanol (13.6%), and (E)-2-decen-1-ol (14.2%) [48].

In addition, compounds identified in trace quantities were (E)-2-dodecenal, (E)-2-tridecen-1-al, undecanol, dodecanal, undecanal, and alkanes [65]. Furthermore, the essential oil extracted from the coriander leaves from Fiji showed the presence of (E)-2-decen-1-ol in the quantity of about 26.0% as the predominant component. Besides, the chief moieties found in the Brazilian coriander essential oil were alcohols including 1-decanol (24.20%), (Z)-2-dodecenol (17.60%), and (E)-2-decenol (18.00%) along with aldehydes (89%) [69].

Moreover, Indian variety possesses (E)-2-decenal, decanal, dec-9-en-1-ol, (E)-2-dodecenal, n-tetradecanol, dodecanal, and decanol as the major essential components present about 18.02%, 14.36%, 11.66%, 8.72%, 6.09%, 5.81%, and 5.77% [70]. Furthermore, the leaf essential oil of Korean variety exhibited the existence of about 39 different compounds making about 99.62% of the total oil. The predominant compounds were cyclododecanol, tetradecanal, 2-dodecenal, 1-decanol, 13-tetradecenal, 1-dodecanol, dodecanal, 1-undecanol, and decanal with quantities about 23.11%, 17.86%, 9.93%, 7.24%, 6.85%, 6.54%, 5.16%, 2.28%, and 2.33%, respectively [71].

2.2.3 Lipids

The fatty acid profile of coriander green part was elaborated for the first time by Neffati and Marzouk [53]. In the research investigation, the impact of salinity was evaluated on the plasma membrane of fatty acid of coriander leaves of Tunisian variety grown in hydroponic culture. It was observed that the maximum content of fatty acids was found in the leaves present near to the base of coriander (61.21 mg/g DW), while in the leaves from the upper part, it was a bit low, i.e., 41.8 mg/g DW.

Furthermore, it has been found that the predominant fatty acids present in the coriander leaves were polyunsaturated fatty acids. Moreover, it was also reported that α-linolenic was the most abundant fatty acid in both basal and upper leaves in a percentage of about 41.1% and 39.4%, respectively, and in terms of mg/g dry weight, it was 17.1 and 24.1 mg/g DW, correspondingly. Next to α-linolenic acid, the predominant acids were linoleic, palmitic, and heptadecenoic acids. Nonetheless, stearic, oleic, stearidonic, trans-, and cis-palmitoleic acids were also found in negligible quantities in both basal and upper leaves, together making about 9.6% and 4.7% of total fatty acid content, respectively [53].

Besides, it was reported that the salinity lowered the content total fatty acids noticeably in basal and upper leaves. Elevating the level of NaCl leads to reduction in the ratio of unsaturated to saturated fatty acid, causing the development of rigid membrane. Moreover, five fractions were isolated from the ether extract of coriander leaves named as β-cryptoxanthin epoxide, β-carotene, violaxanthin, lutein-5,6-epoxide, and neoxanthin [72]. It was also elucidated that coriander leaves have proved to be a good source of β-carotene which is a precursor of vitamin A. Among carotenoids, β-carotene was about 61.14% in ether extract. It was observed that at the pre-flowering stage, β-carotene and total carotenoids content reached to about 73.64 and 217.50 mg/100 g, respectively, in coriander leaves [73].

3 Extraction of Bioactive Molecules

Coriander is being conventionally used as a cooking ingredient all around the globe in both seeds and leaves form. Moreover, it has also been used for its medicinal properties to treat various ailments from ancient times. Chemical analyses of seeds and leaves of coriander have revealed that the chief antioxidant constituent of seeds is linalool which is an oxygenated monoterpene, while quercetin derivatives are the predominant moieties of coriander leaves. These bioactive moieties possess high antioxidant activity and allied therapeutic perspectives [3]. Several methods have been employed for the extraction and isolation of active components from coriander leaves and seeds, i.e., hydrodistillation and Soxhlet extraction method using conventional organic solvents like ethanol, methanol, hexane, etc. along with some advance techniques like microwave-assisted extraction, ultrasonic extraction techniques, and supercritical fluid extraction techniques using carbon dioxide as supercritical fluid (Table 1).

3.1 Traditional/Conventional Extraction Techniques

Conventional extraction techniques include solvent extraction techniques, Soxhlet extraction, hydrodistillation, etc. Traditional methods of extraction with organic solvents and hydrodistillation are being utilized for the extraction of essential oils and healthy lipid fractions from various medicinal plants. Generally, for the efficient recovery of nonpolar moieties, organic solvents like methylene chloride or n-hexane are usually employed, but these solvents impart certain drawbacks like toxicity [73].

A scientific exploration was carried out to compare the extraction efficiency of several extraction methods using coriander as the raw material. In hydrodistillation technique the coriander seeds were grounded and extracted using 150 mL of steam for a period of 3 h, although in Soxhlet extraction technique, coriander sample was extracted by 200 mL hexane for a period of 12 h. In the study, about 18 major components were identified in the extracts by using gas chromatographic technique; among the components, linalool was the predominant one. It was about 77.97% in hydrodistillation and 73.62% was measured in Soxhlet extraction. It was also noticed that the yield of essential oil, in terms of cumulative area ratio of coriander seeds, was maximum in hydrodistillation (21.7) followed by Soxhlet extraction (19.4) [76].

Furthermore, in an investigation Kaiser et al. [76] used solvent extraction technique by extracting the coriander pasty product with aqueous methanol (methanol/water – 70:30 v/v) for a period of 1 h. The extract was filtered and prepared for further sophisticated analyses. It was observed that the maximum total phenolic content in coriander leaves blanched at 100 °C with water for the period of 1 min, i.e., 126.0 ± 9.1 mmol GAE/kg DM, compared to the unheated control sample (49.2 ± 3.4 mmol GAE/kg DM). Likewise, the maximum ferric reducing antioxidant power in terms of mmol TE/kg DM was observed at same conditions, i.e., 109.6 ± 14.1 mmol TE/kg DM. On the other hand, TEAC assay was highest for the

Table 1 Extraction rates of coriander bioactives by various extraction methods

Sr. No	Coriander component	Technique	Solvent	Conditions (time/temp/pressure)	Bioactive components/antioxidant assays	Concentration	References
1	Seeds	Hydrodistillation	Steam	3 h	Linalool	77.97%	[76]
2	Seeds	Soxhlet extraction	Hexane	12 h	Linalool	73.62%	[76]
3	Leaves	Solvent extraction	Aqueous methanol	1 h	TPC	49.2 ± 3.4–126.0 ± 9.1 mmol GAE/kg DM	[76]
4	Leaves	Solvent extraction	Aqueous methanol	1 h	FRAP	109.6 ± 14.1 mmol TE/kg DM	[76]
5	Leaves	Solvent extraction	Aqueous methanol	1 h	TEAC	19.0 ± 0.8 TE/kg DM	[76]
6	Fruits	Solvent extraction	Aqueous methanol	1 h	TPC and FRAP	55.4 ± 0.9 mmol GAE/kg DM and 51.2 ± 2.6 mmol TE/kg DM	[76]
7	Seeds	Soxhlet extraction	Lipid extract	–	Linalool	785.05 mg/100 g	[74]
8	Seeds	Soxhlet extraction	Ethyl acetate	–	TPC	1.9 g GAE/100 g extract	[42]
9	Leaves	Soxhlet extraction	Ethyl acetate	–	TPC	5.5 g GAE/100 g extract	[42]

leaves blanched at 100 °C water for a period of 10 min as 19.0 ± 0.8 mmol TE/kg DM. In case of coriander fruits, maximum total phenolic contents and FRAP assay were measured at the conditions of 100 °C water temperature blanched for a period of 1 min as 55.4 ± 0.9 mmol GAE/kg DM and 51.2 ± 2.6 mmol TE/kg DM, respectively. Overall, it was observed that the steam and water blanching of coriander leaves and seeds enhanced the content of phenolics and antioxidant activity as compared to unheated control samples, although too long heat treatment can decrease the antioxidant potential of leaves as well as seeds.

Furthermore, methanolic extracts of three coriander fruits varieties were compared named as Syrian, Tunisian, and Egyptian for their antioxidant potential. Extraction was carried out using pure methanol for a time period of 30 min. It was observed that Syrian variety exhibited the maximum amount of total polyphenols as well as total flavonoid, but the Tunisian variety showed the highest DPPH scavenging activity. It was concluded that the antioxidant activity is independent of polyphenolic content, while it depends upon the composition of polyphenols [39].

Recently, a research was conducted to compare the extraction efficiency of different traditional and green technologies. The yield of lipid extract by using Soxhlet extraction technique was about 14.45%. Likewise, linalool concentration was also maximum in the extracts taken by Soxhlet technique i.e., 785.05 mg/100 g coriander seeds, though the results from green technologies were also comparable [73]. Furthermore, coriander seeds and leaves were extracted using different solvents like ethanol, butanol, ethyl acetate, and diethyl ether. It was observed that ethyl acetate extracts possessed maximum amount of total phenolic contents in both seeds and leaves, i.e., 1.9 and 5.5 g GAE/100 g extract, respectively [42].

3.2 Modern/Green Extraction Techniques

Generally, Soxhlet extraction techniques and hydrodistillation have widely been used for the recovery of bioactive components from various spices and herbs like coriander seeds and leaves, though it has been suggested by many scientific explorations that the conventional techniques impart several negative impacts on the human life and environment. Furthermore, demerits of conventional techniques include consumption of huge amount of energy which can damage the heat-labile components [77]; time-consuming, uneconomical, and organic solvent needs to be disposed of properly. Nevertheless, the drawbacks of traditional techniques can be overcome by implementation of novel green technologies, like subcritical water extraction (SWE) as well as supercritical fluid extraction technique (SFE).

The subcritical state of water is the state at which the temperature of water is above boiling point but lower than the critical temperature (374.15 °C) and pressure enough to maintain the liquid state of water. At normal conditions water is an excellent polar solvent, so it can be used to extract water-soluble components like polyphenols and flavonoids, but it cannot be used to isolate nonpolar components like essential oils or lipid fraction. Increasing the temperature and pressure of water

can alter its characteristics, and it can be made suitable for the extraction of nonpolar components. Increasing temperature and pressure lowers the dielectric constant of water which is about 80 at normal conditions but lowers to 27 at 250 °C temperature and 50 bar pressure, while it further drops to about 14.86 at 350 °C temperature and 250 bar pressure [78]. In subcritical water extraction (SWE), water exhibits lesser viscosity and more diffusivity, which enhances the diffusion into the sample matrix ultimately releasing more bioactive moieties [79].

Earlier, in a study subcritical water was applied for the extraction of essential oil from the coriander seeds. The parameters for subcritical extraction were water temperature 65–150 °C, pressure 46.5–68.9 bar, and extraction time 15 min. The extraction yield obtained was much higher as compared to hydrodistillation (0.06–0.1%) [80]. Later, it was narrated that the use of supercritical fluid extraction technology greatly solved the problems associated with conventional techniques, i.e., hydrolysis of compounds, thermal degradation, and use of toxic organic solvents [81]. Basically, in supercritical fluid extraction technique, carbon dioxide was used as solvent at critical conditions (temperature = 31.1 °C, pressure = 73.8 bar) to extract nonpolar commodities. It was also reported that supercritical fluid extraction technique provides more dissolvability of moieties associated with essential oil along with better rates of mass transfer. Temperature and pressure of SFE system control both the composition and yield of coriander seed extract, so mild amendments in these two parameters change the density of the supercritical solvent [59]. The advantages of supercritical fluid extracts over conventional techniques include ease to remove solvent from extract, mild extracting temperatures (avoid heat damaging), and nontoxic and environment-friendly technique [82].

Recently, Pavlic et al. [73] used different traditional as well as modern extraction techniques to compare the qualitative and quantitative characteristics of coriander seed essential oil and lipid fraction. The yield of essential oil and lipid extracts was maximum with Soxhlet extraction (14.45 ± 0.32%) followed by supercritical fluid extraction at 300 bar pressure and 40 °C temperature (8.88 ± 0.18%) trailed by subcritical water extraction at 30 bar pressure and 200 °C temperature (2.22 ± 0.26%). Regarding the yield of five important components from essential oil of coriander (linalool, γ-terpinene, camphor, (+)-limonene, and geraniol), maximum yield of linalool, camphor, and geraniol was observed in Soxhlet extraction, i.e., 785, 27, and 22 mg per 100 g of seeds, respectively. Moreover, γ-terpinene and (+)-limonene yield was maximum in supercritical fluid extracts at 40 °C and 300 bar pressure, i.e., 31.08 and 23.98 mg/100 g CS, correspondingly. In the same conditions, SFE showed a particularly high yield of linalool, camphor, and geraniol, i.e., 598.51, 26.64, and 19.54 mg per 100 g of coriander seeds, respectively. Besides lipid fraction and essential oil, polyphenolic components were also extracted by means of subcritical water extraction.

In another study, a comparison was carried out among subcritical water extraction with Soxhlet and hydrodistillation techniques. It was observed that the maximum essential oil yield from coriander seeds was obtained from hydrodistillation (21.7%) followed by Soxhlet extraction (19.4%) and SWE (14.1%). Contrary to lesser total extraction yield from SWE as compared to hydrodistillation and Soxhlet extraction,

the final extract obtained from SWE was of better quality and more valuable owing to predominant presence of oxygenated compounds and very low hydrocarbons. In the essential oil of coriander, the linalool concentration extracted from SWE was between 82.91% followed by Soxhlet extraction (79.62%) and hydrodistillation (77.98%) [75].

Afterward, Grosso et al. [59] extracted essential oil from coriander seeds of Italian variety by employing supercritical fluid extraction technique to evaluate the effect of different extracting parameters on the yield and composition of essential oil. In the exploration, the best conditions are found to be 50 °C temperature, 90 bar pressure, 1.10 kg/h flow rate of carbon dioxide, and particle size of 0.6 mm. The highest amount of linalool recovered by hydrodistillation was 72.3% of essential oil, while linalool extracted by SFE was 78.8% of essential oil at best conditions mentioned above. Other vital components were c-terpinene, geranyl acetate, camphor, geraniol, a-pinene, and limonene, present in a range of 4–7%, 2–4%, 3%, 1–3%, 1–3%, and 1–2%, respectively.

Earlier, extraction of coriander seeds was carried out using supercritical and subcritical conditions (35 °C, 100–350 bar, and 25 °C, 100 bar, respectively) employing carbon dioxide as solvent. In supercritical conditions the complete extraction was achieved at 200–300 bar pressure in 2.0 and 1.5 h, respectively, while under subcritical conditions it took more time, i.e., ~6 h. It was observed that with the increase in pressure, the solubility of nonvolatile oil increases and the highest quantity of 15.3 g was extracted from 100 g coriander seeds at 200 bar and 16.4 g at 300 bar keeping the temperature constant at 35 °C. On the other hand, the concentration of essential oil decreased with an increase in the amount of recovered oil. Essential oil was about 70–80% in the oil obtained after 10–15% of yield, while it lowered to about 3–8% when 30% extraction was completed [83].

In a study, supercritical fluid extraction was employed to obtain volatile oil from coriander seeds under different conditions like temperatures, pressures, flow rates, and particle diameters. It was revealed that the major effect of particle size, flow rate, and pressure was imparted on the extraction yield, while the composition hasn't changed much. It was established that the best conditions to extract good quality and highest extraction ratio of oil were about pressure of 21 MPa, temperature of about 35 °C along with flow rate of 1 kg/h, and particle size of 0.5 mm. The amount of linalool extracted from coriander seeds using SFE was about 74.28% of essential oil [84].

Recently, a study was conducted to extract polar and nonpolar moieties from coriander seeds using modern technologies like supercritical fluid extraction. It was noticed that SFE gave certain advantages over traditional methods of extraction as substantiated by the yield of linalool (877.07 mg/100 g CS from SFE, 68.66 mg/100 g CS from Soxhlet extraction, and 543.33 mg/100 g CS from hydrodistillation extraction). In this exploration, the raffinate from supercritical fluid extraction was further subjected to ultrasound-assisted extraction for recovery of polar fractions, and it was reported that ethanolic extracts exhibited more antioxidant activity as compared to water extracts. It was concluded that along with essential oil, coriander seeds are also an enriched source of polyphenols with high antioxidant activity [85].

Considering the influence of operating conditions on the chemical composition of supercritical extracts, a study was performed using Box-Behnken experimental design (BBD) and response surface methodology (RSM) to optimize the conditions of supercritical extraction by varying pressure, temperature, and carbon dioxide flow rate. The outcome of the study suggested that the optimum conditions were pressure = 99.5 bar, temperature = 40.15 °C, and flow rate of carbon dioxide = 0.396 kg/h. It was reported that linalool was the predominant bioactive component obtained followed by methyl chavicol, camphor, (+)-limonene, eugenol, eucalyptol, geraniol, α-terpineol, and γ-terpinene. The highest amount of linalool (717 mg/g) was extracted at a pressure of 100 bar, at a temperature of 55 °C, and at a flow rate of 0.4 kg/h [86]. In the same year, Zekovic and his colleagues used subcritical water extraction technique and suggested that highest polyphenolic compounds (942 mg/100 g DW) were extracted from coriander seeds at 60 bar pressure and 100 °C of temperature for a period of 10 min. On the other hand, maximum linalool content (59.90 mg/100 g DW) was obtained at 30 bar pressure, 100 °C temperature, and 20-min time period [87].

4 Antioxidant Potential of Bioactive Molecules

The antioxidant potential of coriander is owing to the presence of various bioactive moieties like polyphenols or phenolic compounds and secondary metabolites. These moieties consist of a complex and wide array of phytochemicals exhibiting antioxidant potential and health-enhancing physiological effect. Phytochemicals acting as antioxidant agents have the ability to inhibit lipid peroxidation in food items as well as biological membranes; additionally their tendency to perform as a prophylactic agent has divulged new horizons of research in the field of food, nutrition, and medicine. These substances have been considered as natural antioxidants owing to their health-enhancing characteristics and copious presence in eclectic range of vegetables, herbs, spices, and fruits. Moreover, the vegetable or fruit which possesses these bioactive components is generally known as functional food [88]. Phenolic substances like phenolic acids and flavonoids have been extracted from various raw materials of vegetable/herb origin like sage, rosemary, thyme, oregano, and pepper [4].

Previously, it was observed that coriander aqueous extract possesses total phenolics of about 2.734 mg/100 g DW, demonstrating significant antioxidant activity. In another study, the total polyphenolic contents measured in aqueous extract of coriander were about 17.08 μg CE/mL of extract. Moreover, the antioxidant activity of extracts was about 69.83% in the aqueous extract of coriander [4]. Furthermore, it was reported that the ethyl acetate extracts of leaves and seeds possess maximum amounts of phenolic compounds, i.e., 5.5 ± 0.09 and 1.9 ± 0.08 g GAE/100 g extract, correspondingly. It was noticed that the total phenolic contents were higher in leaves as compared to the seeds. In the case of DPPH scavenging assay, it was studied that the ethanolic extracts of seeds and leaves exhibited a concentration-dependent activity as depicted by IC_{50} values of 510 ± 12 and 389 ± 5 μg/mL,

correspondingly. On the other hand, it was explored that the lipophilic extracts and coriander oil fraction, i.e., diethyl ether extract of leaves and dichloromethane seed extract, do not show any activity in this assay owing to inability of donating hydrogen. Coriander seed essential oil exhibited weak DPPH scavenging activity, while during TBARS antioxidant assay, coriander oil showed high antioxidant potential [4].

Moreover, in 15-lipoxygenase inhibition assay, the ethanolic extracts revealed a concentration-dependent characteristic. It was observed that leaves have higher activity as compared to seeds with value of about 157 ± 9 and 193 ± 11 IC_{50} μg/mL, correspondingly. The maximum 15-LO inhibitory activity was seen in the case of coriander leaf ethyl acetate extract followed by diethyl ether extract, i.e., IC_{50} 45 ± 2 and 88 ± 5 μg/mL, respectively. The essential oil of coriander seeds exhibited lower 15-LO inhibitory effect, i.e., 199 ± 11 μg/mL (IC_{50}). Further investigations reported that the lipid fraction of coriander demonstrated better 15-LO inhibitory activity as compared to DPPH scavenging activity, which has confirmed the independence of 15-LO assay from proton donation. Literature unveiled that the flavonoids and terpenoids are among the most active 15-LO inhibitors [89].

Recently, three varieties of coriander named as Syrian, Tunisian, and Egyptian were compared for their antioxidant activity by using methanolic extracts. Significant variations were observed among the antioxidant potential of the varieties. The total phenolic content varies from 0.94 to 1.09 mg GAE/g DW, and total flavonoids ranged from 2.03 to 2.51 mg EC/g DW. High-performance liquid chromatographic analyses showed that gallic acids and chlorogenic acids were the major phenolics identified in coriander seeds. Furthermore, methanolic extracts demonstrated significant DPPH scavenging assay, i.e., IC_{50} = 27–36 μg/mL. Likewise, the values of β-carotene antioxidant activity assay in terms of IC_{50} ranged from 160.00 to 240.00 μg/mL. Hence, it has been perceived that coriander fruit is an enriched and novel source of bioactive moieties and antioxidants [39].

Moreover, DPPH scavenging activity of methanolic extracts and essential oil of coriander seeds was carried out, and it was reported that methanolic extracts of two varieties, i.e., Tunisian and Canadian, exhibited DPPH scavenging activity of about IC_{50} = 32 and 36 μg/mL of extracts. On the other hand, essential oil showed very low DPPH scavenging activity, i.e., IC_{50} was around 60,000 μg/mL of essential oil [41]. Nevertheless, ethanolic extracts of coriander obtained from Norway exhibited a concentration-dependent DPPH scavenging activity with IC_{50} values of about 510 μg/mL, although it was also reported that essential oils possessing rich non-phenolic components may possess significant antioxidant potentials [90]. The method of β-carotene bleaching assay is generally based on the formation of free radicals upon the oxidation of linoleic acids; the formed free radicals then react with β-carotene and vanished their yellow color. In the presence of antioxidants, the bleaching rate of β-carotene slowed down significantly [91]. In the investigation, the oxidation inhibition values of linoleic acid were measured as 640 and 730 μg/mL in Canadian and Tunisian samples, respectively. Similar to the case of DPPH scavenging assay, the radical scavenging activity of essential oil exhibited very

low anti-bleaching potential, i.e., 56,000 and 52,000 μg/mL IC_{50} for Tunisian and Canadian samples, correspondingly. Furthermore, the ferric reducing power of coriander extracts showed that Tunisian variety exhibited lower capacity as compared to Canadian variety, i.e., $EC_{50} = 780$ and 700 μg/mL, respectively [41].

Furthermore, Kaiser et al. [76] estimated the antioxidant potential of coriander by conducting FRAP assay, and it was observed that the coriander leaves blanched at 100 °C temperature in water for a time period of 1 min exhibited maximum FRAP activity of 109.6 ± 14.1 mmol TE/kg DM, while coriander fruits exhibited FRAP activity of 51.2 ± 2.6 mmol TE/kg DM when blanched at the same condition as used for coriander leaves.

5 Coriander-Based Designer Foods

The association of diet and health has increased the scope for diet-based therapy against various lifestyle-related disorders among people. Nowadays, demand for natural ingredients is mounting day by day due to public awareness about diet-linked health problems [92]. Herbs and spices like coriander plant and seeds have excellent nutritional profile, and they are a promising source of health-promoting compounds. There is a need for optimum utilization of these compounds that require product development as a tool to carry bioactive components to the targeted population [93].

Development of novel food products is a multifarious and uncertain task that depends on scientific obstacle, consumer satisfaction, convenience, price, age, and cultural habits [94]. A large community relies on plant-based foods to fulfill their dietary needs like carbohydrates, protein, fat, vitamin, and minerals. Among them cereal-based products along with various kinds of sauces occupy central position for people of different age groups to satisfy their nutritional requirements. All over the globe, the demand of numerous types of spreads and sauces is escalating with the passage of time.

Coriander seeds and herb have been traditionally used in the formulation of numerous food items like bakery products, sauces, and spices and in some local products of Indo-Pak regions like *chatni*, etc. Coriander has commonly been used as a flavoring agent in two forms, i.e., green herb and seed; the latter is generally used as a vital ingredient of spice. The odor and flavor of these two types of coriander product are evidently different. The herb is generally being used for the flavoring purposes of culinary in the Middle East, Asia, and continent of America. The whole green plant and leaves have been utilized for preparing various kinds of chutneys, sauces, curries, and soups. Leaves have also been used for the garnishing purposes. On the other hand, coriander seeds have been used as an important ingredient of curry powders, pickling spice, sausages, seasoning, buns, pastries, cakes, and other bakery products. Along with this coriander oil has been utilized for flavoring beverages, meat, candies, sauces, and even tobacco. Coriander juice has traditionally been utilized for the treatment of indigestion, dysentery, nausea ulcerative colitis, and hepatitis by adding it in fresh buttermilk. Chutney prepared from coriander seeds has been used as a cure of abdominal pain. Furthermore, coriander water prepared by

boiling coriander seeds helps in lowering the serum cholesterol level by upregulating the kidney function [2]. Nowadays, among various vegetable products, several kinds of sauces are in limelight. Generally, sauces are categorized by water activity and pH values which let their marketability for a small time under cool conditions, though storage for a longer period required the implementation of pasteurization/sterilization treatments.

6 Coriander Against Oxidative Stress-Mediated Dysfunctions

In modern life, a strong link has been recognized between oxidative stress and numerous lifestyle-related dysfunctions. Oxidative stress has been demarcated as a "condition in which the occurrence of oxidation reactions surpasses the natural antioxidant mechanisms of the body, ultimately losing balance among them." Oxidative stress has substantiated to cause perilous events like DNA damage, lipid peroxidation, and regulating the transduction of intracellular signals. Chemical compounds of *Coriandrum sativum* L. and their biological activities have been summarized in Table 2.

6.1 Oxidative Stress and Safety Concerns

Normally, an atom has a pair of electrons orbiting around a central nucleus. Although some atoms don't possess paired electrons, they instead have unpaired electrons and these atoms/molecules are known as free radicals. Free radicals proved to be very unstable and reactive owing to the presence of unpaired electrons which urge to make pair by accepting the electrons. When oxygen molecule metabolized in the body, it generates free oxygen radicals, which are more reactive as compared to original molecule and known as reactive oxygen species. Hydrogen peroxide, superoxide, singlet oxygen, and hydroxyl radicals are the forms of active oxygen species in a narrow sense. In aerobic organisms, highly reactive oxygen species have been removed by natural antioxidant defense system. The oxygen species generated in the body generally do not impose any threat owing to effective defense mechanism of the body. However, if these reactive species generated at unusual site or at a rate which surpasses the natural defense mechanism, then disturbance of balance among the generation of reactive species and their removal would be lost, resulting in oxidative stress. Ultimately, the free radicals and reactive oxygen species can invade the healthy tissues and cells, damaging their cell membranes and initiating numerous dysfunctions [95].

It has been established that vitamin E is among the most important agents required to protect the body against lipid peroxidation. Vitamin E acts as antioxidant as it can bind the lipid peroxyl radicals, preventing the propagation of free radical chain reaction. The exact scavenging mechanism includes the removal of hydrogen atom from the phenyl group of vitamin by lipid peroxyl radicals. The molecule that

receives the hydrogen of atom then becomes stabilized/nonreactive. This whole mechanism transforms the vitamin E into a free radical, but it would also be a less reactive and stable molecule.

Ultimately, this stabilized vitamin E molecule would not attack lipids, though it would react with another lipid peroxyl free radical and then becomes stable. This natural antioxidant mechanism protects the body from cellular membrane injuries caused by lipid peroxides and other free radicals. Interestingly, sometimes oxidative stress proves to be useful for the human body, i.e., during childbirth the oxidative stress initiated the apoptosis process to prepare the birth canal for a delivery; likewise, natural defense systems of the body have also been strengthened by oxidative stress during ischemia and appropriate exercise. It has been reported that oxidative stress induces many lifestyle-related disorders like inflammations, hyperglycemia, hypercholesterolemia, and even cancer, by imparting DNA damage and genetic mutations. The lifestyle-associated disorders have been categorized into three categories, i.e., habitual, environmental, and genetic [95].

In recent era, several genes have been identified which are linked with oxidative stress in the body. Furthermore, among various genes, heme oxygenase (HO) and NO synthase have been recognized as the candidate genes for inducing such lifestyle-related disorders/diseases, though it is difficult to point out the exact cause of maladies because they are multifactorial. Along with genetic malfunctioning, several daily habitual activities are closely linked with oxidative stress like alcohol drinking, tobacco smoking, and irregular dietary patterns. In Japan dietary patterns of masses have been changed dramatically over the years, as the energy intake from lipids is now over 25% of daily energy requirements. Furthermore, active oxygen species generated by environmental factors can cause the serious detrimental effects on the DNA, which can lead to the initiation and propagation of oncogenic events. Assessing the effectiveness of current biological antioxidant mechanism, by estimating the pertinent oxidative biomarkers, along with considering the genetic information of an individual, can be useful to prescribe curative interventions [95].

6.2 Hyperglycemia and Related Complications

Hyperglycemia is the condition in which the human body either synthesizes more pituitary hormone than normal or less insulin, resulting in the elevation of blood glucose to abnormal level. In hyperglycemic conditions the serum glucose level may shoot up to four times as compared to baseline value. Hyperglycemia is commonly used indicator of diabetes mellitus [96]. A strong association has been established between the elevation of oxidative stress and hyperglycemia, ultimately causing diabetic complications. Occurrence of hyperglycemia in the body catalyzes the formation of reactive oxygen species (ROS) from a number of chemical reactions as glucose auto-oxidation, oxidative phosphorylation, lipoxygenase, NADPH oxidase, nitric oxide synthase, and cytochrome P450 monooxygenases.

Globally, among the patients suffering from diabetes mellitus, only 10% are suffering from type 1 diabetes also known as insulin-dependent diabetes. Nonetheless, the most predominant diabetes is the type 2, also known as non-insulin-dependent diabetes. In type 2 diabetes, the decreased glucose uptake by the muscle and adipose tissue elevated the level of serum glucose level imparting some serious pathophysiological dysfunctions involving atherosclerosis, heart disease, peripheral nerve damage, cataract formation, retinopathy, etc. [97].

Indigenous foods of the Indo-Pak region like spices, herbs, vegetables, and fruits are considered a rich source of phytonutrients and antioxidants. These foods are known as "functional foods" as they provide additional health benefits along regular nutrition. The human body also possesses a natural antioxidant defense mechanism, including several enzymatic and nonenzymatic antioxidants. The enzymatic antioxidants include catalase, superoxide dismutase, glutathione peroxidase, and glutathione reductase; on the other hand, the nonenzymatic antioxidants are generally categorized into two subclasses like nutrient antioxidants including α-tocopherol, β-carotene, and ascorbic acid, while the other subclass is metabolic antioxidants, i.e., glutathione [98]. Coriander seeds are among the most commonly used spices possessing numerous medicinal characteristics. Coriander seeds in experimental subjects exhibited a significant antidiabetic behavior as depicted by the values of fasting glucose level which elevated to about 11% in control individuals, while it lowered to about 13% in coriander treated group. Hyperglycemia may cause the overload of glucose in mitochondria, enhance the electron transfer to oxygen, and generate oxygen free radicals. This reaction ultimately activates the pathways which cause diabetic complications [99].

Similarly, it was reported that a single-dose administration of coriander to obese, hyperglycemic, and hypercholesterolemic rats suppressed their hyperglycemia. In a sub-chronic study, reduction in plasma glucose and insulin resistance was observed. It was observed that the dose rate of about 40 mg/kg aqueous coriander extract lowers the plasma glucose level to about 41.63%, tested after 6 h of administration. Furthermore, it was reported that the daily dose of coriander seed extract lowers the plasma insulin level and insulin resistance to about 28 and 80% in a 30-day trial [100].

Furthermore, it was exposed by Deepa and Anuradha [101] that administration of streptozotocin negatively affects the β-cells on setting the diabetes mellitus in the experimental rats, while oral dose of about 1.2 g per rat per day of coriander significantly lowered the serum glucose level (280–124 mg/dL) and increased the plasma insulin level (3.89–9.82 μU/mL) to about 44% and 40%, respectively. Moreover, the effect of ethanolic extracts of coriander seeds on the release of insulin from beta cells of pancreas has been investigated in streptozotocin-induced diabetic rats. It was reported that the ethanol extracts given at a dose rate of 200–250 mg/kg by intraperitoneal injection showed a noticeable reduction in serum glucose, i.e., about 550–400 and 280–200 mg/dL, respectively. Application of streptozotocin lowered the number of β-cells as well as insulin secretory activity as compared to healthy animals, though treating with ethanolic extract of coriander momentously enhanced the β-cell activity [102].

Previously, it was reported that administration of diet and drink enriched with coriander to streptozotocin-induced diabetic rats significantly lowered the hyperglycemia (about 33%) in a 20-day trial. It was further narrated that water extract of coriander seeds at a dose rate of about 1 mg/mL elevated the glucose uptake, glycogenesis, and glucose oxidation to about 1.6-, 1.7-, and 1.4-fold, respectively. Furthermore, the aqueous coriander extract imparted positive effect on insulin secretion by pancreatic cells in a dose-dependent fashion [103].

6.3 Hepatoprotective Perspectives

Hepatic system in the human body referred to the functioning mechanism of the liver. The liver is one of the most vital internal organs of the body. It is regarded as the largest internal organ of the human body. The liver performs >500 distinct functions which are vital for sustaining healthy human life. The essential functions of the liver include assisting the digestion of lipids in food, filtering the wastes and harmful components from the blood, preserving the nutrient reserves, and synthesizing different kinds of proteins along with maintaining levels of various biochemicals in the bloodstream. One of the unique properties of the liver is its ability to regrow its cells, if damaged by some disease or injury. However, chronic conditions can cause irreversible changes in the integrity of liver cells.

The liver stores energy in the form of glycogen which is a polymer of glucose subunits. Furthermore, the liver synthesizes the bile which contains salts for the digestion of lipids. Moreover, it also stored fat-soluble vitamins, i.e., vitamins A, D, E, and K, alongside vitamin B complex. Additionally, hepatic system also helps the body in clearing toxic and harmful chemicals like alcohol and drugs from the bloodstream. Hepatic cells absorb the hazardous chemicals from the bloodstream and chemically modify and convert them into harmless components to be excreted from the body [104].

Reactive oxygen species generated during oxidative stress can attack the healthy hepatic cells as in the case of lipid peroxidation. It can damage the cells to such level that cells would become nonfunctional creating some serious health complications, ranging from inflammation to hyperglycemia, hypercholesterolemia, jaundice, and even oncogenesis. From ancient times, herbs and spice have been well known for their aromatic characteristics and medicinal properties. Over the decades, phytochemicals that exist in herbs and spices have shown their potential of lowering oxidative stress and preventing lipid peroxidation. In this regard, coriander is in limelight owing to presence of a number of health-enhancing components like polyphenols and flavonoids.

In vivo antioxidant assay of essential oil extracted from coriander seeds has been proved to regulate liver biochemical parameters. It was reported that the single-dose administration of CCl_4 momentously enhances the level of lipid peroxidation (LPx) along with increasing the activity of peroxidase enzyme (Px); on the other hand, it lowers the content of reduced glutathione (GSH) and limits the activity of glutathione peroxidase (GSH-Px) and catalase enzymes (CAT). Moreover, CCl_4 application

resulted in elevation of serum alanine transaminase (ALT) and aspartate transaminase (AST). It was further narrated that the introduction of coriander extracts lowers the lipid peroxidation and activity of peroxidase, i.e., 2.82 ± 1.0–1.57 ± 0.3 nmol/mg of protein and 2.96 ± 0.5–1.98 ± 0.4 nmol/mg of protein/min, respectively, while it increased the content of reduced glutathione and activity of glutathione peroxidase as depicted from the values, i.e., 0.80 ± 0.2–1.24 ± 0.2 nmol/mg of protein and 1.08 ± 0.3–1.24 ± 0.2 nmol/mg of protein/min, correspondingly [105].

Recently, a study was conducted to explore the modulatory effects of green part of coriander on CCl_4-induced hepatic toxicity. It was declared that the phenolic components of coriander leaves and stems fed to CCl_4-induced hepatotoxic rats resulted in a significant decrease in liver and kidney biomarkers, illuminating noticeable protective perspectives of coriander against hepatic and renal toxicity. Treatment of CCl_4 resulted in significant increase in plasma level of hepatic enzymes like ALT, AST, and ALP. In contrast, treatment of coriander extracts reduces the elevation of plasma levels of these enzymes as depicted by the measured values; i.e., the contents of AST, ALT, and ALP were about 67.0 ± 1.49, 36.4 ± 1.85 U/mL, and 266.0 ± 10.6 U/L which lowered to about 52.25 ± 2.40, 17.4 ± 0.28 U/mL, and 130 ± 2.57 U/mL, respectively. Likewise, coriander treatment also lowers the biomarkers of kidney damage. It lowered the level of urea, uric acid, and creatinine from 45.9 ± 0.41 to 26.9 ± 1.30, 4.35 ± 0.15 to 2.38 ± 0.12, and 1.16 ± 0.01 to 0.71 ± 0.02 mg/dL, respectively. The results confirmed the hepatic and renal protective potential of coriander herb plant [106].

Another scientific study was conducted to explore the hepatoprotective effects of coriander leaves and seeds. In the study, 48 male rats were divided into four groups named as control (group I), hepatotoxic rats (group II), hepatotoxic rats fed on coriander leaves (group III), and hepatotoxic rats fed on coriander seeds (group IV). It was observed that the level of serum ALT, AST, and ALP activities enhanced significantly in all three hepatotoxic groups, i.e., groups II, III, and IV, though the administration of coriander leaves and seeds lowered the level of these enzymes as well as of nitric oxide and thiobarbituric acid reactive substance as compared to positive control group (group II). It was concluded that the coriander leaves were proved to be more effective in reducing the hepatotoxic effects as compared to coriander seeds owing to the presence of more polyphenols. The hepatoprotective effects of leaves and seeds were obvious from the mean values of ALP, AST, and ALT, which were about 153.08 ± 21.81, 244.25 ± 58.10, and 182.25 ± 37.29 U/L, respectively, in hepatotoxic rats which lowered to 142.16 ± 15.47, 171.33 ± 22.64, and 143.91 ± 18.47 U/L by the administration of seeds and 131.58 ± 17.97, 161.66 + 21.22, and 133.5 + 24.44 U/L, respectively, by feeding rats on coriander leaves [107].

Furthermore, one of their peers conducted a study on CCl_4-induced hepatotoxic albino rats to evaluate the protective potential of coriander. The injection of carbon tetrachloride noticeably raises the serum hepatic markers and lowered the antioxidant enzymes. It was observed that pretreatment of animals with coriander plant extract lowered the level of serum ALT, ALP, AST, and TBARS as compared to the positive control group. Moreover, it also strengthens the biological antioxidant

mechanism by enhancing the levels of superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase (CAT). It was also reported that the activity of 200 mg/kg body weight dose of coriander extract is comparable to the commercially available synthetic drug known as silymarin [108]. On the basis of aforementioned facts, it can be concluded that the coriander has the ability to ameliorate oxidative stress and protect the liver as well as renal cell from damage.

7 Conclusion

Generally, herbs and spices do not majorly contribute to nutrient supplementation of diet because of their use in lesser quantities and mostly utilized for the purpose of garnishing and flavoring. However, keeping in view the health-enhancing potential of these food components, they must be employed in the designing and formulating of functional foods. In this milieu, coriander seeds and herbs have been proved to be responsible for therapeutic effects against inflammation, diabetes, hypercholesterolemia, and hepatorenal toxicity. It can be abridged that coriander seeds and leaves are among the vital spices and herbs for health maintenance and disease prevention owing to their enriched phytochemistry which includes the predominant occurrence of linalool, flavonoids, etc., as the antioxidant potential of these bioactive moieties has been authenticated by a wide spectrum of in vitro and in vivo researches.

Contents

Abstract

Jackfruit (*Artocarpus heterophyllus Lam.*) is an ancient fruit and is consumed either raw or processed into different value-added products. Jackfruit seeds are normally discarded or steamed and eaten as a snack or used in some local dishes;

seed flour is used in some biscuit factories in various bakery products, etc. The use of jackfruit bulbs, seeds, and its other parts has also been reported since ancient times for their therapeutic qualities. The health benefits of jackfruit have been attributed to its wide range of physicochemical applications. It contains high levels of carbohydrates, protein, starch, calcium, vitamins, free sugar (sucrose), fatty acids, ellagic acid, and amino acids like arginine, cystine, histidine, leucine, lysine, methionine, theanine, and tryptophan. The jackfruit has diverse medicinal uses especially antioxidant, anti-inflammatory, antimicrobial, anticancer, and antifungal activity. This chapter describes an overview of the functional, medicinal, nutritional, and health aspects of jackfruit.

UDL	Under detection limit

1 Introduction

Jackfruit (*Artocarpus heterophyllus*) belongs to the Moraceae family, native to India and seen abundant in Western Ghats, a biodiversity spot of India [1–5]. Besides India, jackfruit is commonly grown in home gardens of tropical and subtropical countries especially in Sri Lanka, Bangladesh, Burma, Philippines, Indonesia, Thailand, Malaysia, and Brazil [2, 6–10]. In India, it is widely distributed in the states of Assam, West Bengal, Uttar Pradesh, Maharashtra, Kerala, Tamil Nadu, and Karnataka [5] and considered to be the "poor man's food" [1, 4]. It is a medium-size tree typically reaching 28–80 ft. in height that is easily accessible for its fruit. The fruit is borne on side branches and main branches of the tree. The average weight of a fruit is 3.5–10 kg, and sometimes a fruit may reach up to 25 kg. The ripe jackfruits consisted 29% pulp, 12% seeds, and 54% rind [11]. Figure 1 shows the various parts of a

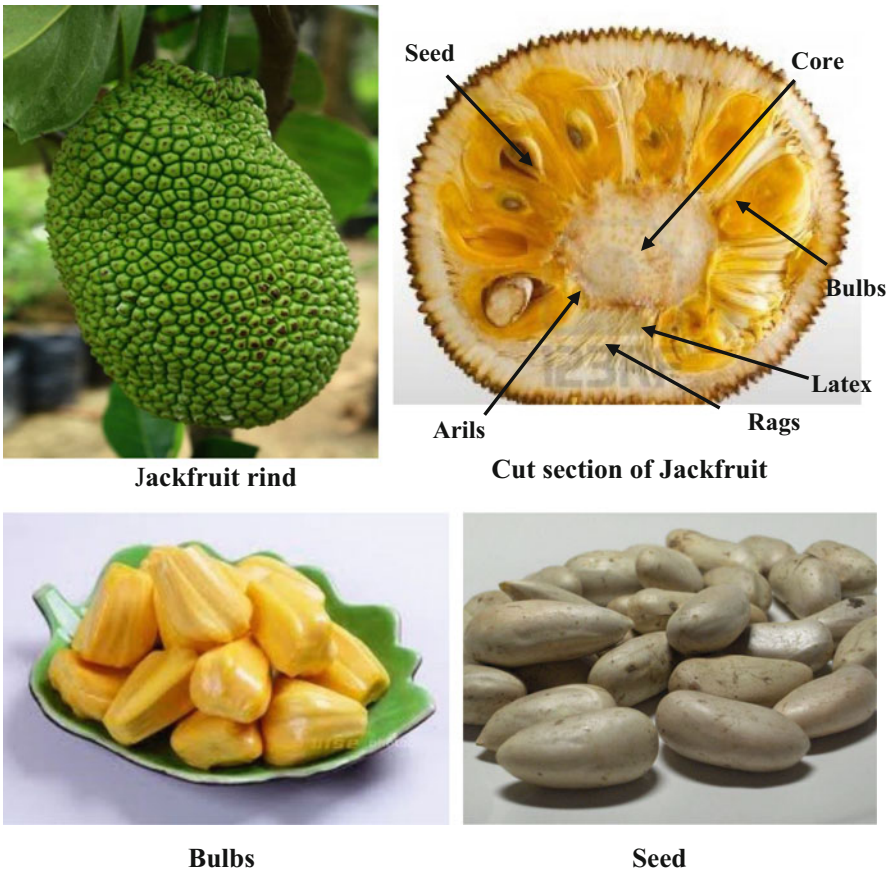

Fig. 1 Different parts of jackfruit

jackfruit. The jackfruit seed is 2–3 cm long and 1–2 cm in diameter, and each fruit contains 100–500 seeds.

There are two varieties of jackfruit in India: one is small, fibrous, soft, and mushy, with sweet carpels and a texture like that of raw oysters, and is called *Barka*, and the other variety is crisp and crunchy, but not very sweet, and is called *Kapa* [12]. In Bangladesh, *Khaja*, *Gala*, and *Durasha* are the main varieties [13]. *Khaja* is characterized by its hard and crispy bulb; *Gala* is soft and juicy and mostly melting bulb. On the other hand, *Durasha* is an intermediate between *Khaja* and *Gala* [14].

Jackfruit is reported to possess many medicinal properties. The phenolic compounds isolated from jackfruit are reported to exhibit anti-inflammatory effect [4]. The prenylflavonoids present in jackfruit had shown strong antioxidant properties [43] and is expected to act against lipid peroxidation of biological membranes [15]. The hot water extract of mature leaves are utilized in *Ayurvedic* treatment for

hyperglycemia and diabetes [4]. The flavonoids present in the extract have been identified to be responsible for the nontoxic hypoglycemic action [16]. Lectins present in the seeds have shown antifungal properties, while the crude methanolic extracts from root bark and stems have shown broad-spectrum antibacterial activity [17].

Resveratrol (trans-3,5,4-trihydroxystilbene, RES) is one of the polyphenols naturally present in jackfruit [18, 19] and is well-known for its health-promoting activities of antioxidant, cardioprotect, and anti-inflammatory [19]. Compounds that can inhibit angiogenesis have great potential for cancer treatment [20]. Jackfruit seeds contain secondary metabolites that display anticancer effects, especially anti-angiogenesis, and belong to the flavonoid group [21]. The jackfruit seed starch as superdisintegrant is suitable for the preparation of fast-dissolving tablets [22]. Extracts of jackfruit pulp show considerable anti-inflammatory activity by suppressing the production of nitric oxide (NO) and prostaglandin E2 (PGE2) [23], its leaf extracts also give remarkable antioxidant activity [43] and exhibit attenuation on hyperglycemia and hyperlipidemia [24]. Its wood was reported to be used as antioxidant, antiaging, anti-inflammatory, and skin care agents [25]. The leaf, root, bark, and fresh fruit of this plant have been certified to contain various compounds like flavonoids, phenolic acids, organic acids, carotenoids, stilbenes, triterpenes, and sterols, especially prenylflavonoids [2, 26, 27].

Jackfruit is also used for further processing. For instance, jackfruit leather and jackfruit chips can be made from dried jackfruit pulp [28]. Pureed jackfruit is also manufactured into baby food, juice, jam, jelly, and base for cordials [29]. Jackfruits are made into candies, fruit-rolls, marmalades, and ice cream [80]. Other than canning, advances in processing technologies too have pushed toward more new products [30]. Freeze-dried, vacuum-fried, and cryogenic processing are new preservation methods for modern jackfruit-based products. Various parts of the jackfruit tree have been used in medicine, and its wood is an important source in timber industries [29].

Nowadays, it is widely accepted that the beneficial health effects of fruits and vegetables in the prevention of disease are due to the bioactive compounds they contain [31]. In recent years, there has seen increased interest on the part of consumers, researchers, and the food industries into how food products can help maintain health; and the role that diet plays in the prevention and treatment of many illnesses has become widely accepted. This chapter describes an overview of the biodiversity of the tree and functional, medicinal, nutritional, and health aspects of jackfruit and its various parts.

2 Biodiversity

Jackfruit is an important crop of India, Burma, China, Sri Lanka, Malaysia, Indonesia, Thailand, and the Philippines. It is also grown in parts of Africa, Brazil, Suriname, the Caribbean, Florida, and Australia. Jackfruit has been cultivated

since prehistoric times and has been introduced to many Pacific islands since post-European contact and is of particular importance in Fiji [32].

Despite numerous advantages, the popularity of jackfruit as a commercial crop is very poor owing to wide variations in fruit quality, the long seed dormancy, and the widespread belief that excessive consumption of jackfruit bulbs leads to certain digestive ailments [33].

The jackfruit has innumerable types in the Western Ghats with varying fruit characteristics. The types differ among themselves in the shape and density of spikes on the rind, bearing, size, shape, latex, flake size, flake color, quality, and period of maturity. Innumerable variations in bulb sweetness, acidity, flavor, and taste are observed in jackfruit growing areas. Such a wide diversity among jackfruit types in Western Ghats offers tremendous scope for improvement of this crop by selection [33, 34]. Due to crosspollination and predominance of seed propagation over a long period of time, there is high degree of variability within the species.

Jagadeesh and others [1] selected 95 jackfruit types from the hilly (65 types) and coastal (30 types) zones of Karnataka situated in Western Ghats, a biodiversity spot of India. The Western Ghats falling in two agroclimatic regions of the state, viz., hilly and coastal, studied the physicochemical characters at edible ripe stage. It was apparent that the majority of selections (19), irrespective of their agroclimatic zone, were grouped in cluster "A," whereas clusters "B," "C," "D," and "E" were mono-tree type. It was found that the genetic drift and natural selection under different environmental conditions could cause considerable diversity than geographical distance. Highest values for TSS (34.33 °B), carotenoids (0.857 mg/100 g), total sugar (31.33%), and reducing sugars (13.37%) were observed in cluster "B," while cluster "D" exhibited highest values for TSS/acid ratio (123.29). Single-bulb mass (26.42 g) was the highest in cluster "A" with the majority of selections, whereas the solitary cluster "C" showed the highest edible portion (37.81%). With regard to fruit mass (14.86 kg) and flake mass (5.62 kg), cluster "C" exhibited the highest value, while titratable acidity (0.768%) was found highest in cluster "E." They conclude that jackfruit, being indigenous and a highly cross-pollinated crop, displays vast diversity in the Western Ghats of India. This wide range of variation existing in nature aids in the selection of superior desirable types.

2.1 Genetic Diversity

Jackfruit is a tetraploid; its somatic chromosome number is (4n) 56. Therefore, the basic chromosome number is 14 [35]. Only one study until now by Schnell and others [36] looked at the genetic diversity of 26 accessions from different parts of the world, using amplified fragment length polymorphism (AFLP) markers, and provided an actual picture of diversity and genetic relatedness in jackfruit. This study included only two accessions from India, and they scored a small number of markers (87), of which 92 (49.2%) were found to be polymorphic. The most recent study by Azad and others [37] looked at isozyme variation in jackfruit in Bangladesh. A total of 50 accessions were evaluated for four enzyme systems, and isozyme patterns were

determined on the basis of number and position of bands. They discovered that morphological traits such as weight, length, girth of the fruits, and percentage of pulp correlated poorly with environmental factors, suggesting that these characters are more likely genetically controlled. However, isozyme markers are also known to be affected by both environment and posttranslation modification, and their practical use is limited [38].

Jackfruit shows a considerable range of variation in morpho-agronomic characters, and this may be because jackfruit trees are cross-pollinated and are mostly propagated by seed. A considerable variation between trees has been observed for the traits such as growth habit, canopy structure, leaf size, fruit shape, size, color, fruit bearing (age and seasonality), and maturity (Table 1). The International Plant Genetic Resources Institute (IPGRI; now Biodiversity International) in 2000 issued a list of descriptor and descriptor states both for characterization of germplasm and for further evaluation. Variation also exists in density, size, and shape of spines on rind, fruit-bearing sensory quality, flesh types, sweetness, flavor, and taste [39].

3 Nutritional Characteristics of Jackfruit

Studies have proved that the nutritional and phytochemical composition among jackfruit varies depending on the cultivar as well as region [2, 30, 39–41]. It is a good source of vitamins (A, C, thiamine, riboflavin, niacin) and minerals (calcium, potassium, iron, sodium, zinc) (Swami and others) [12, 30, 39–41]. Protein and carbohydrate concentration also varied in seeds across India were some varieties contain 6.8% of protein in seeds [2]. The nutritional characteristics of jackfruit bulb, seed, and other part are discussed below.

3.1 Jackfruit Bulbs

Jackfruit is heavy and bulky, and actual recovery of bulbs or edible portion varies from 20 to 25% which is easily digestible. A 100 g portion of edible raw jackfruit provides about 95 calories and is a good source of the antioxidants and vitamin C, providing about 13.7 mg. The fruit is also rich in vitamin B_6, potassium, calcium, and iron.

The bulb of ripe jackfruit is eaten fresh and used in fruit salads. It possesses high nutritional value; every 100 g of ripe fruit pulp contains 18.9 g carbohydrate, 1.9 g protein, 0.1 g fat, 77% moisture, 1.1 g fiber, 0.8 g total mineral matter, 20 mg calcium, 30 mg phosphorus, 500 mg iron, 540 IU vitamin A, 30 mg thiamin, and 84 calories [33]. The jackfruit also contains useful antioxidant compounds [15]. Table 2 shows the composition of jackfruit edible portion of young fruit and ripe fruit. Figure 2 shows the nutraceutical characteristics of jackfruit bulb (pulp) and its effects on various diseases. Figure 3 shows principal functional and medicinal effects of jackfruit. The jackfruit could be considered a functional food because it has valuable compounds in different parts of the fruit that display functional and medicinal effects.

Table 1 Variation in morpho-agronomic characters [40]

Characteristic	Range of variation
Tree habit	Open, spreading, low spreading, sparse upright
Tree growth rate	Fast, moderate, slow
Canopy	Dense, mostly dome-shaped, slightly pyramidal, or flat-toped. It ranges from 3.5 to 6.7 m
Leaf shape	Elliptic, elliptic-obovate, obovate, oblong, lanceolate, oval
Leaf size	4–25 cm in length; 2–12 cm in width
Leaf petiole	1.2–4.0 cm long
Fruit maturity	Variable
Fruiting seasons	Variable
Fruit shape	Oblong, ellipsoid, triangular, spheroid, claviform, round
Number of fruits/tree	15–1450
Fruit weight (kg)	1.2–22.0
Fruit thickness	Thin, medium, thick
Fruit texture	Fibrous, firm, coarse, melting, crisp
Seed shape	Oblong, ellipsoid, irregular, reniform, elongated, spheroid
100 – seed weight (g)	250–1230
Flakes aroma	Mild, strong
Flakes color	Creamy white, light yellow, deep yellow, yellow, reddish, red golden
Flakes texture	Crisp, coarse, fibrous/coarse, fibrous, smooth
Quantity of fiber	Scarce, medium, abundant
Juiciness of pulp	Very juicy, juicy, medium juicy, less juicy, dry
Fruit weight (kg)	1.2–22.0
Fruit length (cm)	20.5–60.6
Fruit diameter (cm)	16.4–29.5
Fruit girth (cm)	50.5–95.8
No. of bulbs/fruit	24.2–580.2
Pulp (%)	18.3–60.9
Seed (%)	2.6–23.1
Rachis (%)	1.5–21.4
Rind (%)	20.6–72.0
TSS Brix (°)	13.8–25.3

3.1.1 Carotenoid Composition

The jackfruit bulb consists of 107.98 total carotenoids [27]. Jackfruit consists all-trans-β-carotene which is an important antioxidant for human health [40]. Jackfruit contains carotenoids that are important for prevention of several chronic degenerative diseases, such as cancer, inflammation, cardiovascular disease, cataract, and age-related macular degeneration [44, 45]. The total carotenoids present in jackfruit are shown in Table 3.

Table 2 Composition of jackfruit bulb (100 g edible portion) [30, 41, 42]

Sr.No	Composition	Young fruit	Ripe fruit
A	**Proximate analysis**		
1	Water (g)	76.2–85.2	72.0–94.0
2	Protein (g)	2.0–2.6	1.2–1.9
3	Fat (g)	0.1–0.6	0.1–0.4
4	Carbohydrate (g)	9.4–11.5	16.0–25.4
5	Fiber (g)	2.6–3.6	1.0–1.5
6	Total sugars (g)	–	20.6
B	**Minerals and vitamins**		
1	Total minerals (g)	0.9	0.87–0.9
2	Calcium (mg)	30.0–73.2	20.0–37.0
3	Magnesium (mg)	–	27.0
4	Phosphorus (mg)	20.0–57.2	38.0–41.0
5	Potassium (mg)	287–323	191–407
6	Sodium (mg)	3.0–35.0	2.0–41.0
7	Iron (mg)	0.4–1.9	0.5–1.1
8	Vitamin A (IU)	30	175–540
9	Thiamine (mg)	0.05–0.15	0.03–0.09
10	Riboflavin (mg)	0.05–0.2	0.05–0.4
11	Vitamin C (mg)	12.0–14.0	7.0–10.0

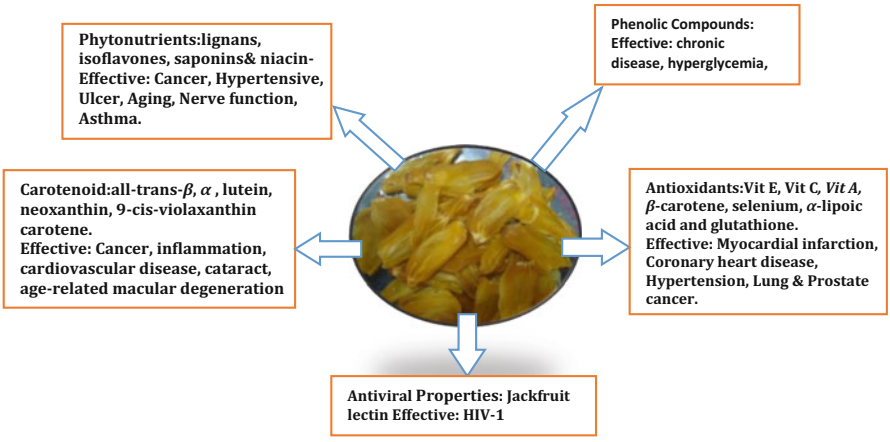

Fig. 2 Nutraceutical characteristics of jackfruit bulb (pulp) and its effect on various diseases

The main carotenoids in jackfruit were all-trans-lutein (24–44%), all-trans-β-carotene (24–30%), all-trans-neoxanthin (4–19%), 9-cis-neoxanthin (4–9%), and 9-cis-violaxanthin (4–10%). Jackfruit is a good source of provitamin A carotenoids, though not as good as papaya [46]. Thus increased consumption of ripe jackfruit could be advocated as part of a strategy to prevent and control vitamin A deficiency.

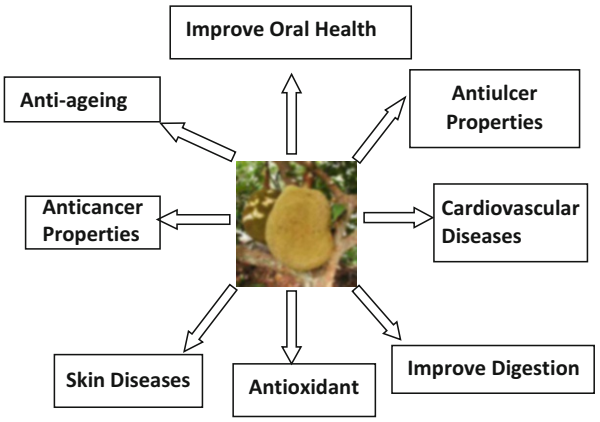

Fig. 3 Principal functional and medicinal effects of jackfruit

Table 3 Concentration (μg/100 g fresh weight) of different carotenoids in jackfruit [27]

Carotenoids	Values	Carotenoids	Values
All-trans-neoxanthin	8.85 ± 5.73	All-trans-zeinoxanthin	1.72 ± 1.20
9-cis-Neoxanthin	6.87 ± 4.25	9-cis-Zeinoxanthin	0.90 ± 1.12
All-trans-neochrome	0.88 ± 1.11	All-trans-α-cryptoxanthin	0.35 ± 0.60
All-trans-luteoxanthin	2.06 ± 0.90	All-trans-β-cryptoxanthin	1.21 ± 0.45
cis-Antheraxanthin	1.12 ± 0.36	15-cis-β-carotene	0.18 ± 0.31
9-cis-Violaxanthin	7.05 ± 5.97	13-cis-β-carotene	2.45 ± 1.40
cis-Luteoxanthin	0.34 ± 0.42	All-trans-α-carotene	1.24 ± 0.93
All-trans-lutein	37.02 ± 20.34	All-trans-β-carotene	29.55 ± 15.46
All-trans-zeaxanthin	0.96 ± 1.20	9-cis-β-carotene	0.79 ± 0.30
Total carotenoids			**107.98 ± 51.46**

3.2 Jackfruit Seed

The jackfruit seeds are around 10–15% of the total fruit weight and have high carbohydrate and protein contents [47]. There are 100–500 seeds in a single fruit. Seeds are normally discarded or steamed and eaten as a snack or used in some local dishes. The fresh seeds cannot be kept for a long time, seed flour can be an alternative product, which can be used in some food products.

The jackfruit seeds are a good source of starch (22%) and dietary fiber (3.19%) [48]. Jackfruit seeds contain lignans, isoflavones, and saponins that are called phytonutrients, and their health benefits are wide-ranging from anticancer to antihypertensive, antiaging, antioxidant, antiulcer, etc. [49].

The jackfruit seeds have medicinal properties. The oval, oblong, or oblong ellipsoid or rounded-shape, light brown color jackfruit seeds are nutritious and rich in potassium, fat, carbohydrates, and minerals. Manganese and magnesium elements have also been detected in seed powder [50]. Table 4 shows the composition of jackfruit seed. Seeds contain two lectins, namely, jacalin and artocarpin. Jacalin has

Table 4 Composition of jackfruit seed (100 g edible portion) [30, 39, 41, 42]

Sr. no.	Composition	Value	Sr. no.	Composition	Value
A	**Proximate analysis**		**B**	**Minerals and vitamins**	
1	Water (g)	51.0–64.5	1	Total minerals (g)	0.9–1.2
2	Protein (g)	6.6–7.04	2	Calcium (mg)	50.0
3	Fat (g)	0.40–0.43	3	Magnesium (mg)	54.0
4	Carbohydrate (g)	25.8–38.4	4	Phosphorus (mg)	38.0–97.0
5	Fiber (g)	1.0–1.5	5	Potassium (mg)	246
6	Total sugars (g)	–	6	Sodium (mg)	63.2
			7	Iron (mg)	1.5
			8	Vitamin A (IU)	10–17
			9	Thiamine (mg)	0.25
			10	Riboflavin (mg)	0.11–0.3
			11	Vitamin C (mg)	11.0

been proved to be useful for the evaluation of the immune status of patients infected with human immunodeficiency virus-1 [40].

Amylose content of jackfruit seed starch was 32% [51]. Jackfruit seed extract was found to inhibit the proteolytic activities of different animal pancreatic preparations effectively [52]. The fresh seed contains crude proteins (606 g), fat (0.4 g), carbohydrates (38.4 g), fiber (1.5 g), ash (1.25–1.50 g), and moisture (51.6–57.77 g), respectively [53].

4 Physicochemical Properties

There have been few studies on physicochemical properties of jackfruit seeds. The physicochemical properties of jackfruit seed is shown in Table 5. Jackfruit seeds are fairly rich in starch [54]. The pasting properties of the jackfruit seed starch against corn and potato starch were studied, and it is reported that the pasting temperature of jackfruit seed starch was higher than those of corn starch and potato starch. The jackfruit seed starch has lower swelling properties because of high amylose content. Jackfruit seed starch was more resistant to heat and mechanical shear and hence less prone to loss viscosity upon holding and shearing. Mukprasirt and Sajjaanantakul [55] also reported that the breakdown viscosity of jackfruit seed starch was lower than that of the commercial starch.

Fat absorption is an important property in food formulations because fats improve the flavor and mouthfeel of foods [57]. The jackfruit flour has 2.8 g/ml fat absorption characteristic. Jackfruit seed flour has a lot of potential in the food industry, especially its uses as thickener and binding agent in the food systems.

Kumar and others [58] studied the proximate compositions of two varieties of jackfruit seeds and reported considerable biochemical difference between the two varieties. The starch content of the seed increases with maturity [59].

Table 5 Some physicochemical and functional properties of jackfruit seed flour [56]

Sr. no.	Particular	Value (% dry matter)
	Physicochemical properties	
1.	Moisture	6.09 ± 0.01
2.	Crude fat	1.27 ± 0.01

14.	Foam stability (%)	33.00 ± 0.01
15.	Swelling power (g/g)	4.77 ± 0.10

5 Phytochemical Analysis

Gupta and others [60] analyzed phytochemical content of jackfruit seeds found high quantity of saponins (6.32 ± 0.098 g/100 g). Saponins have been known for their medicinal uses, including antispasmodic activity and toxicity to cancer cells. Some alkaloids function as spasmolytic, anticholinergic, and anesthetic agents. The alkaloid content in jackfruit seeds was found to be 1.16 ± 0.09 g/100 g. Polyphenolics are known to function as antioxidants through a number of mechanisms including radical scavenging by H-donation, prevention of chain initiation by donating electrons, or binding of transition metal ion catalysts. Flavonoids prevent platelet stickiness and hence platelet aggregation.

5.1 Primary Metabolites in Jackfruit Seed

Organic acids control acetic-alkali equilibrium, which affects human health and all the reactions in the body. Table 6 shows the various organic acid content of jackfruit seed kernel (SK) and seed coating membrane (SCM). In addition, they have a disinfecting function, and affect metabolism, etc. By interacting with other substances, organic acids affect the acetic-alkali balance, alkalizing the whole body. As a result, the person's health improves. Also the organic acids are involved in digestion, stimulate the stomach and pancreas, and increase intestine motor function.

Table 6 Organic acid content in jackfruit seed kernel (SK) and seed coating membrane (SCM) [61]

Sr. no.	Compounds (mg/kg dry matter)	SK	SCM
1	Oxalic	649.45 ± 26.38	122.38 ± 12.36
2	Aconitic	650.51 ± 6.93	96.52 ± 6.53
3	Citric	8086.95 ± 807.60	1745.72 ± 120.31
4	Pyruvic	–	59.32 ± 6.25
5	Malic	3539.64 ± 335.53	877.97 ± 137.97
6	Quinic	460.84 ± 10.50	230.38 ± 44.69
7	Shikimic	–	12.95 ± 0.30
8	Acetic	–	84.28 ± 5.82
9	Fumaric	535.88 ± 1.37	26.33 ± 1.47
	Total	**13923.26 ± 1188.30**	**3255.85 ± 335.70**

Oxalic acid that is a normal element in the blood has been reported to have a mean value of 288 mcg of anhydrous oxalic acid/100 ml of blood. Oxalic acid must be available for the immune system to fight the diseases such as cancer and viral, bacterial, and vascular conditions. When oxalic acid falls below an effective level, the immune system can no longer protect the body from various diseases. When the immune system can no longer eliminate abnormal cells, radical cells are allowed to develop and give rise to a detectable tumor.

Amino acids build proteins, and proteins are life-sustaining macronutrients. Table 7 shows the amino acid content in jackfruit seed kernel and seed coating membrane (SCM). When cells need protein, they follow instructions from DNA that define the specific amino acids and the order in which they must connect to build the protein. DNA depends on another macromolecule RNA to make the protein. RNA takes a copy of the code from your DNA, leaves the cell, finds the amino acids, and brings them back to the cell, where they bind into a chain. Each amino acid must be available at the time it's needed or the protein won't be synthesized. When the chain is complete, it twists and folds into a specialized shape. The chemical structure of each amino acid controls the final shape, and the shape determines the function of the protein. Several amino acids produce neurotransmitters, but two well-known examples are the amino acids tryptophan and tyrosine. Tryptophan is available in jackfruit seed in fair quantity which produces serotonin, regulates your moods, and makes the hormone melatonin. Food proteins vary depending on their amino acid content and contain varying concentrations of essential and nonessential amino acids [61].

Fernandes and others [61] identified 67 compounds and reported for the first time in jackfruit seed. Table 8 shows fatty acid content in jackfruit seed kernel (SK) and seed coating membrane (SCM).

The seed kernel is significantly richer in all metabolites. As expected, the accumulation of primary metabolites was higher, organic and amino acids being predominant in jackfruit seed kernel and seed coating material. Phenolic compounds allowed a more clear distinction of the two materials, being mainly accumulated in the seed kernel. Seed kernel and seed coating membrane showed antioxidant capacity.

Table 7 Amino acid content in jackfruit seed kernel (SK) and seed coating membrane (SCM) (mg/kg dry matter) [61]

Amino acids		SK	SCM
A. Essential			
1	Threonine	387.00 ± 1.40	48.20 ± 0.11
2	Valine	290.54 ± 3.62	37.43 ± 0.44
3	Isoleucine	157.01 ± 0.79	11.82 ± 0.29
4	Leucine	396.43 ± 7.61	71.39 ± 0.60
5	Tryptophan	94.69 ± 0.91	8.30 ± 0.14
6	Phenylalanine	210.92 ± 2.56	29.51 ± 0.10
7	Lysine	242.59 ± 0.63	29.04 ± 0.24
8	Histidine	104.90 ± 0.04	32.08 ± 0.25
	Total	**1884.08 (17.56)**	**267.76 ± 2.18**
B. Nonessential			
1	Aspartic acid	247.64 ± 20.35	25.83 ± 0.02

	Total	**9850.21 ± 96.07**	**1076.87 ± 9.47**

The jackfruit leaves and stem show the presence of sapogenins, cycloartenone, cycloartenol, β-sitosterol, and tannins; they show estrogenic activity. A root contains β-sitosterol, ursolic acid, betulinic acid, and cycloartenone [62].

6 Health Benefits

The health benefits of jackfruit are still underway. The jackfruit bulb and jackfruit seeds are good sources of protein, starch, and minerals. Jackfruits also contain phytonutrients, i.e., lignans, isoflavones, and saponins, and they have numerous health benefits such as anticancer, antiaging, and antioxidant. Fig. 2 shows the nutraceutical characteristics of jackfruit bulb and its effect on various diseases.

6.1 Anticancer

Angiogenesis is the outgrowth of new blood vessels from preexisting vessels. It commonly occurs during the normal physiological process of blood vessel formation and during cancer growth [63].

Table 8 Fatty acid content in jackfruit seed kernel (SK) and seed coating membrane (SCM) (mg/kg dry matter) [61]

Sr. no.	Fatty acids	SK	SCM
1	Dodecanoic (C12:0)	–	12.69 ± 0.27
2	Tridecanoic (C13:0)	–	1.70 ± 0.06

17	Docosanoic (C22:0)	112.41 ± 4.96	91.12 ± 1.58
18	Tricosanoic (C23:0)	20.65 ± 1.06	25.60 ± 0.07
19	Tetracosanoic (C24:0)	64.62 ± 4.30	85.98 ± 0.63
	TOTAL	**2348.06 ± 47.77**	**1961.20 ± 27.52**

The recent studies show all phytonutrients in jackfruit bulb shave anticancer benefits. The main role of these nutrients is to help prevent the harmful free radicals that have been known to develop cancer and many other chronic diseases. The phytonutrients prevent the very initial stage of cancer cell formation. Saponins are also strong anticancer agents. According to a study, saponins show colon cancer preventative properties. These phytonutrients have been found to induce mitotic arrest in the case of leukemia cells. The study also found that it helped in some cases to cause remission. Saponins were found to react to the outer layers of cancer cells. They bound the cells and prevented their further growth [64]. Swastika and others [21] reported that the effective dose of jackfruit seed methanolic extract for angiogenesis inhibition is 35.00 mg/ml.

Phytoestrogens are naturally occurring polycyclic phenols found in certain plants that may, when ingested and metabolized, have weak estrogenic effects. Two important groups of phytoestrogens that are present in jackfruit pulp are isoflavones and lignans (Swami and others) [12]. According to studies, these nutrients help in reducing the risk of endometrial cancer.

Jackfruit is rich in fiber. It also has a unique sticky form. Both these properties combine together to work as a great colon cleanser. It helps in removing toxins from your digestive tract. This further helps in reducing the risk of colon cancer. Three phenolic anticancer compounds of jackfruit were characterized as

artocarpesin [5,7,2′,4′-tetrahydroxy-6-βmethylbut-3-enyl) flavones] [65], norartocarpetin (5,7,2′,4′-tetrahydroxyflavone), and oxyresveratrol [trans-2,4,3′,5′tetrahydroxystilbene] [66]. Gowri and others [66] also reported that the reactive oxygen species (ROS) production is a common feature of tumor promotion. The Cressa critica aqueous extract (CCAE) showed higher antioxidant activity than single plant extracts of *P. zeylanica* (45%) [67], *L. acidissima* (19%) [68], and *A. heterophyllus* (36%) [69].

6.2 Diabetics

Diabetes mellitus is a metabolic disorder characterized by hyperglycemia resulting from defects in insulin action, insulin secretion, or both. The most common type of diabetes mellitus is type 2 diabetes mellitus, which accounts for 85–95% of all cases and constitutes a major public health problem [70]. Hot water extract of mature jack leaves is recommended by Ayurvedic and traditional medical practitioners as a treatment for diabetes mellitus (Fernando et al. 1991 [71]. It is already indicated that an extract of jackfruit improves the glucose tolerance in normal human subjects and diabetic patients [72]. The leaves and stem show the presence of sapogenins, cycloartenone, ß-sitosterol, and tannins [73]. Jackfruit contains vitamin A, vitamin C, thiamin, riboflavin, niacin, calcium, potassium, iron, manganese, and magnesium among many other nutrients. It is good for diabetes as they improve insulin resistance.

Ajaiya Kumar and others [74] reported that consuming 100 g of the jackfruit meal per day for 4 months leads to quantitative reduction in fasting blood glucose (FBG), postprandial blood glucose (PBG), and hemoglobin A1c (HbA1c) compared with the baseline. The HbA1c decreased by 13.59%, FBG by 22.68%, and PBG by 25.69%. They have concluded that the dietary supplementation of the jackfruit raw fruit meal preparation has an impact in reducing type 2 diabetes.

Hettiaratchi and others [75] studied Nutritional assessment of a jackfruit meal. The total energy contribution of the jackfruit meal is 1370 kJ. Jackfruit meal provides 20% of daily energy requirement of a moderately active individual. Jackfruit seeds contained high amount of resistant starch (RS) (undigestible starch). Resistant starch is categorized into four types (RS_1–RS_4) [76], and jackfruit seeds may contain RS_1 type. The undigestible starch escapes digestion in the small intestine, passes into the colon, and is reported to act like dietary fiber (Hettiaratchi and others) [75]. The postprandial glycemic response and glycemic index (GI) of the jackfruit meal were determined. Jackfruit meal elicited a low GI (Table 9). This is the first reported data on GI of a jackfruit meal in spite of having 2487 data on GI of different foods in the recent "International Tables of Glycaemic Indices and Glycaemic Load Values" [77]. Jackfruit has beneficial nutritional parameters and a low GI. This could be due to the collective contributions of dietary fiber, slowly available glucose, intact starch granules in seeds, and influence of different sources of carbohydrates. Table 10 shows phenolic acids in different parts of jackfruit.

Table 9 Nutritional parameters of jackfruit flesh, seed, meal, and the standard [75]

Parameter	Jackfruit flesh	Jackfruit seeds	Jackfruit meal	Standard
Carbohydrate	10.0 ± 0.3	21.9 ± 0.8	50 g	50 g
Insoluble dietary fiber	1.5 ± 0.1	7.9 ± 0.5	13.5	0.8
Soluble dietary fiber	1.1 ± 0.1	3.2 ± 0.3	6.5	2.4
Total dietary fiber	2.6	11.1	20.0	3.2
Protein	0.9	4.7	6.8	8.2
Fat	0.8 ± 0.1	1.3 ± 0.3	11.5	3.2
Resistant starch	0.3	8.0	5.2	0.7
Slowly available glucose %	17%	33%	30%	16%
Amylose	29	54	31	15
Glycemic index (SEM)	–	–	75 ± 11	100
IAUC (SEM)	–	–	132 ± 19	181 ± 18
GL (NSS)	–	–	13	20

Table 10 HPLC analysis of various phenolic acids in different parts of jackfruit [54]

Plant parts	Phenolic acids (μg/g fresh wt.)			
	TA	**GA**	**FA**	**Caf – A**
Raw fruit skin	6.70 ± 0.05	22.73 ± 2.04	4.64 ± 0.02	UDL
Ripe fruit skin	5.73 ± 0.04	12.08 ± 1.03	13.41 ± 1.2	UDL
Raw fruit flesh	4.87 ± 0.05	9.70 ± 0.09	8.04 ± 0.07	UDL
Ripe fruit flesh	5.24 ± 0.06	19.31 ± 1.8	2.66 ± 0.06	UDL
Raw fruit pulp of seed	2.29 ± 0.01	11.05 ± 1.02	2.16 ± 0.05	UDL
Ripe fruit pulp of seed	UDL	6.26 ± 0.04	2.56 ± 0.02	UDL
Raw fruit seed	6.59 ± 0.07	11.3 ± 1.6	2.38 ± 0.01	2.84 ± 0.02
Ripe fruit seed	2.21 ± 0.01	11.30 ± 1.07	2.71 ± 0.01	UDL

6.3 Immune System

Jacalin, the major protein from the *Artocarpus heterophyllus* seeds, is a tetrameric two-chain lectin combining a heavy chain of 133 amino acid residues with a light β chain of 20–21 amino acid residues [78]. Jacalin's uniqueness in being strongly mitogenic for human CD4 + T lymphocytes has made it a useful tool for the evaluation of the immune status of patients infected with human immunodeficiency virus HIV-1 [79].

6.4 Improve Digestion

The presence of high fiber (3.6 g/100 g) in the jackfruit prevents constipation and helps in smooth bowel movements. These fibers also offer protection against colon mucous membrane by removing or driving away the carcinogenic.

6.5 Cardiovascular Health

One of the major risk factors for the development of coronary heart disease is dyslipidemia, which is mainly characterized by elevated levels of low-density lipoprotein cholesterol (LDL-C) and/or reduced high-density lipoprotein cholesterol (HDL-C) [81].

Epidemiological studies have shown that high concentrations of serum total cholesterol and LDL-C are independent risk factors for cardiovascular disease [82] and could produce atherosclerosis. Atherosclerosis, a major degenerative disease of the arteries, involves a series of inflammatory and oxidative modifications within the arterial wall [83]. Oxidative excess in the vasculature reduces levels of the vasodilator nitric oxide, causes tissue injury, promotes protein oxidation and DNA damage, and induces proinflammatory responses [84]. Oxidative stress induces inflammation by acting on the pathways that generate inflammatory mediators like adhesion molecules and proinflammatory cytokines [85].

6.6 Fast-Dissolving Tablets

The major storage carbohydrate in plants is starch. The annual worldwide production of starch is 66.5 million tons (FAOSTAT) [86]. Growing demand for starches in the industry has created interest in new sources of this polysaccharide, such as leaves, legume seeds, and fruits [87]. It has immense industrial use in the manufacture of products such as food, textile, paper, adhesives, and pharmaceuticals. Starch can also serve as a thickening, gelling, and film-forming properties [88, 89].

Jackfruit seed cotyledons are fairly rich in starch and protein. The recent investigation shows that the jackfruit seed starch has potential in pharmaceutical industries. The starches extracted from jackfruit seeds are used as superdisintegrants for the formulation of fast-dissolving tablets (FDT).

The FDT technology makes tablets dissolve or disintegrate in the mouth without additional water intake. The FDT formulation is defined by the Food and Drug Administration (FDA) as "A solid dosage form containing medical substances whish disintegrates rapidly, usually within a seconds, when placed upon the tongue." Fast-dissolving tablets are also called mouth-dissolving tablets, melt-in-mouth tablets, orodispersible tablets, rapidmelts, porous tablets, quick dissolving, etc. [90]. The basic approach in the development of FDT is the use of superdisintegrants, which provide instantaneous disintegration of tablet after putting on tongue, thereby releasing the drug in saliva [91]. The fast-dissolving tablets are rapidly dissolved or disintegrate by the use of superdisintegrants.

Vidyadhara and others [22] reported as Irbesartan (IRB), which is anangiotensin II type, receptor antagonist, is selected as a model drug. IRB and FDT formulations that contained various concentrations of jackfruit starch extracts and CCS (croscarmellose sodium) were prepared by wet granulation technique using IPA (Isopropyl alcohol) as granulating fluid. The evaluated pre-compression parameters indicated that the granules exhibited good flow properties. In vitro dissolution

studies were performed on all prepared matrix tablets using the USP apparatus II with 900 mL of 0.1 N HCl. From the results of dissolution studies, it was observed that the type of starch as superdisintegrant and the proportion of superdisintegrant have considerably influenced the dissolution parameters of various formulations. The tablets prepared from jackfruit seed starch as superdisintegrant were found to be suitable for preparation of fast-dissolving tablets.

Jackfruit is well known to have antibacterial property against 24 species of bacteria [92]. A jackfruit lectin, i.e., jacalin, inhibits DNA viruses such as herpes simplex virus type II (HSV-2), varicella-zoster virus (VZV), and cytomegalovirus (CMV) [93].

The jackfruit could be considered a functional food because it has valuable compounds in different parts of the fruit that display functional and medicinal effects (Fig. 2).

"Functional foods" are those that provide more than simple nutrition; they supply additional physiological benefit to the consumer. Because dietary habits are specific to populations and vary widely, it is necessary to study the disease-preventive potential of functional micronutrients in the regional diets.

6.7 Dental Health

In jackfruit tree, latex or resin are found on the trunk of tree as well as the fruit. All parts of jackfruit tree contain sticky white latex which produced from special secretory cells called laticifers. Latex is an aqueous emulsion containing many ingredients, for instance, lipids, rubbers, resins, sugars, and proteins including proteolytic enzymes [94].

Rao and others [95] reported that the jackfruit latex extract which is rich in flavonoids and alkaloids was checked for antibacterial and antifungal properties which shows fairly well and significant comparison with standard antibacterial and antifungal drugs. They concluded that this information gives about the several important uses of jackfruit latex or resin, or both can be utilized as the cementing medium, irrigation solution (washing of a body cavity or wound by a stream of fluid), denture cleaning solution, resin, and other future dental filling material in terms of cost-effectiveness.

7 Conclusion

There is a need for commercial utilization of the jackfruit in developing countries and can serve as a possible alternative of many vitamins in the body. An activity of certain phytochemicals along with their antioxidant properties further supports the cause of commercial utilization of the fruit. The antioxidant constituents present in the fruits play important role in scavenging free radicals and reactive oxygen species which are responsible for a number of human disorders. The jackfruits and fruit

products hold potential in the diet as they possess not only pleasant taste but also source of naturally and readily available source of instant energy.

In Ayurveda the jackfruit is used as a cooling tonic and pectorial, roots in diarrhea and fever, leaves to activate milk in women and animals, as a source to treat antisyphilic and vermifuge, leaf ash applied to ulcers wounds and the warmed leaves have healing properties if pasted on the wounds. The richness of jackfruit in bioactive natural metabolites encourages their consumption. Furthermore, the aqueous extracts activity suggests that it may be useful for food and pharmaceutical industries. The valued jackfruit material, which nowadays is largely discarded by the population, might have an important economic impact for the producers.

Abstract

European elder plant, *Sambucus nigra* L., has been used as an important part of the folk medicine and as multipurpose foods and dietary supplements. The scientific developments in nutrition research, in evaluation of biological activities, and in prospection of bioactive compounds reveal a set of potential health benefits associated with *S. nigra* berries and flowers. This chapter aims to briefly cover aspects linked to elder plant taxonomic classification, geographic distribution, and typologies of products available in the market. Current challenges regarding in vitro and in vivo assays will be also discussed. Despite in vitro studies are often used to predict the health benefits due to the high amount of generated data and their low cost, the use of in vivo assays is crucial to predict such health benefits, as the real contribution of foods, extracts, or specific bioactive compounds to human health is largely modulated by their bioavailability that cannot be accessed at in vitro level. Thus, the main findings regarding the potential health benefits of *S. nigra*-based preparations using in vitro and/or in vivo assays, namely, anti-infective, antioxidant, anti-inflammatory, immunomodulatory, anticancer, and antidiabetic, will be critically revisited. Finally, current challenges related to nutrivigilance systems, which are crucial to ensure consumer health and safety, will be presented.

Keywords

Sambucus nigra L. · Elderflowers · Elderberries · Bioavailability · Health benefits · Nutrivigilance

Abbreviations

ABTS	2,2'-Azino-bis(3-ethyl-benzothialzoline-6-sulfonic acid)
ACN	Anthocyanins
AOx	Antioxidant activity

NO	Nitric oxide
NP	Nanoparticle
ORAC	Oxygen radical absorption capacity
Peo	Peonidin
PI3K	Phosphatidylinositol 3-kinase
PPAR	Proliferator-activated receptor
QR	Quinone reductase
RIP	Ribosomal-inactivating proteins
ROS	Reactive oxygen species
Sam	Sambubioside
SOD	Superoxide dismutase
TE	Trolox equivalents
TNF-α	Tumor necrosis factor α
TPC	Total phenolic content

1 Introduction

Elderberry plant from *Sambucus nigra* L. species is a worldwide-spread plant, from which both flowers and berries have been used on folk medicine for prophylactic and therapeutic purposes, being considered the medicinal "chest" from the days of Hippocrates [1]. Many phytochemicals such as vitamins, phenolic compounds, sterols, and terpenic compounds are documented on elderflowers and berries [2–6], being these compounds often connected with diverse potential health benefits on humans [7–11].

Due to those human health benefits potential and peculiar sensorial characteristics, a wide range of food products and nutraceuticals are homemade and/or commercially available, including elderflowers' infusions and decoctions [12–15], pastry products [16], nonalcoholic cordials and fermented beverages [16, 17], as well as elderberries' decoctions [12, 18], infusions [16], juice and syrup/concentrate [18], extracts, supplements, pies, ice creams, jellies, juices, beverages, beers, wines, liqueurs, fruit bars, and coloring agents [19–21].

Nowadays, new nutritional strategies reflect the way consumer perceives health, as those show an increasing knowledge regarding the impact of diet on regulation at the genetic and molecular levels [22]. Hence, plants and their extracts or isolated components are believed to have a positive human health effect; therefore, the evaluation of the efficacy and safety of these naturally occurring bioactive compounds is a major challenge to scientists [23]. Thus, this chapter aims at giving a general perspective of *S. nigra* L. berries and flowers' potential health benefits, covering aspects ranging from its taxonomic classification and geographic distribution, current applications, and a critical perspective about their health benefits from lab testing to human consumption. The data related to *S. nigra* possible toxicity and drug interaction will be also addressed.

2 Botany

S. nigra L. is a deciduous multistemmed shrub in which their suckering is made from the roots and branching from the base of the main stems stimulating the plant to form dense thickets. Elder shrub can reach up to 9 m in height, with average height values of 2–3 m, and contains large (5–15 cm long) leaves with 5 to 11 leaflets with sharply serrated margins [16, 17, 24, 25]. Elderberry belongs to genus *Sambucus* being recently included on Adoxaceae family [16, 26]. The most common subspecies from elderberry plant are the American elder [*Sambucus nigra* sbsp. *canadensis* (L.) R. Bolli] and black elder or European elder [*S. nigra* sbsp. *nigra* (L.) R. Bolli], being formerly designated as *S. canadensis* and *S. nigra*, respectively [25].

Elderberry leaves emerge around February or March, and the shrubs bloom around May to June, depending on the geographic location and cultivar, generating creamy-white flowers as illustrated on Fig. 1 [17]. Berries' ripening process happens for a period of 1–2 months, starting from a green color, and, when ripe, they became deep purple (Fig. 1) [16].

S. nigra is classified as European temperate with ideal growth conditions in terms of yield and quality on full sun or partially shaded exposures and in moist soils [27]. Different cultivars from *S. nigra* are currently explored for cultivation, for instance, Hachberg and Rubim in Austria; Albida and Bohatka in Czech Republic; Allesoe, Blangstedgaard, and Finn Sam in Denmark; Road Due in England; Alleso, Sampo, and Samyl in Poland; and Bastardeira, Sabugueira, and Sabugueiro in Portugal, among others [28–36].

3 From Folk Medicine to Food Products and *S. nigra* Supplements

S. nigra has been used for centuries, as far back as the Ancient Rome for a wide range of applications, namely, musical instruments as flutes, whistles, or textile artifacts and dyes, and even used on ritual ceremonies [25]. Leaves and inner bark have been used for their purgative, diuretic, laxative, expectorant, and

Fig. 1 *S. nigra* L. flowers and berries

diaphoretic action [25]. Elderflowers and elderberries have been used to alleviate or cure several illnesses in folk medicine and they have many applications in European countries. Elderflowers, for instance, were used to treat bronchial and pulmonary diseases, tumors, and ulcers [17]. Their infusions have been reported as having soothing and laxative properties and were used to "sweat out fever" [12], on asthma treatment [13], and to treat toothache, colic, cold and rheumatic conditions [14]. Their decoctions are used for cold treatment [15] and as expectorant, as well as to treat bronchitis, whooping cough, asthma, hemorrhoids [13], insect bites, and fever [14]. Elderflower's traditional use for the relief of early symptoms of common cold has been found to fulfill the requirement of medicinal use for at least 30 years according to the Committee on Herbal Medicinal Products [37]. As reviewed by the European Medicines Agency [18], dried elderberries were traditionally used as a decoction to act as laxative, and elderberry juice or syrup were used as a diaphoretic. Elderberry decoction was also documented for fever reduction [12], while their infusions were consumed as an antirheumatic and to treat colic in infants [16]. Their juice has also been used to treat sciatica, headache, dental pain, heart pain, and nerve pain, while the syrup was recommended to treat coughs and colds [18].

For the last few decades, a special attention has been given to elderberries and elderflowers. With the increasing number of studies on this plant and with the revealed potential health benefits related with its composition, industries started to develop new food products and dietary supplements using parts of this plant in order to meet consumers' needs. In Europe, countries such as Austria, Germany, Denmark, and Italy are the major producers of elder plant based products [38]. Currently, elderflowers and elderberries are used in a wide range of products, mainly food- and beverage-derived products followed by nutraceuticals/supplements [16, 19, 20]. One of the main uses of elderberries is the production of juices, concentrates, and natural food colorants, due to their high content in phenolic compounds, with remarkable antioxidant capacity compared to other red fruit juice concentrates [39]. Numerous products containing elderberry juice, pureed, or dried elderberries, such as extracts, syrups, supplements, cosmetics, pies, ice creams, jellies and jams, candies, juices, beers, wines, liqueurs, fruit bars, infusions, and coloring agents, are currently available throughout the world [19–21]. The flowers are commonly used as an ingredient of pastry products as pancakes, muffins, or waffles [16]. In England, elderflowers are considered important wild plant resources, commercially exploited mainly for beverage production (e.g., flavored sparkling water and wine), while in other countries, these flowers are soaked in water and sugar with citrus juices to make a nonalcoholic cordial or for the preparation of infusions [16, 17, 40].

In the last years, consumers' demands have changed remarkably, and diet has been considered not only in providing adequate nutrients, but to have a huge role on human health and well-being [23, 41–43]. The growing demand for natural and healthy food products can be explained by several reasons like transitional health, urbanization and its effect, changing demography with aging population, food security, loss of traditional food cultures, and awareness of deterioration in personal health as consequence of busy lifestyles with poor choices of convenience foods, and competitive food market have converged and propelled for development of

functional foods [44, 45]. Also, insufficient exercise, increased incidence of self-medication, increased level of information from health authorities and media on nutrition, link between diet and health, and scientific developments in nutrition research promote the current interest for healthy food products [46]. In this context, the consumption of the so-called functional foods has been considered as a convenient dietary strategy to address the consumers' demands. The functional food designation was firstly used in Japan in 1984, where scientists studied relationships between nutrition, sensory satisfaction, fortification, and modulation of physiological systems [46]. This concept suffered a few changes over the years with specific rules for the approval of a specific health-related food category being announced [43, 47, 48]. Nowadays, a food can be classified as a functional food, "if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects, in a way which is relevant to either the state of well-being and health or the reduction of the risk of a disease. Health claims are expected to be authorized for functional foods based either on enhanced function (type A claim) or disease risk reduction (type B claim)" [49]. Since elderberries and elderflowers are rich in bioactive compounds, many food products containing them with potential health benefits can be found in the market and, thus, potential candidates for being designated as functional foods.

4 In Vitro Versus In Vivo Assays: Current Challenges

In the last decades, there was an increasing interest to obtain scientific evidences to support the claimed folk medicine benefits resulting from *S. nigra* consumption. In spite of the huge importance to satisfactorily demonstrate that plant extracts or food product affects beneficially one or more target functions in the human body, a wide range of in vitro [50–53] and in vivo assays using animal models [3, 54] were performed. Nonetheless, the information regarding the use of clinical trials is scarce [53].

In vitro studies are often used to predict the health benefits of plants and their formulations. These studies are widely used due to the high amount of results they can provide in a short period, their considerably lower cost when compared with in vivo studies, and also by overcoming the legal and ethical restriction associated with the use of animal models and humans [55, 56]. A striking difference between in vitro and in vivo assays is the absence, in the former, of processes related to absorption, metabolism, and excretion [55]. Additionally, in in vitro studies, the hormonal and nutritional factors, the interaction with other cells, and hypoxia conditions are not usually considered [57]. Efforts have been done to overcome these limitations as in vitro digestion models are able to estimate the stability of phytochemicals under gastrointestinal conditions [58, 59], and, despite their inability to reproduce the complexity of the gastrointestinal tract, they have been used to study the changes in the dietary components throughout digestion [60–64]. In vitro digestion models face great chanllenges that include simulation of oral, stomach, and intestinal conditions, as, for instance, the simulation of the peristalsis and realistic shape and

motility of gastric and small intestines, as well as to evaluate the interactions between ingested compounds and microbiota [60].

Animal in vivo trials resort on different animals to evaluate the toxicological effects and/or potential health benefits. Those are frequently performed with mammals and most often with rat or mice. Animal trials raise ethical concerns, and researchers need to follow ethical codes and decrease the number of animals being used [57]. Although in in vivo animal trials there is a more complex system, these models represent specific aspect of a given human disease and not all of its characteristics [65], and since there is a different body weight/body volume ratio and biokinetic properties, the obtained data does not provide a correlation but gives an estimation of the activity of the extracts in humans [57]. It is worth mentioning that allometric scaling for dose conversion from animal to human studies is often applied, despite being controversial, considering the differences in body surface area [66]. Likewise, interspecies correlations are often used in order to sustain and establish a possible correlation between different models [67].

Despite expensive and time-consuming, human trials offer important and complete outcomes about an extract or compound over human health. Different assays can be performed that range from a basic (experimental) research to clinical and epidemiological research, either designed as interventional or noninterventional ones [68]. Interventional human trials are able to demonstrate the effects of a compound or a preparation, to establish possible side effects, considering the absorption, distribution, metabolism, or elimination parameters [68]. This is achieved by appropriate measures, particularly by random allocation of the patients to the groups, thus avoiding bias in the result. Interventional clinical studies are subject to a variety of legal and ethical requirements, including the Medicines Act and the Law on Medical Devices [68]. Clinical studies ideally include randomization of the patients in order to maximize the homogeneity between groups and to ensure that the patients will be allocated to the different groups in a balanced manner and that possible confounding factors, such as risk factors, comorbidities, and genetic variabilities [68, 69]. Single and double blinding are also suitable methods to avoid bias, in which the former the patient is unaware which treatment he is receiving, while with double blinding, neither the patient nor the investigator knows which treatment is planned [68, 69]. A control group is included in most clinical studies, by receiving another treatment regimen and/or placebo.

To study the contribution of foods, extracts, or specific bioactive compounds in the human health, it is important to analyze the impact of the digestion process, as it will affect the bioavailability and therefore the bioactivity. Bioavailability is defined as the relative amount of an administrated dose that reaches the general circulation and the rate that occurs [70]. This comprises a complex network of phases and parameters. For instance, for absorption to take place, the target molecule must first pass through the membrane that separates the lumen of the stomach and the intestine from the systemic circulation. This membrane is a complex structure made of lipids, proteins, lipoproteins, and polysaccharides that is selectively permeable. Thus, active transport and passive diffusion may take place. After absorption, distribution (to tissue and/or organs), metabolism, and elimination processes occur. Thus, in vivo

studies, either in animal or human assays, share the particularity of considering the phytochemical bioavailability, as their biological activities could be altered by digestive processes. Actually, bioactive components or related metabolites from a diet must be bioavailable to achieve a biological effect in a target organ or tissue (except for the gastrointestinal tract) [71]. Hence, considerations about the bioavailability of *S. nigra* extracts and constituents must be highlighted [72]. Most of the research done so far has been focused on the absorption, metabolism, and urinary excretion of elderberry anthocyanins, as systematically described in Table 1.

To sum up Table 1 data, it can be concluded that research has been mainly focused on the absorption and urinary excretion of the anthocyanin constituents from elderberry formulations upon a single-dose oral administration. Elderberry anthocyanins were absorbed from the intestine to the blood, with low recoveries reported in urine [73–83]. Anthocyanins are both absorbed in their unchanged form or might be hydrolyzed in the gut and metabolized in the liver by glycosylation to increase the solubility prior to excretion via the kidneys [74, 75, 78, 80, 81].

The absorption of phenolic compounds takes place mostly in the small intestines before the microbial degradation. However, these compounds can be partially degraded under gastric fluid conditions leading to a decrease in the extension of their absorption [84]. In respect to glycosylated flavonoids, bacteria in the colon hydrolyze glycosidic bonds, releasing the corresponding aglycones [85]; nonetheless, anthocyanins as cyanidin-3-glucoside or cyanidin-3-sambubioside from elderberry have been also detected in human blood and urine, showing that they can resist to bacterial hydrolysis and be absorbed in the glycoside forms (Table 1).

Sugar moieties of the elderberry phenolic compounds play an important role, as the addition of sugar to elderberry juice delayed anthocyanins excretion [82]. The authors suggested that cyanidin group might be drawn into the enterocyte by its glucose moiety, which is transported by the glucose carrier, and the sugar addition may lead to a saturation of the glucose transporter, therefore the intake of anthocyanins is reduced [82]. Additionally, studies that used standards instead of elderberry formulations concluded that cyanidin-3-glucoside and peonidin-3-glucoside were more bioavailable, stable, and/or cleared more slowly than either the galactosides or arabinosides of cyanidin and peonidin [86, 87]; also, quercetin glycosides were found in plasma much more rapidly following the ingestion of the glucoside form compared with the rutinoside [84].

Most of the plant constituents, and specifically phenolic compounds, are at least partially water soluble, and so their bioavailability is conditioned by the ability to cross the membranes of the intestine [88]. Parameters like partition coefficient; chemical structure, including the number and type of sugar molecules; and microflora seem to play an effective role in the absorption of phenolics [89]. The anthocyanin bioavailability is usually low (recoveries in urine of 0.01–0.4% of the oral dose), and their transport/absorption efficiency is commonly lower than other aglycone phenolics, even though it was reported that structures with more free hydroxyl groups and less methoxy groups can show a decrease of their bioavailability [87], or higher hydrophobic nature of aglycones might increase partitioning into cells and tissues [71].

Table 1 Follow-up of *S. nigra* berry's anthocyanin human bioavailability during one day, after single-dose administration

Population	Product and dose[a]	Dosage (g)	Urine recovery (%)[b]	Main results	Kinetics	Metabolites	Ref.
7: 4M, 3F	4 g of spray-dried juice	0.5	0.05	Low urinary ACN excretion and the low serum levels suggest low ACN bioavailability	Max. excretion after 3–4 h	Detected but not identified	[73]
1M	25 g of extract[c]	1.5	–	ACN absorbed in their glycosidic forms	–	–	[74]
4F	12 g of extract[c]	0.720	0.077	Low rates of ACN absorption and excretion	Max. excretion after 4–6 h	Peo-3-glc, peo-3-sam, peo-glucuronide, cy-3-glc glucuronide	[75]
6	30 or 200 mL of extract[c]	0.278 or 1.852	0.39 and 0.27	Dose-proportional in plasma of major ACN	Total renal clearance of ACN was 196 and 169 $mL.min^{-1}$	–	[76]
4F	12 g of extract[c]	0.720	0.055	The two main ACN detected unchanged in plasma and urine; ACN excreted in urine within 4 h	97.4 $nmol.L^{-1}$ of C_{max} in 72 min; First-order kinetics of ACN plasma elimination	Detected but not identified	[77]
7: 6F, 1M	150 mL of concentrate	3.57	0.053	Only 0.003% of the ingested ACN was excreted as cy-glucuronide	First-order excretion kinetics; Max. excretion after 1 h	Glucuronides ACN derivatives	[78]
6	30 mL of extract[c]	0.147	0.037	ACN absorption was higher comparing intake of elderberry with blackcurrant extract	$t_{1/2}$ of 1.74 h of urinary excretion	–	[79]
4F	12 g of extract[c]	0.720	0.055	Most ACN were excreted in urine during the first 4 h	Elimination of plasma ACN was 1st-order kinetics; $t_{1/2}$ 132.6 min	ACN are absorbed in their unchanged forms	[80]

(*continued*)

Table 1 (continued)

Population	Product and dose[a]	Dosage (g)	Urine recovery (%)[b]	Main results	Kinetics	Metabolites	Ref.
7	150 mL concentrate	3.57	0.06	The low urinary excretion of ACN indicated that a large proportion of ACN are metabolized before entry into the circulation	$t_{1/2}$ of 1.35 h of urinary excretion	ACN metabolized before entry into the circulation	[81]
16: 8F, 8M	11 g of concentrate	1.9	0.012	ACN detected unchanged in urine; sucrose ingestion reduced excretion	Maximum excretion occurred after 1–3 h	Detected but not identified	[82]
8: 4F, 4M	200–400 mL of juice	0.361–0.722	0.033–0.040	Dose-independent urinary excretion of elderberry ACN	–	–	[83]

[a]Single-dose administration
[b]Percentage of the ingested amount
[c]Solvent for extraction not described, *M* male, *F* female, *ACN* anthocyanins, *Cy* cyanidin, *Peo* peonidin, *Glc* glucose, *Sam* sambubioside, C_{max} maximal plasma concentration

Concluding, phenolic compound absorption is mainly modulated by the chemical structure of the aglycones and by the sugar side chains, to which the aglycones are often bound in plants [90, 91]. Also, the vehicle of administration, antecedent diet, sex and gender, and colon microbial population may interfere on bioavailability phenomena [72]. In respect to metabolism of phenolic compounds, the major conjugates derived from kidneys and liver enzymes activities are glucuronides, sulfates, and conjugates with both glucuronide and sulfate moieties [85], being the former the most reported after elderberry oral ingestion (Table 1).

5 Potential Health Benefits

The scientific developments in nutrition research, in evaluation of biological activities, and in prospection of bioactive compounds from natural products, demonstrated by several published evidences, indicate a set of potential health benefits associated with the *S. nigra* berries and flowers [18, 37]. These have been conducted aiming to sustain the empirical knowledge that folk medicine claimed and to identify the molecules that might contribute for disease prevention or even management through a dietary strategy that includes *S. nigra*-based products. It is important to note that when a deregulation occurs in a biological system, several processes are affected. For instance, epidemiological evidences relate diets rich in fruits and vegetables with a reduction in the risk of cardiovascular and neurodegenerative diseases, metabolic processes, and some types of cancer, all of which involve inflammation and oxidative stress [92]. Thus, despite the following topics are discussed separately, it is important to bear in mind that a disease is the outcome of diverse imbalances on a complex network of biochemical mechanisms. This is an advantage in a nutrition research point of view, as the consumption of *S. nigra* bioactive components may act and have a preventive role on a broad spectrum of processes.

Anti-infective, antioxidant, anti-inflammatory, immune-active, colorectal cancer modulation, and antidiabetic activities were selected by the fact that those are of major concern worldwide, being projected millions of affected people (for instance, diabetes, with 300 million before 2025 [93]), but also, these processes are recurrently studied on elderberry and elderflower matrices [93–95].

5.1 Anti-Infective Activity

Several in vitro assays revealed the antimicrobial effects (fungi, bacteria) of aqueous elderberry polar extracts (phenolic-type extracts), against pathogenic microorganisms to humans. For instance, the antimicrobial activity of elderberry extracts was assessed against the growth of common nosocomial Gram-positive and Gram-negative pathogens, as *Streptococcus* from Groups C and G, *Staphylococcus aureus* (methicillin-resistant and methicillin-sensitive), *Streptococcus mutans*, *Streptococcus pyogenes*, *Haemophilus influenza*, *Haemophilus parainfluenzae*, *Branhamella*

catarrhalis, and *Helicobacter pylori* [96, 97]. The results indicated that for the applied concentrations (50–200 mg of standardized elderberry aqueous extract, Rubini®, per mL of liquid broth media), the elderberry extract exhibited antimicrobial activity against the tested bacterial pathogens. At an extract concentration of 100 mg extract.mL^{-1}, the bacterial strains in liquid culture media decreased their growth by >70% in comparison with untreated samples, while at 200 mg.mL^{-1}, it resulted in bacterial development below 1 percent of the originally measured values. Elderflower polar (80% ethanol) extracts (phenolic-type extracts) showed activity against *Bacillus subtilis*, *S. aureus*, *Salmonella typhi*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*, being those activities linked to the presence of chlorogenic and caffeic acids [37, 98]. These studies indicated the potential of *S. nigra* extracts to inhibit certain pathogens in vitro, being required more studies, including on humans, to fully confirm the real impact of such effects in vivo, which bacterial and fungal pathogens are susceptible [99], and also their mechanisms of action.

One of the most studied applications of *S. nigra* berries is related with their potential to inhibit the influenza virus. Influenza virus A or B causes an acute, febrile illness that occurs in outbreaks of varying severity almost every winter. Standardized elderberry extracts reduced hemagglutination and inhibited replication of various human and animal influenza viruses A and B in in vitro assays, as schematically illustrated on Fig. 2 [53, 100].

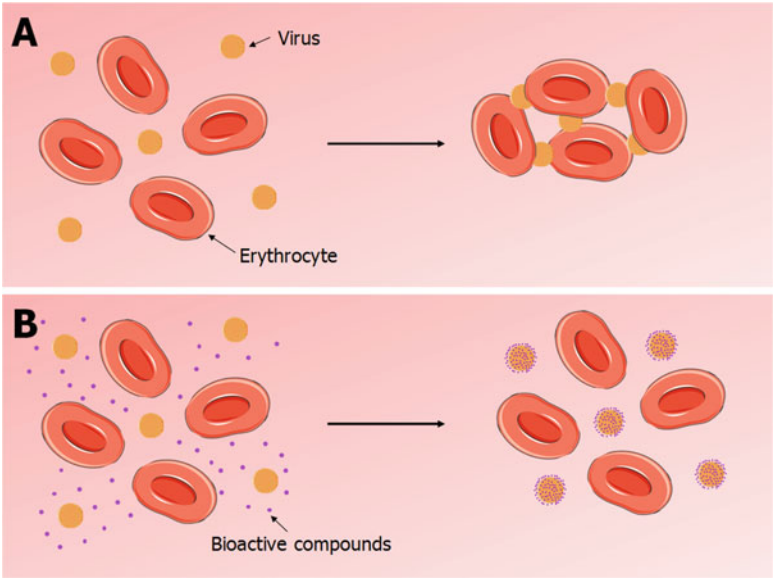

Fig. 2 Virus hemagglutination (**a**) is inhibited by elderberry bioactive compounds (possibly phenolic compounds) that bind to hemagglutinin structure of virus, inhibiting hemagglutination and replication of influenza virus by blocking their ability to infect the host cell (**b**)

Antiviral effects were also reported against HIV-infected peripheral lymphocytes and herpes simplex virus 1-infected human diploid fibroblasts and buffalo green monkey cells [101]. Flavonoids, including quercetin, cyanidin and petunidin, and proanthocyanidins, identified in European elderberry extracts blocked HIV-1 entry and infection in host cells. The action of flavonoids is exerted through binding to HIV-1 virions, thus effectively blocking their ability to infect host cells (Fig. 2b) [52, 102]. *S. nigra* flowers, *Hypericum perforatum* aerial components, and *Saponaria officinalis* root infusions inhibited HIV-1 in vitro and influenza A and B in vitro and in vivo animal trials [99, 103], while methanolic flower extracts exhibited anti-dengue virus serotype-2 activity [104], illustrating the potential of elderflowers' formulations on antiviral activity.

In vivo studies performed on chimpanzees supported the in vitro findings of a standardized elderberry aqueous extract, reporting a reduction of flu-like symptoms by two thirds [105]. Additionally, clinical studies revealed promising results as the flu-related symptoms were reduced [53, 100, 106], as well as a higher inhibition of the hemagglutination on treated groups [53]. The suggested mechanisms of action of elderberry extract on influenza virus are that its bioactive constituents (i) stimulate the immune system, (ii) inhibit the hemagglutination of the influenza virus and thus prevent the adhesion of the virus to the cell receptors (Fig. 2), and (iii) present anti-inflammatory effect. In summary, the antiviral activity of aqueous elderberry polar extracts (phenolic-type extracts) in vitro, in animal models, but also on human trials (standardized aqueous extracts, Sambucol®, at daily doses of 60 mL during 5 days and 2–4 spoons of daily doses during 3 days) indicates possible effectiveness for flu treatment/management in two controlled clinical studies (20 and 40 individuals) [53, 100]. The absence of side effects of this *S. nigra* preparation offers a possibility for a safe treatment for influenza [53, 100], as these results highlight positive indicators on flu prevention and management through a diet rich in *S. nigra*-based formulations.

5.2 Antioxidant Activity

Oxidative stress is a result of an imbalance from the pro-oxidant-antioxidant equilibrium in favor of the pro-oxidants [107]. Tissue destruction and degeneration can result in increased oxidative damage, by such processes as metal-ion release, phagocyte activation, lipoxygenase activation, and disruption of mitochondrial electron transport chains, being accompanied by increased formation of reactive oxygen species [108]. Oxidative stress may result in an increased lipid peroxidation, DNA damage, GSH depletion, and protein damage [108], being a number of disturbs linked to these processes, namely, arteriosclerosis, different types of carcinoma, diabetes, respiratory diseases, and aging, accompanied with inflammatory processes, among others [107].

Antioxidants are believed to protect cells against the detrimental effect of reactive oxygen species (ROS), and the measurement of the antioxidant activity is a common practice for the determination of the potential inhibition or scavenging capacity of

foods against ROS. Several in vitro assays including 2,2'-azino-bis(3-ethylbenzothialzoline-6-sulfonic acid) (ABTS), 2,2-diphenyl-1-picrylhydrazyl (DPPH), ferric reducing antioxidant power (FRAP), and oxygen radical absorption capacity (ORAC), among others, are frequently used to estimate antioxidant capacities in fresh fruits and vegetables [109]. A systematic screening of the total antioxidants in dietary plants reported that elderberry had an overall mean of 4.31 mmol Trolox equivalents (TE).100 g^{-1} fresh fruit being comparable to wild raspberry 3.97 and wild/cultivated blackberry (6.13/5.07, respectively) [110]. Another survey showed that elderberries presented a high antioxidant activity (ORAC value of 14697 μmol TE.100 g^{-1}), which might be linked to the high content of total phenolic compounds but also with the presence of other components as minerals, selenium, vitamins (namely, ascorbic acid and vitamin E), and carotenoids [93, 111–113].

S. nigra bioactive compounds, including anthocyanins, may act as preventive compounds of diverse diseases via antioxidant mechanisms, although the epidemiological evidence is still insufficient, illustrating the need of more research on this topic [114]. Table 2 summarizes the main findings regarding the antioxidant activity of elderflowers and elderberries preparations.

Table 2 Relevant findings regarding antioxidant activity documented on *S. nigra* berry and flower preparations

Preparation	Scope	Main results	Proposed bioactive compounds	Ref.
Elderflowers				
In vitro studies				
Ethanol–water mixture (80:20 v/v): 20–200 °C	AOx of alcoholic extracts of DPPH and β-carotene/linoleic acid methods	No direct correlation between the level of flavonoids in the extracts and their AOx	Flavonols (rutin)	[115]
Aqueous extracts	Ability to inhibit the pro-inflammatory activity of periodontal pathogens	AOx connected with inhibition of the oxidative burst of neutrophils	Flavonols	[116]
Extract (solvent not described)	AOx to neutralize DPPH and hydroxyl radicals	Greater AOx when compared to standards (rutin, quercetin, BHT, and BHA)	Rutin and other phenolic compounds	[117]
Extract (methanol)	Effect of altitudinal variation on the AOx (DPPH)	Samples collected at 670 m had lower IC_{50} values than extracts from 1000 m	Flavonols and hydroxycinnamic acids	[118]

(*continued*)

Table 2 (continued)

Preparation	Scope	Main results	Proposed bioactive compounds	Ref.
Extracts (water and ethanol)	AOx using DPPH	Higher AOx using hot water when compared to ethanol	–	[119]
Methanol:water (80:20, v/v) extracts	Extract and components AOx on-line by cupric reducing antioxidant capacity	Water-soluble groups such as sugars attached to position 3 were less effected on the AOx	Phenolic acids and flavonols	[120]
Aqueous extracts	Antioxidant properties (ABTS, FRAP)	Prolonged extraction in water solvent caused higher antioxidant activity	Correlated with total phenolic content	[121]
Elderberries				
In vitro studies				
Spray-dried juice	Effects of copper and peroxyl-radical-mediated LDL oxidation	Pro-oxidant activity is probably marginal	ACN	[122]
Concentrate and isolated ACN and anthocyanidins	Extracellular and intracellular AOx	The intracellular steady state of oxidized DNA bases was not altered, although AOx was observed extracellularly	ACN or anthocyanidins	[114]
Extract (solvent not described)	ACN potential benefits against various oxidative stressors	ACN conferred significant protective effects in endothelial cells	ACN	[123]
Juice	Hydrogen-donating ability, reducing power, chelating ability, and total AOx	AOx correlated with the TPC	ACN	[112]
Hexane/dichloromethane (1:1) and acetone/water/acetic acid (70:29.5:0.5) extracts	Lipophilic and hydrophilic antioxidant capacities (ORAC)	TPC in general paralleled hydrophilic AOx	ACN	[124]
Purified ACN extract from elderberry concentrate	Radical scavenging activities (DPPH)	Radical scavenging activity weaker than positive control, Trolox	Not necessarily parallel with the anthocyanidin amount	[125]

(*continued*)

Table 2 (continued)

Preparation	Scope	Main results	Proposed bioactive compounds	Ref.
Juice	Scavenging capacity against peroxyl and hydroxyl radicals and peroxynitrite	Nonlinear correlations between sample concentration and AOx were observed	ACN	[126]
In vivo (animal trials) experiments				
Ethanolic extract	One-month diet containing 4% of extract on acute colitis in rats	Lower response to oxidative stress was documented and lower level of primary products of lipoperoxidation-conjugated dienes in the liver and colon	Flavonoids	[127]
Ethanol extract	Dietary supplementation of 8-week diet (dosage of 0.046 $g.kg^{-1}$ body weight), on total AOx levels and blood pressure parameters	AOx was lower after extract supplementation. Blood pressure with induced hypertension was reduced by polyphenolic extract	Phenolic compounds	[128]
Concentrate and cyanidin-3-glucoside	Effects of dietary concentrate and cyanidin-3-glucoside on male rats for 4 weeks	ACN may act synergistically with vitamin C and the antioxidant defense system in sparing vitamin E	ACN	[54]
Human trials				
Spray-dried juice (400 mg or 4000 mg of anthocyanins)	AOx in a cohort of young volunteers (34)	Minor effect AOx capacity	ACN	[129]
400 mL of juice	Elderberry juice intake effects on postprandial plasma AOx in healthy humans (8)	Plasma AOx and TPC were significantly increased 1 h after ingestion	ACN	[83]

ACN anthocyanins, *AOx* antioxidant activity, *TPC* total phenolic content.

Several studies analyzed the antioxidant activity of *S. nigra* preparations using in vitro and in vivo studies (Table 2) [54, 83, 112, 114–127, 129]. These activities are often linked to phenolic compounds, although it is important to point out possible interactions between extract components, including non-phenolic compounds,

influence of extraction parameters [115, 121], and pre- and postharvest conditions [118, 130], which play a critical role on the outcome of the antioxidant data.

Despite the complex composition of elderberry and elderflower matrices, and the possible contribution of other families to the antioxidant action as mentioned above, phenolic compounds, and particularly anthocyanins and flavonols, are assumed to be the key players related to antioxidant activity. The possible protective mechanisms in mammalian cells of elderberry anthocyanin-rich extracts were compared to their extracellular and intracellular antioxidative potential in vitro (ferric reducing ability assay) and in human colon tumor cells [114]. Although extracellularly, these compounds showed strong antioxidant activity; however, the intracellular steady state of oxidized DNA bases was not altered by anthocyanins or anthocyanidins [114]. In this context, the protection of cells may occur through the extracellular reduction of exposure to oxidative and carcinogenic factors, which, indirectly, might also protect the intracellular steady state [114]. Additionally, other authors concluded that the incorporation of elderberry anthocyanins into the plasma membrane and cytosol of endothelial cells conferred significant protective effects against oxidative stressors [123]. These results show that vascular endothelial cells can incorporate anthocyanins into the membrane and cytosol, conferring protective effects against oxidative species.

Dietary phenolic compounds may facilitate homeostasis of oxidative stress once consumed, although during digestion their stability and bioavailability might be compromised [131]. Despite there was a reported loss of elderberry bioactive compounds due to the in vitro digestion process (e.g., losses of anthocyanins of ca. 44%), the colon-digested aqueous extract (resuspended freeze-dried elderberry powder in water, 50 $mg.mL^{-1}$, treated with pepsin, pancreatic-bile salts, and human fecal bacterial culture) was able to reduce the excessive intracellular ROS production (22%) and oxidative DNA damage (46%) in the colon cells at a dose of 1 mg of freeze-dried elderberry $powder.mL^{-1}$ [132]. Concluding, gastrointestinal in vitro digestion of elderberry aqueous extracts decreased radical scavenging activity and oxidative DNA damage, inhibited the oxidant-induced mutagenicity, and inhibited pro-inflammatory pathway in LPS-stimulated macrophages, and regarding the levels of phenolic compounds, there was not a clear consensus, whether a significant reduction or a no effect on phenolic compound levels were reported [131–133].

Beyond the oxidation of lipoproteins, oxidative stress may also play an important role in the etiology of inflammatory bowel diseases. The effect of 1-month diet containing 4% of 70% ethanol elderberry polar extract (phenolic-type extract) in rats with induced acute colitis was evaluated [127]. A decrease on the disposition to colitis was observed at macroscopic level, being the damage score and the myeloperoxidase activity in the experimental group one half of that observed in the control group [127]. Higher activities of lysosomal enzymes (acid phosphatase, cathepsin D) found in the group fed with elderberry diet were considered to be an indication of higher integrity of the colonic mucosa [127]. The lower response to oxidative stress in the experimental group was also documented by a lower level of primary products of lipoperoxidation-conjugated dienes in the liver and colon, accompanied by a higher level of colonic reduced glutathione, and by higher

activities of glutathione-S-transferase in the erythrocytes [127]. The results indicate that long-term diet with the antioxidant active elderberry extract provided a protective effect on the rat colon exposed to acetic acid-induced colitis. Furthermore, it is important to highlight that the nutritional stimulation of the antioxidative defense of the organism could also have beneficial effect on the course of inflammation [127], suggesting that the bioactive compounds present on elderberry and elderflower matrices may have different (indirect) mechanisms to prevent or regulate illness that alter the inflammatory status. As previously stated, a disease is currently accompanied by diverse imbalances, namely, on inflammatory and pro-oxidant processes, which might be managed or prevented through a balanced diet.

5.3 Anti-Inflammatory and Immunological Activities

Inflammation is an important factor involved in different human diseases, including, among others, asthma, diabetes, allergy, multiple sclerosis, cardiovascular diseases, neurodegenerative disorders, metabolic syndrome, hypertension, and some types of cancer [92, 133, 134]. An important process of organism self-protection involves inflammation, aiming to remove harmful stimuli including damaged cells, irritants, or pathogens [135]. Often, the inflammation process involves the activation of monocytes and/or macrophages (located in various tissues), which plays a central role in the regulation of inflammation through the release of several inflammatory cytokines, such as interleukins (IL), tumor necrosis factor (TNF-α), and inflammatory mediators including reactive oxygen species (ROS), nitric oxide (NO), and prostaglandin E2 [135], which are generated by inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX2) [133] (Fig. 3). In this perspective, research conducted on elderberry and elderflower's formulations often connects anti-inflammatory and immunomodulatory activities, being for this reason discussed on the same topic.

Cytokines as TNF-α and interleukins (ILs) are multipotential mediators of the cellular immune system, having a wide variety of biological activities, and they can have favorable or unfavorable effects on the host immune response, depending on their local concentration, where the balance between the production of inflammatory and anti-inflammatory cytokines will be responsible for the outcome and the duration of the immune response [139]. Elderberry aqueous extracts downregulated the expression of IL-1, IL-1β, IL-6, and TNF-α, as illustrated on Fig. 3 [133, 136]. The effect on the induction of pro-inflammatory cytokines' expression by human serum in cell culture (in vitro and ex vivo assays) was also studied. A decrease in the pro-inflammatory activity of blood serum was observed, and the cytokine expression was suppressed for 8 h after a single treatment. An aqueous polar elderberry extract, Sambucol®, modulated the production of four inflammatory cytokines (IL-1β, TNF-α, and IL-6 and IL-8) and one anti-inflammatory cytokine (IL-10) using blood-derived monocytes from 12 healthy donors [139, 140]. An increase of the production of five cytokines (1.3-fold) compared to the control was revealed, which allows to

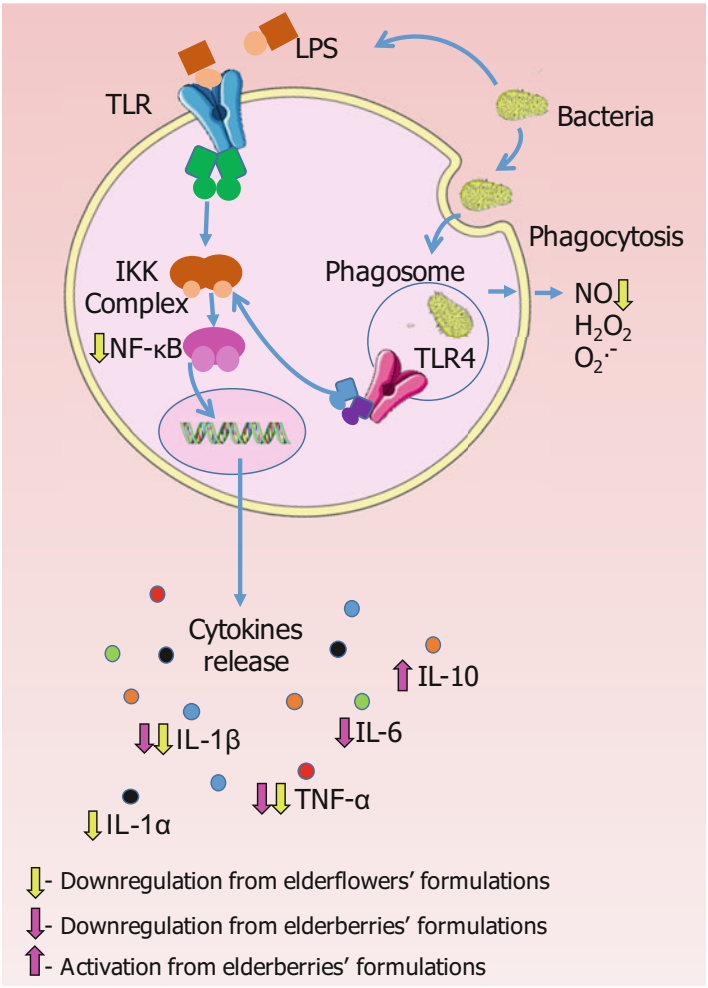

Fig. 3 Inflammation process involving the activation of monocytes and/or macrophages caused by pathogens or another harmful stimulus. Pathogen-derived molecules, including lipopolysaccharide (*LPS*), activate macrophages toll-like receptors (*TLR*) signaling which leads to the production of inflammatory cytokines as interleukins (IL-1β, IL-6 and IL-8) and tumor necrosis factor (*TNF-α*), via activation of IκB kinase (*IKK*) complex and release of nuclear factor nuclear factor κB (*NF-κB*). Elderflower and elderberry bioactive compounds may regulate the expression of marked inflammation mediators [116, 133, 135–137] (Inflammation mechanism adapted with permission from [138])

infer that the increase on inflammatory cytokines production may promote the immune system activation.

Concerning elderflowers, it was reported that aqueous extracts inhibited the macrophage release of pro-inflammatory cytokines and suppressed the activation of neutrophils (as illustrated on Fig. 3) [116]. These effects were linked to the

inhibition of activation of NF-κB and phosphatidylinositol 3-kinase (PI3K), an enzyme that plays a central role in the immunity and inflammation processes. The active ingredients responsible for the anti-inflammatory action of elderflower aqueous extract are unknown, although the ability of aqueous extract to inhibit P13K has been suggested to be mediated at least partially through quercetin. Another study revealed that methanolic and hexane extracts possessed a medium to low inhibitory effect on the biosynthesis of IL-1α, IL-1β, and TNF-α (Fig. 3) [137].

Modulation of NO production by macrophages and dendritic cells may have therapeutic value in inflammatory diseases [135]. Ethanolic elderflower extracts showed an inhibitory activity on NO production in RAW cells and dendritic cells (Fig. 3) [135]. Moreover, phenolic compounds in the range of 0.1–100 μM showed a dose-dependent inhibition of NO production, with quercetin, rutin, and kaempferol as the most potent ones [135]. Complement fixating activity and macrophage-stimulating activity were also observed on pectic elderflower polysaccharides [141, 142]. In vivo studies corroborated the potential elderflower anti-inflammatory, as an 80% ethanol extract had moderate anti-inflammatory activity in rats, inhibiting carrageenan-induced footpad [143].

The available information regarding *S. nigra* berries and flowers' anti-inflammatory and immunological effects on human models is still scarce. As far as we know, only three studies are available, including a few dozen of healthy individuals, and significant alterations were not observed on inflammatory biomarkers (as C-reactive protein, IL-6, and TNF-α), as well as serum lipidic profile, serum antioxidant levels, and cardiovascular disease risk biomarkers between 2 and 12 weeks of treatment with different elderberry-derived formulations with daily doses of 200 mL elderberry concentrate enriched with elderflower 90% ethanol polar extract, 400 mg spray-dried juice, and 500 mg of aqueous polar Artemis® extract [129, 144, 145]. Although, studies conducted on humans with vegetarian diets revealed positive results related to inflammatory and immunological diseases [146], namely, a vegetarian diet during 2 months ameliorated atopic dermatitis by reduction in eosinophils and neutrophils and PGE2 production, on an open-trial study carried out in 20 patients with atopic dermatitis [147]. This indicates that the increased consumption of fruit and vegetables would reduce inflammation and improve clinical outcomes in inflammation-related diseases.

5.4 Colorectal Cancer Modulation

Colorectal cancer is the third most common cancer and the third leading cause of cancer death among men and women, and it is assumed that dietary factors are responsible for 70–90% of the occurrences and diet optimization may prevent most cases [148]. Phenolic components, fiber, minerals, and other bioactive components present in plants may have a positive effect on intestinal cancer prevention, through modulation of DNA damage, oxidative stress, angiogenesis, inflammatory processes, and probably gut microbiota [148], allowing to infer the potential of *S. nigra* on intestinal cancer prevention and/or management.

In vitro assays using a human colorectal adenocarcinoma (HT29) cell line were performed to evaluate the inhibition of colon cancer cell proliferation [149]. Aqueous standardized elderberry polar extract (Artemis International®) suppressed HT29 cell growth with reported growth inhibition (GI_{50}) of 130.3 μg of cyanidin-3-glucoside eq.mL^{-1}. The chemical structure of anthocyanins is known to have a significant impact on their biological activity, and data suggest that non-acylated monoglycosylated anthocyanins are more potent inhibitors of colon cancer cell growth proliferation [149]. Also, the 3,5-glycosylation pattern on anthocyanidins might indicate lower biological activities as compared to 3-monoglycosylation. The chemopreventive potential of berry aqueous acetone extracts was also reported through the induction of quinone reductase (QR) and inhibition of cyclooxygenase-2 (COX-2), which is indicative of anti-initiation and antipromotion properties, respectively [150]. The elevation of phase II enzymes, such as NAD(P)H:quinone reductase, was already linked with the protection against chemical-induced carcinogenesis in animal models, in the stage of promotion and initiation [151]. The *S. nigra* polar extract produced from the 70% aqueous acetone extraction did not exhibit significant activity in either COX assay, though different fractions were screened for inhibition against both COX-1 and COX-2, and those showed great percentage of inhibition of those related inflammatory enzymes [150]. The elderberry fractions containing phenolic compounds (quercetin, quercetin monoglucoside, proanthocyanidins, and epigallocatechin) and non-phenolic ones (i.e., iridoid monoterpene glycosides, sesquiterpenes, and phytosterols, among other unidentified compounds) were active against the initiation and promotion stages of carcinogenesis.

The in vitro studies conducted so far indicate the dietary relevance of *S. nigra* preparations to positively modulate colorectal cancer, by modulation of inflammatory factors, initiation and promotion of tumoral factors, and oxidation processes. The presence of anthocyanins, flavonols, flavan-3-ols, but also non-phenolic compounds, as monoterpene glycosides, sesquiterpenes, and sterols, among other unidentified compounds, was related to the reported activities. The dietary *S. nigra* on cancer prevention and management highlights the need for in vivo studies but also for studies that are able to understand the underlying anticancer mechanisms.

5.5 Antidiabetic (Types 1 and 2) Activity and Related Complications

The term *diabetes mellitus* describes a metabolic disorder of multiple etiologies characterized by chronic hyperglycemia with disturbances of carbohydrate, fat, and protein metabolism resulting from defects in insulin secretion, insulin action, or both [152]. Along with hypertension, dyslipidemia, and obesity, these clinical traits are the main characteristics of this metabolic syndrome. Diabetes is mainly caused by a combination of insulin resistance and β-cell failure (pancreatic cells) and can be treated with insulin-sensitizing drugs that target the nuclear receptor peroxisome proliferator-activated receptor (PPARγ) [153]. Various extracts of elderflowers (hexane, dichloromethane, methanol, ethyl acetate, and water) showed in vitro activation of PPAR(α, δ or γ),

between 20 and 250 μg extract.mL^{-1} without the stimulation of adipocyte differentiation [153, 154]. These extracts had a beneficial effect on insulin-stimulated glucose uptake suggesting that elderflowers produce compounds with bioactivities similar to those of partial PPARγ agonists [154]. Dietary supplementation with elderflower aqueous extracts (100–200 mg.kg^{-1} body weight) and kaempferol (32–64 mg.kg^{-1} body weight) revealed acute (6 h) and sub-chronic (8 days) antidiabetic potential in alloxan-induced diabetic mice by lowering blood glucose and increasing mice weight and catalase serum levels [155]. Elderflower lipophilic extract (dichloromethane extract from 20 mg extract.L^{-1} of solvent) and polar extract (aqueous extract from 250 mg elderflowers.L^{-1} of solvent) led to an increase of the glucose uptake in the presence and absence of insulin (on mouse abdominal muscle), reduction of fat accumulation (*Caenorhabditis elegans* model) [156], and insulin secretion (clonal pancreatic β-cells) [51]. Naringenin and 5-*O*-caffeoylquinic acid partially explained the increase in glucose uptake in primary porcine myotube cultures, while naringenin and kaempferol were linked to the reduction of fat accumulation on *C. elegans* model. Insulin secretion was not stimulated by rutin, lupeol, and *β*-sitosterol [51], while PPARγ (without stimulating adipocyte differentiation) was activated by the fatty acids α-linolenic and linoleic acid, as well as the flavanone naringenin [153, 154]. Quercetin-3-*O*-rutinoside, quercetin-3-*O*-glucoside, kaempferol-3-*O*-rutinoside, isorhamnetin-3-*O*-rutinoside, isorhamnetin-3-*O*-glucoside, and 5-*O*-caffeoylquinic acid were unable to activate PPARγ [153, 154].

Elderflower aqueous extracts also led to diuresis in rats observed from 2 to 24 h [157]. Likewise, the intragastric administration of an elderflower infusion (20 mL.kg^{-1} body weight) or of an extract rich in potassium and flavonoid of the elderflower extract had a diuretic effect in rats [37]. These studies indicate that elderflowers may have diuretic effects in rats, but this has not been established in humans. Diabetes is also often associated with excess body sodium and frequently accompanied by hypertension, which could be reduced by this potential diuretic effect.

Antidiabetic potential of elderberry extracts was also evaluated through in vivo assays using STZ-induced diabetic rats' dietary supplemented with acidified (0.5% HCl) methanol polar extracts (phenolic-type extract), with doses ranging from 28 to 350 mg of extract.kg^{-1} body weight, and dichloromethane extracts (lipophilic-type extracts) with doses of 190 mg of extract.kg^{-1} body weight, during from 4 to 16 weeks of treatment [3, 158–166]. The serum lipidic, glycemic, inflammatory, oxidative, and immunological status of the diabetic rats and control group was monitored. On the tested conditions, no remarkable alterations were observed on the hematological indices, sera, and tissular trace element homeostasis, and the blood sera aminotransferases remained unaltered [3]. In vitro assays revealed that the toxicity of these extracts (9–1995 mg.L^{-1}) using the *Aliivibrio fischeri* bioluminescence toxicity model (light output reflects the cells' metabolic rate) had only a slight impact in the viable bacterial activity [3]. The reduction of the glycemic serum levels and pro-inflammatory interleukin levels (as IL-6 and IL-1β) was documented with the supplementation with these extracts when compared to the diabetic/not supplemented group [3, 158, 160–163]. Hypolipidemic and hypocholesterolemic effects were also reported, through the significant reduction of total and LDL

cholesterol and triglycerides and increase of HDL cholesterol during long dietary supplementations (12–16 weeks) [158, 163], although for supplementations of 4 weeks no alterations were observed on lipidic pattern [3]. Serum oxidative status was altered by increasing the activity of superoxide dismutase (SOD) and glutathione peroxidase (GSH) enzymes and serum total antioxidant activity and reducing uric acid content when compared to diabetic group/not supplemented group [158, 160, 161, 163]. The ability of phenolic compounds, namely, elderberry anthocyanins, to decrease lipid peroxidation and LDL oxidation might be mediated through the uptake of lipid-peroxyl radicals and lipoxygenase activity reduction [158, 166], which is corroborated by the significant decrease of the serum malondialdehyde content (an index of lipid peroxidation) on diabetic rats/supplemented group [160, 161]. Acidified methanol (0.5% HCl) elderberry polar extracts (phenolic-type extracts) also affected the immune system imbalances on diabetic rats, in which the authors beyond linked the potential antidiabetic activity to diabetes mellitus type 2, also connected with type 1, as the latter is an auto-immune illness mediated by the T cells [159, 161–163, 165]. The increment of the population of lymphocytes (T CD3+ and T helper naive CD4+CD45RA+) and the levels of cytokines (TNF-α and IFN-γ), and reduction of monocytes population and levels of fibrinogen (a cardiac risk factor [164]), was reported, when compared to the group of diabetic and not supplemented rats [159, 161–163, 165]. Recent studies, resorted on the use functionalized nanoparticles (NPs) with elderberry extract (acetone:water) on diabetic rats, revealed that functionalized NP administration (tube feeding) increased the muscle and systemic GSH/GSSG ratio and decreased malondialdehyde (MDA) levels and COX-2 expression and metalloproteinases activity also decreased after pretreatment with NPs [167].

Atherogenesis is assumed to be related to the oxidation of low-density lipoprotein (LDL) in the arterial wall, a common complication on obesity that is another component of the metabolic syndrome diabetes, along with hypertension or dyslipidemia. Dietary antioxidants may be helpful in relieving symptoms and complications observed in diabetes patients and inherent complications due to their positive action against the oxidative damage caused by dysregulation of glucose metabolism [168]. Despite the fact that hyperglycemia by itself does not cause diabetic complications, a common endpoint of hyperglycemia-dependent cellular changes is the generation of reactive oxygen intermediates and the presence of elevated oxidative stress, thereby suggesting that oxidative stress plays a crucial role in the pathogenesis of late diabetic complications [169]. The known biochemical mechanisms of hyperglycemia-induced tissue and cell damages come along with, among others, the production of reactive oxygen species inside the aortic endothelial cells [169, 170]. Thus, strategies that reduce the production of reactive oxygen species, or increase its degradation, such as with antioxidant supplementation, could be a possibility to slow down the development and progression of diabetes and its complications [171]. Oxidation resistance of LDL and also the antioxidant potential of plasma and whole blood play an important role in the assessment of the risk for developing atherosclerosis [122]. Elderberry anthocyanin glucosides gave considerable antioxidant protection, both from copper-induced LDL

oxidation and from the attack of peroxyl radicals, and the pro-oxidative properties of the extract were neglected [122].

6 Nutrivigilance System to Improve Consumer Health and Safety

Food industry faces an era of rapid and constant innovation and development of new products, being resorted on the use of innovative ingredients and technologies, and creation of dietary supplements, medical foods, functional foods, and beverages. Within this food industry trend, a nutrivigilance platform that aims to establish "the implementation of the vigilance system" which refers to "novel foods, food supplements, foods that are added to nutritional or physiological substances" and to identify risk situations upon the consumption of these products should be established [172, 173]. Nutrivigilance allows a better management of benefit/risks related to food supplements, fortified foods, and novel foods by identifying possible adverse effects as chemical and toxicological effects; it also assesses their health impacts, and thus, it strengthens the consumer health and safety. This information is the basis for preventive and corrective risk management measures. This section focuses on the nutrivigilance of *S. nigra* formulations at the level of possible toxic components from this matrix, as well as possible drug-botanical interaction. The criteria for these two themes are solely based on the available literature, thus highlighting the need for more data about other parameters covered by nutrivigilance systems.

The reported potential toxicity from *S. nigra* matrix is mainly related with two chemical families, the cyanogenic glucosides and the ribosomal-inactivating proteins. Elderberry leaves, stems, bark, roots, flowers, and unripe fruits contain the cyanogenic glycosides sambunigrin, prunasin, holocain, and zierin (Fig. 4) [6, 174].

Cyanogenic glycosides are considered toxic due to their decomposition into hydrogen cyanide [175]. The consumption of uncooked berries or nonthermally processed elderberry products can result in gastrointestinal disorders, such as vomiting and diarrhea but also nausea, weakness, and dizziness [101, 175]. However this risk is normally easily circumvented since elderberry-based products most often involve thermal processing steps that lead to the degradation of those cyanogenic compounds and elimination of hydrogen cyanide [6, 18, 176, 177].

Those assumptions point out to elderberry extract safety. However, adverse events have been reported, namely, abdominal pain after oral administration of elderberry syrup and knee pain after oral administration of elderberry food supplement. However, those formulations were homemade using not only raw elderberries but also leaves and branches, and the cyanogenic glucosides from branches and/or leaves have been associated with the reported episodes [18]. Despite the lack of enough information on elderberry and flowers toxicity during fetal development, pregnancy, or lactation, the Committee on Herbal Medicinal Products, European Medicines Agency recommendation is to avoid plant parts other than the flowers and ripe berries by pregnant and lactating women, as well as children and adolescents under 18 years of age [18, 37].

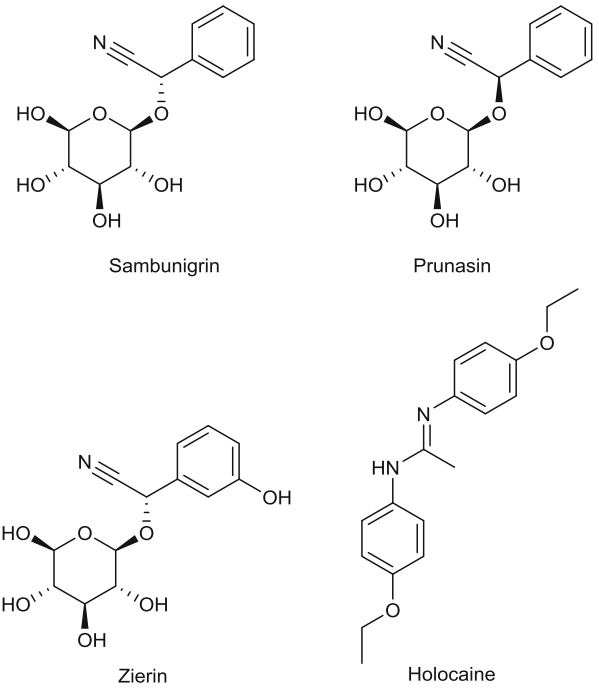

Fig. 4 Cyanogenic glucosides from *S. nigra* L

Another class of components with potential toxicity documented on *S. nigra* are the ribosomal-inactivating proteins, as, for example, agglutinin (SNA-I), a plant glycoprotein reported on elderberries with interesting features on sugar binding sites as it binds reversibly with specific sugars [178–180]. SNA-I is unique among lectins in recognizing sialic acid residues, being a very important probe to detect cell surface sugars, enzymes, and immunoglobulins, leading to many uses in medicine and physiology [178–180]. These include studies in the development of cancer, in the understanding of immunological and allergic disorders, and in the study of the cell surfaces of normal tissues compared to the surface properties of normal and diseased tissues and used to facilitate gene transfer into epithelial cells [17]. However, these proteins may also show some allergenicity, as demonstrated in a study where about 1% of 3668 patients tested ribosomal-inactivating proteins (RIPs) were connected with type-1 allergy to *S. nigra* as evidenced by positive-skin prick or RAST test [181].

The knowledge regarding interactions between dietary supplements and pharmaceutical drugs is rather vague, especially among patients with chronic diseases [182]. Plants, vitamins, and other dietary supplements may augment or antagonize the actions of drugs [183], and thus, drug interactions with foods or dietary supplements may also raise precautions upon *S. nigra* consumption. So far, only a few studies about the interaction of elderberry or flowers (or their extracts) with drugs have been reported, namely, with antidiabetic, analgesic, hypnotic, diuretic, and immune-active drugs [6, 18, 37, 183]. The ability of *Sambucus* flower aqueous polar extracts

(phenolic-type extracts) to potentiate diuresis in in vivo animal models [37, 157] may result in hypokalemia, especially in the case of excessive or prolonged use of any elderflower-derived formulation, including tea. Moreover, elderberry and elderflower decoctions administered orally (2 $mL.kg^{-1}$) to rats caused a reduction of the sleep induction time of pentobarbitone and increased sleeping time when compared with rats administered only with pentobarbitone [183]. No significant effect was observed on the analgesic activity of morphine taken in combination with elderberry or elderflower decoctions for the administrated doses (2 mL of decoction per kg of body weight). According to the Committee on Herbal Medicinal Products, the evidence of any interaction between elderberry (decoctions) and pentobarbitone appears to be limited to this study, being concluded that it is not known whether this effect will occur in humans, but even if it does, it is unlikely to be clinically relevant [18]. To sum up, no robust data is still available to support *S. nigra* drug-botanical interactions.

7 Final Remarks

S. nigra plant parts have been used in folk medicine since ancient times to treat a wide variety of diseases only based on experience and empirical knowledge; however the scientific advances improve the knowledge related with the detailed chemical composition of elderberries and flowers and the systematic in vitro assays allowed to unambiguously demonstrate their potential, as antibacterial, antiviral, antioxidant, anti-inflammatory, antidiabetic, and anticancer agents. It is important to point out that the quantities are necessary to promote the reported biological effect, i.e., the dose is effect-dependent, and for the studies reported above, the doses are in the order of few $\mu g.mL^{-1}$ to $mg.mL^{-1}$, depending on the biological effect and type of tested extract.

Nonetheless, the extension of these biological effects for animal testing (which, with allometric scaling would allow a better extrapolation to humans) is limited, and the extension to human clinical trials is even more scarce. These would be fundamental steps in future research to prove the efficiency of the *S. nigra*-related extracts or products on human health and well-being, strongly supported in scientific evidence rather than in folk knowledge. Finally, the use of *S. nigra*-based products will require a careful nutrivigilance system that would allow maximizing the understanding of their benefits by the adequate tuning of formulations, to prevent any problems arising from the presence of cyanogenic or allergenic compounds.

Acknowledgments Thanks are due to FCT/MEC for the financial support to the QOPNA research Unit (FCT UID/QUI/00062/2013) and CICECO (FCT UID/CTM/50011/2013), through national funds and where applicable co-financed by the FEDER, within the PT2020 Partnership Agreement. Bioactive Compounds and Health Benefits of Jamun (*Syzygium cumini*)

78

Shalini S. Arya, Kakoli Pegu, and Prajakta D. Sadawarte

Contents

Abstract

Jamun (*Syzygium cumini*) which is indigenous to India has been used as medicine for century in Unani and Ayurveda. The presence of bioactive compounds such as alkaloids, tannins, phenols, lipids, flavonoids in its leaves, barks, fruits, stems,

and roots contributes to rich source for nutrition and medicine. Due to the presence these compounds, they have pharmacological effects with antioxidant, antimicrobial, antidiabetic, central nervous system activity (CNS), chemo preventive, anti-inflammatory, antiallergic, hepatoprotective, etc. properties. Jamun is commonly known for its antidiabetic activity as it has been proved to be the most promising nutraceutical value. Bioactive compounds are result of evolution, which may be due to specific requirement of plant by mutualistic or antagonistic interaction with another organism. The structure, action, metabolism, and health benefits of bioactive compounds in Jamun have been discussed in this article.

1 Introduction

Bioactive compounds are secondary metabolites, natural products that originate from plant, animal, marine, and microorganisms. The early day's plant extracts have been used for the treatment of various diseases. And it is the secondary metabolites of plants that have pharmacological and toxicological effects in animal and human being. Secondary metabolites are produced in the phase subsequent to plant growth and development besides primary biosynthesis. They are not needed for daily functioning of plant and hence are regarded as side tracks. Several of them are found to hold various types of important functions in the living plants such as protection, attraction, or signaling. Metabolic pathways of plant leading to the formation of bioactive compounds are shown in Fig. 1 following the erythrose-4-phospahtes and pyruvate primary pathways. Production of secondary metabolites by plants is a result of evolution of mutualistic (volatiles, pigments, and floral scent for attracting pollinators) or antagonistic (synthesis of toxic compounds as a function of defense against pathogens and herbivores) interaction [1]. They are classified in three classes: (i) phenolics are aromatic components that are synthesized through acetyl-coA and erythrose-4-phosphate; (ii) terpenes are organic compounds that have the properties that contribute in scent, flavor, and color; and (iii) nitrogen-containing secondary metabolites (e.g., alkaloids) that are synthesized primarily from amino acids. It has been proposed that by utilizing the bioactive properties of secondary metabolites by animal can provide a "treatment" against various challenges that perturb homeostasis in animals [2]. Secondary metabolites that are toxic at higher dose have pharmacological effects on humans and animals. Thus, bioactive compounds in plants benefit humans and animals.

Jamun is plum fruit with sour-sweet taste, dark purple in color, and round-oval shape. The color is due to the presence of anthocyanins and astringency taste due to tannins. Jamun is known by many names: botanical name (i.e., *Syzygium cumini*), Indian blackberry, jambu, mahaphala, javaplum, Malabar plum, duhat, jambolana, mesegerak, jamelonguier, jamblang, jambolana, and kavika [3]. Jamun is native to

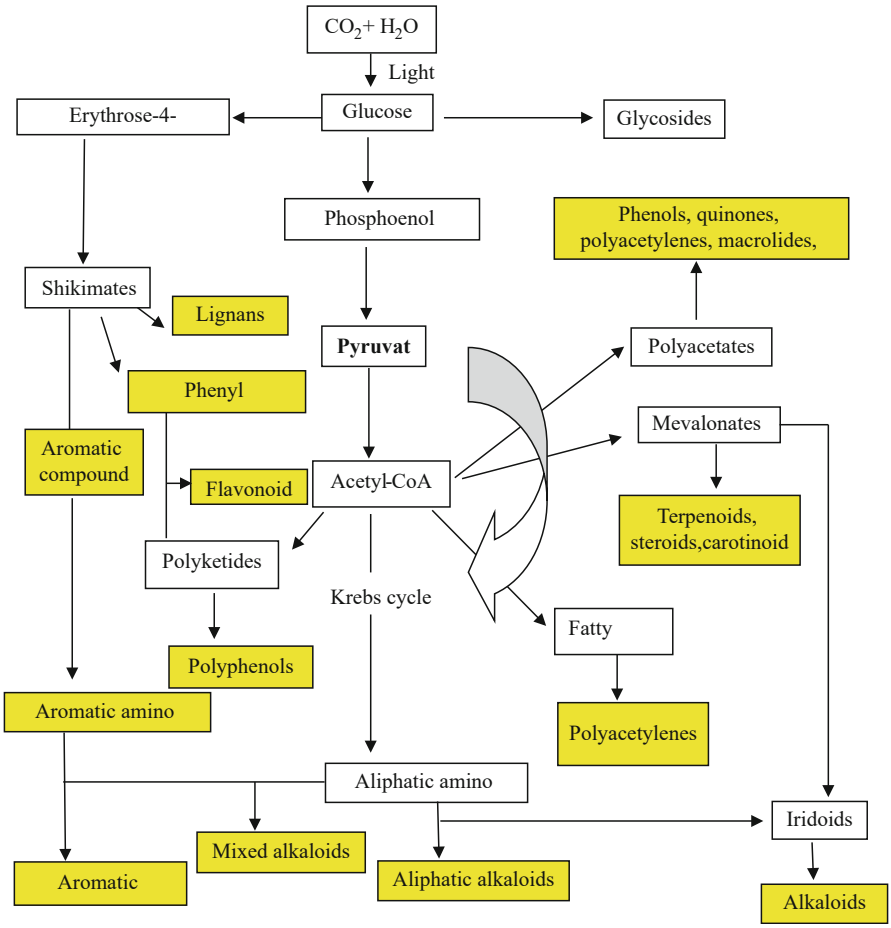

Fig. 1 Biosynthetic pathways of plants. The highlighted compounds are the bioactive compounds produced during plant metabolism [5]

Asian subcontinent, adjoining regions of Southeast Asia, China, and Queensland and nowadays is found growing throughout Eastern Africa, South America, and Madagascar [4]. The extracts of Jamun parts have been in use for the prevention and curing of various diseases and today it is commonly known for its antidiabetic property. Parts of Jamun having therapeutic effects are shown in Fig. 2. It has the ayurvedic characteristics such as RASA: Kasaya (astringent), amal (sour), madhura (sweet); ANURASA (aftertaste): kasaya (astringent); VIRYA (potency): sheeta (cold); VIPAKA (resultant): katu (pungent). The extracts of Jamun parts have been in use for prevention and curing of various diseases for centuries and today it is commonly known for its anti-diabetic property. Essential oils like lauric acid, phytochemicals, lipids, phenols with their antioxidant property, present in Jamun, have medicinal effects.

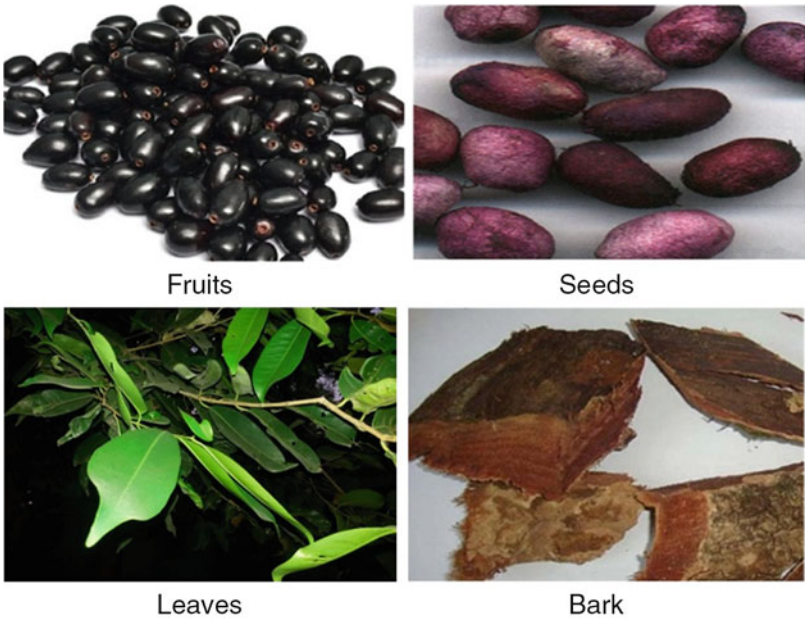

Fig. 2 Parts of Jamun (*S. cumini*)

2 Phytochemistry of Jamun

Jamun is a rich source of phytochemicals in its different parts: leaves, fruit, seed, and bark. Studies have showed the presence of phenols, flavonoids, alkaloids, glycosides, steroids, cardiac glycosides, saponins, terpenoid, and tannins in the Jamun leave extract [6, 7]. The abundant constituents of the oils in Jamun leaves are: α-pinene (32.32%), β-pinene (12.44%), trans-caryophyllene (11.19%), 1, 3, 6-octatriene (8.41%), delta-3-carene (5.55%), α-caryophyllene (4.36%), and α-limonene (3.42%) [8]. *Syzygium cumini* seed oil was found to contain lauric (2–8%), myristic (31.7%), palmitic (4–7%), stearic (6.5%), oleic (32.2%), linoleic (16.1%), malvalic (1.2%), sterculic (1.8%), and vernolic (3.0%) acids [9]. Chemicals present in different parts of Jamun are given in Table 1.

References [10] and [11] have reviewed the potential food application of Jamun and its health benefits and found that seed and pulp have antidiabetic, antimicrobial, and antioxidant effect, leaf buds have laxative effects, and bark have wound healing effects. They also suggested that these beneficial contributions of Jamun parts are due to the phytochemicals present in them. References [12] and [13] have reported that phenolic, flavonoid, and anthocyanin content of Jamun have antioxidant activity that involves inhibition of α-glucosidase which is vital in management of diabetes mellitus and prevention of oxidative cell damage.

Table 1 Phytochemicals present in the Jamun plant

Sr. No	Plant part	Chemicals present
1	Seeds	Jambosine, gallic acid, ellagic acid, corilagin, 3,6-hexahydroxy diphenoylglucose, 1-galloylglucose, 3-galloylglucose, quercetin, *β*-sitosterol, 4,6 hexahydroxydiphenoylglucose
2	Stem bark	Friedelin, friedelan-3-*α*-ol, betulinic acid, *β*-sitosterol, kaempferol, *β*-sitosterol-D-glucoside, gallic acid, ellagic acid, gallotannin and ellagitannin, and myricetin
3	Flowers	Oleanolic acid, ellagic acids, isoquercetin, quercetin, kaempferol, and myricetin
4	Fruit pulp	Anthocyanins, delphinidin, petunidin, malvidin-diglucosides
5	Leaves	*β*-sitosterol, betulinic acid, mycaminose, crategolic (maslinic) acid, n-hepatcosane, n-nonacosane, n-hentriacontane,noctacosanol, n-triacontanol, n-dotricontanol, quercetin, myricetin, myricitrin and the flavonol glycosides myricetin 3-O-(4″-acetyl)-*α* L-rhamnopyranosides
6	Essential oils	*α*-Terpineol, myrtenol, eucarvone, muurolol, *α*-myrtenal, 1, 8-cineole, geranyl acetone, *α*-cadinol and pinocarvone

3 Bioactive Compounds Present in Jamun

3.1 Terpenes

Terpenes are organic compounds that consist of multiple isoprenes units. They have neuroprotective, antitumorigenic, anti-inflammatory, antimicrobial, antifungal, antiviral, antihyperglycemic, and antiparasitic activities [14, 15]. They also have pleasant odor; thus, they are used in fragrance, as additives in food, and pharmaceutical industries. Terpenes present in *S. cumini* are monoterpenoids (1,8-cineole, linalool oxide, mysterol, nerol, terpinolene, α-terpeneol, α –terpenene, β-phellandrene, β-pineme, citronellol, eugenol) and triterpenoids (acetyl oleanolic acid, betulinic acid, oleanolic acid, β-sitosterol), and some of the structures are shown in Fig. 3. 2- and 3-Hydroxylated products of 1,8-cineole catalyzed by the isoenzyme CYP3A4 were seen in human liver microsome and also in human urine, and two other hydroxylated products 7- and 9-hydroxy-1,8-cineole are also identified [16].

3.2 Flavonoids

The basic structure of flavonoids is made up of skeletal diphenylpropane, namely, two benzene rings linked by a three-carbon chain that forms a closed pyran ring (heterocyclic ring containing oxygen) with benzenic ring. Therefore, their structure is also referred to as C_6-C_3-C_6 and is subdivided into six group by the nature of C_3 elements: Flavones, isoflavones, flavanones, flavanols, anthocyanidins, and flavan-3-ols [17]. Flavonoids are known for its antioxidant with anti-inflammatory activity in human and its bioavailability, metabolism, and biological activity of flavonoids depend upon the

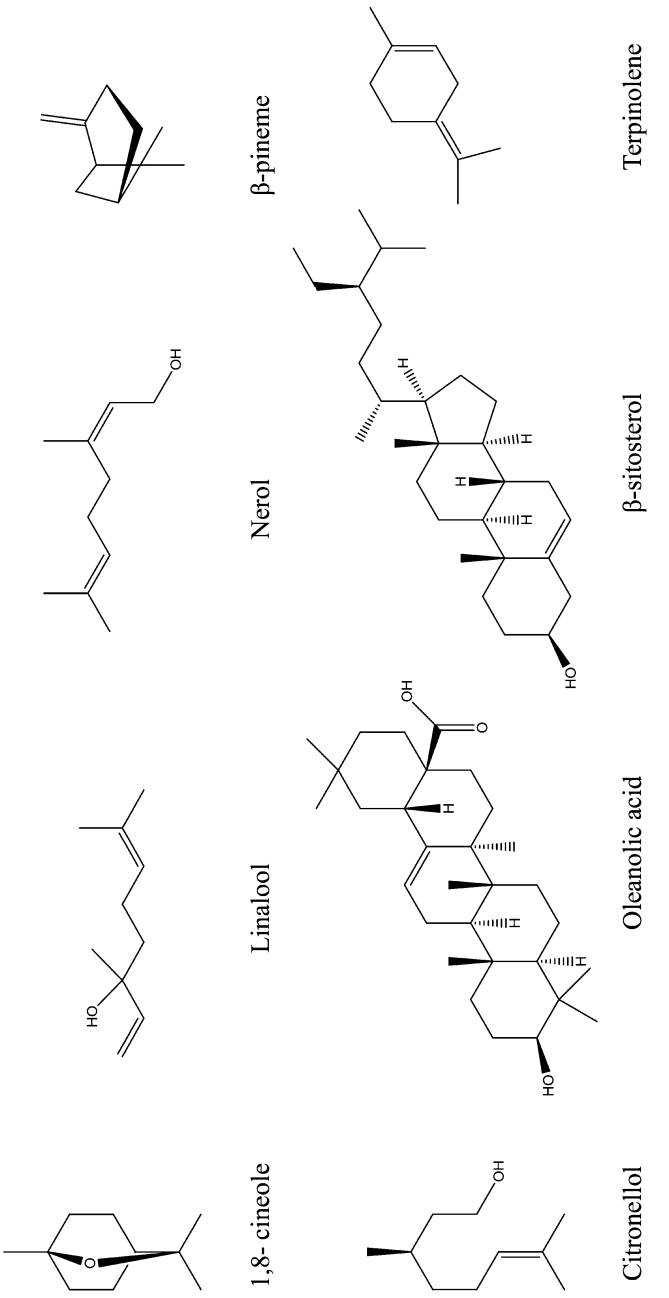

Fig. 3 Structures of terpenes found in Jamun (*S. cumini*)

configuration, total number of hydroxyl groups, and substitution of functional groups about their nuclear structure [18]. Flavonoids present in *S. cumini* are isoquercetin, kaempferol, malvidin (anthocyanin), malvidin-3-O-L-d-laminaribioside (anthocyanin), malvidin-diglucosides (anthocyanins), myricetin, petunidin, quercetin (flavanol), anthocyanins, cyanidin diglycoside, delphinidin-3-o-ß-d-gentiobiosid (anthocyanin), and delphinidin-3-gentiobioside (anthocyanin) as shown in Fig. 4. Of all the flavonoids present, anthocyanin is the most important one as they are present in bulk and the color of *S. cumini* fruit is the result of this. Reginold jebitta and Jeyanth allwin [19] have studied the phytochemicals content of *S. cumini* pulp powder considering different drying methods and found that freeze drying at −40 °C giving high antioxidant property (70.4–75.8%) and total flavonoids (104.8 mg quercetin equivalents (QE)/g), total phenolic (13.99 mg GA equivalents/g), and anthocyanin (7.56 mg/g) content. Five anthocyanins are yield on hydrolysis of anthocyanin (0.08%) as detected by HPLC and confirmed by mass spectral analysis namely delphinidin (20.3%), cyanidin (6.6%), petunidin (24.6%), peonidin (2.8%), and malvidin (44.2%) [20].

Kay [21], Clifford, and Brown [22] have describe the metabolism of anthocyanin in human by flavonoid metabolism as reference. The flavonoid found in food may be either in glycosylated (e.g., aglycones) or nonglycosylated form or in both form. The nonglycosylated flavonoids are absorbed through passive diffusion, and the glycosylated form may follow either of the two routes: sodium-glucose co-transporter (transport of intact glucoside, e.g., anthocyanin) in the enterocytes or at the brush border via lactate phlorizin hydrolase. And the metabolites that are not hydrolyzed by these enzymes are absorbed in the colon but influence the liberated aglycones.

3.3 Other Bioactive Compounds in Jamun (*S. cumini*)

Other bioactive compounds in Jamun are: lipid (lauric acid, linoleic acid, N-hentriacontane, N- nanocosane, stearic acid), alkane (malic acid and citric acid); phenols like ferulic acid and caffeic acid, and phenylpropanoid (cinnamaldehyde, cinnamyl acetate, cinnamyl alcohol, coniferyl alcohol) as shown in Fig. 5.

3.4 Summary of General Metabolic Pathway of Bioactive Compounds in Human Anatomy

When we talk about metabolism of bioactive compounds in human body, we come across two terms: bioavailability and bioefficacy. Bioavailability refers to the extent and rate at which the active moiety (drug or metabolite) enters systemic circulation, thereby accessing the site of action. Bioefficacy is a unit of measure to show levels of effectiveness by measuring changes to anatomy and physiology. Bioavailability of bioactive compounds is affected by its structure (high molecular weight compounds need to be broken down so that they can pass through intestinal cells) and transport mechanism (facilitated diffusion, passive diffusion, and active transport) [23]. In order to gain beneficial effects of bioactive compounds, they must have to be bioavailable.

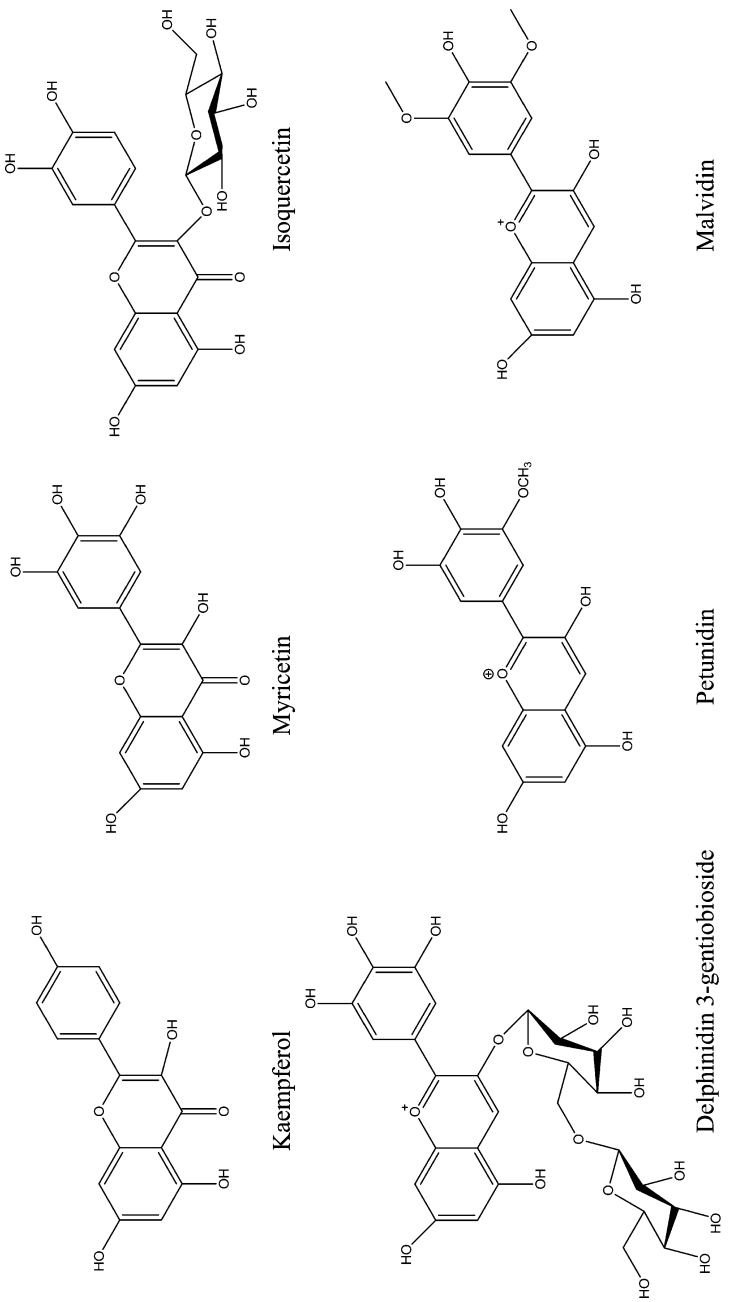

Fig. 4 Structures of some flavonoids found in Jamun (*S. cumini*)

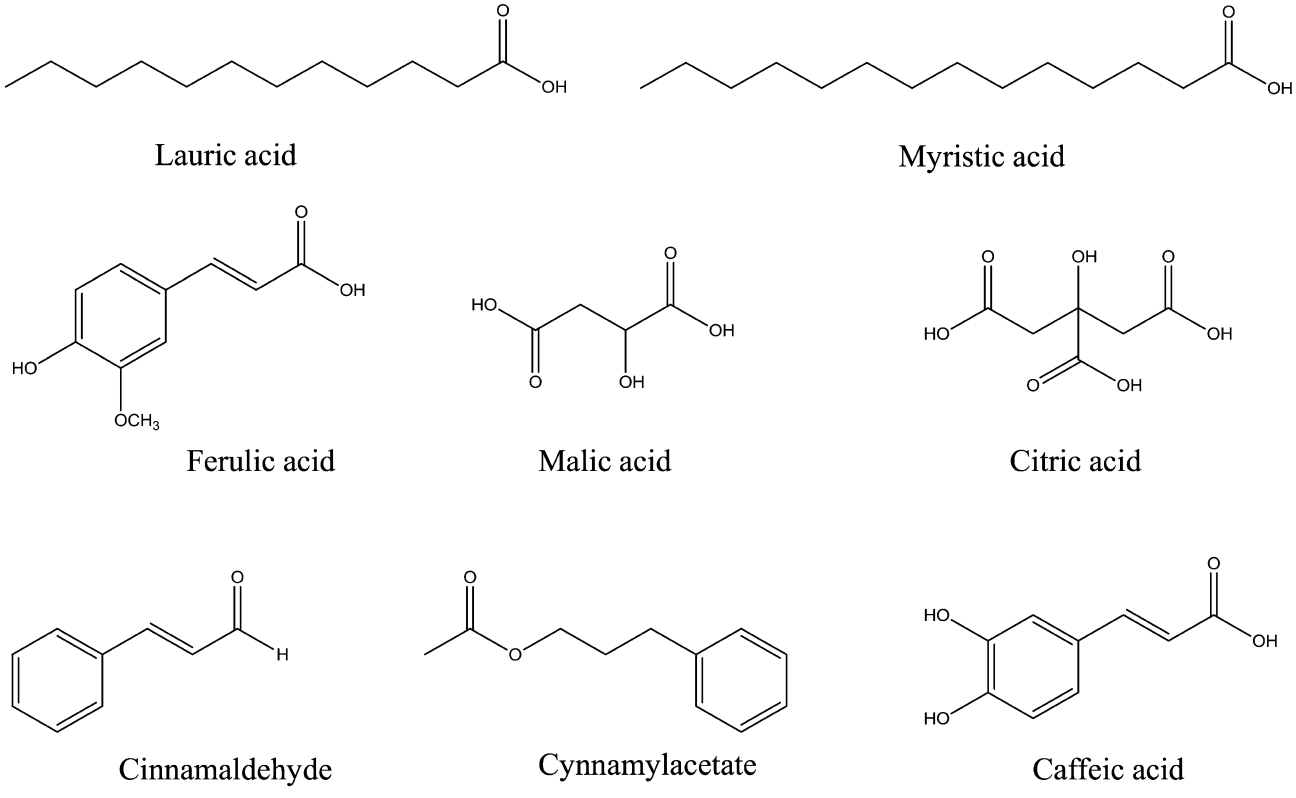

Fig. 5 Structure of other some bioactive compound present in Jamun (*S. cumini*)

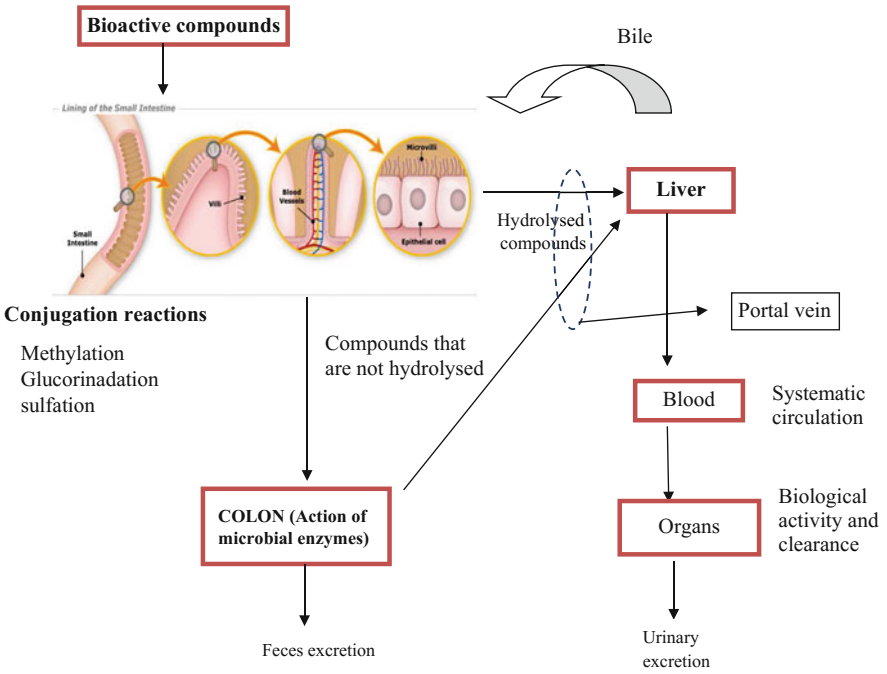

Fig. 6 General metabolic pathway of bioactive compounds in lower human anatomy [25, 26]

Fig. 6 shows the general metabolism in human anatomy. Vinicyus Teles Chagas et al. [24] have reported that some bioactive compounds target different metabolic pathway, thus acting as potential pharmacological tools. In contrast to this they have taken the example of compounds like myricetin, quercetin, rutin, ellagic, and gallic acids act as potential multitargeted drugs on distinct pathways of cardiometabolic disorder. Quercitin and rutin act as an antihypergylcemic by blocking L-type calcium channels on pancreatic beta cell, thus affecting the stimulus of insulin secretion. Vasorelaxant and antihypertensive properties of quercetin and myricetin follow the same path. Myceritin also acts on GLUT-4 expression in both skeletal muscles and adipose tissue and thus improves glucose homeostasis. Phenolic acid such as ellagic acid and gallic shows antihyperlipidemic properties by inhibiting 3-hydroxy-3 methly-glutaryl (HMG)- CoA reductase in liver.

4 Health Benefits of Jamun

4.1 Antimicrobial Activity

Patel and Rao [27] have studied on the antimicrobial activity of Jamun pulp. Four grams positive bacterial cultures, namely, MTCC-430 *Bacillus cereus* (BC), MTCC-121 *Bacillus subtilis* (BS), MTCC-106 *Micrococcus luteus* (ML), and MTCC-435

Staphylococcus epidermidis (SE), and four grams negative bacterial cultures, namely, MTCC-443 *Escherichia coli* (EC), MTCC-109 *Klebsiella pneumoniae* (KP), MTCC-735 *Salmonella paratyphi* (SP), and MTCC-734 *Salmonella typhi* (ST) were used. They found that the diethyl ether extracts gave high percentage of inhibition against the organisms tested followed by methanol, water, acetone, and ethyl acetate fractions. The activity of the extracts varied along with the fruits maturity, signifying the role of maturity indices in accumulation of bioactive compounds.

Gowri SS et al. [6] have reported that the Jamun leaves extracted in methanol and water have inhibitory activity against clinical isolates of the gram negative bacteria such as Salmonella *enteritidis*, *Salmonella typhi*, *Salmonella typhi A*, *Salmonella paratyphi A*, *Salmonella paratyphi B*, *Pseudomonas aeruginosa*, and *Escherichia coli* and Gram positive bacteria *Bacillus subtilis* and *Staphylococcus aureus* using the disc diffusion method. And the methanol extract was more potent than the aqueous extract.

The activity of leaf oil and leaf methanol extract was found to be quite comparable with the standard antibiotics screened under similar conditions as shown in Table 2. They can be considered as good sources of natural antioxidants and antimicrobial compounds and can be incorporated into the drug formulations [7].

Table 2 Inhibition zones formed by *S. cumini* leaf essential oil and leaf extracts compared with standard antibiotic [7]

	Diameter of inhibition zones (mm/50 µL)									
	S. cumini leaf oil		Leaf extracts				Standard antibiotics			
Microorganisms	5%	1%	A	B	C	D	Tob 10 µg	Gen 10 µg	Oflo 10 µg	Cip 10 µg
1. *Bacillus cereus*	20	18	18	14	12	10	28	32	34	30
2. *Enterobacter Faecalis*	22	20	24	14	11	10	26	32	32	26
3. *Salmonella paratyphi*	20	18	22	16	11	10	25	30	28	30
4. *Staphylococcus aureus*	26	24	26	15	11	10	26	28	24	24
5. *Escherichia coli*	14	10	25	16	14	12	30	36	32	34
6. *Proteus Vulgaris*	24	20	24	18	12	11	26	30	24	32
7. *Klebsiella pneumonia*	20	18	20	14	12	11	26	32	32	36
8. *Pseudomonas Aeruginosa*	24	22	22	20	16	14	26	24	32	28
9. *Serratia Marcescens*	20	16	24	20	14	12	24	32	30	30

A: methanol; B: ethyl acetate; C: chloroform; D: petroleum ether
Tob: tobramycin; Gen: gentamicin sulfate; Oflo: ofloxacin; Cip: ciprofloxacin
Used concentrations: 50 µL of 5% and 1% essential oil samples in DMSO and 50 µL of 10 mg/mL of plant extracts

4.2 Antidiabetic Activity

Diabetes is a serious, chronic disease that occurs either when the pancreas does not produce enough insulin (a hormone that regulates blood sugar, or glucose) or when the body cannot effectively use the insulin it produces. Globally, an estimated 422 million adults were living with diabetes in 2014, compared to 108 million in 1980. The global prevalence (age-standardized) of diabetes has nearly doubled since 1980, rising from 4.7% to 8.5% in the adult population. Diabetes caused 1.5 million deaths in 2012. Higher-than-optimal blood glucose caused an additional 2.2 million deaths, by increasing the risks of cardiovascular and other diseases.

Ethanol Jamun seed extract showed dose-dependent decrease in blood glucose level in streptozotocin-induced diabetes in rats and also reported the antiulcer activity of *S. cumini* against both physical (4 h pylorus ligation and 2 h cold restraint stress)- and chemical (aspirin and alcohol)-induced gastric ulcers in rats [28].

Glycemic control is beneficial in preventing the incidence and progression of diabetic retinopathy, loss of vision, and need for photocoagulation treatment (Diabetes Control and Complications Trial Research Group, 1993). Treatment with *S. cumini* (200 mg/day of lyophilized powder for 8 weeks) prevented the development of diabetic cataract even after 4 months of alloxan (120 mg/kg, s.c) administered in rats. Rathi et al. [29] and Kumar et al. [30] have reported antidiabetic activity against streptozotocin-induced diabetes in rats by isolated compound "mycaminose" from *S. cumini* and suggested to have same the mechanism of action of glibenclamide.

Oral administration of 50 and 100 mg/kg of the aqueous and methanol extracts of roots, leaves, seeds, and barks of *S. cumini* in alloxan monohydrate (150 mg/kg i.p.) induced diabetic male Sprague Dawley (SD) rats for 21 days resulted in the significant reduction in blood glucose level and biochemical parameters in dose-dependent manner [31].

4.3 Cardioprotective Effects

Researchers have found that when blood sugars are abnormally high (hyperglycemia), this activates a biological pathway that causes irregular heartbeats – a condition called cardiac arrhythmia – which is linked to heart failure and sudden cardiac death. According to the World Heart Federation, people who suffer from diabetes are two to four times more likely to develop cardiovascular disease, compared with people who do not have diabetes.

Diabetic heart disease is caused by complex interactions that result from overlapping mechanisms. The driving forces are related to the phenotypic alterations associated with diabetes – in particular hyperglycemia, dyslipidemia, hypertension, and possibly insulin resistance. A vicious circle develops, leading to increased oxidative stress and enhanced glycosylation of several humoral and vessel wall proteins, which cause endothelial damage and structural changes in coronary arteries. In turn, damaged endothelial cells can become a source of ROS and reactive nitrogen species in addition to other factors, sustaining the proatherosclerotic

process. Production of reactive oxygen takes place through oxidative and non-oxidative phosphorylation with increase in glucose levels [32].

Traditionally, seeds of *S. cumini* have been using in Ayurveda and Unani to fight against diabetes. Neha Atale et al. [33] have studied the antiglycoxidative potential of *S. cumini* and the effect of *S. cumini* on glucose-induced cardiac stress was observed, and they found that the methanol seed extract showed maximum potential compared to aqueous and ethanol extract and significantly suppresses the glucose-induced stress on H9C2 cardiac cell lines by inhibiting glycation event.

4.4 Anti-Inflammatory and Wound Healing Activity

It is found that the formulations (10% ointment) of crude ethanolic extract of *S. cumini* bark have accelerated healing effect than the control Nitrofurazone ointment (0.2% w/w, Smithkline – Beecham) in deep burn wound model in Albino rats [34].

Kumar et al. [35] have studied on the anti-inflammatory effect of ethyl acetate and methanol extract of Jamun seed. The extracts did not exhibit any mortality up to the dose level of 2000 mg/kg and were found to significantly inhibit the carrageenan-induced rat paw edema, a test which has significant predictive value for anti-inflammatory agents acting by inhibiting the mediators of acute inflammation. The methanol extract at the dose of 400 mg/kg showed high significant anti-inflammatory activity at 4 h, where it caused 62.6% inhibition, as compared to that of 5 mg/kg of diclofenac sodium.

The root bark ethanol extract that are successively fractionated into petroleum ether fraction, chloroform fraction, n-butanol fraction, and methanol fraction was evaluated for the antinociceptive activity by acetic acid-induced writhing test and formalin-induced nociception test, and anti-inflammatory activity was screened by carrageenan-induced rat paw edema, cotton pellet-induced granuloma formation, and adjuvant-induced arthritis in rat models [36]. At 400 mg/kg b.w., p.o. dose petroleum ether fraction significantly inhibited 54.28% writhing response and 73.77% formalin induced nociception in mice. The fraction with same dose showed significant 79.31% inhibition of carrageenan-induced rat paw edema, 57.78% antiproliferative effect, and 77.93% inhibition of adjuvant-induced arthritis. And the fractions were isolated with three compounds, namely, β-sitosterol, stigmasterol, and lupeol, which may be the bioactive compound responsible for anti-inflammatory and antinociceptive activity.

Leaves extract of Jamun showed the presence of chemical compounds with hydroxyl, ester, carbonyl, and olefin functionalities, exhibited dose-dependent anti-inflammatory activity in acute and chronic models, and showed anti-inflammatory activity in acute carrageenan paw edema and chronic granuloma pouch model administration in albino rats [37]. Considering that anthocyanins decrease cellular lipid peroxidation and oxidative stress, Donepudi et al. [38] hypothesized that Jamun fruit extract administration could protect against cholestatic liver injury and inflammation in mice; they found that Jamun fruit phytochemicals decreased hepatic inflammation and oxidative stress and protected against hepatocellular injury in mice.

4.5 Chemo Preventive

Chemotherapy used in prevention of and treatment for tumorigenesis is likely to cause many side effects. Extracts of Jamun can be used as an alternative for chemotherapy as they have shown to have cancer preventive properties and antioxidant potential as in Table 3.

4.6 Antiviral Activity

The leave extracts of *S. cumini* were studied for antiviral activity against two emerging and re-emerging contagious diseases: buffalo pox and goat pox. An outbreak of buffalo pox in domestic buffaloes, with high morbidity and significant production loss, was recorded in the Aurangabad district of Maharashtra State in India in November 2003 associated with several cases of human infection, particularly in milkers working with the affected herd [22]. Goat pox (SGPX) is probably the most serious infectious disease of small ruminants in many parts of the world. The disease inflicts substantial losses in terms of reduced productivity and lower quality of wool and leather [39]. *Syzygium cumini* leaves at their maximum nontoxic concentrations 1999.73 ± 0.50 μg/ml had inhibition 99.92% and 98.52%, in all cytopathic effect (CPE) inhibition assays for goat pox and buffalo pox, respectively [40, 41].

Influenza virus is a major health concern as they are significant human respiratory pathogens that cause both seasonal, endemic infections and periodic, unpredictable pandemics [42]. Annual outbreaks of influenza occur regularly in temperate regions of the world with remarkable seasonality, defined by peak incidence in the colder months of the year [43]. Avian influenza virus (H5N1), an RNA virus that belongs to the family *Orthomyxoviridae*, emerged in Hong Kong in 1997, causing severe human disease. It is the serotype that causes bird flu in 2004. Hot and cold aqueous leave and bark extracts of *S. cumini* showed significant virucidal activity (100% inhibition) that was further confirmed in virus yield reduction assay (~98–99% reduction) and by egg based in ovo assay against avian influenza virus (H5N1 serotype) [44].

4.7 Antiallergic Activity

HPLC analysis revealed that hydrolyzable tannins and flavonoids are the major components of the extract. Aqueous extract of *S. cumini* showed antiallergic effect and indicate that its antiedematogenic effect is due to the inhibition of mast cell degranulation and of histamine and serotonin effects, whereas the inhibition of eosinophil accumulation in the allergic pleurisy model is probably due to an impairment of CCL11/eotaxin and IL-5 production [45].

4.8 Central Nervous System (CNS) Activity

Kumar et al. [46] have worked on the Central Nervous System Activity of ethyl acetate and methanol extracts of Jamun (*S. cumini)* seed on Albino mice in rota rod

Table 3 Chemo preventive effects of phytochemicals in Jamun and its mechanism

Sr. No	Agent	Chemo preventive effects and the mechanisms operating
1	Oleanolic acid	(1) inhibits tumor promotion in mouse skin; (2) inhibits azoxymethane (AOM)-induced colonic aberrant crypt foci and multicrypt aberrant crypt/foci in a dose-dependent manner; and (3) suppress preneoplastic lesions induced by 1, 2-dimethylhydrazine in rat colon
2	Ellagic acid	(1) inhibitor of benzo[a]pyrene-induced pulmonary adenoma and 7,12-dimethyl benz[a]anthracene-induced skin tumorigenesis in Swiss mice; (2) topical application as well as oral feeding of ellagic acid rendered protection against 3-methylcholanthrene-induced skin tumorigenesis in mice and decreased tumor incidence, number of tumors, tumors per mouse, and tumors per tumor bearing animal; (3) topical application of ellagic acid and oral before a tumor-initiating by B[a]P 7,8-diol-9,10-epoxide-2 and promotion with 12-O-tetradecanoylphorbol-13-acetate inhibits the number of skin tumors per mouse; (4) ellagic acid applied topically to female CF-1 mice 20 min before each 12-O-tetradecanoylphorbol-13-acetate (TPA) treatment inhibits the inductions of epidermal ornithine decarboxylase activity, hydroperoxide production, and DNA synthesis and also inhibits the promotion of skin papillomas and carcinomas in the two-step initiation-promotion protocol; (5) topical application of ellagic acid simultaneously with phorbol-12-myristate-13-acetate (PMA) or mezerein results in significant protection against 7, 12-dimethyl-benz[a]anthracene-induced skin tumors in mice; (6) the levels of aryl hydrocarbon hydroxylase (AHH) activity in skin and liver and the extent of 3H–BP-binding to skin, liver, and lung DNA are decreased; (7) it is a potent inhibitor of benzo[a]pyrene metabolism and its subsequent glucuronidation, sulfation, and covalent binding to DNA in cultured BALB/C mouse keratinocytes; and (8) inhibits the epidermal microsomal aryl hydrocarbon hydroxylase (AHH) activity and of benzo[a]pyrene (BP)-binding to both calf thymus DNA in vitro and to epidermal DNA in vivo
3	Gallic acid	(1) inhibits the TPA-induced inductions of epidermal ornithine decarboxylase activity, hydroperoxide production, and DNA synthesis and also inhibits the promotion of skin papillomas and carcinomas in the two-step initiation promotion protocol; (2) administering (0.3% to 1%) for 20 consecutive weeks from 4 weeks of age to the male TRAMP mice (a transgenic mice develops prostate tumor) caused decrease in tumor cells with decreasing the proliferative index with a concomitant increase in the apoptotic cells which were due to decrease in the expression of Cdc2, Cdk2, Cdk4, Cdk6, cyclin B1, and E
4	Quercetin	(1) possesses chemopreventive effects against 4-nitroquinoline 1-oxide-induced and its administration during both initiation and post-initiation phases caused a significant reduction in the frequency of tongue carcinoma in rats. It reduced the polyamine levels and the proliferation; (2) prevents N-nitrosodiethylamine-induced lung tumorigenesis in mice; (3) prevents 20-methyl cholanthrene-induced cervical neoplasia in virgin Swiss albino mice by increasing the antioxidant enzymes, decreasing DNA damage, and the lipid peroxidation; (4) decreases DMBA-induced DNA damage; (5) in a bioengineered human gingival epithelial tissue, quercetin was observed to inhibit BaP-DNA binding, a precursor for mutagenesis and carcinogenesis; (6) quercetin supplementation prevents benzo(a) pyrene-induced carcinogenesis by modulating the antioxidants and decreasing lipid peroxidation, aryl hydrocarbon hydroxylase, gamma glutamyl transpeptidase, 5′-nucleotidase, lactate dehydrogenase, and adenosine deaminase

(*continued*)

Table 3 (continued)

Sr. No	Agent	Chemo preventive effects and the mechanisms operating
5	Myricetin	(1) inhibits epidermal growth factor (EGF)-activated cell transformation of JB6 cells by modulating DNA binding and transcriptional activity of STAT3, and mitogen-activated protein kinase (MEK)and inhibitor of neoplastic cell transformation and MEK1; (2) prevents TPA-induced transformation, PKC activation, and c-jun expression in mouse fibroblast cells; (3) suppresses UVB-induced skin cancer by targeting Fyn in JB6 cells. Inhibits Akt survival signaling and induces bad-mediated apoptosis in immortalized human keratinocytes (HaCaT cells); (4) inhibits matrix metalloproteinase 2 protein expression and enzyme activity in colorectal carcinoma cells and also down-regulates phorbol ester-induced cyclooxygenase-2 expression in mouse epidermal cells by blocking activation of nuclear factor kappa B; and (5) inhibits polycyclic aromatic hydrocarbon-DNA adduct formation in epidermis and lungs of SENCAR mice
6	Kaempferol	(1) possess inhibitory effects on phosphatidylinositol 3-kinase and inhibits the neoplastic transformation
7	Betulinic acid	(1) topical application of betulinic acid inhibited the TPA-induced inflammation and decreased the levels of ornithine decarboxylase; and (2) markedly inhibited the 7, 12-dimethylbenz[a]anthracene and TPA promoted skin tumor formation in mice
8	β- sitosterol	(1) topical application of β-sitosterol inhibited the TPA-induced inflammation; (2) induces dose-dependent growth inhibition, induces apoptosis, and suppresses the expression of β-catenin and PCNA antigens in human colon cancer cells (COLO 320 DM cells); and (3) β-sitosterol supplementation reduced the number of aberrant crypt and crypt multiplicity in DMH-initiated rats in a dose-dependent manner with no toxic effects
9	Delphinidin	(1) suppresses 12-O-tetradecanoylphorbol-13-acetate (TPA)-induced cell transformation and activator protein-1 transactivation in the JB6 cells by blocking the phosphorylation of protein kinases in the extracellular signal-regulated protein kinase (ERK) and the c-Jun N-terminal kinase (JNK) signaling pathways; (2) possess chemopreventive effects against prostate carcinogenesis in both in vitro and vivo study models; and (3) suppresses ultraviolet B-induced cyclooxygenases-2 expression through inhibition of MAPKK4 and PI-3 kinase

Source: Farrukh Aqil et al. [20], Swami et al. [10]

and actophotometer at the dose level of 200 mg/kg and 400 mg/kg. They found that the safety dose for animals to be 2000 mg/kg body weight and both the extracts significantly decrease the spontaneous loco-motor activity in mice thus, indicating central depressant effect.

4.9 Hepatoprotective Activity

Medicine or drugs that are consumed during medication to treat various diseases may get accumulated in the liver and cause damage, for example, paracetamol if given as overdose causes acute liver damage. Das and Sarma [47] have studied hepatoprotective effect in albino rats by ethanol extract of Jamun pulp (*S. cumini*). Hepatotoxin used was paracetamol. They found that the rats (induced with paracetamol) have significant hepatoprotective activity against hepatotoxin when 100 and 200 mg/kg/day of Jamun pulp extract was given, thus showing reduction in the serum levels of all liver enzymes and total bilirubin and an increase in the total protein.

5 Conclusion

Studies have suggested the usefulness of the bioactive compounds present in Jamun (*S. cumini*) in enhancing the various ailments associated with cardiac, gastrointestinal, and nervous system. Their pharmacological effects are attributed due to the presence of flavonoids, terpenes, alkaloids, phenyl propanoids, tannins, and lipids. Out of all the pharmacological effects, the antidiabetic activity is important. Based on their pharmacological property, this traditional medicinal plant with rich source of bioactive compounds must be carried out for further studies on phytochemical and clinical research for safer drugs that can be used for treating various diseases.
