This reference works series provides a platform for all information on plant metabolites and phytochemicals, their chemistry, properties, applications, and methods. By the strictest definition, phytochemicals are chemicals derived from plants. However, the term is often used to describe the large number of secondary metabolic compounds found in and derived from plants. These metabolites exhibit a number of nutritional and protective functions for human welfare such as colorants, fragrances and flavorings, amino acids, pharmaceuticals, hormones, vitamins and agrochemicals. Besides food, fibers, fuel, cloth and shelter, a vast number of wild plants can hence provide important sources for medicines, especially in developing countries for their traditional health systems. Natural products have inspired and provided the foundation to the bulk of FDA-approved compounds and there is tremendous increase in natural products and natural products derived compounds that have been registered against many prevailing diseases. Natural product industry has shown tremendous growth and is expected to continue to do so in the near future. The present series compiles reference information on various topics and aspects about phytochemicals, including their potential as natural medicine, their role as chemo-preventers, in plant defense, their ecological role, their role in plants as well as for pathogen adaptation, and disease resistance. Volumes in the series also contain information on methods such as metabolomics, genetic engineering of pathways, molecular farming, and obtaining metabolites from lower organisms and marine organisms besides higher plants. The books in the series are hence of relevance in various fields, from chemistry, biology, biotechnology, to pharmacognosy, pharmacology, botany, or medicine. Each volume is edited by leading experts and contains authoritative contributions by renowned authors.

Preface

We are pleased to present a three-volume treatise on *Bioactive Molecules in Food*. Bioactive molecules are present in all the food consumed, and we come to know more about them with the availability of more and more sophisticated tools and techniques. As we know more about benefits of food and their molecules, we intend to improve food quality and fortify the food for human welfare and disease prevention. The aim of the book is to present the state of information about bioactive molecules present in various foods we consume daily and their effect on our physical and mental state of body. The concept of functional foods is of recent origin, but in old civilizations like that of China and India, there are sayings about consumption of selected food and their effect on well-being. Hence history is being revisited.

Selection, cultivation, and domestication of plants for human welfare is almost 9,000 years old which is reconfirmed by a recent report from the remains of domesticated crop plants at an archaeological site in southwest Amazonia. Plants are easy to catch as compared to animals, and hunting evolved with evolution of tools and techniques with civilization of men. Thus, fruits, tubers, bulbs, and seeds were easy to gather and consumed by early men. Some chapters deal with cultivation and improvement of nutrients in food plants.

The debate about food consumption and vegetarian and nonvegetarian diet or consumption of various fatty acids in oils (PUMA, MUFA, omega-3 FA) may continue for another decade. With the new facts coming out day by day, this scene changes for a while and then resets to a new concept. Whatever the diet regimen, a cereal, a pulse, and a fruit make an essential part of all diets. With the advent of new and sophisticated technology, more information available about bioactive molecules present in the food, best combinations of food components to meet nutritional requirement, and fate of ingested molecules as well as their beneficial effects are known. Major part of the book is devoted to this aspect.

Consumers have become very attentive to quality, safety, and health benefits of food. This has direct repercussion on food industry to develop such foods, especially processed and packaged foods and particularly in terms of calorie, quality, nutritional value, and bioactive molecules present in them. Market for nutraceuticals and food supplements is growing at rapid pace with increasing middle class in developing countries and elderly population in developed countries. Therefore, this is a very

timely compilation of information about bioactive molecules present in our daily food.

Longevity of life is associated with preferential consumption of selected food which can prevent diseases and keep overall health in good condition. Society is keen to know the benefits of organic food, bioactive molecules present in their food, and possibility of food fortified with beneficial molecules. This has direct impact on research related to this field by all those involved in food cultivation, processing, and production including meat quality. Certain chapters are devoted to this aspect in the book.

The book is divided into ten parts (I. Favorable Regimen for Good Health and Epidemiological Studies, II. Proteins and Their Biological Activity, III. Lipids and Their Biological Activity, IV. Food Carbohydrates and Derived Compounds, V. Food Carotenoids, VI. Food Polyphenols, VII. Functional Foods, VIII. Agricultural Practices and Food Quality, IX. Methods of Food Analysis and Quality Control, X. Miscellaneous Case Studies) covering entire gamut of bioactive molecules present in daily foods like cereals (carbohydrates), pulses, and other sources (peptides and proteins); oils (lipids, fatty acids); mushrooms, wine, and fruits and vegetables (carotenoids, polyphenols, etc.); and fibers and methods of analysis of some foods. Concepts like French paradox, Mediterranean diet, healthy diet of eating fruits and vegetables, vegan and vegetarian diet, and functional foods are also described with suitable case studies.

Well-recognized international specialists in their respective fields of research contributed these chapters. This book will be useful to all those working in the field of botany, phytochemistry, pharmacy, drug delivery, molecular biology, forestry, biotechnology, industrial food, and medical products. This work is arranged in 78 well-illustrated chapters.

Because of the voluminous work for the treatise, this project was spread over almost 2 years, from concept to print. We would like to acknowledge the cooperation, patience, and support of our contributors who have put their serious efforts to ensure the high scientific quality of this book with up-to-date information. We are thankful to the staff at Springer, namely, Drs. S. Costa, S. Blago, and N. Clifford, for their professional support in this project.

About the Editors

Prof. Dr. Jean-Michel Mérillon received his M.Pharma. (1979) and Ph.D. (1984) from the University of Tours, France. He joined the university of Tours as assistant professor in 1981, became associate professor in 1987. In 1993 he moved to the faculty of Pharmacy, University of Bordeaux, France, accepting a position as full professor. He has been the director of the research group on biologically active plant substances for over 15 years, at the Institute of Vine and Wine Sciences (University of Bordeaux, France), which comprises 25 scientists and research students. The group has been working on phenolic compounds from vine and wine for many years, mainly complex stilbenes and their involvement in health. He is involved in developing teaching on plant biology, natural bioactive compounds and biotechnology. Prof. Mérillon has published more than 160 research papers in internationally recognized journals, and has coedited books and reference works on secondary metabolites and biotechnology. In 2004, he founded the technology transfer unit "Polyphenols Biotech", providing support for R&D programs for SMEs and major groups from the cosmetic, pharmaceutical, agricultural and health-nutrition sectors. He is currently the manager of this unit.

Prof. Dr. Kishan Gopal Ramawat is former professor and head of the Botany Department, M.L. Sukhadia University, Udaipur, India, and has a long-standing research experience. He received his Ph.D. in Plant Biotechnology in 1978 from the University of Jodhpur, India, and afterward joined the university as a faculty member. In 1991, he moved to the M.L. Sukhadia University in Udaipur as associate professor and became professor in 2001. He served as the head of the Department of Botany (2001–2004, 2010–2012), was in charge of the Department of Biotechnology (2003–2004), was a member of the task force on medicinal and aromatic plants of the Department of Biotechnology, Government of India, New Delhi (2002–2005), and coordinated UGC-DRS and DST-FIST programs (2002–2012).

Professor Ramawat had done his postdoctoral studies at the University of Tours, France, from 1983 to 1985 and later returned to Tours as visiting professor (1991). He also visited the University of Bordeaux 2, France, several times as visiting professor (1995, 1999, 2003, 2006, 2010) and, in 2005, in Poland in an academic exchange program (2005). Through these visits in France, Prof. Ramawat and Prof. Mérillon established a strong connection, which has resulted in productive collaborations and several book and reference work publications.

Professor Ramawat has published more than 170 well-cited peer-reviewed papers and articles and edited several books and reference works on topics such as the biotechnology of medicinal plants, secondary metabolites, bioactive molecules, herbal drugs, and many other topics. His research was funded by several funding agencies.

In his research group, Prof. Ramawat has supervised doctoral thesis of 25 students. He is an active member of several academic bodies, associations, and editorial boards of journals. Botany Department, M.L. Sukhadia University, Udaipur, India.

health benefits. However, their role in human health is dependent on interactions with the gut microbiota and conversion to further bioactive compounds. Dietary compounds have a wide range of effects that are play after the binding and/or interaction between these compounds and other molecules.

Keywords
Phenolic compounds · Polyphenols · Polyamines · Biogenic amines · Fruit · Vegetable · Beverage · Gut microbiota

Abbreviations

ADC	Arginine decarboxylase
AIH	Agmatine iminohydrolase
BHA	Butylated hydroxyanisole
BHT	Butylated hydroxytoluene
CANSpdDC	Carboxynorspermidine decarboxylase
CANSpdDH	Carboxynorspermidine dehydrogenase
CPA	N-carbamoylputrescine amidohydrolase
DAO	Diamine oxidase
DDC	3,4-dihydroxyphenylalanine decarboxylase
DOPA	3,4 Dihydroxyphenylalanine
E4-P	Erythrose 4-phosphate
GABA	γ-aminobutyric acid
HDC	Histidine decarboxylase
ODC	Ornithine decarboxylase
PAL	Phenylalanine ammonia liase
PAO	Polyamine oxidase
PEP	Phosphoenolpyruvate
POD	Peroxidase
PPO	Polyphenol oxidases
ROS	Reactive oxygen species
SAM	S- adenosylmethionine
SAMDC	S-adenosylmethionine decarboxylase
SAT1	Spermidine/spermine-N1-acetyltransferase
SPDS	Spermidine synthase
SPMS	Spermine synthase
TAL	Tyrosine ammonia-lyase
TGFβ	Transforming growth factor-β

1 Introduction

Phenolic compounds are natural compounds occurring in vegetables, fruits, and derived beverages that humans usually obtain through the diet. Structurally, phenolic compounds are characterized by the presence of one or several phenolic groups, conferring their complexity and allowing to classify them into flavonoids

(polyphenol) or nonflavonoids. This large class of compounds has a well-established antioxidant activity and other beneficial effects on human health. However, its interactions in human body after dietary ingestion should be better addressed. Polyamines are a group of aliphatic amines, ubiquitously produced by humans and vegetables. These compounds are able to bind to many cellular macromolecules as DNA, RNA, and proteins, conferring them the ability to promote cell proliferation, signal transduction, and membrane stabilization. Phenolics and polyamines are produced by vegetables, whereas in human organism, only polyamines can be synthesized. Considering the possible interaction of these dietary components, this chapter summarizes some phytochemicals in vegetables and the mechanisms by which these compounds are absorbed, metabolized, and affect physiological functions in humans.

2 Phenolic Compounds

Phenolic compounds constitute an important class of secondary metabolites, notably in function of its recognized antioxidant activity, which confers quality to the food and beneficial potential to the human health. These antioxidants neutralize the free radicals, by inhibiting or interrupting the chain of initiation/propagation of oxidative reactions, converting the free radicals in less harmful molecules, and repairing the oxidative damages in human cells [1]. The functionality and stability of these phytochemicals in the human body depends not only on the quantity, but also on their location in the food matrix, on the presence of other bioactive compounds and, mainly, on the binding and/or interaction between these compounds and other molecules. Interestingly, the interaction between polyphenols and biogenic amines metabolic pathways should be pointed out to emphasize the role of both molecules on the healthy or harmful characteristics of a certain food.

Derived from the secondary plant metabolism, phenolic compounds constitute a group of molecules with a diversity of functions in the plant and different beneficial properties for health [2, 3]. The antioxidant activity and the free radical scavenging capacity depend on their structure, number of hydroxyl groups (OH), and position on the structure [4]. These heterogeneous characteristics are due to the complex metabolic pathways, for which the phenolic compounds are synthesized and the shikimic acid pathway is the most important biosynthesis route [5, 6].

By the shikimate pathway (present in plants and absent in animals), the binding of primary metabolism occurs (carbohydrates production) with the secondary metabolism, using phosphoenolpyruvate (PEP) and erythrose 4-phosphate (E4-P, pentose phosphate pathway), synthesizing chorismate, from which aromatic amino acids can be synthesized, such as phenylalanine, tyrosine, and tryptophan. These amino acids are used in the protein synthesis and also as secondary metabolites, including phenolic compounds, meaning that this biosynthetic route may contribute as a regulator of primary and secondary plant metabolism [7–9].

Phenylalanine ammonia lyase (PAL, EC 4.3.1.24) catalyzes the synthesis of trans-cinnamic acid from phenylalanine. In addition to PAL, tyrosine ammonia-lyase

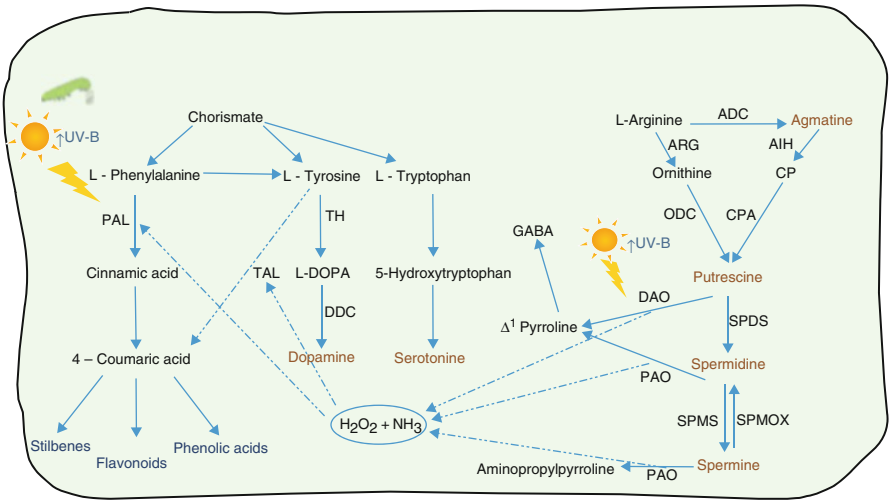

Fig. 1 Interaction of polyamines (primary metabolism) and phenolics (secondary metabolism) in plants. *ARG* arginase, *AIH* agmatine iminohydrolase, *ADC* arginine decarboxylase, *ODC* ornithine decarboxylase, *CP* N-carbamoyl putrescine, *CPA* N- carbamoylputrescine amidohydrolase, *SPDS* spermidine synthase, *SPMS* spermine synthase, *SPMOX* spermine oxidase, *DAO* diamine oxidase, *PAO* polyamine oxidase, *PAL* phenylalanine ammonia-lyase, *TAL* tyrosine ammonia-lyase, *TH* tyrosine hydroxylase, *DDC* dopa decarboxylase

(TAL, EC 4.3.1.23) has great importance in this metabolic route. TAL catalyzes the conversion of tyrosine to p-coumaric acid [9]. On the other hand, tyrosine can be converted in DOPA (3,4 dihydroxyphenylalanine) by tyrosine dehydrogenase and in dopamine (biogenic amine) by 3,4-dihydroxyphenylalanine decarboxylase (DDC; EC 4.1.1.27) (Fig. 1). Both enzymes are relevant for phenolic compounds synthesis.

On the other hand, phenolic compounds may be oxidized by polyphenol oxidases (PPO, EC 1.10.3.2 or EC 1.14.18.1), such as tyrosinase, cresolase, catecholase, diphenolase, and phenolase or peroxidases (POD, EC 1.11.1.7). High POD and PPO activities are related to the production of browning compounds, with decrease in the commercial value and loss of quality, including nutritional benefits [10, 11]. To reduce oxidative enzymes activities (PPO and POD), it may be necessary for physical and chemical treatments to guarantee the nutritional quality, maintaining some phytochemicals contents, such as anthocyanins, other phenolic compounds, and antioxidant activity [12–15].

3 Polyamines/Biogenic Amines

Polyamines and/or biogenic amines have been investigated in food matrixes due to the interest regarding the nutritional paradox and its possible action as antioxidants. Previous studies indicate a possible role of polyamines, present abundantly in food of the Mediterranean diet, with the prolongation of human life [16]. Diamines, as

putrescine, and polyamines (spermidine and spermine) can be formed through the decarboxylation of specific amino acids [17]. The biogenic amines are the aliphatic, cationic organic compounds of low molecular weight, formed after amino acids decarboxylation or by amination and transamination of aldehydes and ketones [18, 19], which include histamine, serotonin, tyramine, 2-phenylethylamine, tryptamine, putrescine, cadaverine, and agmatine. In raw vegetables, the amines are formed from the activity of some enzymes, while in processed foods they are formed by the action of microorganisms, which can often be, depending on the amine found and on the concentration, a signal of contamination [20].

In mammals, the polyamines can be synthesized, obtained from the diet, or even, synthesized for intestinal microorganisms. In mammals, the putrescine biosynthesis comes from the ornithine decarboxylation by the action of ornithine decarboxylase (ODC) (EC 4.1.1.17), forming the diamine putrescine. In plants, there is an alternative pathway by the action of arginine decarboxylase (ADC, EC 4.1.1.19) forming putrescine. Arginine is decarboxylated by ADC, forming agmatine, which forms N- N- carbamoylputrescine by the action of agmatine iminohydrolase (AIH, EC 3.5.2.12). The enzyme N-carbamoylputrescine amidohydrolase (CPA, EC 3.5.1.53) converts the product in putrescine (Fig. 1). The suppression of the putrescine synthesis from arginine could increase the amount of available arginine available for the synthesis of nitric oxide, which is responsible for maintaining normal vascular functions [21], retarding the progression of vascular diseases associated to the aging process. The diamine cadaverine is produced by microorganisms and originated from lysine decarboxylation, by lysine decarboxylase [22].

Both in mammals and plant cells, spermidine is formed from the addition of aminopropyl group in putrescine by the action of spermidine synthase (SPDS, EC 2.5.1.16) and spermine synthase (SPMS, EC 2.5.1.16) and adds another aminopropyl group to the spermidine, forming spermine. In parallel, S-adenosylmethionine (SAM) is decarboxylated by SAM decarboxylase (SAMDC, EC 4.1.1.50) and provides aminopropyl groups to the formation of spermidine and spermine. All three, ODC, ADC, and SAMDC, are regulatory enzymes (rate-limiting) of the polyamines synthesis [23, 24].

The polyamines oxidation occurs via amines oxidases. Diamine oxidase (DAO, EC 1.4.3.6) oxides putrescine or cadaverine in primary amino groups, forming 4- aminobutanal, which cyclics, forming delta-1-pirroline and hydrogen peroxide, and polyamine oxidase (PAO, EC 1.5.3.3) oxides spermidine and spermine. Tri- and tetramines oxidations produce hydrogen peroxide (Fig. 1). During the polyamines oxidation, there is also a formation of γ-aminobutyric acid (GABA), a nonprotein amino acid that acts as a endogenous molecular marker, with inhibitory action of neurotransmitters in animal cells [25]. The food enriched with GABA became popular due to their functional effects and regarding the health in the arterial pressure regulation, cardiac frequency, relieve of pain, and anxiety [26].

Polyamines present a series of functions in cells from prokaryotes and eukaryotes organisms. In plants, they have an important role in the growth,

differentiation, synthesis of nucleic acids and proteins, membrane stability, resistance, senescence, programmed cells death, adaptive responses to the environment, among others [27–30]. In addition, these molecules in mammals are involved in some diseases as Alzheimer and cancer [31]. Studies demonstrate increase in polyamines levels in the urine and serum [32], as well as induce the activity of enzymes involved in the polyamines synthesis, as ODC in tumor cells [33].

Biotic and abiotic stresses lead to oxidative stress, which is, many times, quickly manifested with accumulation of reactive oxygen species (ROS). ROS are important signaling molecules, but are toxic in high concentrations. ROS affect many cell functions by damaging the nucleic acids, oxidizing proteins, and causing lipid peroxidation [34]. The polyamines have a double role against the ROS accumulation in stressful conditions and are considered osmoprotectors and ROS scavengers. The polyamines putrescine, spermidine, and spermine are positively charged at physiological pH and can bond to membrane cell groups negatively charged and prevent damages caused by stress factors in plants [35]. In addition, polyamines can interact with negatively charged molecules as DNA and RNA through electrostatic bonding [36]. This bonding stabilizes the DNA structure, mainly by bonding with spermidine and spermine [37, 38]. Spermidine and spermine (not putrescine), when in high concentrations (above 10 mM), provide protection against damages from DNA radiation [39]. However, in sub-mM levels, it is ineffective and can slightly promote damages caused by gamma radiation. Other studies affirm that the polyamines have the ability to induce the DNA compaction and aggregation, besides acting as a scavenger of free radicals, mainly OH^- generated by gamma irradiation [39, 40], thus becoming a DNA protector cell.

The antioxidant action of some biogenic amines and polyamines correlates to the quantity of amino groups in their chemical structures. Studies have shown that amines as dopamine present a higher in vitro antioxidant capacity (through DPPH test), comparing to other natural antioxidants, as ascorbic acid [41]. In addition, it has been claimed that the increased intake of polyamines present in foods led to augmented intracelular amounts of these metabolites, promoting vascular health in humans. The increase in intracelular polyamines suppresses the enzymatic activity required for their synthesis.

Some biogenic amines (histamine, tryptamine, tyramine, putrescine, and cadaverine) are undesirable in high concentrations in the food, because they can promote respiratory problems, headaches, cardiac palpitations, hypertension, or hypotension, among other allergic diseases. Simultaneously, some polyamines (e.g., putrescine, spermidine, and spermine) in high concentrations can cause the proliferation of cancer cells [42]. The association of polyamines to cancer growth/progression may be related to polyamines catabolism. The excessive ingestion of food rich in polyamines, with a consequent increase of its content in the cells, can induce apoptosis, possibly due to the increasing peroxide content which is the product of the degradation of di- and polyamines by the oxidative enzymes DAO and PAO [43], leading to the cell death.

The intake of polyamines by feed and to control of some diseases has been studied by many researches groups, with the intention of decreasing or preventing damages provoked by these amines. Cipolla et al. [44] observed, in patients with prostate cancer, that reducing polyamine diet and partial intestinal decontamination was beneficial to improving the life quality and pain control. The authors also describe that 3 months after the end of this treatment, the pain came back.

4 Processing Methods – Effects in the Content of Phenolic Compounds and Polyamines

Changes in the phenolic compounds and polyamines compositions are of great complexity because they vary according to the structure and the type of analyzed food, besides the cooking method used to its preparation. The most of the vegetables and some fruits are preferably consumed after some type of thermal processing, which causes favorable changes in the flavor and texture, increasing the food palatability. Previous studies indicate that the retention of phytochemicals and the antioxidant properties after the cooking vary considerably among the different vegetables, among the methods used in their preparation, and mainly, among the specific analyzed compounds [45, 46]. The phenolic compounds are generally considered stable to the heat, and the occasional loses in the different thermal processes are probably attributed to lixiviation. Studies indicate that rutine and other polyphenols present in vegetables (e.g., asparagus) do not degrade when heated. The rutine's stability to heat was confirmed by recovering the compounds from the water used in the boiling process [47]. Generally, methods that do not use water, e.g., steaming, lead to an increase in the total phenolic compounds, flavonoids and phenolic acids in comparison to the *in natura* vegetables [48]. This can be explained by the rupture of complexes among the phenolic compounds and other compounds (e.g., proteins) generated by the extraction by steam, resulting in a better availability of these compounds [49].

The polyamines are original from amino acids, such as arginine and ornithine, which act as precursors and can suffer decarboxylation processes by the action of putrefactive bacteria. This explains why a higher concentration of polyamines is found after the fermentation of products as sauerkraut, some sausages, cheeses, and wines [50–52]. In addition, it is known that the processing of vegetables, such as the heating or freezing, can rupture the cell wall, leading to the liberation of these compounds that were free or binding to the membrane, inducing an increase of bioavailability of some compounds [49, 53]. However, for polyamines there are no differences on the content, in organic or conventional green beans, after thermal processing [46]. Besides this, organic green beans presented higher spermidine and spermine contents. These data can be important when the relation of polyamines with diets for cancer patients is studies, as described by [44], or even when it is wanted to obtain food with antioxidants, since these amines are considered free radicals scavengers [54]. Thus, studies with polyamines acting as antioxidants and their relation to diets should be deepened, due to the duality of these substances function.

5 Organic Versus Conventional Fruits and Vegetables

Several studies highlight the benefits of ingesting of organic foods, due to the higher content of some bioactive compounds and higher antioxidant activity, besides being free of chemical residues [46, 55–57]. The plant exposition to a stressful environment, as attack by insects or fungi, can induce the production of natural defense substances, as well as the phenolic compounds [58, 59]. The organic plant-based food contains higher polyamines levels (that can be protection mechanisms against many types of stress) in comparison to the conventional farming [57]. Studies with fruits indicate an increased polyamine content and a protective effect against damages caused by biotic and abiotic factors in the membranes [60]. However, this profile was not verified in collard green, where the highest putrescine levels were found in the conventionally cultivated vegetables [57].

Currently, the pharmaceutical industry has searched for organic plants with higher contents of bioactives. It is known that the interaction between different food metabolites (as biogenic amines and polyphenols) and their biosynthetic pathways can contribute to the healthy or harmful characteristics of the own food. In a research developed in our laboratory using two jambu cultivars (*Acmella oleracea* cv. Jambuarana and Nazaré), a medicinal plant used in the cosmetic and pharmaceutical industries and also consumed by the population from North region of Brazil, the polyamines levels was affected by the cultivation practice. Organic jambu (both varieties) showed higher spermine content in leaves and spermine and spermidine in inflorescences compared with the conventional fertilization. Besides the polyamines levels, the phenolic compounds content was increased by the organic cultivation [61]. The results show that the organic cultivation can induce positive alterations regarding the antioxidants levels.

Biotic or abiotic stress can induce high phenolic compound contents by increasing the activity of the enzymes. Phenolic compounds act as cell protectors against free radicals generated by stress [62, 63]. Some plant-based foods produced under moderate stress, such as organic farming, tend to show higher antioxidant activity due to phytochemical levels, such as phenolics, compared with conventional ones. Organic food may contain more phenolic compounds due to the absence of agrochemicals, which collaborates in the defense against some types of stress [30]. An increased 139% in the total phenolic content of organic tomatoes in relation to conventional farming, which may be a consequence of increased PAL activity, was observed during development [64]. Even after the processing, this quality seems to be maintained. Organic tomato juice presents higher phenolic compounds levels and higher antioxidant activity when compared to those conventionally grown [65].

6 Beneficial Effects of Phenolic Compounds

Phenolic compounds play an important role in sensory characteristics and are responsible for some organoleptic properties such as aroma, color, taste, bitterness, and astringency in fruits and vegetables, as well as their derivatives [66, 67].In addition,

they are directly or indirectly related to quality and health benefits. Flavonoids, anthocyanins, tannins, and resveratrol (stilbene) have proven action against different diseases in humans [68–71]. Quercetin shows beneficial properties and is found in onion, apple, brassicas, among other vegetables. This flavonoid has antidiabetic, anti- inflammatory, and anticancer activity [72]. Other flavonoids, such as kaempferol and catechin, act as antioxidants. Studies demonstrated the inhibition of tumor cell growth, reducing the progression of breast cancer in a rat model after treatment with both flavonoids [73, 74].

Some species of the genus *Citrus*, *Brassica*, *Allium,* and *Mallus* contain kaempferol, a flavonoid with potential to be used in individuals with cardiovascular diseases. In vitro studies showed its action on the decrease of cellular apoptosis induced by LDL cholesterol in human cells and antithrombotic action [75–77].

Beneficial effects are enhanced with resveratrol, a molecule considered effective in preventing different pathological conditions, for example, in the reduction of blood pressure and repression of lipid peroxidation, oxidative stress, and lipid levels [78, 79]. In vitro studies demonstrate that this stilbene has a beneficial effect as a coadjutant in the control of norovirus, a pathogenic agent involved in food diseases (at great risk in the elderly and in the immunocompromised). In addition, the resveratrol action has been demonstrated in the expression of genes that decrease insulin resistance, meaning possible beneficial effects for diabetics [80, 81].

Anthocyanins are natural pigments found in fruits and vegetables. These compounds provide blue, purple, and red colors and with proven activity as nutraceuticals. Grapes and their derivatives are sources of antioxidant substances and are rapidly absorbed, with various physiological activities in animal cells [82]. Cyanidin-3-O-β-glucoside is present in a large number of fruits and vegetables, and studies have been demonstrated its protective effect against lipopolysaccharide-induced lung injury by lowering cholesterol levels and suppressing the inflammatory response [83]. This anthocyanin has also shown to decrease the negative effects of free fatty acids, decreasing insulin resistance through the activation of cellular and cytoprotective antioxidant genes [84], as well as having preventive or complementary activity against inflammatory chronic diseases [85, 86]. It was demonstrated by in vitro study using *Morus alba* L. that the presence of cyanidin-3-O-β-glucoside, together with cyanidin 3-rutinoside, has an inhibitory effect on the migration and invasion of human lung carcinoma (A549) cells.

Malvidin-3-O-β-glycoside, the main anthocyanins in grapes, is a potent anti-inflammatory; it aids in the balance and inhibition of pro-inflammatory pathways, promoting cardiovascular health benefits. When malvidin-3-O-β-glycoside is in combination with peonidine, there is an increased beneficial effects activity. Studies in vitro and in vivo showed decreases of transcription of genes encoding proinflammatory cytokines, causing a decrease in anti-inflammatory activity in arthritic rats [87, 88].

Pelargonidine, another anthocyanin found in large quantities in grapes and derivatives, has a neuroprotective effect, improving memory deficit by mitigating oxidative stress, helping to reduce the symptoms of individuals with Alzheimer's disease. In addition, pelargonidine provides potential benefits against atherosclerosis in albino mice. This compound acts against stress generated by environmental toxicants (urethane and diepoxybutane), compounds classified as possible human carcinogens [89–91].

Delphinidin also has a beneficial activity and its anticancer action has been demonstrated. In vitro study has demonstrated inhibition of proliferation and migration of ovarian carcinoma cells. This effect may be an important health response, meaning a potential natural chemotherapeutic to prevent the development and progression of cancer cells [92, 93]. In addition, it has regenerative effect on cells exposed to UVB radiation (100 mJ/cm^2), demonstrating great potential in protecting skin damaged by the sun.

Several phenolic acids have been studied in reducing symptoms or diseases. It has been demonstrated that p-coumaric acid has the ability of eliminating free radicals and lowering LDL cholesterol [94]. Ferulic acid has been related to the protection of oxidative stress in rat renal tissue caused by cisplatin (anticancer agent). The use of this phenolic acid avoided renal damage and helped to recover the histological parameters of the kidney under normal conditions [95]. Chlorogenic acid found in sweet potatoes and coffee has antibacterial and anti-inflammatory activity and can inhibit tumors. Besides that, this phenolic acid has protective effects on the liver and antihypertensive function. In rats with the cerebral ischemia reperfusion injury, chlorogenic acid improves pathological lesions in brain tissue, reducing mortality. Studies demonstrated an effect against prostatic hyperplasia in mice, besides reducing the negative effects of high consumption of glucose and lipids, avoiding the occurrence of diabetes, obesity, cardiovascular diseases, and cancer in humans [96–98].

7 Interaction of Phenolic Compounds and Polyamines on Plants

Besides the effect of some polyphenols on the polyamines, the plants can form phenolamides, which are polyamines combined by amide bonding with some phenolic acids such as coumaric, caffeic, and ferulic acids, through the substitution of 1, 2, or 3 amino groups. This combination of the phenolic acids that occurs with the aliphatic polyamines (putrescine, cadaverine, spermidine, and spermine) forms the basic amides.

When occurs the bonding with the aromatics (tyramine, tryptamine, dopamine, and octopamine) or with aliphatics, forms the neutral amides [99, 100]. The phenolamides has been described as specific secondary metabolites and related to the development of plants defense mechanism, and the structure of these molecules are similar to the ones found in the insects toxins [101].

The phenolamides content can be affected in response to the pathogens attack, as during the hypersensitive reaction towards fungi or virus diseases. Some plant organs, as the leaves, can synthesize phenolamides as defense mechanism, decreasing the pathogens action [99]. Reference [102] describes an increase of phenolamides and decrease of the powdery mildew infection. Reference [103] suggests that the low incidence of virus diseases in flowers and seed can be related to the phenolamides content. However, in some cases of host-pathogen interactions, especially during the hypersensitive reaction towards fungi or viruses, leaves of

vegetative plants synthesize some phenolic amides at the same time as defense mechanisms, limit pathogen expansion.

Many foods can produce harmful substances from the oxidation of fatty acids [104] with mutagenic and carcinogenic activities during the processing, the storage, or by contaminants [105]. In order to fight the oxidation, synthetic or natural antioxidants can be used. Some species contain high phenolamides levels that can be used as antioxidants. Reference [106] described phenolamides in *Piper* and demonstrated a higher antioxidant capacity compared to alfa-tocopherol, and feruperine showed an antioxidant activity almost as high as BHA (butylated hydroxyanisole) and BHT (butylated hydroxytoluene).

8 Interaction of Phenolic Compounds and Polyamines on Human Health

Studies that related the beneficial effects of the interaction of the phenolic compounds with the polyamines indicate that phenolic compounds, as the chatequins, interact with the biosynthetic pathways of polyamines. This reaction occurs specifically reducing the production of histamine and putrescine due to the inhibition of the histidine decarboxylase (HDC; EC 4.1.1.22) and ODC activities and increase spermidine/spermine N1-acetyltransferase activity, which promotes the polyamines catabolism [107, 108]. High activity of ODC is characteristic of the tumor cells [109], and the inhibition of ODC expression may be one of several targets involved in the antiproliferative effects of resveratrol [42]. Resveratrol and piceatannol (Piceat) (derived from resveratrol) also were able to reduce the ODC levels in Caco-2 colorectal cancer cells [110]. This enzyme is directly related to the cellular proliferation and carcinogenesis. Similar results were observed by [42], where resveratrol induced a decrease in the ODC activity in Caco-2 cells and a significant decrease of intracellular putrescine content. However, it did not affect the SAMDC activity, not affecting the content of spermidine and spermine.

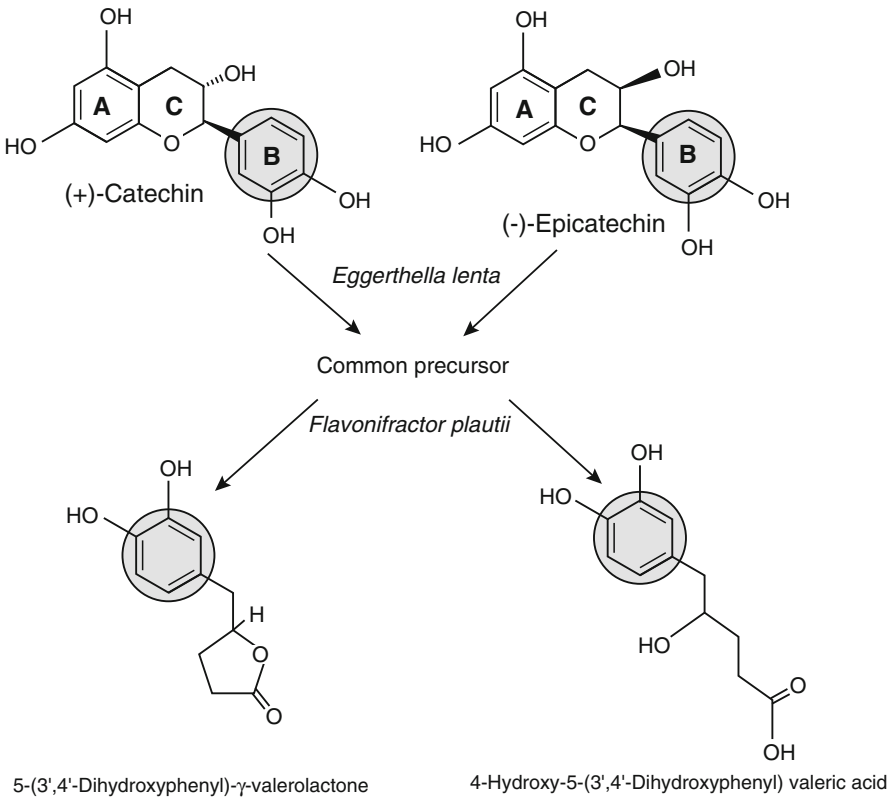
Polyphenols has the ability to targeting polyamines or biogenic amines. Besides the possible synergic activity of both compounds, some classes, as flavonoids, have shown the capacity of blockage key enzymes from biogenic amines biosynthetic pathways [108]. Dopamine and serotonin play critical role in neuropsychiatric disorders, such as depression, schizophrenia, and Parkinson's disease. Both biogenic amines are essential for serotonergic and dopaminergic systems to regulate the neurotransmission. Most of the psychotropic drugs used in the treatment of neuropsychiatric disorders, including antidepressants, antipsychotics, anxiolytics, and psychostimulants, exerted their pharmacological actions by interfering with serotonergic and dopaminergic transmission. Thus, deregulations in their levels (amines) are a key step in the control of neurological diseases. It is interesting to note that epigallocatechin gallate and epigallocatechin showed the ability to interact with and bind to the enzyme Dopa decarboxylase (converts L-Dopa and L-5-hydroxytryptophan into dopamine and serotonin, respectively), leading to its irreversible inhibition [111]. Histamine is other biogenic amine that can be regulated by

epigallocatechin gallate. To produce histamine neurons, mast cells, basophils, and monocytes/macrophages, among others, produce the enzyme HDC that catalyzes the conversion of histidine in histamine. A dual effect of epigallocatechin gallato was observed against histamine. The first was demonstrated in rat basophilic leukemia cells that epigallocatechin gallato prevented histamine release from mast cells [112]. The second effect was observed in mammalian cells, where epigallocatechin gallato demonstrated a potent inhibitory effect of HDC activity [113].

Interestingly it has also been reported that high concentrations of some phenolic compounds affect biogenic amine production by inhibiting lactic acid bacterial growth [114]. Low levels of biogenic amines in some types of wines can be related to the presence of large phenolic compounds quantities (e.g., anthocianins and stilbenes) that, by inhibiting the activity of naturally present bacteria, can reduce the formation of histamine, tyramine, and putrescine.

Usually the polyphenols are not absorbed by small intestine, and it has been estimated that only 10% is absorbed and the remaining 90% is metabolized in the large intestine by gut microbiota or excreted [115]. The polyphenols conversion in the human gut is a complex process and should be considered when assessing the bioavailability of plant compounds. For example, compounds as procyanidins are poorly absorbed in its original molecular structure, but the human gut microbiota might play an important role in the absorption process. This interaction was observed in the conversion of catechin and epicatechin [116]. Bacterial strains *Eggerthella lenta* and *Flavonifractor plautii*, isolated from human feces, showed the capacity to convert both compounds in active metabolites. The strain *Eg. lenta* was able to cleave the heterocyclic C-ring of both (+)-catechin and (−)-epicatechin to produce a common precursor, 1-(3,4-dihydroxyphenyl)-3-(2,4,6-trihydroxyphenyl)propan-2-ol, that was subsequently converted in 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone and 4-hydroxy-5-(3′,4′-dihydroxyphenyl) valeric acid by *F. plautii* strain (Scheme 1). To produce catechin metabolites, bacterial strains promote cleavage and/or dehydroxylation of C and A rings of catechins molecules and the B ring is preserved. Despite the well-known antioxidant capacity induced by polyphenols, several of these compounds act as redox-dependent poisons against type II enzymes [117]. This poisoning effect is the capacity of enhance DNA cleavage by topoisomerase II and depends on the number of -OH groups on the B and C-rings. Considering that many anticancer drugs target the type II enzyme, this feature can represent an interesting mechanism by which dietary polyphenols or its metabolites act preventing cancer [118].

Two of the most consumed beverages worldwide are coffee and tea, and both beverages are source or phenolic compounds. These beverages have shown several beneficial effects on health, in part due to the high content of phenolic substances. Tea is a rich source of catechins, epicatechin, epigallocatechin, epicatechin gallate, and epigallocatechin gallate, compounds which can promote diverse effects in humans. Catechins and its metabolites may be involved in the insulin signaling pathway, regulation of various transcription factors, and inhibition of pro-oxidant enzymes such as nitric oxide synthase, lipooxygenase, cyclooxygenase, and xanthine oxidase [119]. Similarly to tea, the coffee consumption may induce different



Scheme 1 Conversion of (+)-catechin and (−)-epicatechin by human intestinal bacteria. Both compounds are converted by *Eggerthella lenta* in a common precursor, which is further converted by *Flavonifractor plautii* to active metabolites that retain the polyphenol B-ring (gray background) (Adapted from: Kutschera et al. [116])

health benefits, according to the processing method used to obtain the beverage. Green coffee beans contain large amounts of chlorogenic acids, a family of water-soluble phenols formed by the esterification of (−)-quinic acid with one or more cinnamic acids. However, with the roasting process of coffee grains, the chlorogenic acid progressively decreases in relation to light to dark roasting degree. In addition to effects in phenolic compounds, the roasting process induces the formation of Maillard reaction products (high molecular weight products). Some of these high molecular weight compounds (such as melanoidins, which also have antioxidant capacity) increase in dark roasting compared to light roasting [120]. It is well known that polyphenols and melanoidins present in foods and beverages are involved in their antioxidant activity [121]. Therefore, the antioxidant capacity of coffee beverages is not only contributed by the components originally present in green grains, but also by the components generated during the roasting process.

Coffee is probably the richest dietary source of chlorogenic acid, with a single dose of espresso coffee supplying 24–423 mg [122]. Nonespresso beverages are also rich sources, and many regular coffee drinkers can easily consume 1–2 g per day of this phenolic compound, surpassing even the intake coming from fruit and vegetables. In addition to chlorogenic acid, other polyphenols, phenolic acids, and melanoidins have been linked to several health benefits, such as suppression of postprandial hyperglycemia and hyperinsulinemia (by inhibiting digestive enzymes) [123] and protection of DNA oxidative damage (by decreasing deoxyribose degradation, DNA scission, and inhibition of 8-hydroxydeoxyguanosine formation) [121]. Probably these effects are associated to direct interactions with membrane structures, enzymes, and receptors, besides the antioxidant capacity. The oxidative stress and the resulting oxidative damage are closely related to the development of inflammation and chronic diseases. In addition to the effects described above, the oxidative scavenger activity of coffee beverage has been shown in humans. The plasma antioxidant activity measured on subjects (1 and 2 h after the ingestion of 200 ml of coffee) exhibited a significantly higher antioxidant capacity than the controls that did not ingest coffee [124].Further, healthy subjects consuming instant coffee (800 mL/day, for 5 days), co-extracted from green and roasted grains, also showed a significant protection against oxidative damage [125]. In these subjects, urinary marker of lipid peroxidation (8-isoprostaglandin F2α) and plasma marker of functional protein modifications induced by nitric oxide (3-nitrotyrosine) were decreased by 15.3% and 16.1%, respectively [125].

The main drawback to using polyphenols as agents to prevent or treat diseases is their poor bioavailability and the variable bioaccessibility in the human body. Thus, to improve the desired effects in health promotion, consumption of several polyphenols or the association of polyphenols and drugs has been recommended [126–128]. In addition, it is necessary to consider that dietary fruits and vegetables provide other bioactive compounds, beside polyphenols, that help the human body to prevent chronic diseases as cancer, diabetes, hypertension, obesity, and cardiovascular disease [129–132]. An interesting mechanism of anticancer activity induced by polyphenols was showed in compounds coming from cocoa samples. The flavanols and procyanidins from cocoa were able to induce nonapoptotic cell death in cancer cell line Caco-2 [133]. This effect was mainly induced by decreasing ODC and SAMDC activities, two key enzymes of polyamine biosynthesis. High expression of ODC is an important characteristic of tumor cells and tumor development; therefore, the interaction of polyphenols with polyamines biosynthesis are interesting targets for cancer prevention.

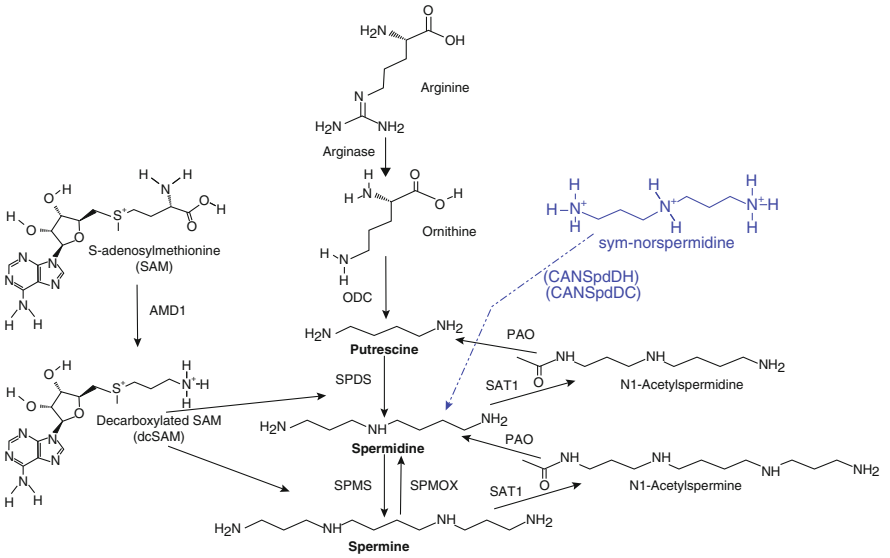
The human intestinal tract contains high levels of polyamines, which are derived from the diet and/or from de novo production by host and its microbiota. Besides that, humans cells have the ability to ubiquitously produce polyamines as putrescine, spermidine, and spermine, from amino acid arginine, which is converted in ornithine by ODC. These endogenous molecules play an essential role in the process of cell development, growth, and differentiation. However, deregulated levels of polyamines at low concentrations are linked to cell growth defects and at high concentrations to toxic effects and carcinogenesis. Diets based on foods and beverages rich

in arginine may induce increased synthesis of polyamines. Further, knowing that arginine is the amino acid precursor of polyamines and nitric oxide, it is expected that the enzymes arginase 1 and nitric oxide synthase compete for arginine and promote a bypass in metabolic pathways. The immune response, mainly induced by M1 macrophages, is dependent of nitric oxide to induce the production of pro-inflammatory cytokines. Spermine can inhibit M1 macrophage activation by suppressing the expression of ODC. However, even blocking nitric oxide pathway and M1 macrophage activation and the synthesis of anti-inflammatory transforming growth factor-β (TGFβ) and IL-10 were not altered [134].

In addition, polyamines have been associated to multiple effects in the central nervous system, acting as neurotransmitters or neuromodulators. Injuries in the central nervous system, such as ischemia and trauma, are associated to increased activities of ODC and spermidine/spermine-N(1)-acetyltransferase. The increased activity of these enzymes results in accumulation of putrescine, a candidate marker of brains injury. Increased amount of putrescine seems to be more associated to brain injury than spermine and spermidine, once levels of the former two were unaltered in three different models of forebrain ischemia and traumatic brain injury [135]. On the other hand, the administration of polyphenols and their supposed interaction with polyamines biosynthesis were demonstrated in animal model of ischemia-induced neuronal injury [136]. Neuronal damages and the polyamines content (in the ischemic tissue) were decreased after epigallocatechin gallato administration. In this study, authors speculated that although administration of epigallocatechin gallato did not show complete neuroprotection, it seems to be a promising strategy for attenuation of global ischemia-induced neuronal injury [136]. In this same study, the levels of spermine and spermidine were unaltered in the injured brain tissue, whereas the levels of putrescine were significantly decreased. It is well known that the spermidine may be synthesized from the putrescine, so is not unexpected the maintenance in its levels.

The spermidine biosynthesis is mediated SAMDC and aminopropyltransferase spermidine synthase (SPDS) through the addition of aminopropyl group (donated by decarboxylated S-adenosylmethionine (dcSAM)) to putrescine molecules (Scheme 2). The following steps are capable to convert spermidine to spermine through the spermine synthase (SPMS). When necessary, spermine and spermidine can be recycled to spermidine and putrescine, respectively, by spermidine/spermine-N1-acetyltransferase (SAT1) followed by oxidation by polyamine oxidase (PAO) [137]. In addition to dietary polyamines consumed by each individual, the gut microbiota of these individuals may be responsible for spermidine biosynthesis [138–140]. Several bacterial strains have the capacity to produce spermine via SAMDC and SPMS enzymes, or the orthologues enzymes carboxynorspermidine dehydrogenase (CANSpdDH) and carboxynorspermidine decarboxylase (CANSpdDC) that convert *sym*-norspermidine in spermidine [138].

The relevance of human microbiota in polyphenols and/or polyamines absorption is remarkable. In a human study, volunteers that consumed orange juice containing hesperetin-7-O-rutinoside showed increased concentrations of hesperetin-7- O-glucuronide in the plasma and urine [141]. Probably the disaccharide glycoside moiety of hesperetin-7-O-rutinoside was cleaved by colonic bacteria releasing hesperetin, which



Scheme 2 Polyamines biosynthetic pathway in human body. Arginine is the precursor amino acid converted to ornithine by arginase. Putrescine is synthesized through ornithine decarboxylase (ODC) or S-adenosylmethionine decarboxylase (SAMDC). S- adenosylmethionine (SAM) is decarboxylated (dcSAM) and the molecule provides aminopropyl groups to produce putrescine. After that, putrescine is converted in spermidine by spermidine synthase (SPDS) and/or spermine by spermine synthase (SPMS). Spermine can be recycled to spermidine directly by spermine oxidase (SPMOX). Spermine and spermidine can be recycled to spermidine and putrescine, respectively, by spermidine/spermine-N1-acetyltransferase (SAT1) followed by oxidation by polyamine oxidase (PAO). Alternatively, gut microbiota can synthesize spermidine (blue route) from *sym*-norspermidine by expressing orthologues enzymes carboxynorspermidine dehydrogenase (CANSpdDH) and carboxynorspermidine decarboxylase (CANSpdDC) (Adapted from: Brooks [137])

was acted upon by UDP-glucuronosyltransferases in the colonocytes, producing hesperetin-7-O-glucuronide. In addition, an unidentified hesperetin-O- glucuronide was found in plasma, showing that these metabolites passed into the portal vein to reach the blood stream [141]. Hesperetin and its conjugated metabolites are the major forms of hesperidin in human plasma. It occurs after hesperidin hydrolysis in the gastrointestinal tract and conjugation during absorption. In several situations, the metabolites have similar, or even, higher physiological effect than their precursors. An interesting example of this effect was observed in spontaneously hypertensive rats. The hesperetin-7-O-β-D-glucuronide exerted hypotensive, vasodilatory, and anti-inflammatory activities, similarly to hesperetin. On the other hand, the metabolite hesperetin-3′-O-β-D-glucuronide had little effect on these parameters [142].

The interaction of polyphenols and polyamines, as observed for catechins metabolites, was also described for hesperetin and naringerin [143]. Both compounds produced a remarkable reduction of B16-F10 melanoma cell, in vitro and in vivo, and the proposed mechanism was by lowering of the intracellular levels of polyamine, spermidine and spermine.

9 Concentrations of Phenolic Compounds and Biogenic Amines in Some Foods

The phenolic compounds and the polyamines are present in variable quantities in many foods and the knowledge of its content can influence positively or negatively in various diseases. Alterations in the content of these phytochemicals are verified depending on the food matrix used, on the method of cultivation, and on the treatment and/or on the processing the raw material is submitted [57, 61, 144]. In addition, following previous considerations, it should be useful to actively promote the production of functional beverages and foods, having a modified balance between amines and polyphenols, by using different agricultural management practices and processing methods.

10 Conclusion

Regular consumption of phenolic compounds and polyamines rich food has been shown to improve the human health. There is a need for detailed investigation of the complexities of effects on the absorption of these compounds, as well as their metabolism and de novo synthesis in the human organism. The gut microbiota produces metabolites, different from those that can be generated by human enzymes, and in most cases, reduces the activity of dietary compounds; however, sometimes the metabolites formed exhibit enhanced properties.

The gut microbiota and the dietary components are involved in a complex metabolic metabolism. Interactions between these components are essential for human responses to food-based interventions and to achieve desired health improvement.

Intake of Mediterranean Foods

2

Charalampos Siotos, Marco Vinceti, and Androniki Naska

Contents

Abstract

The traditional Mediterranean diet is characterized by: (a) high consumption of cereals, vegetables, fruit, nuts, legumes, fish, and seafood; (b) the use of olive oil as the main, if not the only, added lipid; (c) moderate consumption of milk and dairy products; (d) moderate intake of alcohol, in the form of wine and preferably during meals; and (e) low consumption of meat and meat products. The prevalent consumption of olive oil and the low consumption of animal products are reflected in the high ratio of monounsaturated to saturated fat intake, typical of the dietary pattern in the region. There is increasing evidence from observational and experimental

epidemiological studies, further enriched by the conclusions of their systematic reviews and meta-analyses, that adherence to the Mediterranean dietary pattern promotes health and reduces the risk of premature death from chronic degenerative diseases. Mediterranean countries and especially the European ones have experienced a "westernization" process of their food habits, and have increased the per capita supply of non-Mediterranean foods (animal fats, vegetable oils other than olive oil, sugar, and meat) and decreased the supply of legumes and alcoholic beverages, including wine. The evidence that Mediterraneans are gradually departing from their traditional eating habits does not only refer to the adult population in the region, but it has also been reproduced in large-scale nutritional surveys among children, adolescents, and young adults – the trend-setters for future generations. Next to the effect on people's health, the gradual abandoning of the traditional Mediterranean diet cannot support sustainable development in the way the Mediterranean diet does. Being adjusted to the cultural, climatic, and other environmental characteristics of the region, the Mediterranean diet is protective and helpful to biodiversity, accessible and economically affordable, and contributes to food and nutrition security.

1 Introduction

The Mediterranean basin has historically been a crossroad of civilizations and this is reflected in the culture, the scenery, the flora, and the food resources. Some plants, like the olive tree, wheat, and the grapevine, have been in this area for millennia, whereas citrus fruit, tomatoes, eggplants, corn, rice, beans, and potatoes were imported at different time periods. Over the years, this large variety of plant foods has been integrated in people's culinary habits paving the way to what has become in the twentieth century the worldwide famous Mediterranean diet [1].

The countries bordering the Mediterranean Sea have their own dietary traditions, and olive oil occupies a central position in all. Without the presumption of a scientific definition, the Mediterranean diet could be considered as the dietary pattern found in the olive oil growing areas of the Mediterranean region in the late 1950s and early 1960s [2]. Traditionally, in addition to olive oil, the daily intake included a high intake of cereals, fruit, nuts, vegetables, and legumes combined with a low intake of dairy products, meat, and meat products. In the traditional Mediterranean diet, fish and seafood intake depended on the vicinity to the sea and ethanol intake was moderate and mainly in the form of wine during meals [3]. This combination of intakes is rich in components with well-established cardioprotective functions: the liberal use of olive oil guarantees an increased intake of monounsaturated fatty acids and tocopherols; fish, vegetables, and nuts are good sources of n-3 and n-6 polyunsaturated fatty acids; the high consumption of vegetables, fresh fruit, and cereals provide fiber, a variety of vitamins (such as vitamin C, vitamin E, and beta-carotene), important minerals (potassium, for instance), and other beneficial substances (such as polyphenols and anthocyanins) [4, 5]. The limited

consumption of meat and dairies provided few saturated fatty acids and the consumption of locally grown products, such as the wild green leafy vegetables, conveys additional benefits due to their high flavonoid content [6].

Contrary to other also highly cited dietary regimes, the Mediterranean dietary pattern has not been developed by health professionals on the basis of analytical evidence for health-promoting dietary choices. It is rather a natural experiment, a holistic lifestyle that existed in the region for years and was discovered in the second half of the twentieth century after ecological observations that people in this region experienced mortality rates which were far lower than those of more developed and affluent countries [7]. The first systematic attempt to investigate dietary patterns in the Mediterranean region dates back to 1948 on the island of Crete. At that time, the Greek government was worried about the post-war conditions and invited the Rockefeller Foundation to undertake an epidemiological study in order to provide advice on how to raise the population's standard of living. The study assembled data collected from 128 Cretan households. The final report was published in 1953 and provides a succinct but vivid description of people's diet. In particular, the investigators wrote: "olives, cereal grains, legumes, fruits, wild greens and herbs, together with limited quantities of goat meat and milk, game and fish, consist the basic Cretan food. . .no meal was complete without bread. Olives and olive oil contributed heavily to the energy intake. Food seemed literally to be "swimming" in oil. . ." and concluded that the food consumption levels ". . .were surprisingly good. On the whole, their food patterns and food habits were extremely well adapted to their natural and economic resources, as well as their needs" [8].

2 Mediterranean Diet: Definition and Assessment of Adherence

Overall, the traditional Mediterranean diet has the following characteristics:

- High consumption of cereals, vegetables, fruit, nuts, and legumes
- High consumption of fish and seafood
- Use of olive oil as the main, if not the only, added lipid
- Moderate consumption of milk and dairy products
- Low consumption of meat and meat products
- Moderate intake of alcohol, in the form of wine

The traditional Mediterranean diet has predominantly been a plant-based diet with olive oil as the principal added lipid, allowing a high intake of monounsaturated and a low intake of saturated fatty acids – the latter contributed 7% to 8% of total energy intake [2].

The operationalization of the Mediterranean dietary pattern has been achieved through various computational scores, which are used to reflect the aggregated dietary exposure particularly when diet-disease associations are evaluated. The first and more often cited index to assess adherence to the Mediterranean diet among adults and elderly is the Mediterranean diet score calculated on the basis of the aforementioned

characteristics of the Mediterranean diet [9]. According to this score, individuals receive a value of +1 if their daily intake of foods frequently included in the traditional Mediterranean dietary pattern (i.e., vegetables, legumes, fruit and nuts, cereals, fish and seafood, and monounsaturated to saturated fat ratio to reflect the high olive oil intake) is above the gender-specific median value of the study sample. Correspondingly, individuals are assigned a value of 0 if their daily intake of the aforementioned foods is below the gender-specific median. Hence, an individual receives +1 value if his daily intake of vegetables is above the median vegetable consumption in this study sample. Similarly, the individual will receive an additional +1 value if his intake of fruit and nut is also above the sample median. However, if the individual's daily intake of fish and seafood is below the sample median, he will receive the value of 0. In addition, individuals receive values of +1 if their daily intake of milk and dairies, meat and meat products is equal to or lower than the gender-specific median and are assigned values of 0 otherwise. Thus, an individual with daily meat intake below the sample median will receive an additional +1 value, but if his daily intake of milk and dairies is above the sample median, he will receive a 0 value. Lastly, a value of +1 is further given to individuals consuming a moderate amount of alcohol (i.e., between 5 and 25 g per day for women and between 10 and 50 g per day for men) and a value of 0 otherwise. Finally, all values received are added and the total score ranges between 0 (minimal adherence to the traditional Mediterranean diet) and 9 (maximal adherence to the traditional Mediterranean diet) (Fig. 1).

Variations of this score, as well as other indices to assess conformity to Mediterranean dietary traditions are also available in the literature [10–15]. Although these employ various scoring techniques, they are all based on the dietary characteristics described above, which capture the essence of the Mediterranean dietary profile.

Among children and adolescents, adherence to the Mediterranean diet is usually assessed through the KIDMED index [16], which comprises of 16 questions combining principles of a Mediterranean dietary pattern (i.e., eating fruit, vegetables, and legumes regularly; using olive oil at home), together with general dietary guidelines for children (for instance, always to have breakfast). Respondents receive positive scores if they conform to principles of the Mediterranean diet and follow nutritional guidelines and negative scores otherwise. The total score of the KIDMED index for children and adolescents is usually classified into three levels: equal or higher than 8 indicates an optimal adherence to Mediterranean diet; scores between 4 and 7 denote a necessity for improvement in order to adjust intake to the Mediterranean diet; and scores below or equal to 3 point to a diet of very low quality. Next to the KIDMED index, other scores have also been proposed in the literature to assess adherence to the Mediterranean diet among children and adolescents [17].

3 Mediterranean Diet and Health

The ecological observation that adults living in the Mediterranean area have displayed favorable health statistics induced the classic Seven Countries Study which has prospectively investigated long-term incidence and mortality from coronary heart

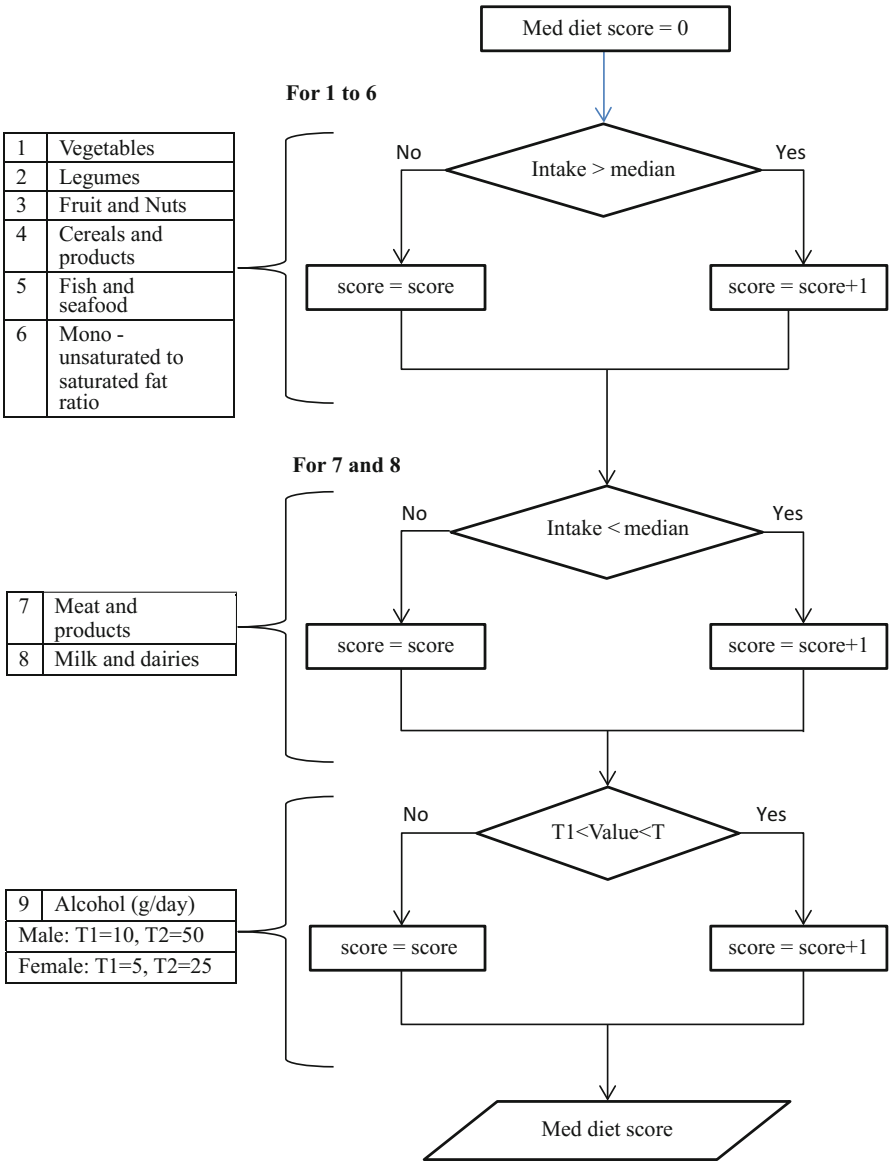

Fig. 1 Schematic presentation for the estimation of the Mediterranean diet score (Med diet score) [9]

disease in cohorts of men aged 40–59 years in seven countries, including three Mediterranean ones: Italy, Greece, and Croatia [18]. The baseline survey was carried out between 1958 and 1964 and information on diet was collected through food diaries in random subsamples of the 16 study cohorts. The study primarily provided evidence

for a strong positive association between the average saturated fat intake and overall mortality or mortality from coronary heart disease [19]. Although the Seven Countries Study mainly contributed to the understanding of the importance of the type of fat consumed on coronary heart disease risk, it certainly assisted in putting the whole diet of populations around the Mediterranean into the limelight. Indeed, the health indices observed in the region could not be explained by differences in education levels, financial status, or health care systems, simply because in this area in the 1960s, socioeconomic indicators were much lower than those in more developed areas of the world. Therefore, attention has focused on the overall diet of Mediterranean populations through a holistic approach, as one of the key explanatory factors [19].

The interest of the scientific community in the traditional diet of populations in the Mediterranean region and its health promoting effects thrived after mid 1990s and the publication of a prospective study conducted among elderly Greeks residing in rural areas [20]. The researchers recorded the usual dietary intakes of about 180 males and females aged 70 years and over and observed that higher adherence to Mediterranean diet (as assessed by the score described above) was significantly associated with a reduced risk of death from any cause by 17% per one unit increase in the score (95%CI: 1–31%). Authors additionally evaluated the association of each one of the components of the Mediterranean diet with overall mortality and noted that the individual components of the diet score had weak and generally nonsignificant associations with survival, whereas the overall score had a substantial and statistically significant effect.

In several case-control and prospective cohort studies, as well as experimental studies, mostly conducted among Mediterranean populations in Europe, the Mediterranean diet has been associated with a reduced incidence of coronary heart disease, stroke, and cancer, and with beneficial effects on cardiovascular disease-related markers [21–23]. Dietary intakes following the principles of Mediterranean diet have also been associated with self-perceived mental and physical health, global cognitive function, as well as an overall higher quality of life [24–26]. The consistent evidence from large-scale observational studies for its protective effects lead a group of investigators in Spain to the undertaking of the "Prevención con Dieta Mediterránea" (PREDIMED) study, a large nutritional trial assessing the long-term effects of Mediterranean diet on the primary prevention of cardiovascular disease. Men (55–80 years of age) and women (60–80 years of age) with no cardiovascular disease at enrolment were eligible for inclusion in the study if they had either type II diabetes mellitus or at least three of the following risk factors: smoking, hypertension, elevated low-density lipoprotein cholesterol levels, low high-density lipoprotein cholesterol levels, overweight or obesity, or a family history of premature coronary heart disease. About 7500 individuals at high cardiovascular risk were randomized to follow: (a) a Mediterranean diet supplemented with freely provided extra virgin olive oil, (b) a Mediterranean diet supplemented with mixed nuts again provided to participants at no cost, or (c) the control diet (advice to reduce all dietary fats). The main findings of the trial showed that a Mediterranean diet supplemented with extra virgin olive oil reduced the incidence of major cardiovascular events by approximately 30% [hazard ratio (HR) 0.70; 95% CI: 0.54, 0.92) and by 28%

[HR 0.72; 95% CI: 0.54, 0.96] when supplemented with nuts, in comparison to the control diet [27]. Although PREDIMED was planned as a 6-year trial, it was stopped after a median follow-up time of 4.8 years (interquartile range, 2.8–5.8 years) on the basis of early statistically significant results on the beneficial effect of following a Mediterranean diet on premature mortality. Subsequent analyses identified further benefits on blood pressure, insulin sensitivity, lipid profiles, lipoprotein particles, inflammation, oxidative stress, and carotid atherosclerosis [4, 28], providing strong experimental support for the advantages of consuming a Mediterranean diet.

The bulk of publications around the health-promoting effects of the Mediterranean diet have been systematically reviewed through several meta-analyses. In a review of prospective cohort studies that investigated possible associations of adherence to the Mediterranean diet and overall or disease-specific mortality, Sofi et al. [29] observed that a two-point increase of adherence to the Mediterranean diet was associated with a significant protection against premature death and the incidence of cardiovascular and other chronic degenerative diseases. These findings were further confirmed in 2010 in a meta-analysis which considered the studies of the earlier analysis, together with seven prospective studies published in 2009 and 2010 (one study for overall mortality; three studies for cardiovascular incidence and mortality; one study for cancer incidence and mortality; and two studies for neurodegenerative diseases) [21]. The meta-analysis included 50,000 incident cases or deaths from any cause and/or cause-specific. Authors observed that a two-point increase in adherence to the Mediterranean diet was associated with a significant reduction of overall mortality (pooled relative risk (RR): 0.92; 95% CI: 0.90, 0.94, cardiovascular incidence and mortality (pooled RR: 0.90; 95% CI: 0.87, 0.93), cancer incidence and mortality (pooled RR: 0.94; 95% CI: 0.92, 0.96), and occurrence of neurodegenerative disease (pooled RR: 0.87; 95% CI: 0.81, 0.94). There was no evidence for publication bias in the included results [21].

In their systematic review of randomized controlled trials assessing the effect of diets with unrestricted fat intake and following the principles of the Mediterranean diet to CVD risk compared to any control diet, Liyanage et al. [30] retrieved six studies among adults with follow-up periods longer than 3 months. The studies reported effects on major vascular events ($n = 477$), death from any cause ($n = 693$), and vascular deaths ($n = 315$). When data from all studies were combined, a Mediterranean-type diet protected against major vascular events (pooled RR: 0.63, 95% CI: 0.53–0.75), coronary events (pooled RR: 0.65, 95% CI: 0.50–0.85), stroke (pooled RR: 0.65, 95% CI: 0.48–0.88), and heart failure (pooled RR: 0.30, 95% CI: 0.17–0.56), but not for all-cause mortality (pooled RR: 1.00, 95% CI: 0.86–1.15) or cardiovascular mortality (pooled RR: 0.90, 95% CI: 0.72–1.11). Schwingshackl and Hoffmann [31] reviewed observational (case-control and cohort) studies to assess the effect of adherence to Mediterranean Diet on overall cancer mortality, incidence of different types of cancer, as well as fatality among cancer survivors. An overall population of 1,784,404 individuals from 56 studies was included in this analysis. The highest score of adherence to Mediterranean diet was associated with a lower risk of death from cancer at any site (pooled RR: 0.87, 95% CI 0.81–0.93), colorectal cancer (pooled RR: 0.83, 95% CI

0.76–0.89), breast cancer (pooled RR: 0.93, 95% CI 0.87–0.99), gastric cancer (pooled RR: 0.73, 95% CI 0.55–0.97), prostate cancer (pooled RR: 0.96, 95% CI 0.92–1.00), liver cancer (pooled RR: 0.58, 95% CI 0.46–0.73), head and neck cancer (pooled RR: 0.40, 95% CI 0.24–0.66), pancreatic cancer (pooled RR: 0.48, 95% CI 0.35–0.66), and respiratory cancer (pooled RR: 0.10, 95% CI 0.01–0.70). Based on a small number of studies among cancer survivors, there was no association between the highest adherence to Mediterranean diet and risk of death (three cohort studies), or cancer recurrence (one cohort study). In particular, the pooled RR for death from cancer among patients was 1.01 when individuals with highest adherence to Mediterranean diet were compared to those with lower adherence (95% CI: 0.81–1.26).

In order to summarize the evidence and evaluate the validity of the association between adherence to the Mediterranean diet and multiple health outcomes reported by several systematic reviews, Dinu et al. [32] reviewed evidence across meta-analyses of observational studies and randomized clinical trials. Thirteen meta-analyses of observational studies and 16 meta-analyses of randomized trials investigating the association between adherence to Mediterranean diet and 37 different health outcomes were analyzed. The evidence for a beneficial effect of Mediterranean diet was robust and supported by a strong statistically significant finding, large simple sizes, and not considerable heterogeneity among studies for overall mortality, cardiovascular diseases, overall cancer incidence, neurodegenerative diseases, and diabetes. For most of the site-specific cancers, as well as for inflammatory and metabolic parameters, the evidence was only suggestive or weak. No evidence was reported for bladder, endometrial and ovarian cancers, as well as for low density lipoprotein-cholesterol levels.

Furthermore, investigations among individuals residing in non-Mediterranean regions such as Denmark and the Netherlands in Europe, Melbourne in Australia, China, and the US provided additional evidence that adherence to the principles of the Mediterranean diet affects the survival of elderly people [33–37]. In these studies, an increase in a diet score derived from the key features of the traditional Mediterranean diet was associated with a significant reduction in overall and cause-specific mortality. The evidence that the beneficial effect of adherence to Mediterranean diet on the risk of premature death prevails also among individuals in areas distant to the Mediterranean basin rejected the possibility of an association confounded by nondiet-related factors, as well as the probability of effect modifiers shaping the health-promoting effects of the Mediterranean diet. Thus, one could safely argue that it is not the climatic, social, and cultural conditions that shaped this association, that the evidence for an independent effect of diet on overall survival is reinforced.

The findings of epidemiological studies are additionally supported by accumulating evidence from laboratory studies, which point to the converging effects of Mediterranean diet and olive oil (particularly the virgin or extra virgin olive oil that has not undergone excessive process) on the homeostatic control of genes implicated in cardiovascular risk, such as lipid metabolism, vessel protection, and blood pressure control, immune-inflammatory pathways, metabolic regulation, and detoxification of reactive species [5]. The impressive growth of the omic technologies provides new insight in the molecular and metabolic effects of functional components

of olive oil and other Mediterranean foods. Transcriptomic fingerprints revealed molecular targets in the area of primary prevention and clinical management of cardiovascular disease, as well as other degenerative age-related disorders [38].

4 Spatial and Time Differences in Food Intake

4.1 Sources of Dietary Data

In spite of the catholic recognition of Mediterranean diet as a health-conducive pattern, several populations in the region seem to be gradually abandoning it. Data to monitor food consumption over time and among different regions can be derived from three main sources: (a) the Food and Agriculture Organization assembled Food Balance Sheets (FBS), (b) the Household Budget Surveys (HBS), and (c) Nutrition Surveys, the latter collecting detailed, quantitative data on the usual food and beverage intake of a large – and often representative – sample of the target population.

The FBS provide information on food quantities assumed to be available for human consumption in the country, estimated on the basis of the annual food production, imports and exports, changes in stocks, agricultural and industrial uses within a country, as well as losses during storage and transportation (http://www.fao.org/faostat/en/#data/FBS). The data refer to the early stages of the food chain and the per capita supply is obtained by dividing the respective food quantity by the population partaking of it. The total population estimates, however, refer as a rule to resident population only, while nonresident population, such as tourists, illegal immigrants, refugees, etc., are generally not included. This omission may therefore result in an underestimation of the total partaker population and an overestimation of the various per-person food supplies. The accuracy of FBS data are further dependent on the reliability of the underlying basic statistics, which vary in terms of coverage and accuracy. Although import and export data are generally accurate, in some cases there may be some trade across national boundaries that goes unrecorded. Data on own food production are collected in some countries, but this information can be substantially under-recorded where there is a thriving economy in home production. Waste and food given to pets may also be sources of error. Hence, given the nature of the FBS and their inherent limitations, the data are interpreted to provide information on annual per capita supply of foods to the population.

Household budget surveys are systematically conducted by National Statistical Offices and aim at collecting, among others, data on food availability at household level. Household budget surveys provide information on products available for consumption to a nationally representative sample. The members of the participating households are asked to record information on all foods and beverages available in the household during a reference period, including purchases, contributions from own production, and food items offered to members as gifts. The survey is implemented over a period of a year, with due attention to capture seasonal variation in food intake. Information on the demographic and socioeconomic characteristics of the household

members is also recorded, allowing analyses on the effect of socioeconomic determinants on food choices (http://www.hhf-greece.gr/DafnesoftWebV2/). The HBS are not primarily designed to collect nutritional information and the food data bear limitations, which need to be considered when they are used for the purpose of nutritional surveillance. In most cases, no records are collected on the type and quantity of food items and beverages consumed outside the home (at restaurants, canteens, and similar establishments, for example); food losses and waste, foods given to pets, as well as meals offered to guests are not consistently collected; and gender- and age-specific estimations of food consumption require the application of statistical modeling [39]. The data collected though the HBS provide information on the daily availability of foods and beverages to a nationally representative sample of each country's households.

The individual-based nutrition surveys constitute the optimal method for assessing dietary patterns, quantifying determinants of food choices, and evaluating diet-disease associations. Being expensive and labor intensive, however, representative individual-based surveys are undertaken regularly in only a limited number of countries, usually those with robust economies and years of experience in this field. Furthermore, the implementation of various protocols and data collection methods limits the potential to undertake comparisons between countries.

Notwithstanding their caveats, countries with no routine information on the food consumption of large samples of their population, as well as those interested in comparing their national dietary patterns over time or with those of other populations, have traditionally used the FBS or the HBS data [40, 41]. They both provide a resource for conducting comparative nutritional analyses and could help highlighting issues such as (a) the dietary patterns prevailing in different countries and their sociodemographic determinants; (b) time trends in the food habits of populations; and (c) the evaluation of nutrition action plans, interventions, and related strategies implemented at national or international level [42].

5 Monitoring the Intake of Mediterranean Foods

Making use of FBS data referring to the periods between 1961 and 1963 and between 1998 and 2000, Balanza et al. [43] calculated changes in total energy, energy provided from macronutrients, and specific food groups for three European regions: Southern or Mediterranean (including Spain, Portugal, Italy, Greece, France, Cyprus, and Albania), Northern (combining the UK, Sweden, Norway, Finland, Germany, Ireland, Denmark, and Iceland), and Eastern Europe (comprising the Czech Republic, Slovakia, Poland, Bulgaria, Hungary, and Romania). Over the study period, the supply of total energy and energy from lipids increased considerably in all European areas, while the percentage of energy from carbohydrates decreased. The greatest changes have occurred in Mediterranean Europe where, contrary to traditional eating habits, a significant reduction in the energy supplied by cereals (30%) and wine (55%) and an increase in the supply of milk (78%) and dairy products (24%) was noted. Overall, such changes led to an increase of 20% in

the total supply of calories, comprising an increase of 48% in calories from lipids, mostly of animal origin and a fall of 21% in calories from carbohydrates.

In another comparison of FBS data referring to the periods 1961–1965 and 2000–2004 and covering Mediterranean countries in Europe, Africa and the Middle-East, as well as countries in other regions (North and Central Europe, North and South America, Asia, and Australia), Vareiro et al. [41] confirmed previous findings that the greatest changes in food supplies took place in Mediterranean Europe, with an increase in the per capita supply of non-Mediterranean foods (animal fats, vegetable oils other than olive oil, sugar, and meat) and a decrease in the supply of legumes and alcoholic beverages, including wine. However, although gradually abandoning some of its typical characteristics, the Mediterranean countries of Europe still recorded higher per capita supplies of olive oil, vegetables, fruit, and fish than other areas. Interestingly, during the same periods, northern European countries tended to increase the consumption of Mediterranean foods such as olive oil and fruit.

According to an analysis of HBS data collected in the 1980s and early 1990s including nationally representative samples of households from several European countries [44], in Greece and Spain the mean daily population intake exceeded the WHO recommendations of at least 400 g of combined fruit and vegetable intake per day. However, the correlation between the proportion of low fruit and low vegetable consumers was unexpectedly weak (Spearman's correlation coefficient: +0.18), suggesting differential preferences toward the consumption of fruit and vegetables among the surveyed populations. Moreover, more than 50% of the households in the surveyed populations were likely to consume less than the recommended daily vegetable intake of three portions, and this applied even to the two Mediterranean populations included in this analysis. In particular, 56% of the households in Greece and 76% of the households in Spain failed to report three portions of vegetables per day.

Using FBS data collected from 1961 up to 2013 (http://www.fao.org/faostat/en/#data/FBS), Tables 1 and 2 present the annual supplies as well as the average change in the annual supply of food groups, components of the Mediterranean diet. Table 1 presents the supply of foods of livestock production and milk (animal foods); vegetables, fruit, cereals and cereal products, beans, peas, and other legumes (plant foods); and all types of fish, crustaceans, cephalopods, and mollusks (fish and seafood) in 15 countries surrounding the Mediterranean basin. Table 2 presents data for the supply of olive oil and wine. In general, annual supplies reflect local production and food preferences shaped by cultural norms. For instance, the supply of olive oil is highest in the three main olive oil producing countries (Greece, Italy, and Spain), while the supply of wine is low in countries with a high percentage of Muslims in the population (Algeria, Egypt, and Turkey). In the 50-year period between 1961 and 2013, all Mediterranean countries recorded an increase in the supply of animal foods, fish, and seafood. The supply of plant foods increased in the majority of countries; a decrease between 1961 and 2013 was however recorded in Cyprus (approximately 80 kg/capita) and in Spain (about 65 kg/capita) and to a lesser extent in Israel (7 kg/capita). On average, all countries recorded a small – and

Table 1 Supply of animal and plant foods, fish and seafood (kg/capita/year) in Mediterranean countries in 1961 and 2003 and average changes per year

[b]1992
[c]2006

in many cases negligible – increase in the supply of fish and seafood. Regarding olive oil, some countries recorded remarkable reductions in the per capita supply between 1961 and 2013. The per capita annual supply of olive oil reduced by 3.6 kg in Tunisia, 2.5 kg in Turkey, and 1 kg in Greece. The changes in the per capita annual supply of wine were more variable – some countries recorded an increase (such as Malta and Montenegro), while others recorded a substantial decrease (Italy and Croatia).

Yearly trends in food supply are graphically presented in Figs. 2–6 for six countries (Algeria, Greece, Italy, Spain, Tunisia, and Turkey) selected on the basis of geographical coverage and observations from Tables 1 and 2. In the years between 1961 (when the Mediterranean diet was registered through the Seven Countries Study) and 2013 (the latest year available in the database), the daily supply of animal foods (livestock products and milk) was steadily increasing (Fig. 2). A slight decrease in the daily supply of animal foods was recorded in Italy in the period between 1983 and 1993, but in 2013, per capita supplies were higher than the ones in early 1960s. The pattern of changes over time is more variable in the case of foods of plant origin (Fig. 3). Overall, the daily supply increased in Algeria and Tunisia, remained rather stable in Italy and Greece and since late 1980s decreased in Spain. The consistency in the daily supply of fish and seafood present in Table 1 is also

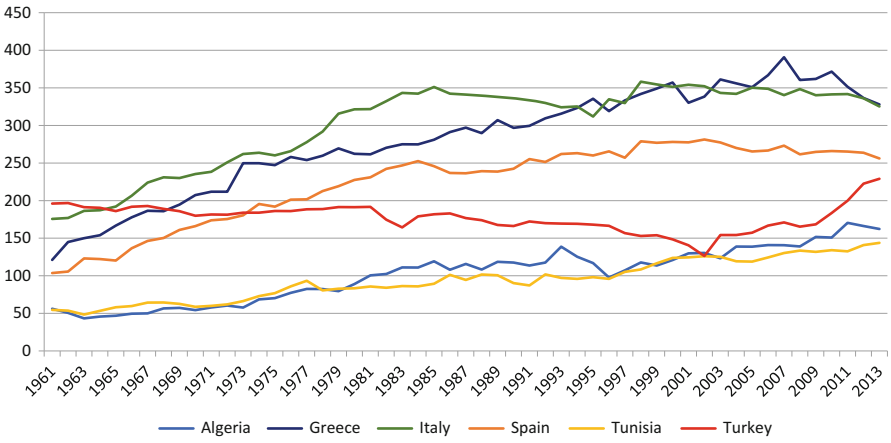

Fig. 2 Trends over time in the supply of animal foods (kg/capita/year) in Mediterranean countries

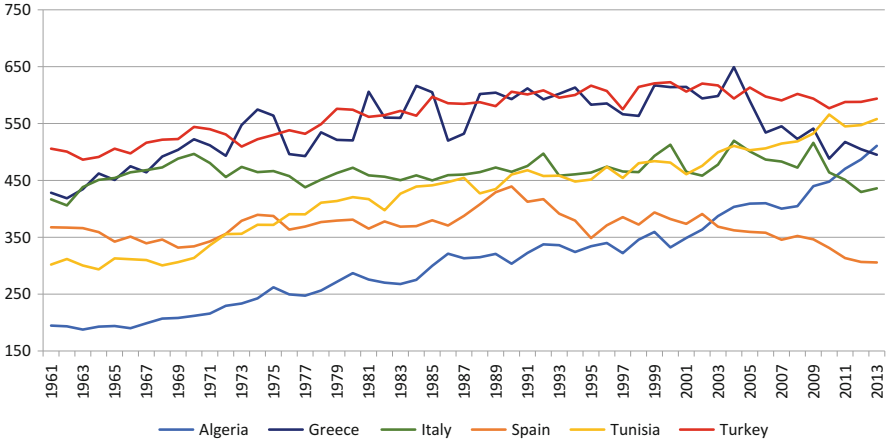

Fig. 3 Trends over time in the supply of plant foods (kg/capita/year) in Mediterranean countries

evident through Fig. 4, where changes per year are presented. Fish intake in Spain is popular, since not only the daily supply constantly outweighs that of the other Mediterranean countries, but it increased steadily leading to 10 kg/capita higher daily supply in 2013 in comparison to 1961. Greece has been leading the daily supply of olive oil since the early 1960s (Fig. 5), followed only by Italy and Spain after the late 1970s. However, the daily supply of olive oil has been constantly decreasing in Greece since mid-1970s, and although it remains the highest, the difference with the other Mediterranean countries in Europe is narrowing. Over time, changes in the daily supply of wine are presented in Fig. 6. Values are very low among countries with large percentage of Muslims in their population and they probably reflect the consumption of wine by tourists visiting these countries. Differences over the years were not remarkable in Greece and Spain, while in Italy the

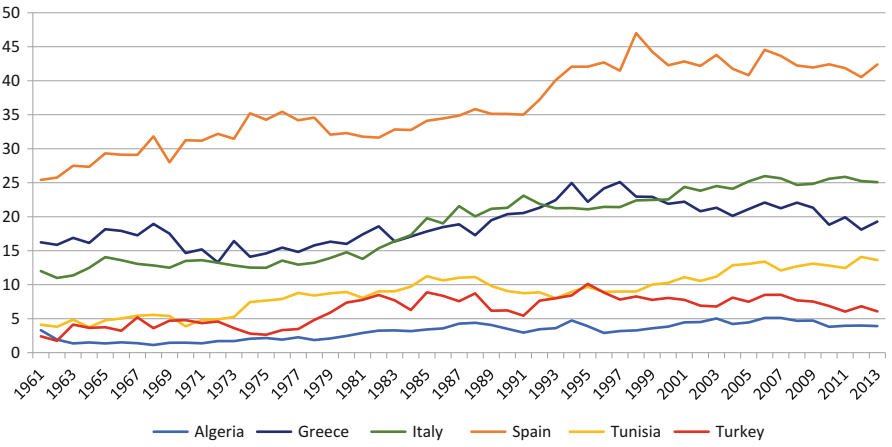

Fig. 4 Trends over time in the supply of fish and other seafood (kg/capita/year) in Mediterranean countries

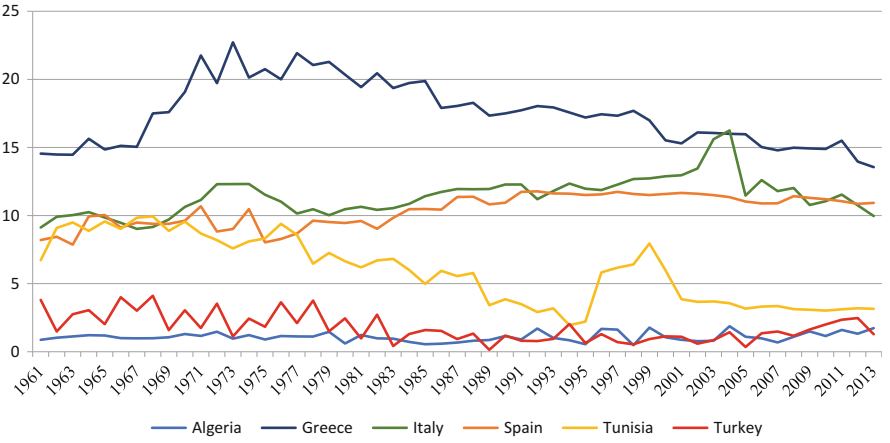

Fig. 5 Trends over time in the supply of olive oil (kg/capita/year) in Mediterranean countries

supply of wine continuously decreased since mid-1970s and is now closer to that recorded in other European Mediterranean countries.

6 Monitoring Adherence to the Overall Mediterranean Dietary Pattern

The ecological evidence that Mediterranean populations are gradually departing from their traditional eating habits has been reproduced in large-scale nutritional surveys among children, adolescents, and adults [45, 46]. In a report presenting harmonized data for nutrition and health indices in Europe based on studies with

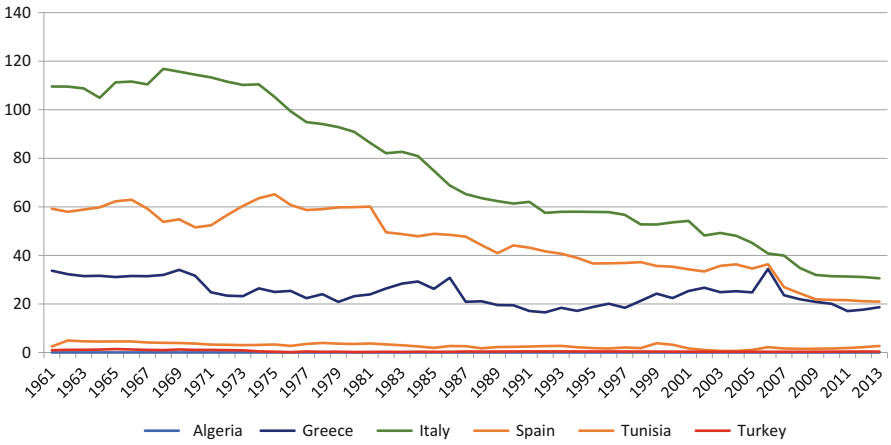

Fig. 6 Trends over time in the supply of wine (kg/capita/year) in Mediterranean countries

wide population coverage, individuals in the Mediterranean region reported higher intakes of red meat and saturated fatty acids and lower intakes of plant products in comparison to their European counterparts [47]. Publications presenting changes over time in the dietary habits of populations participating in the Seven Countries Study further support that the Mediterraneans are abandoning their traditional eating choices. In early 1990s, Kafatos and colleagues conducted a follow-up study of 245 surviving men in Crete aged 70–89 years, who had participated in the Seven Countries Study in the 1960s [48]. A representative subsample of 21 among them further provided 3-day weighed food records, which indicated increases in the intake of saturated and decreases in monounsaturated fatty acids [48]. De Lorenzo and colleagues [49] studied differences in food habits in Nicotera, one of the south Italian rural areas of the Seven Countries Study, between 1960 and 1996. In the second assessment, 80 inhabitants of Nicotera (43 males, 37 females, aged 40–59 years) with no indication of chronic disease and not under regular medication or on a special diet were selected at random. Based on dietary data collected through a food frequency questionnaire, authors estimated the participants' Mediterranean Adequacy Index and noted that the mean index decreased from 9.4 for males and 11.4 for females in 1960 to 2.8 and 2.5, respectively, in 1996. Regarding specific food items, authors observed an increase in the consumption of animal foods, cakes, pies, cookies, and sweet beverages among both men and women. Not disregarding methodological characteristics of the 1996 study that may limit direct comparisons with the 1960 data, results indicate a significant reduction to the extent through which the population adhered to the Mediterranean diet. Similar results were also observed in Crevalcore (northern Italy) and Montegiorgio (central Italy), the other two rural Italian cohorts participating to the Seven Countries Study [49], as well as to other studies among adult Mediterranean populations [45].

Lower adherence to the traditional Mediterranean diet has also been consistently reported among children, adolescents, and young adults, the trend-setters of dietary

habits and lifestyle choices of future generations. In their review of studies assessing the adherence to Mediterranean diet among children and adolescents, Iaccarino Idelson et al. [46] analyzed the results of studies which applied the KIDMED index and were mainly conducted in European Mediterranean countries (49 out of the 55 eligible studies). Adherence varied widely both within and between Mediterranean populations. Based on studies covering large samples, poor adherence to Mediterranean diet varied from 1.6% in Spanish children to 62.8% in Greek adolescents; average adherence from 28.0% in Greek adolescents to 73.8% in Italian adolescents residing in rural areas; and good adherence from 4.3% in Greek 10–12 year olds to 53.9% in Spanish children. According to most of the studies, adherence to Mediterranean diet was directly associated with physical activity (and possibly with diet adequacy) and inversely with sedentary behavior. Gender, age, the family's socioeconomic status, and the children's body weight were possible determinants of the level of adherence.

Low consumption of plant foods and a prevalent intake of commercial sweet and savory cereal products have been the main components explaining poor to average adherence. In their review of the diet of preschool children in the Mediterranean countries of the European Union, Pereira-da-Silva et al. [50] reported that in the majority of countries, young children consumed frequently fruit and vegetables, but also sugared beverages and snacks. The majority of children reported high energy and high protein intakes mainly from dairy products, together with excessive sodium intake. The consumption of energy-dense foods and overweight were recorded as early as in toddler and preschool ages. Furthermore, most children reported low adherence to the Mediterranean diet, which was associated with being overweight or obese, lower maternal educational level, and parental unemployment.

In a study among 1740 Italian children 8–9 years old who were recruited from regions all over the country, a low consumption of fruit, vegetables, and legumes, and a high intake of commercially baked goods for breakfast and sweets were identified as contributors to the low adherence. About one-third of the sample reported that hindrances to the consumption of fruit, vegetables, and legumes were affecting their ability to follow a Mediterranean diet. In this study, only 5% of the children were identified as high adherers based on the KIDMED index [51].

In the cross-sectional analysis of the IDEFICS study, Tognon and colleagues [17] assessed adherence to the Mediterranean diet of 16,220 children aged 2–9 years old from eight European countries (Sweden, Germany, Hungary, Italy, Cyprus, Spain, Belgium, and Estonia), using a Mediterranean Diet Score based on the relative frequency of food group consumption. One point was given for intakes higher than the median relative frequency for (a) potatoes, vegetables, and legumes; (2) fruits and nuts; (3) cereals; or (4) fish; and one point if intakes were below the median for: (5) dairy and (6) meat products. The final score added up to a maximum of 6 points and a score equal or higher to 3 was interpreted as high adherence to a Mediterranean-like dietary pattern. In this study, the largest proportion of children with high intake frequencies of cereals, vegetables, potatoes, fruits, and nuts was recorded in Sweden. More than half of the Swedish children (56.7%) reported high adherence to components of the Mediterranean diet, followed by the Italians (37.5%) and the Germans (35.1%). The lowest levels were observed in Cyprus, where 75.8% of children had score values below 3 [17]. The

highest prevalence of children with a score higher than 3, which could be interpreted as average to high adherence, was recorded among the Italian preschool boys (55.9%) and the lowest among the Spanish school-aged girls (26.0%). Apparently, higher adherence to a Mediterranean-like dietary pattern was generally not associated with living in a Mediterranean country or in a highly educated or high-income family. Differences in adherence between boys and girls or age groups varied between countries without any general pattern. It should be noted, however, that the results on the level of adherence also varied according to the index used: for example, the proportion of children with high adherence ranged from 24.2% in Cyprus to 56.7% in Sweden using the score described above, and from 29.4% in Germany to 49.3% in Italy using a different score, formulated on the basis of an adaptation of the Mediterranean diet score [46].

In the multi-center IDEFICS study, different food groups contributed to high adherence levels in each country. Hence, among Italian children, the low adherence could be attributed to a low consumption of vegetables and legumes (prevalence of high consumers: 36.2%), while in Sweden high adherence was achieved through a low consumption of dairy and meat products (prevalence of high consumers of dairies: 24.6%; and prevalence of high consumers of meat: 30.9%). The consumption of olive oil and vegetable oils is still more prevalent among children in the Mediterranean region than in other European countries – the prevalence of children above the median for the unsaturated to saturated fatty acid ratio was equal to 72.6% in Italy and to 58.7% in Cyprus. The children in Spain have consistently been identified among the highest consumers of fish and other seafood.

Some alarming findings have been reported from studies conducted in Greece and Cyprus. In a representative sample of 554 Greek children and 358 adolescents, Kontogianni and colleagues assessed adherence to the Mediterranean diet using the KIDMED index [52]. Only 11.3% of children and 8.3% of adolescents had an optimal score ($\geq$8). Among children, KIDMED scores did not differ between boys (mean $\pm$ SD: 5.4 $\pm$ 1.9) and girls (5.4 $\pm$ 1.7), but in adolescents, the index tended to be higher among females (4.9 $\pm$ 2.1) than among males (4.6 $\pm$ 2.0) (p-value: 0.07). In a study of 1140 Cypriot children aged 9–13 years old using the KIDMED score too, only 8.7% of the boys and 5.3% of the girls were classified as high adherers (score $\geq$ 8) and 38.5% of boys and 36.3% of girls had a KIDMED score ranging from 0 to 3 [53]. In the context of the GRECO study, including a representative sample of Greek children aged 10–12 years old, Farajian et al. [54] reported that only 4.3% of the children had an optimal KIDMED score ($\geq$8) and about half of the children (46.8%) were classified as poor adherers ($\leq$3). The score values did not differ between boys and girls, normal weight, overweight, or obese children. Children with higher KIDMED scores resided in semiurban or rural regions and reported higher physical activity levels.

7 Conclusion

The Mediterranean diet is characterized by a high intake of plant foods (fruit, vegetables, cereals, nuts, legumes) and fish, together with a low intake of products of animal origin (meat, milk and diaries). Olive oil is the most frequent – if not the

only – lipid added to food, and alcohol intake is moderate and mostly in the form of wine, preferably during meals. There is increasing evidence from observational and experimental epidemiological studies that adherence to the Mediterranean dietary pattern promotes health and reduces the risk of premature death from chronic degenerative diseases. These conclusions are further supported by large systematic reviews and meta-analyses. Nonetheless, Mediterranean countries and especially the European ones have experienced a "westernization" process of their food habits, and have increasingly been exhibiting patterns of food choices similar to non-Mediterranean ones. In a period when other western countries experience a nutrition transition that favors the Mediterranean dietary pattern [47], traditional food choices in Italy, Greece, and other Mediterranean regions are abandoned. This could be attributed to the globalization of the food supply, the overall improvement in socioeconomic conditions in Europe that made food (especially of animal origin) more affordable, and the urbanization of life, which primarily affects the younger generations.

The westernized diets – particularly followed by the youth in the region – have been associated with higher disease and mortality rates in North Europe and USA [55, 56]. Unfavorable changes in disease rates may eventually appear and may lead to an increase of the demand and the cost of health services, an issue of concern in era of limited resources both at the individual and governmental levels. Moreover, these food choices cannot support sustainable development, in the way the Mediterranean diet does. Being adjusted to the cultural, climatic, and other environmental characteristics of the region, the Mediterranean diet is protective and helpful to biodiversity; accessible and economically affordable; can lead to a cut down of country's expenses for food imports; and contributes to food and nutrition security, as well as to the health of present and future generations [57, 58].

Flavonoids – Food Sources, Health Benefits, and Mechanisms Involved

3

Aleksandra Kozłowska and Dorota Szostak-Węgierek

Contents

Abstract

In recent years, growing attention has been focused on the use of natural sources of antioxidants in the prevention of chronic diseases. Flavonoids are the examples of such substances. It is a group of bioactive compounds that are widely distributed in many plant-based foods and beverages. Flavonoid-rich products include,

among others, berries, citrus fruits, grapes, cherries, dock, arugula, onions, artichokes, soybeans, cowpeas, black beans, parsley, oregano, and tea. Flavonoids exhibit a wide range of positive effects, such as strong antioxidant, anti-inflammatory, and antiplatelet activities. They may contribute to the prevention of chronic diseases, including metabolic disorders, diabetes, and cardiovascular disease, because of their beneficial effect on blood lipids, blood pressure, plasma glucose levels, and also stabilization of athetosclerotic plaque. Furthermore, evidence from epidemiological, animal, and in vitro studies support protective effects of foods and dietary supplements rich in flavonoids against some types of cancer, Alzheimer's disease, Parkinson's disease, some viral infections, cataract, erectile dysfunction, and inflammatory bowel disease. Consumption of flavonoids with diet appears to be safe. There is a growing body of evidence that a diet rich in these substances is beneficial for health and its promotion is thus justifiable.

1 Introduction

This chapter provides the current state of knowledge about the role of flavonoids in prevention and treatment of chronic diseases (CD). It is a comprehensive review of literature on both flavonoids as the whole group and also flavonoid subclasses. We believe that the presented data will be useful for both researchers and practitioners in medicine and dietetics.

The history of research on flavonoids goes back several decades. In 1930, a new substance was isolated from lemon juice by Hungarian Nobel laureate Albert Szent-Gyorgyi, who also discovered vitamin C. At that time, it was believed to be a member of a new class of vitamins and was referred to as vitamin P. Later, it became clear that this substance was a flavonoid (rutin) and till now at least 6000 different types of flavonoids have been identified [1, 2].

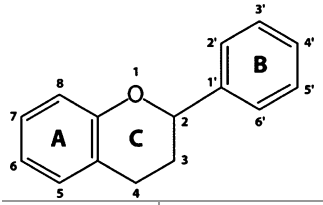
Flavonoids are secondary metabolites of higher plants and represent a large class of phenolic compounds found in fruits, vegetables, herbs, cocoa, and some beverage products [3]. They have several important functions in plants, such as providing protection against harmful UV radiation or plant pigmentation. In addition, they regulate gene expression and modulate enzymatic action. They also have antiviral and antibacterial properties, as well as high antioxidant capacity. These compounds are primarily synthesized for the plants' own defense against oxidative stress. However, they maintain antioxidant properties also ex planta and hence contribute to the pharmaceutical and dietary attributes of plant foods. Therefore, antioxidant properties of flavonoids are all-important for both plant and human biology [4, 5].

2 Flavonoids: Classification, Sources, and Dietary Intake

Flavonoids constitute a class of polyphenols. All naturally occurring flavonoids possess three hydroxyl groups, two of which are on the ring A at positions five and seven and one is located on the ring B, position three. They can be subdivided into different subgroups depending on the number of the carbon atom of the C ring to which the B ring is attached and also the degree of unsaturation and oxidation of the C ring. Flavonoids in which the B ring is linked in position 3 of the C ring are called isoflavones. Those in which the B ring is linked in position 2 can be further subdivided into several subgroups on the basis of the structural features of the C ring. These following subgroups are: flavones, flavonols, flavanones, flavanols or catechins, and anthocyanins. Some authors have additionally distinguished flavanonols, chalcone, and neoflavonoids subclasses [6]. Table 1 presents the basic structure of flavonoid and examples of specific substances in each flavonoid subclass.

Important dietary sources of flavonoids are vegetables, fruits, seeds, and some cereals, together with wine, tea, and certain spices (Table 2). The most abundant sources are berries, cowpeas, dock, kale, dark chocolate, parsley, oregano, capres, green and black tea. It is important to note that the presence of flavonoids in vegetables and fruits may greatly vary depending on the crop variety, processing, climate, seasonality, plant species, manufacture, and storage. Differences in flavonoid contents between plant species are usually moderate, although in a few cases very high amounts have been observed, e.g., in certain berries and tea prepared from leaves of the Quingmao tree [7].

Table 1 Basic structure of flavonoid and subclasses of flavonoids (Authors' selection based on Refs. [5–8])

Basic structure of flavonoid	
	


Subclass	Examples of compounds
Anthocyanins	Pelargonidin, cyanidin, delphinidin, peonidin, petunidin, malvidin
Flavanols	Epicatechin, catechin, epicatechin gallate (ECG), gallocatechin, epigallocatechin (EGC), epigallocatechin gallate (EGCG)
Flavanones	Naringenin, naringin, hesperetin, eriodicytol
Flavones	Sinensetin, isosinensetin, nobiletin, tangeretin, luteolin, apigenin, chrysin, galangin
Flavonols	Kaempferol, quercetin, fisetin, isorhamnetin, myricetin
Isoflavones	Daidzein, genistein, daidzin

Table 2 Content of flavonoids in chosen foodstuffs (mg/100 g foodstuff) (Authors' selection based on Ref. [7])

Range of flavonoids' content	Products (flavonoids mg/100 g)
>1500 mg/100 g	Parsley, dried (4854.49), oregano, Mexican, dried (1545.79)
300 mg–1500 mg/100 g	Elderberries (518.13), Capres, raw (493.03), chokeberry (368.66)
100 mg–300 mg/100 g	Cowpeas (277.41), parsley, fresh (233.16), currants, black (167.47), blueberries (158.51), blackberries (137.66), green tea, brewed (121.27), black tea, brewed (119.32), cranberries (113.58), dark chocolate (108.60), cocoa, dry powder (106.68), dock (102.20)
70 mg–100 mg/100 g	Kale (92.98), fennel (84.50), currants, red (79.49), kumquats (79.26), black currant juice (78.04) white tea, brewed (74.60)
40 mg–70 mg/100 g	Arugula (69.27), cabbage, red (64.34), peppermint, fresh (60.48), grapefruit (55.40), lemons (53.38), oolong tea, brewed (52.37), limes (48.60), grapes, red (48.35), thyme, fresh (47.75), raspberries (47.58), onions, red (44.87), oranges (43.49), wine, table red (40.84), cherries (40.00)
10 mg–40 mg/100 g	Strawberries (34.31), pecans (34.01) beans, black (28.00), radishes (26.52), wheat, purple (25.85), Orange juice (24.13), celery hearts, green (22.60), artichokes (22.20), chives (21.67), pears (21.53), peppers, hot chili (21.17), broadbeans, cooked (20.63), lettuce, red (19.40), pink grapefruit juice (17.97), buckwheat (15.38), asparagus, cooked (15.16), milk chocolate (15.04), pistachio (14.37), plums (14.23), cress, fresh (14.00), apple (13.73), bananas (13.69), hazelnuts (11.96), chicory, green (11.79), spinach (11.44), almonds (11.00), beans, kidney, red (10.87), apricots (10.67), chard (10.43), endive (10.10)
<10 mg/100 g	Sorghum, red (8.43), Brussels sprouts, cooked (7.68), peppers, green (6.98), beer (3.34)

Extent of biological effects of flavonoids depend not only on their content in food, but also on bioavailability that is influenced by the source type (food or pharmaceutical formulation), consumers' characteristics, such as gender and age, their interindividual variations, including physiological and molecular factors, composition and activity of gastrointestinal microflora, and also differences in mechanisms of absorption and biotransformation of different compounds [2]. The main food sources of substances from particular subgroups are shown in Table 3.

There are several databases of flavonoids contents in foods which can be used to assess their consumption with human diet. Most studies estimate flavonoids intake using food composition tables such as the USDA databases and the online Phenol-Explorer database (www.phenol-explorer.eu). However, these tables might be of limited use because only a restricted number of foods have been analysed for their polyphenol content using different analytical techniques. For this reason, the results of nutritional assessments may vary depending on the sort of database used. It should be emphasized that many surveys performed in 1990s could underestimate the actual intake of flavonoids as the databases of flavonoid content of foodstuffs were incomplete at that time. For

Table 3 Content of flavonoid subclasess in chosen foodstuffs (mg/100 g foodstuff) (Authors' selection based on Ref. [7])

Anthocyanins (mg/100 g)					
Elderberry juice concentrate	411.40	Blackberries	90.64	Pecan nuts	25.02
Chokeberry	349.79	Red currants	75.02	Red table wine	23.18
Bilberries	285.21	Red cabbage	63.50	Black grapes	21.63
Chickpeas	262.49	Raspberries	40.63	Pears	12.18
Black currants	154.77	Red bilberries	40.15	Morello cherries	7.45
American bilberries	141.03	Strawberries	27.76	Hazel nuts	6.71
Flavanols (mg/100 g)					
Green tea, brewed	116.15	Blackberries	42.50	Apples	9.17
Black tea, brewed	115.57	Cooked broad beans	20.63	Peaches	8.60
Dark chocolate	108.60	Pecan nuts	15.99	Apricots	8.41
Cocoa, dry powder	52.73	Red table wine	11.05	Apple juice	5.96
Flavanones (mg/100 g)					
Dried Mexican oregano	412.13	Limes	46.40	Grapefruit juice	18.98
Grapefruit	54.50	Oranges	42.57	Artichokes	12.51
Lemons	49.81	Orange juice	18.99		
Flavones (mg/100 g)					
Dried parsley	4523.25	Artichokes	9.69	Chicory	2.85
Dried oregano	1046.46	Green pepper	4.71	Lemons	1.90
Fresh parsley	216.15	Celeriac	3.90	Red grapes	1.30
Flavonols (mg/100 g)					
Fresh capers	493.03	Goji berries	31.20	Chicory	8.94
Dried parsley	331.24	Fresh cranberries	21.59	Buckwheat	7.09
Elderberry juice concentrate	108.16	Cooked asparagus	15.16	Dried and sweetened cranberries	6.91
Sorrel	102.20	Blackcurrants	11.53	Fresh figs	5.47
Rocket lettuce	69.27	American bilberries	10.59	Cooked brussel sprouts	5.24
Red onions	38.34	Morello cherries	9.41	Apples	3.40
Isoflavones (mg/100 g)					
Soy flour	166.66	Soybeans, raw	48.95	Clover, red	21.0
Soybeans mature seeds (Europe)	103.56	Miso	41.45	Soybeans, cooked	17.92
Natto	82.29	Soy yoghurt	33.17	Sufu	13.75
Tempeh	60.61	Tofu, different types	28.91	Pistachio nuts	3.63

proper interpretation of the results of assessment of flavonoids intake with diet, a kind and year of release of used database should be considered.

Recent evidence suggests that the total daily intake of flavonoids varies among nations and cultures. Habitual dietary intake of flavonoids is variable and in USA, estimated daily intake was on average 200.1 ± 8.9 mg/d, while in Europe, mean intakes among European adults ranged from 506 mg/d (the Central region) to 348 mg/d (the Northern region) and the 301 mg/d (the Southern region) [9, 10]. The mean total flavonoid intake in the Polish population was equal to 403.5 mg/day, when calculated with the use of the Phenol-Explorer database, and 525 mg/day, when the USDA databases were used [11]. These results contrast with our own results that demonstrated that the average daily flavonoid consumption among Polish students was equal to 801 mg [12].

3 Flavonoids Action and Current Research and Trends

It seems that a diet rich in flavonoids may be beneficial for human health [3]. Emerging evidence from epidemiological and randomized controlled trials support protective effects of foods and dietary supplements rich in flavonoids against chronic diseases, including coronary heart disease, type 2 diabetes mellitus, cancer, Alzheimer's disease, Parkinson's disease (PD), cataract, erectile dysfunction, and inflammatory bowel disease. In this subsection, we summarized results of epidemiological and animal studies, human clinical trials, and also in vitro studies on both flavonoids and flavonoids subclasses, that showed the main effects and mechanisms of flavonoid action.

3.1 Antioxidant and Anti-Inflammatory Action of Flavonoids

Flavonoids possess many biochemical properties, but the best investigated effect of almost all subclasses of flavonoids is their antioxidants activity. Almost every group of flavonoids has a capability to act as antioxidants. It was reported that flavones and catechins seem to be the most powerful flavonoids for protecting the body against reactive oxygen species [13, 14].

Antioxidant activity of flavonoids depends on their functional hydroxyl groups that can mediate antioxidant effects by scavenging free radicals and/or by chelating metal ions. Mechanisms of antioxidant action include suppression of reactive oxygen species (ROS) formation, either by inhibition of enzymes, or by chelating trace elements involved in free radical generation, scavenging ROS, and upregulation or protection of antioxidant defenses [2]. The chelation of metals seems to be crucial in the prevention of radical generation which damage target biomolecules. Some flavonoids are capable of inhibiting the enzymes involved in ROS generation, for example, microsomal monooxygenase, glutathione S-transferase, mitochondrial succinoxidase, NADH oxidase [15]. Antioxidant action of flavonoids may also

result from activation of antioxidant enzymes, such as catalase, glutathione peroxidase, and heme oxygenase-1 (HO-1), which have radical scavenging ability.

Flavonoids also may exhibit also anti-inflammatory action what can be mediated by inhibition of both the activity and production of various proinflammatory substances and enzymes, such as tumor necrosis factor α (TNF-α), cyclooxygenase (COX), and lipoxygenase (LOX) [16]. Moreover, flavonoids may play a role in resolution of inflammation also by inhibition of activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), which is responsible for control of transcription of DNA, cytokine production, and cell survival, and also by suppression of prostaglandin E2 (PGE2), which impairs T cell receptor signaling [17].

3.2 Cardioprotecive Action of Flavonoids

The well-recognised antioxidant properties of flavonoids resulted in the interest in their potential role in prevention of cardiovascular disease. Interestingly, the direct mechanisms are not well understood. It seems that the action of flavonoids is multifaceted and depends on parallel processes. Among the main mechanisms, there are: antioxidant and anti-inflammatory activities, regulation of blood pressure, decreases in cholesterol levels, protection of LDL against oxidative modification, and antiplatelet effects.

Lipid peroxidation is a common consequence of oxidative stress. High blood concentration of oxidatively modified low-density lipoproteins (ox-LDL) is one of the most important factors wich accelerates development of atherosclerosis. Flavonoids protect lipids against oxidative damage by various mechanisms. Because of their antioxidant and chelating properties, flavonoids inactivate reactive oxygen species (ROS) and this way counteract plasma LDL oxidation and ameliorate inflammation of the blood vessel endothelium [18].

Antiarteriosclerotic action of flavonoids is related also to the reduction of inflammation in the blood vessel wall through inhibition of the influx of leukocytes. It has been reported that some flavonoids exert also antiplatelet aggregation effects through various mechanisms, among which the inhibition of the arachidonic acid-based pathway seems to be the most representative [19]. They decrease activity of enzymes that participate in the formation of prostaglandins leukotrienes and thromboxane A2, substances that mediate inflammation and aggregation, from arachidonic acid. This results in decrease in inflammation and platelet aggregation. Inhibition of these enzymes results also in protection of LDL against oxidation and regulates capillary pressure back to normal [20].

Beyond of protection of blood vessels against ox-LDL, antiatheromatous action of flavonoids results also from suppression of 3-hydroxy-3-methylglutaryl-coenzyme A reductase (hHMGR) activity. This enzyme plays a key role in the synthesis of cholesterol in the human body and thereby influences its plasma levels. Inhibition of its activity lowers intracellular cholesterol concentrations and results in the following increase in expression of LDL receptors. This in turn raises the cellular lipoprotein uptake and removal of cholesterol from the circulation. Based on the

criteria of inhibition of hHMGR activity, many cholesterol-lowering drugs, such as statins, have been developed, and their efficacies in controlling blood cholesterol levels have been well recognized [20].

Anthocyanins, found in berries, blackcurrants, red grapes, plums, and cherries, are a good example of a flavonoids which reduce blood cholesterol level in patietns with high CVD risk. In a 6-month study, low-density lipoprotein cholesterol (LDL-C) concentrations were reduced following anthocyanins supplementation (320 mg/d) in 122 hypercholesterolemic patients, while the similar result was observed in another study performed among 58 diabetic patients who received purified anthocyanin supplementation (320 mg/d). This intervention significantly decreased serum LDL cholesterol (by 7.9%; $P < 0.05$), triglycerides (by 23.0%; $P < 0.01$), and increased HDL cholesterol (by 19.4%; $P < 0.05$) compared with placebo after the 24 weeks [21, 22]. Another randomized, double-blind, placebo-controlled clinical trial (80 hyperlipidemic patients) showed that 2 months supplementation with extract from fruit rich in anthocyanins, whortleberry fruit (350 mg capsule every 8 h) reduced serum levels of total cholesterol, triglyceride, and LDL-C by 27.6%, 19.2%, and 26.3%, respectively and increased that of HDL-C by 37.5% [23]. In turn, a 8-weeks dose-response study (50 g freeze-dried blueberries, which is egual to approximately 350 g fresh blueberries), performed in 48 participants with metabolic syndrome, demonstrated beneficial effects on plasma oxidized LDL (ox-LDL) and combined serum malondialdehyde (MDA) and hydroxynonenal (HNE) concentrations, which are biomarkers of lipid and lipoprotein oxidation and have also been associated with coronary artery disease. The decreases in ox-LDL and combined MDA and HNE were greater in the blueberry supplemented group (−28 and −27%, respectively) than in controls (−9 and −9%) ($P = 0.009$ and $P = 0.005$) (Basu et al. 2010).

It is also important to emphasize the remarkable role of anthocyanins in reduction of biomarkers of CVD risk. Results of four out of five analyzed recent studies suggested that increased habitual anthocyanins intake is significantly associated with a reduction in risk of coronary heart disease (CHD) by 12–32% in multivariate analyses [24–28].

Catechins, next to anthocyanins, play an important role in amelioration of cardiovascular disease risk factors. Catechins are the generic terms of flavanols, as well as the most important tea flavonoids. It was found that the intake of catechins at a rate of 576 mg per day for 24 weeks can significantly decrease body fat mass among 40 obese or near-obese children. Catechins could regulate the RNA and protein expression of fatty acid metabolism enzymes in the liver. They may affect the activity of metabolic enzymes, which can improve the oxidation of fatty acids and the inhibit fatty acid synthesis. This specific action of catechins may result in reduction of lipid levels in the blood and liver, as well as may decrease body fat deposition, thus reducing early onset of cardiovascular disease in children [29].

Quercetin, a flavonoid from the flavonol subclass, may be also effective as a cardioprotective agent. It was shown that its anti-inflammatory, antioxidant, and antiapoptotic effects can effectively protect against myocardial damage in rats. Compared with the control group, mRNA and protein levels of TNF-alpha and

IL-1beta and also malondialdehyde (MDA) content in myocardial tissue of rats in both the low-dose (100 mg quercetin/kg/daily) and high-dose (400 mg quercetin/kg/daily) groups decreased significantly. Antioxidant enzymes, such as superoxide dismutase (SOD) and catalase (CAT) activities increased significantly. The cell apoptosis index was significantly reduced [30]. In turn, human intervention studies demonstrated positive effects of 6 week treatment with quercetin-rich onion skin extract (162 mg/d quercetin) on blood pressure and endothelial function in 70 overweight-to-obese patients with (pre-) hypertension [31]. The mechanisms responsible for the BP-lowering effect remain unclear. The putative pathways include improvement of vascular function in an endothelium-dependent or endothelium-independent manner, decrease in oxidative stress, and/or interference with the renin–angiotensin–aldosterone system. Importantly, flavonoids can improve endothelial function by stimulating the nitric oxide (NO) bioavailability, a key regulator of vascular function, leading to improvements in vascular tone and blood pressure regulation [31, 32].

However, while many studies demonstrated significant inverse associations between flavonoid intake and CVD incidence, the Framingham Offspring Cohort failed to support such observation [28]. The results showed that there was no significant association between flavonoid intake and CVD incidence after multivariable adjustment. This finding, based on a long-term follow-up of middle-aged and elderly Americans, suggests that the relationship between flavonoid intake and CVD risk is not clear and requires further investigation.

Data from intervention studies suggest that there is a wide interindividual variability in flavonoid metabolism as 15–99% of their ingested dose was recovered as a wide range of flavonoid metabolites. It implies that flavonoids' metabolism may play a critical role in explaining the differential responses in CVD risk biomarkers observed in clinical trials (responders vs nonresponders) [33–35].

This diversity in responsiveness to flavonoids intake may relate to a number of factors, where the microbiome is likely to be critical and it plays a key role in flavonoids metabolism. Furthermore, it is likely that intake alters the composition and function of the gut microbiome and conversely, that the microbiota may enhance the metabolism of flavonoids, but this bidirectional relationship has not been studied enough yet [34]. To understand the importance of metabolism, particularly microbiome-mediated biotransformation, in explaining the CV health effects of flavonoids, a combination of epidemiological studies and dietary intervention trials are needed.

3.3 Antidiabetic Action of Flavonoids

Flavonoids may exert beneficial effects in diabetes by various, parallel intracellular signaling pathways in pancreatic β-cells, liver, adipose tissue, and skeletal muscles. These compounds are able to influence β-cell mass and function, as well as energy metabolism and insulin sensitivity in peripheral tissues. Flavonoids can increase glucose uptake through translocation of GLUT4 vesicles to the cell membrane. They

may also enhance glucose uptake in response to insulin through the stimulation of adenosine monophosphate-activated protein kinase (AMPK) and other kinases such as ERK1/2 and p38 mitogen-activated protein kinase (p38MAPK) [36].

Epidemiological studies and meta-analyses suggested an inverse relationship between the consumption of flavonoid-rich diets and development of diabetes. A recent study evaluated the relationship between dietary intake of total flavonoid intake and type 2 diabetes (T2DM). This analysis, consisting of six prospective cohort studies including 18,146 cases and 284,806 participants, reported that the highest intake of total flavonoids could reduce risk of diabetes by 9%, when compared with the lowest. Moreover, an increase in the total flavonoids intake of 500 mg/d was associated with a significant risk reduction of 5% [37]. Furthermore, in another epidemiological study, it was shown that high consumption of flavonoids from flavanones subclass was also associated with a reduced risk of diabetes. After multivariable adjustment, the authors observed a 31% reduction in new-onset diabetes in the highest compared with the lowest tertile of flavanones intake in near 6 years of follow-up (18,900 person-years) [38]. Population-based studies have also suggested that flavonoids-rich foods, such as soy (isoflavones, genistein), tea (flavanols), citrus fruit (flavanones), and blueberry (anthocyans), exerted beneficial effects on blood pressure, lipid metabolism, insulin resistance, and glucose uptake, which are related to the development of T2DM [39–42].

Numerous in vitro and animal studies also support a beneficial effect of dietary flavonoids on glucose homeostasis. The supplementation of a dietary apple/kale extract (AKE), which is rich in flavonoids, significantly improved both blood glucose levels and oral glucose tolerance test (OGTT) in mice. Furthermore, in situ uptake of glucose was significantly inhibited by AKE. Authors concluded that AKE exhibits antidiabetic properties by a dual mechanism, including the inhibition of α-glucosidase and sodium-dependent glucose transporter 1 (SGLT1) [43]. Some studies support the concept that naringenin is a potent insulin sensitizer in vivo. Fibroblast growth factor 21 (FGF21) regulates energy homeostasis and the metabolic adaptation to fasting. After naringenin supplementation of diet of both genotypes of wild-type mice, FGF21-positive and FGF21-negative, improvement of glucose tolerance was observed [44]. Moreover, in streptozotocin-induced diabetic rats fed high-fat diet, naringenin improved postprandial hyperglycemia. Oral intake of naringenin (25 mg/kg body mass) exerted significant inhibition of intestinal α-glucosidase activity in vivo and thereby delayed the absorption of carbohydrates in T2DM rats, thus resulting in significant lowering of postprandial blood glucose levels [45].

In a study performed in women (n = 1997), it was shown that the highest intakes of both flavones and anthocyanins, when compared with the lowest, were linked to reduced risk of diabetes. These flavonoids consumption was also inversely associated with biomarkers of inflammation, insulin concentration, and also value of HOMA-IR (homeostasis model assessment of insulin resistance) index. Participants with high intakes of flavones had lower HOMA-IR and insulin concentrations and higher adiponectin concentrations, with respective differences of −0.1 (P-trend = 0.04), −0.5 μU/mL (P-trend = 0.02), and 0.6 μg/L (P-trend = 0.01)

comparing extreme quintiles of intake [46].Thus, the described results suggest that total flavonoids, their particular subclasses, and specific substances have the potential to serve as natural plant bioactive compounds for dietary prevention strategies against T2DM.

3.4 Anticancer Action of Flavonoids

Flavonoid compounds display a remarkable spectrum of biological activities, including those that may affect such stages of carcinogenesis as initiation, promotion, and progression. In the initiation and promotion stages, they include: inactivation of carcinogens, inhibition of cell proliferation, enhancement of DNA repair processes, and reduction of oxidative stress. In the progression phase, flavonoids may induce apoptosis, inhibit angiogenesis, exhibit antioxidant activity, and also induce cytotoxic or cytostatic action against cancer cells [47].

Preventing carcinogen metabolic activation is one of the most important mechanism by which flavonoids can exert their chemoprevention effects. Flavonoids may interact with phase I metabolizing enzymes (e.g., cytochrome P450), which metabolically activate a large number of procarcinogens. Flavonoids inhibit certain cytochrome P450 isozymes, such as CYP1A1 and CYP1A2, and thus protect against cellular damage by carcinogens. Another important mechanism of action is possibility induction of phase II metabolizing antioxidant enzymes such as glutathione S-transferase (GST) and UDP-glucuronyltransferase (UDP-GT).

Stimulation of apoptosis is the next important mechanism by which flavonoids may be recognized as anticancer substances. Dysregulation of apoptosis plays a critical role in oncogenesis. Flavonoids were shown to induce apoptosis in some cancer cell lines, while sparing normal cells. It was recently reported that flavonoids possess antiproliferative and apoptosis-inducing activities in several cancer human cell lines, i.e., gastric, colon, breast, lung liver, head, and neck cancers [48–55]. The molecular mechanisms by which flavonoids induce apoptosis have not been clarified.

The anticancer effects of flavonoids may be also explained by the cell cycle inhibition. Cyclin-dependent kinases (CDKs) are recognized as key regulators of cell cycle progression. Various types of cancers exhibit hyperactivation of CDKs due to mutation of CDK genes or CDK inhibitor genes. These disturbances may be constrained by flavonoids [47]. Moreover, such flavonoid as quercetin stimulates the inhibition of HMGB1-induced TNF-α and IL-1β mRNA expression, which suggests that quercetin modulates cell signaling that in turn regulates the action of proinflammatory cytokines. The HMGB1 protein, which is present outside the cell, can increase the release of tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and other inflammatory mediators from monocytes (Khan et al. 2016). All of the described mechanisms help to explain the chemopreventive effects of flavonoids against carcinogenesis.

Increasing evidence from both epidemiological and laboratory studies suggests that the high dietary intake of flavonoids reduces the risk of developing certain types

of cancers. It concerns, among others, the breast cancer. In general, the prevalence of the breast cancer is lower in Asian than in North American and European countries [56]. It may be explained by higher intake of soy in Asian populations, that is an abundant source of isoflavones. A meta-analysis of 22 observational studies showed that high isoflavone intake was linked to reduced breast cancer risk rather in Asian than in Western populations. The protective effect of isoflavones in Asian subjects concerned both pre- and postmenopausal women [57]. On the contrary, a population-based prospective cohort study performed in Japan (15,607 women) showed a beneficial effect only in postmenopausal females [58]. These results suggest that soy and isoflavone intakes may have a protective effect mainly against postmenopausal breast cancer in Asian populations, but their beneficial action is possible also in premenopausal women.

High consumption of total flavonoids was also reported to be associated with a significant reduction of ovarian cancer risk by 18% [59], as well as of the risk of smoking-related cancers, such as aerodigestive tract cancer (33% risk reduction) and lung cancer (16% risk reduction) [60]. Guo et al. demonstrated that higher green tea consumption (above 7 cups/day) was linearly linked to reduced prostate cancer risk. It was concluded that green tea catechins were effective for preventing prostate cancer [61].

The epidemiological data presented above concern only prevention and the results of the studies are not always unambiguous and apply only to some types of tumors. The present review of literature suggests that results may be promising but are inconclusive. Further, prospective cohorts assessing dietary flavonoid intake and studies using other methods to evaluate exposure (i.e., markers of consumption, metabolism, excretion, bioavailability, drug–drug interactions) are needed to overcome the limitations emphasized in observational studies testing dietary intakes and determine consumption levels required to achieve health benefits [62, 63].

Results of laboratory studies which consider flavonoids as anticancer agents are very promising. Recently, epigallocatechin-3-gallate (EGCG) – a major flavonoid constituent in green tea – has received much attention as a potential cancer chemopreventive agent with DNA topoisomerase I (Topo I) inhibitory activity [64]. Topo I is a crucial enzyme that works to relax supercoiled DNA during replication, transcription, and mitosis. In a number of human solid tumors, the intracellular level of Topo I is higher than that in normal tissues. It seems that controlling the Topo I level is essential in treating cancers and a large number of Topo-directed agents (e.g., camptothecin, topotecan, and irinotecan) are currently in clinical use. Topo I inhibitors exert their antitumor activities by stabilizing the cleavable Topo I–DNA ternary complex, blocking rejoining of the DNA breaks, and inhibiting enzyme binding to DNA. It should be emphasised that EGCG possessed low cytotoxicity with much higher half maximal inhibitory concentration (IC50) to human tumor cell lines than the traditional Topo-directed agents [64].

Another interesting substance is kaempferol, flavonoid from flavonols subclass. It was recently reported that this flavonoid possesses antiproliferative and apoptosis-inducing activities in several cancer cell lines, i.e., human cervical cancer cells (SiHa and Hela), human osteosarcoma cells, cholangiocarcinoma cells, human breast

carcinoma (MCF-7) cells, human bladder cancer cells (5637, T24), human stomach carcinomacells (SGC-7901), and human lung carcinoma cells (A549) [48–54]. It was also found that kaempferol may play an important role as a potential therapeutic agent for cancer metastasis [54]. The antimetastatic action of kaempferol is related to inhibition of matrix metalloproteinases (MMPs) that are regarded as major critical molecules assisting tumor cells during metastasis, because of excessive degradation of the extracellular matrix, and thus facilitation of cancer cells invasion [65].

These findings demonstrate that kaempferol and epigallocatechin-3-gallate may be novel anticancer agents but more detailed studies should be performed to confirm their anticancer effects for clinical use.

The biological properties of citrus flavonoids and their effectiveness in cancer prevention have been widely studied. Recenty, Wang et al. have reported on anti-cancer ability of flavonoids composition of citrus fruits varieties [13]. In vitro tumor cytotoxicity of the citrus extracts were measured on three gastric cancer cell lines, i. e., SGC-7901, BGC-823, and AGS. For the cytotoxicity of individual compounds, the highest correlation coefficient with cytotoxicity of extracts on all three gastric cancer cell lines was shown for nobiletin, a flavonoid from flavones subclass [13].

Not only citrus exctract but also apple exctrat was shown to have a positive effect in vivo. George et al. demonstrated that preexposure with apple flavonoids protected from various carcinogen-induced toxicity in normal human bronchial epithelial cells significantly reduced toxic effects of various carcinogens, especially nicotine-derived nitrosamine ketones, by inhibiting DNA damage response signaling and initiated DNA repair mechanisms [66].

Other promising phytochemicals are Grape Seed Proanthocyanidins (GSPs). GSPs have been shown to have cytotoxic activity against various cancer cell lines with no significant toxic effects on normal cells. Treatment with GSPs significantly reduced the viability and induced apoptosis of human head and neck squamous cell carcinoma (HNSCC) cells, including HNSCC cell lines derived from the oral cavity, larynx, pharynx, and tongue [55].

A number of human, animal, and cell-culture studies reported the potential effects of genistein on different types of cancer, including breast, prostate, and ovarian cancers. Genistein belongs to isoflavone subclasses. The mechanism of its influence on cancer is complex and requires detailed investigations. Depending on the cancer type, the same molecule may exert adverse or beneficial effects. Among breast cancers, there are three subtypes: Triple Negative BC (TNBC, which do not express estrogen, progesterone, or HER2 receptors), HER2 (that possess HER2 receptors), and ER (that possess estrogen receptors). It was demonstrated that genistein plays different roles in this triple scenario [67]. Some studies showed favorable effects of both high and low doses of genistein as they decreased proliferation of ERα-β and HER2 breast cancer cells [68–70]. However, it was reported by other authors that high doses of genistein may enhance markers of proliferation, such as FGFR2, E2F5, BUB1, CCNB2, MYBL2, CDK1, and CDC20 [71]. On the other hand, genistein and daidzein and their metabolites may interact with ATP-binding cassette (ABC) G2 efflux transporter, which is also called the breast cancer resistance protein (BCRP) and mediates the disposition and excretion of numerous endogenous chemicals and xenobiotics. These

isoflavones may serve the BCRP as substrates, inhibitors, and/or modulators of gene expression. When acting as BCRP inhibitors, these substances may induce reversal of multidrug resistance and may enhance effectiveness of chemotherapy. On the other hand, they may bring about also negative outcomes, such as increase in the toxicity or a decrease in the efficacy of specific medications [72].

3.5 Flavonoids and the Nervous System

Enhancing cognitive abilities has become an important scientific challenge, recently driven by the interest in preventing age-related cognitive decline and sustaining normal cognitive performance in response to cognitively demanding environments. Effectiveness of flavonoids in prevention of age-related neurodegenerative diseases has been much investigated in the recent years. It concerns particularly dementia, Parkinson's (PD), and Alzheimer's diseases (AD). It seems that flavonoids can modulate neuronal function. Diets rich in these substances were shown to beneficially affect maintenance of human cognitive functions, probably through protection of neurons, enhancement of their function and regeneration [73].

The main pathological mechanisms of neurodegenerative diseases, including AD, are both increased oxidative stress and inflammation [74–76]. It seems that flavonoids may protect effectively against oxidative neuronal damage and may also decrease inflammation and thus have positive effects on the nervous system.

The multiplicity of beneficial effects of flavonoids exerted on the nervous system seems to result from variety of mechanisms. One of them is regulation of the neuronal signal cascade what brings about inhibition of cell apoptosis caused by neurotoxic substances, such as amyloid β (Aβ) or 6-hydroxydopamine, (6-OHDA). This promotes neuronal survival and differentiation. Another mechanism is improvement of the cerebral blood flow, what can induce angiogenesis and growth of new neurons in the hippocampus. Furthermore, flavonoids may increase the amount of the brain-derived neurotrophic factor (BDNF) which is crucial to adult neurogenesis, synaptic growth, and neuronal survival. All of these processes are crucial for maintenance of neuronal and cognitive brain functions [77, 78].

The neurodegenerative process in Alzheimer's diseases is characterized by the presence of cerebral extracellular deposition of amyloid-β plaques, intraneuronal neurofibrillary tangles, and cerebral atrophy [79]. The enzyme β-Secretase 1 (BACE1) controls the rate-limiting step of Aβ generation. The newly synthetized Aβ rapidly aggregates to form neurotoxic amyloid fibrils. Shimmyo et al. demonstrated that four flavonols (myricetin, quercetin, kaempherol, and andmorin) and one flavone (apigenin) could inhibit BACE-1 activity in both the cell-free system and neuronal cells. Each flavonoid significantly decreased concentrations of amyloid β peptide-40 (Aβ1-40) and amyloid β peptide-42 (Aβ1-42) in neurons. These results showed that flavonoids may reduce neuronal Aβ level and that this phenomenon is related to BACE-1 inhibition [80].

Some studies also show that catechins, which are found in tea, may prevent the formation of amyloid-β plaques, enhance cognitive functions, and may slow down

the onset and progression of AD. These substances (or their metabolites) can pass the blood-brain barrier (BBB) and exert neuroprotective effects. Several studies demonstrated that EGCG and other flavonoids, such as luteolin, could reduce toxic levels of Aβ in the brain, and also mitochondrial dysfunction in AD brains [81]. EGCG also prevented Aβ peptides-induced neurotoxicity, elongation of the fibrils, and stabilization of the formed fibrils in cell cultures, and also enhanced clearance of phosphorylated tau protein in primary neurons in rats [82–84].

Parkinson's disease (PD) is a progressive neurodegenerative disease, characterized by selective loss of dopaminergic neurons in the human midbrain region known as the substantia nigra pars compacta (SNpc). The factors that trigger the onset of this disease still remain unknown. Some evidence supports the role of oxidative stress and imbalance in the natural antioxidant defense system. It is presumed that these factors may contribute to the formation and/or accumulation of abnormal or "toxic" proteins in the neuronal cells, which can lead to neuronal death [76].

Flavonoids such as quercetin glycosides, rutin, and isoquercitrin have distinct features in upregulating the production of intracellular antioxidant enzymes such as superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase (CAT) and glutathione in a 6-hydroxydopamine (6-OHDA-) induced in PC-12, rat pheochromocytoma cells [85, 86]. It can protect neuronal cells from oxidative stress through elevation of intracellular antioxidant enzymes. Apart from that, the neuroprotective effects of flavonoids were further demonstrated in animal studies using tangeretin [87]. Tangeretin, which is found mainly in citrus fruit, given to mice passes the BBB and protects the nigrostriatal pathway against adverse effects of 6-hydroxydopamine.

Not only research performed on animals but also on humans confirm an important role of flavonoids (or their metabolites) in PD's. In a prospective study, it was observed in men that in the highest quintile of total intake of flavonoids there was a 40% lower PD risk than in the lowest quintile. However, the authors admitted that a protective effect of other constituents of plant foods should be taken into account, and that it seems that the whole dietary pattern is of a great importance [88].

Effectiveness of flavonoids in prevention of age-related cognitive impairment, particularly among patients at risk, has been much investigated in the recent years. Research investigating the relations between cocoa flavanols and cognition shows dose-dependent improvements in general cognition, attention, processing speed, and working memory. Moreover, cocoa and cocoa-derived food could also improve normal cognitive functioning and exert a protective role on delaying or preventing age-related deterioration of cognitive decline [89].

In another study, compared to the consuming a low cocoa flavanol (48 mg) drink, administration of intermediate (520 mg) and high (993 mg) cocoa flavanols drinks over an 8-week period was associated with reduction of some measures of age-related cognitive dysfunction in healthy aged participants. Interestingly, such cognitive beneficial effects were paralleled by improvements in insulin resistance, suggesting a role of glucose sensitivity in modulating cognitive function in these patients. These data suggest that the habitual intake of flavanols can support healthy cognitive function with age [90]. These results were consistent with the findings of the study performed by Samieri et al. who showed that high flavonoid intake in

midlife helped to maintain good health and well-being during aging among women. In this large prospective study (13,818 women from the Nurses' Health Study), higher intake of several flavonoid subclasses (i.e., flavonols, flavones, flavanones, flavan-3-ol polymers, and anthocyanins), as well as total flavonoids in the age-adjusted analyses were associated with better odds of healthy aging. Healthy aging was defined as survival to more than 70 years with maintenance of four health domains (no major chronic diseases or major impairments in cognitive or physical function or mental health). In analyses of each component of healthy aging, such flavonoid subclasses as flavones and flavanones were significantly associated with two of four domains in authors' definition of healthy aging, although associations were generally weaker than for overall healthy aging. For example, compared with women in the lowest quintile, women in the highest quintiles of flavone and flavanone intakes had 32% and 24%, better odds of no mental health limitations, respectively, and 23% and 15%, better odds of no physical function limitations, respectively [91].

Collectively, it seems that regular consumption of foods rich in flavonoids reduces the risk of neurodegenerative diseases and counteracts or delays the onset of age-related cognitive disorders. Flavonoid compounds have been found to activate the endogenous antioxidant status in neuronal cells and hence protect them against neurodegeneration. Studies also show that catechins may prevent the formation of amyloid-β plaques and enhance cognitive functions, and thus may be useful in treating patients with Alzheimer's disease or dementia.

3.6 Flavonoids: Promising Natural Compounds Against Erectile Dysfunction

It should be emphasized that such disorders as Parkinson's and Alzheimer's diseases, stroke, and cerebral trauma often cause erectile dysfunction (ED) by decreasing libido or causing inability to initiate the erectile process [92]. Besides of neurological diseases also, endothelial dysfunction may result in erectile disorder. Pathophysiology of ED is multifactorial and and is usually triggered by impaired release of NO. Although NO-mediated vessel relaxation plays a central role in erection, other mediators such as cyclic-guanine monophosphate (cGMP), acetylcholine (ACh), prostaglandins, and bradykinins are also important. Angiotensin-I-converting enzyme (ACE) deactivates bradykinin, a vasodilator which is involved in erectile function via the release of NO and relaxation of corpus cavernosum. The conversion of angiotensin I to angiotensin II and deactivation of bradykinin can also induce high blood pressure which in turn additionally impairs erectile function [92, 93].

Oboh et al. have shown a relationship between ED and oxidative stress due to excessive generation of free radicals [94]. In an animal study, flavonoid and other polyphenols-rich extract inhibited angiotensin-I-converting enzyme (ACE) and arginase activities – key enzymes linked to erectile dysfunction – and oxidative stress markers in rats' penile tissues [94].

Furthermore, in a prospective study performed among 25,096 men from the Health Professionals Follow-Up Study, it was shown that higher intakes of flavonoids from such subclasses as flavanones, anthocyanins, and flavones were significantly associated with a reduction in the risk of erectile dysfunction in men below 70 years of age but not in older [95].

3.7 Flavonoids: Promising Natural Compounds Against Cataract

Cataract is the major ophthalmic dysfunction of lens in which the clear lens gradually develops into a cloud opaque and impairs vision. Cataract is one of the secondary complications of diabetes affecting more than 20 million people and accounts 51% of all blindness globally [96, 97]. It appears that flavones apigenin,and chrysin play an important role in attenuation of sugar-induced cataractogenesis. Aldose reductase (AR) is a key enzyme of polyol pathway that is responsible for the reduction of glucose and galactose. Under normoglycemic condition, less than 3% of glucose is metabolized through polyol pathway. However, in the case of hyperglycemia more than 30% of glucose enters polyol pathway that leads to excessive accumulation of sorbitol in the lens, what in turn results in several adverse pathological changes which ultimately accelerate the process of cataractogenesis and other diabetic complications. The mechanism of anticataract action of apigenin and chrysin includes inhibition of AR, what was shown in sugar-induced lens cataract animal model studies [98, 99].

A panel of ten dietary flavonoids from different subclasses was evaluated as possible inhibitors of sugar-induced cataractogenesis using bovine lens organ culture studies. The results of lens organ studies clearly indicate that addition of rutin and silibinin in the cultured lenses containing glucose significantly prevented the progression of lens opacity and maintained the lens transparency as compared with other tested flavonoids. It clearly demonstrated the efficacy of rutin and silibinin as promising agents that lead to inhibition of glycation reaction and amelioration of sugar-induced cataractogenesis. The findings of this study may be useful for designing and development of the novel safe molecules for the management of diabetic cataract [96].

Anthocyanins also seem to protect against cataract. It is commonly regarded that in the pathogenesis of this disease apoptosis of the lens epithelial cells plays an important role, similarly as oxidative stress seems to be the major cause of lens opacity. It was demonstrated that anthocyanin from black soybean may protect human lens epithelial cell line (HLE-B3) from oxidative stress. This substance was shown to reduce HLE-B3 cell death in oxidative stress circumstances [100].

3.8 Flavonoids: Promising Natural Compounds Against Viral Infections

Research focused on antiviral agents isolated from plants started in 1950s, when the activity of 142 plants against influenza A virus was evaluated in embryonated eggs. Twelve of them suppressed virus multiplication [101]. Nowadays, the main

directions of the research include the efficacy of flavonoids in the treatment of hepatitis B virus (HBV), herpes simplex virus (HSV), and human immunodeficiency virus (HIV) infections.

One of the examples is amelioration of chronic hepatitis by flavones. Luteolin-6-C-β-D-boivinopyranosyl-3′-O-β-D-glucopyranoside and chrysoeriol-6-C-β-D-boivinopyranosyl-4′-O-β-D-glucopyranoside, flavones isolated from Alternanthera philoxeroides, an aquatic plant originated from South America, were shown to have significant anti-HBV activities. These substances inhibited the secretion of HBsAg from in the HepG2.2.15 cells [102]. Similarly, in HepG2.117 cells, EGCG inhibited HBV replication through impairing HBV replicative intermediates of DNA synthesis, thereby reducing the production of HBV [103]. Furthermore, in the culture of hepatoma HepG2 cells, it was shown that EGCG treatment raised lysosomal acidification, and thus enhanced autophagy, which appeared to inhibit HBV replication [104]. Thus, botanical agents may be attractive sources of a new anti-HBV drugs.

Behbahani et al. found that kaempferol and kaempferol-7-O-glucoside have strong HIV-1 reverse transcriptase inhibitory activity. These compounds exerted their potent inhibitory effects, at a concentration of 100 μg/ml, on the early stage of HIV replication in target cells [105]. Furthermore, quercetin exerted a significant effect on the pharmacokinetics of ritonavir in rats. Liang et al. have suggested a new strategy of treatment that might result in higher brain distributions, reduced toxicity, and improved efficacy of HIV-1 protease inhibitors (HPIs) which are key components of the highly effective antiretroviral therapy (HAART) currently used to treat HIV-1 infection. Among the eight investigated flavonoids, quercetin was shown to exert the strongest effect on the accumulation of ritonavir in human brain-microvascular endothelial cells (HBMECs), by improving the intracellular accumulation of ritonavir by 76.9% [106].

Numerous studies reported anti HSV-1 and HSV-2 effects of flavonoids, especially of EGCG and quercetin, in animal and cell-culture studies [8, 104, 107–110]. Oral infection with herpes simplex virus type 1 (HSV-1) or genital infection with HSV type 2 (HSV-2) represent the most common infectious diseases in humans. Isaacs et al. found that EGCG can inactivate HSV virions by binding to the envelope glycoproteins gB and gD, which are essential for HSV infectivity. Moreover, the EGCG digallate dimers theasinensin A, P2, and theaflavin-3,3′-digallate inactivated HSV-1 and HSV-2 more effectively than did monomeric forms. These dimers are stable at vaginal pH, indicating their potential to be antiviral agents against HSV infections [111]. In addition, modification of green tea flavanol EGCG with palmitate increased the effectiveness of EGCG as a potent inhibitor of herpes simplex virus 1 [108]. Hung et al. have suggested possible mechanisms whereby quercetin may exert its anti-HSV activity. They revealed that quercetin inhibits the infection of HSV-1, HSV-2 and acyclovir-resistant HSV-1 mainly by blocking viral binding and penetration in the beginning of infection. They also reported that quercetin suppressed NF-κB activation, which is essential for HSV gene expression [112]. Flavonoids may also influence autophagy that plays a crucial role in the regulation of viral replication. Enhancement of autophagy is therefore regarded to be a potential therapeutic strategy for viral infection [113].

3.9 Flavonoids and Their Therapeutic Benefits in Inflammatory Bowel Disease

Ulcerative colitis (UC) and Crohn's disease are two major manifestations of inflammatory bowel disease (IBD). An increasing number of studies have associated the intake of flavonoids-rich foods, especially catechin-rich food, with the prevention and treatment of IBD. Mechanisms by which flavonoids benefit IBD have not yet been entirely recognized, while human experiments demonstrating that catechins can improve IBD are still scarce so far. However, there is abundant evidence showing that flavonoids may work through a combination of parallel processes such as oxidation inhibition, alteration of cellular signaling, and regulation of intestinal flora [114, 115]. Such flavonoids as catechins epicatechin (EC), epicatechin gallate (ECG), epigallocatechin (EGC) and its stereoisomer gallocatechin (GC), EGCG and its stereoisomer gallocatechin gallate (GCG) could significantly reduce the oxidative damages of the colon by promoting the activation of the antioxidative agents, such as glutathione peroxidases (GPO) and glutathione (GSH). In addition, reduction of the inflammation by regulation of the infiltration and proliferation of immune related-cells, such as neutrophils, colonic epithelial cells, macrophages, and T lymphocytes by catechins can provide benefits to IBD. Such anti-inflammatory properties of catechins as regulating the activation or deactivation of inflammation-related oxidative stress-related cell signaling pathways, such as NF-κB, MAPKs, transcription factor nuclear factor (erythroid-derived 2)-like 2 (Nrf2), signal transducer and the activator of transcription 1/3 (STAT1/3) pathways can be also important for IBD treatment. Finally, catechins can also stabilize the structure of the gastrointestinal microecological environment via promoting the proliferation of beneficial intestinal bacteria and regulating the balance of intestinal flora, which seems be beneficial for IBD [115].

Catechins may be effective agents to relieve IBD without obvious side effects in animal and in vitro studies [114]. It was demonstrated that EGCG applied orally at the dose of 6.9 mg/kg body weight, in combination with piperine which was used to enhance the bioavailability of EGCG, inhibited colon inflammation in colitis in murine model of colitis. Additionally, it significantly reduced the loss of body weight, improved the clinical course, and increased overall survival in comparison with untreated groups [116]. Reduction of tissue concentrations of malondialdehyde and increase in activity of SOD as well as GPO have been shown. In another study by Vasconcelos et al., EC (10 mg/kg) was also shown to benefit colitis induced by 2,4,6-trinitrobenzenesulfonic acid (TNBS) in acute and chronic rat models. In the chronic colitis model, EC treatment was linked to lower macroscopic and microscopic lesion scores and increased glutathione levels, decreased COX-2 expression and increased cell proliferation [117].

Extensive laboratory and epidemiological studies have generally reaffirmed that catechins, depending on their structures and dose, exert preventive effects against chronic inflammatory diseases [118, 119]. However, it should be emphasized that relevant evidence indicated that in the case of application of high concentrations of catechins their pro-inflammatory capacity may exceed the benefitial effect on gut

inflammation. A high dose of EGCG was also demonstrated to act as a prooxidant, instead of antioxidant, by generating ROS, causing even damage to cellular DNA in various kinds of cells [119, 120]. The growing body of evidence indicates that dietary catechins and their condensed sources may play a beneficial role in IBD; however, further clinical and epidemiological trials are greatly needed.

4 Summary

Epidemiological, cell cultures, animal, and human studies support positive effects of flavonoids on health. Over the past decades, flavonoids have attracted interest due to their presumed roles in various beneficial activities, such as antihypertensive, antibacterial, antiinflammatory, antioxidative actions. They were also shown to be protective agents against atherosclerosis. These compounds have also strong chemopreventive potential including anti-inflammatory, antimutagenic, and anticarcinogenic activities. Moreover, increasing numbers of studies have demonstrated that flavonoids may protect against cancer of varios locations, including the stomach, colon, breast, lung, and liver. Furthermore, their consumption may improve postprandial hyperglycemia, protect LDL particles against oxidative modification, reduce neuroinflammation, and improve lipid profile in hyperlipidemic patients. However, there is a great need for better understanding of the underlying molecular mechanisms.

Research challenges and future studies required in flavonoid research include trials to understand the bidirectional relation between flavonoid metabolism and the microbiome. Findings on potential associations between dietary flavonoids intake and chronic diseases risk should ultimately be integrated with studies using appropriate methods to evaluate exposure (i.e., markers of consumption, metabolism, excretion, bioavailability) to overcome the limitations of observational studies. Moreover, detailed research on dietary intakes would provide better insights into the role of specific classes of flavonoids and would show which of them are the most important in disease prevention. It would also indicate the most appropriate level of their consumption. Finally, future reaserch should include prospective clinical trials that would consider evaluation of the extent of absorption and metabolism to establish dose-response relations.

At the present state of knowledge, it should be recommended to consume abundant dietary sources of flavonoids, such as fruits and vegetables, legumes, nuts, spices, and herbs every day.

Bioactive Molecules, Nutraceuticals, and Functional Foods in Indian Vegetarian Diet and During Postpartum Healthcare

4

Jaya Arora and Kishan Gopal Ramawat

Contents

Abstract

Traditionally the majority population of the Indian subcontinent is vegetarian since ancient times due to social and religious guiding principle of the society. Consumption of whole grains of cereals and pulses, fruits, vegetables, and milk products is associated with vegetarian diet. Essentially all meals consist of flatbread, cooked pulses, a vegetable, curd/butter milk, and/or rice. Pulses are consumed in very large quantity, and several salted snacks and sweet preparations are available in the market. Beneficial effects of such products are now being revealed and scientifically validated by modern tools and techniques. In this review, we presented a concise and comprehensive scenario about vegetarian diet in Indian region enforced by caste system associated with religion. This leads to progression of hale and hearty brain and intellectual community of Brahmins consuming only vegetarian diet rich in fruits. Brahmin is a varna (class, caste) in Hinduism specializing as priests, teachers (acharya), and protectors of sacred learning across generations. Marriages within the caste further helped in gradual evolution of Brahmins (a kind of hybridization between superiors). Vegetarian diet is maintained from birth to until death. There is a well-defined and programmed vegetarian herbal diet starting from postpartum care,

and beneficial effects of such diet are discussed in light of scientific information available. Effect of bioactive molecules present in these foods and safety aspect are also discussed.

Vegetarian diet · Postpartum · Functional foods · Bioactive molecules · Caste system · Hindu · Brahmin diet

1 Introduction

Vegetarian diet refers to nonconsumption of meat or animal products including sea animals, fish, and eggs. However, in India milk and milk products are consumed by vegetarians. This tradition of vegetarian diet is part of Hindu philosophy, religion, and society where cruelty to animals is forbidden. Indians in general and majority of Hindus in particular are vegetarian since time immemorial. About 30–40% of the population of the Indian subcontinent is vegetarian, varying between 10% and 62% according to the region [1–4], whereas it is around 10% elsewhere in the world such as Sweden (10%), Austria (9%), Australia (2–11%), and Brazil (7.6%) [4]. Vegetarianism in Western countries is a luxury associated with higher socioeconomic position, greater physical activity, and lower rates of smoking which may result in the observed health benefits [2, 3], whereas in India, it is a tradition- and caste-based lifestyle since centuries. In contrast, vegetarianism is of recent origin in the Western world [5]. A well-planned vegetarian diet has all the essential components required for a healthy living [6].

Traditionally Indian foods can be divided into three categories: cooked vegetables, milk, and fresh fruits. Ayurveda means the science of life. It is an ancient system of healthcare and longevity. Ayurveda takes a holistic view of human beings, their health and illness. It aims at positive health, which has been defined as a well-balanced metabolism coupled with a healthy state of being. Ayurvedic concepts are thus deep rooted in day-to-day Indian culture, and hence food is considered as responsible for physical, mental, and temperamental state of an individual [7, 8].

Several recent studies show that vegetarian diet is associated with protective effect of diet on blood cholesterol [9–11], blood pressure [11–14], fasting blood sugar [15, 16], and cross-sectional evidences suggesting beneficial effects on blood insulin [17, 18], C-reactive protein [17–19], many amino acids [20], and insulin-like growth factors [17, 21]. Consumption of vegetarian or nonvegetarian diet results in different bowel microorganisms [22], which may have beneficial implications for diabetes, cardiovascular disease, and some cancers. Vegetarian diet has also been associated with low rate of mortality, new types of cardiovascular diseases [23–25], and diabetics [15]. Specific works showed reduction in incidence of prostate cancer [26] and colorectal cancers [27, 28], whereas increased incidences of cancer as well as diabetes and cardiovascular diseases were correlated with nonvegetarian diet [29–33]. These studies have shown an advantage for vegetarian diet over

nonvegetarian diet in disease prevention and long-term health. India is a vast country in which food, dialect, and dress change after every 500 km. Shridhar and co-workers [3] found significant cardiovascular health benefits associated with the vegetarian diet in four geographic regions of India. Traditionally food preparations and basic ingredients are more or less same but with different or variable spices and condiments and cooking medium [ghee (cleared butter) or any of the vegetable oils: mustard, ground nut, sesame, or coconut]. Being an old civilization, these cooking practices have been long established about processing of food, its preservation techniques, and their therapeutic effects. This diet has profound effect, as it contains body-healing chemicals, antioxidants, dietary fibers, and probiotics, on the development and social behavior of the population. The food is rich in functional components and provides prophylactic effect to various diseases such as diabetes, cardiovascular diseases related to high cholesterol, and obesity. These effects are further enhanced by processing the food as sprouting, malting, and fermentation [34]. In this chapter, we have reviewed the information about development of socioreligious faith to consume vegetarian diet in majority of the Indian population, and vegetarian diet is blended with herbal medicine during postpartum care for long-term benefit of the mother and the newborn. Available scientific information about these foods is also discussed.

2 Food Habit Influenced by Caste System

Composition of Indian food is influenced by Aryan belief. Aryans were heterogeneous group of people who lived mainly in northern ancient India. They migrated from Indo-Iranian borderlands about 3000–8000 years ago with their cultures and customs [35] and laid down caste system and its governing *Vedas* for society. The four *Vedas*, namely, *Rigveda*, *Samaveda*, *Yajurveda*, and *Atharva veda*, describe the use of different cereal grains and their use in our daily life. Aryans believed that food was not simply meant for body nourishment, but was the basic part of a cosmic moral cycle [36].

The present-day Indian population is descendents of two ancient groups known as "Ancestral North Indians" and "Ancestral South Indians" [37, 38]. The earliest archaeological evidence for agriculture in the northern region is 8000–9000 years old (Mehrgarh in present-day Pakistan) and involved wheat and barley derived from crops originally domesticated in West Asia [39, 40]. In contrast to this, agriculture in southern India is about 4600 years old, mainly cultivating mung bean, horse gram, and local millets (pearl millet, ragi, sorghum) which are not related to west Eurasian agriculture [41]. This is also supported by linguistic correlation of north Indian population speaking Hindi derived from Sanskrit (which is Indo European language), whereas Dravidian languages are not related to any of the Eurasian language [42]. There are 4635 anthropologically well-defined human populations in India; 532 are tribes, including 72 ancestral tribes with the hunter and gatherer lifestyle. Each population differs in terms of language, culture, physical features, and, most importantly, genetic architecture. The total population count of India has reached 1.21 billion [43, 44].

The exact date of origin of caste system is not clear but *Rigveda* contains written description of the system. Caste system was a social arrangement based on occupation. There were four broad categories of castes in a Hindu society, Brahmins, Kshatriya, Vaishya, and Sudra, having a specific job to perform: preaching and teaching, ruler or warrior, agriculture or business, and laborers, respectively. Brahmin is a varna (class, caste) in Hinduism specializing as priests, teachers, and protectors of sacred learning across generations. It is believed that caste system was associated with Indo-Aryan, who established themselves as superior caste and pushed the original Dravidian population to southern part and Sri Lanka. These conclusions are based on mitochondrial DNA and Y chromosome markers [45]. Brahmins and Vaishya were forbidden to eat nonvegetarian food and supposed to eat cereals, fruits, and vegetables by this social system. Now we know that high consumption of fruits and vegetables is associated with reduced risk of stroke and good health. Eating vegetarian diet rich in fruits and vegetable has/had a beneficial effect on brain functioning associated with arranged marriages within the caste resulting in a kind of forced breeding or hybridization between elites. This has a long-term consequential effect on the evolution of Brahmins as preachers and teachers of the society, whereas Kshatriya and Sudra were allowed to eat non-vegetarian diet including spiced food which results in high metabolism and muscle building required for their work [7, 46, 47]. Under this social system, vegetarian food is consumed during all rituals from child birth, in marriages to until death. Hindu rituals are not discussed here.

3 Indian Foods

Since Hippocrates, whose well-known dictum stated "Let food be thy medicine and medicine be thy food," diet has been key for health. It is imperative that food is not medicine for quick change, but long-term preventive measures are important for process of aging and health. Therefore, it is truly said that "you are what you eat" [48]. We have come to know day by day with new reports that bioactive molecules present in food have direct impact on our long-term health besides their nutritional value. It is better to consume what is produced in the region. Long-term consumption of a locally grown food has direct impact on metabolism and well-being of the population.

Whole grains or whole flour is staple food in the Indian subcontinent. Several food plants native to this subcontinent and/or cultivated since ancient times are wheat, rice, barley, cowpea, sugarcane, citrus, mango, onion, eggplant, pigeon pea, *Aegle*, and jujube [41]. There are several preparations of grains (wheat, rice, pulses, pearl millet, maize, pseudocereals), fermented grains/coarse grains (idli, dhokla, dosa, kanji), fruits and green vegetables, and milk products (milk, curd, butter milk, lassi, milk cake, and cottage cheese) [7, 49]. A typical meal consists of flatbread made of whole wheat grain flour, boiled and salted-spiced pulse, a cooked vegetable, and curd or butter milk. Boiled rice may or may not be included. Porridge prepared from a mixture of rice or wheat semolina and pulse is also a common practice. Pulses are consumed in large quantities in daily life as

whole, split, or ground into flour making several types of preparations as boiled and cooked and fried and salted and a variety of desserts. Some representative preparations shown here (Fig. 1) are (A) dal, (B) khaman dhokla, (C) sev, (D) kofta, (E) dahi vada, (F) sambar vada, (I) laddu, and (J) barfi. Besides this, frequent fasting or consumption only of pseudocereals and fruits is common practice in this region. There are convincing evidences that effect of whole extract of medicinal plants is more effective than isolated molecules. Similarly the disease protection offered by all grains in prospective epidemiological studies far exceeds the protection from isolated nutrients and phytochemicals in all grains [50, 51]. Therefore, the concept of functional foods includes foods or food ingredients that exert a beneficial effect on human health and/or reduce the risk of chronic disease beyond basic nutritional functions [52]. Generally, alcohol is not associated with vegetarian diet and forbidden for some caste by social and religious directives.

All grains and millets are the ideal base for a wholesome diet. This is because all variants of grains and millets are low-cost, nutritious, and locally available foodstuff. Moreover, all grains affect glucose and insulin responses, and on the other side, they have slower rate of digestion due to the presence of more dietary fiber, resistant starch, and oligosaccharides in grains [53]. All grains are rich in antioxidants; phenolic compounds; phytate; phytoestrogens such as lignan, plant stanols, and sterols; and vitamins and minerals. Epidemiological studies establish that all grains intake is protective against cancer, cardiovascular diseases, diabetes, and obesity [54]. Asian Indians may be benefitted from ancient whole-grain diet by decreasing the overall amount of dietary carbohydrate and increasing carbohydrate quality in food [55]. Nutrition plays a significant role in the prevention of disease such as diabetes (low glycemic index), cholesterol-lowering effects, ability to decrease the risk of heart diseases, and their protective effects against some cancers. Whole-grain cereals not only contain a large number of nutrients and bioactive compounds, but consumption of pulses provides complementary nutrients and a synergistic health benefit. Epidemiological evidence shows a consistent inverse association between whole-grain intake and the risk of chronic disease [56]. Among these bioactive compounds, γ-aminobutyric acid (GABA), a non-proteinogenic amino acid with several health benefits such as antidiabetic and hypotensive effects (a well-known blood pressure-lowering compound) and depression and anxiety reduction, is of particular interest [57].

India is the largest producer (26%), consumer (nearly one third), and importer of pulses in the world [58]. During 2014–2015, pulses were grown in an area of 25.23 million hectares with a total production of 17.38 million tons and consumption of 22.68 million tons. Pulses have high contents of protein (20–25%), carbohydrates (55–60%), calcium, and iron. Being vegetarian, pulses constitute the major source of protein in Indian diet. Before the Green Revolution of the 1960s in India, traditional meals and recipes were derived from whole-grain carbohydrates and also included amaranth, barley, millet, and other ancient grains that have been grown on the Indian subcontinent for the past few millennia. With more so-called Westernization, food habits are gradually changing particularly in urban populations with increased consumption of refined flour [59].

Fig. 1 Pulses are consumed in large quantities as whole, split, or ground into flour in daily life as boiled and cooked and fried and salted and prepared as various desserts. Some representative preparations are presented here: (**a**) dal, (**b**) khaman dhokla, (**c**) sev, (**d**) kofta, (**e**) dal, (**f**) mixture, (**g**) Dahi Vada, (**h**) Sambar Vada, (**i**) laddu, (**j**) barfi

4 Bioactive Molecules, Nutraceuticals, and Health Benefits

Food provides not only essential nutrients for growth and development but also bioactive molecules for prevention of diseases. Consumption of fruits, vegetables, cereals, and pulses is associated with prevention of several diseases including serious illnesses like cardiovascular disease and cancer. It was inferred that the additive and synergistic effects of phytochemicals present in fruit and vegetables were responsible for their potent antioxidant and anticancer activities and that the benefit of a diet rich in fruit and vegetables is attributed to the complex mixture of phytochemicals present in whole foods. This effect cannot be attained by providing purified bioactive molecules individually [50, 60, 61].

Nutraceutical, a word created by combining "nutrition" and "pharmaceutical," was coined in 1979 by Dr. Stephen L. DeFelice, founder and chairman of the Foundation for Innovation in Medicine, Cranford, New Jersey, USA [62]. It is a food or food product that provides health and medical benefits, including the prevention and treatment of disease. They are the product isolated or purified from foods and generally sold in medicinal forms not usually associated with food and demonstrated to have a physiological benefit or provide protection against chronic disease. Most of the Indian food preparation contains spices and condiments, and these have various bioactive molecules and exert antioxidant effect. Some of the most frequently used are turmeric, asafetida, saffron, cardamom, ginger, clove, fenugreek leaves and seeds, coriander leaves and seeds, mustard leaves and seeds, chillies, nutmeg, mace, cinnamon, nigella seeds, etc. These all are proven effective medicinal herbs and impart beneficial effects on health.

Indian food habits are in practice for at least the last two millennia and mainly comprised of cereals, pulses, fruits, vegetables, and milk [59]. More and more recent researches, particularly epidemiological studies, suggest a beneficial effect of such diet due to increased antioxidant potential of such foods resulting in reduced incidence of cancer, cardiovascular diseases, and stroke. This property is mainly attributed to fruits, and now we recommend eating five fruits a day or one apple a day keeps the doctor away. Slowly and slowly molecular mechanism and mode of action of bioactive molecules present in such foods are being unraveled. Health-promoting effects of isoflavonoids of pulses, antioxidants, and dietary fiber and various carbohydrates and bioactive lipids and consumption of fruits and vegetable are described in detail in this book; hence, details are not presented here.

Cereals (principally corn, wheat, and rice and sorghum and millets to a lesser extent) are staple food in many developing countries of the southern hemisphere with consumption of more than 400 million tons in 2017 [63]. Predominant Indian diet is rich in cereals, pulses, oils, and spices which are source of dietary fiber, vitamin E, carotenoids, and phenolic compounds. This diet exerts strong antioxidant activity (μg α-tocopherol equivalent/100 g fresh weight) and antioxidant activity of

some of the prominent Indian foods such as rice (80–102), whole wheat (220–500), spinach (750–890), amaranth (620–810), coriander leaves (610–750), and fenugreek leaves (520–690) [64]. Daily intake of about 40 g dietary fiber is recommended for an adult which varies in India due to socioeconomic conditions from 60 to 70 g depending upon the type of cereal consumed. Dietary fibers in major cereals and pulses consumed in India are rice (8.3), wheat (17.2), pearl millet (20.5), and mung (15.2), while the soluble dietary fiber content of foods is reported to vary widely: cereals, 8–20%; legumes, 20–50%; vegetables, 25–67%; and fruits, 20–65% [64, 65]. Cereals are not only rich in soluble and non-soluble carbohydrates but also contain vitamins, minerals, phenolics, carotenoids, tocopherols, tocotrienols, anthocyanins, and phytosterols and impart health beneficial effects like immunomodulatory effect; antioxidant activity; antiproliferative and hepatoprotective effects [66, 67]; protection against coronary heart diseases, type 2 diabetes, and cancer; and antiaging, antiallergic, and cholesterol-lowering abilities [68, 69].

Pulses (beans, peas, and lentils) have been consumed for at least 10,000 years and are among the most extensively used foods in the world. Pulses are main source of protein in a vegetarian diet and chickpea is consumed all over the globe. In Indian diet, chickpea (Bengal gram, *Cicer arietinum*) is consumed in large quantities not only in vegetable but in sweet and salted fried preparations, followed by mung bean (green gram, *Vigna radiata*), arhar (pigeon pea, *Cajanus cajan*), urad (black gram, *Vigna mungo*), lentil (*Lens culinaris*), and cowpeas (*Vigna unguiculata*). Pulses have several health-promoting components, including vegetable protein, complex carbohydrate, dietary fibers, vitamins, minerals, oligosaccharides, isoflavones, phospholipids, and antioxidants. Its regular consumption has been associated with protective effects against various diseases. Major bioactive phytoconstituents such as phytic acid, lectins, sterols, saponins, dietary fibers, resistant starch, oligosaccharides, and carotenoids and isoflavones have shown protective effects to various human diseases such as diabetes, obesity, cancer, osteoporosis, and cardiovascular diseases [70–73].

A balance between antioxidants and free radicals is necessary to maintain good physiological functioning of the body, and therefore, great attention has been given to understand the mechanism of free radical action and protective effect of antioxidants present in food. If free radicals overpower the body's ability to control them, a condition known as oxidative stress ensues [74]. Thus free radicals alter the metabolism of lipids, proteins, and DNA leading to deranged physiology or diseased state. Therefore, search for natural and safe antioxidants has been intensified in recent years. A significant role of oxidative stress has been correlated with several diseased conditions like atherosclerosis, arthritis, certain cancers, and process of aging. Oxidative stress is now thought to make a significant contribution to all inflammatory diseases (arthritis, vasculitis, glomerulonephritis, lupus erythematous, adult respiratory disease syndrome), ischemic diseases (heart diseases, stroke, intestinal ischemia), hemochromatosis, acquired immunodeficiency syndrome, emphysema, organ transplantation, gastric ulcers, hypertension and preeclampsia, neurological disorder (Alzheimer's disease, Parkinson's disease, muscular dystrophy), alcoholism, smoking-related diseases, and several others [75]. It is needless to mention that an excess of oxidative stress can result in the

oxidation of lipids and proteins, which always causes changes in their structure and consequently functions.

Fruit consumption is directly related to society's economic status and is variable in different countries. Anticancerous phenolics from *Phyllanthus*, tea polyphenols (epigallocatechin gallate) as antioxidant and anticancer, radioprotective litchi phenolics/flavonoids, hypoglycemic *Syzygium*, quercetin and hydroxyl cinnamates of sweet cherries, xanthones of mangosteen, ellagitannins of pomegranate, ursolic acid of sea buckthorn, muscle relaxative watermelon, anti-cholesterolemic soluble fiber and sterols, cardioprotective saponins, ACE-inhibitory potato hydrolysates, anti-pancreatic cancerous ascorbic acid, and carotenoids including pro-vitamin A are some of the well-known examples [76]. Selected tropical fruits and vegetables and their bioactive molecules and biological effects are presented in Tables 1 and 2. Some of them are grown since millennia, while some are improved recently from their wild relatives. The commonly consumed fruits are mango, banana, papaya, guava, custard apple, pomegranate, apple, sapota, orange, and watermelon. These fruits and vegetables contain diverse bioactive molecules with health benefits ranging from antioxidants, immunomodulators, antidiabetic, and hepatoprotective to anticancer. The other prominent food-based bioactives include tea polyphenols (epigallocatechin gallate) as antioxidant and anticancerous, β-carotene, lycopene and isoflavones for prostate cancer prevention, omega-3 and -6 fatty acids, licorice, quercetin, curcumin as anticancer (antiangiogenesis), curcumin (anti-inflammatory and anticancer).

In an extensive literature survey, Bhattacharya [59] observed that Indian food habit has gradually shifted from large quantities of indigestible fiber carbohydrate, small amounts of digestible carbohydrate, moderate fat, and moderate protein to an increasing intake of high-fiber and refined carbohydrates associated with a decreasing intake of animal proteins. Major shift in intake of high-fiber carbohydrate was observed from1775 to 1947. After 1947, slight change in food habit was observed with increased frequency of small quantities of refined carbohydrates and improvement in protein intake associated with socioeconomic conditions of the country. Therefore, Indian vegetarian food is not a single ingredient but a cocktail of many nutritional materials and herbs to impart nutraceutical effect on human health because of its long-term continuous consumption from childhood.

5 Vegetarian Diet in Postpartum Healthcare

Pregnancy is a unique situation in the life of to-be mother, and diet during this not only affects the health of the mother but also the newborn and has bearing on health throughout life. Similarly, nutrition and functional foods given during the postpartum care have long-term effect on growth, health, and metabolism of the mother and newborn. The postpartum period is commonly defined as beginning 1 h after delivery of the placenta and lasting 6 weeks [122]**.** The postpartum period is a time of increased physical, emotional, and social change for the parents of newborn. In many Southeast Asian cultures including India,

Table 1 Selected subtropical fruits, their bioactive molecules and biological activities

Plant species, name	Part used	Bioactive molecules	Biological activity	References
Aegle marmelos, bael		Coumarins such as marmelosin, umbelliferone, and scopoletin	Antihyperglycemic, chronic diarrhea, dysentery, peptic ulcers, as a laxative	[77, 78]
Artocarpus heterophyllus, jackfruit		Artocarpin, moracin C	Chemoprevention of colorectal cancer, antioxidant activity, anti-inflammatory activity	[79, 80]
Carica papaya, papaya		Papain, carotene	Antioxidant activity	[81, 82]
Citrus reticulata, orange		Ascorbic acid, citric acid, carotene	Antioxidant, antiallergic, improved lipid profile	[83]
Fragaria sp., strawberry		Flavonoids, anthocyanins, hydrolyzable tannins (gallotannins, ellagitannins), phenolic acids (hydroxycinnamic, hydroxybenzoic acids), condensed tannins, vitamin C, folate	Antioxidant, anti-inflammatory, antiatherosclerotic, anticarcinogenic, antidepressant properties	[84, 85]
Malus, apple		Chlorogenic acid, epicatechin, procyanidin B2, phloretin and quercetin, vitamin C, benzoic acids (gallic acid), hydroxycinnamic acids (chlorogenic acid), flavanols (catechin), flavonols (rutin), chalcones (phloridzin), terpenes (ursolic acid)	Antioxidants, antiproliferative, breast cancer treatment	[86, 87]
Mangifera sp., mango		Phenolic compounds, mangiferin, vitamins A and C, β-carotene and	Antioxidant activity, analgesic, antidiabetic, antisclerotic, antimicrobial,	[88–91]

postpartum period is considered important from point of view of recovery, by offering a period of confinement ranging from 10 to 45 days. Many activity and dietary restrictions are applied during this period, and the main emphasis is given on proper nutrition.

The following traditions are followed:

1. Covering of head: By north Indian traditions, the mother is supposed to cover the head with scarf to prevent heat loss and catching cold.
2. Daily oil massage is given to the mother and newborn by experienced elderly lady or nurse to impart strength to the body. Sesame oil for the body and coconut oil for the head (or cleared butter for all purposes) are used which are absorbed quickly.
3. Hot/lukewarm water is used for bath.
4. Diet is fortified with cleared butter whether it is bread, mixed porridge, wheat porridge, or vegetables. Too much emphasis is given on consumption of milk, cleared butter, and high-calorie diet (sweet preparations) prepared with herbs.
5. Decoction of cumin, carom, and/or curcuma in milk is given during initial days in the morning.
6. Like headscarf, belly binding with a large cotton cloth is also practiced to facilitate repositioning of the uterus, perfectly position the baby during feeding, and put the stomach muscles back together.

Table 2 Some of the subtropical vegetables, their bioactive molecules and biological activities

Plant species, part used	Principal nutrient source	Bioactive molecules	Biological activity	References
Brassica oleracea, cauliflower, inflorescence		Lectins, essential oils, glucosinolates	Immunomodulatory, hepatoprotective, antioxidant, anticancer effects	[104, 105]
Capsicum annum, chilli, fruit		Capsaicin	Stimulation of gastrointestinal defense and absorption, stimulation of salivary, intestinal, hepatic, and pancreatic secretions	[106]
Chenopodium album, bathua, leaves		Vitamin A, oxalic acid	Anthelmintic, antimicrobial, antioxidant	[107]
Cyamopsis tetragonoloba, cluster bean, immature pods		Flavonoids, isoflavonoids (daidzein, genistein), luteolin, quercetin, kaempferol	Anticancer, antioxidant, antidiabetic, antiulcer, cytoprotective, anticholinergic, hypolipidemic	[108, 109]
Daucus carota, carrot, root		Polyacetylenes, carotenoids (beta-carotene and lutein)	Potential treatment for chronic lymphocytic leukemia	[110, 111]
Lagenaria siceraria, bottle gourd, fruit		Sterols, terpenoids, flavonoids, saponins	Controlling diabetes, hypertension, liver diseases, weight loss, and other associated benefits	[112]
Momordica charantia, bitter gourd, fruits		Cucurbitane-type triterpenoids, triterpene glycosides, phenolic acids, flavonoids, essential oils, saponins, momordicosides Q−U, charantin	Antidiabetic, immunomodulatory effect, antioxidant, anti-inflammatory, anticancer, antibacterial, anti-obesity activity	[113, 114]
Raphanus sativus, radish, root		Raphanusamide, cyanidin, vanillic acid, kaempferol, quercetin	Antiulcer, antimicrobial, antifungal, anti-inflammatory, diuretic, antioxidant, anticarcinogenic,	[115]

Table 2 (continued)

Plant species, part used	Principal nutrient source	Bioactive molecules	Biological activity	References
			antitumor promotor, and anti-HIV activities	
Solanum lycopersicum, tomato, fruit		Polyphenols, β-carotene, lycopene, vitamin C, quercetin, rutin, hydroxycinnamic acid derivatives	Prevention of cancer and neurodegenerative and cardiovascular diseases, improving immunity	[116, 117]
Solanum melongena, brinjal, fruit		Flavonoids, tropane, glycoalkaloids, arginine, lanosterol, gramisterol, aspartic acid	Analgesic, antipyretic, antioxidant, anti-inflammatory, hypolipidemic, hypotensive, antiplatelet, intraocular pressure reducing	[118]
Spinacia oleracea, spinach, leaves		Ascorbic acid, folate, phylloquinone, alpha-tocopherol, and the carotenoids lutein, violaxanthin, zeaxanthin, and beta-carotene	Protective effect against metabolic syndrome, anti-obesity, anti-inflammatory, anticancer, hypoglycemic, and lipid-lowering effect	[119–121]

In Asia, the dietary choices of women during pregnancy and the postpartum period are principally influenced by traditional healthcare system and cultural beliefs whispered for these periods. It is believed that a "hot-cold balance" should be maintained in order to stay healthy and that this can be achieved by following special prescriptive diets during pregnancy and the initial postpartum period, commonly termed "the confinement period" [123, 124]. Several studies indicate that maternal diet during pregnancy and the postpartum period has not only important effects on the offspring's health but also the diet of a lactating mother which influences the composition of breast milk [125–127].

Vegetarian diet is considered safe for pregnant women and long-term health of the newborn [128]. The major population in the Indian subcontinent is vegetarian, and health of babies is not a problem in general except in cases of malnutrition. Traditionally postpartum care includes hygienic condition with feeding mother with several nutrients and functional foods as enumerated in Table 3. All these herbal plants are used in 50–200 g quality in several preparations for postpartum

Table 3 Bioactive molecules and biological activity of plants used in diet therapy during postpartum healthcare (compiled from [130–134])

Plant species (family), part	Bioactive molecules	Biological activity				
		Total polyphenols (mg GAE/g)	DPPH% inhibition	SOD% inhibition	FRAP (mM Fe^{+2}/g)	Others/remarks
Aegle marmelos (Rutaceae), fruit	*Furocoumarins*, flavonoids, *rutin*, and *marmesin*; a number of essential oils	95.33 ± 2.31	80.25 ± 1.03iu	54.94 ± 0.88	884 ± 5.13	Treatment of chronic diarrhea, dysentery, and peptic ulcers, as a laxative
Anethum graveolens (Apiaceae), fruit	Essential oils, coumarins, flavonoids, phenolic acids, and steroids	4.73 ± 0.23	75.53 ± 2.91	37.25 ± 1.18	62 ± 1.13	Carminative, stomachic, and diuretic
Anogeissus latifolia (Combretaceae), gum	High molecular weight polysaccharic acid (ghattic acid)	300.0 ± 4.55	86.94 ± 2.57	84.95 ± 1.62	975 ± 6.86	Reduction in serum total cholesterol
Areca catechu (Arecaceae), nut	Alkaloids of the pyridine group, ß-sitosterol, leucocyanidins, catechu (tannins, catechin, gallic acid)	393.33 ± 3.77	72.71 ± 0.91	43.23 ± 0.74	1003.33 ± 9.55	Diuretic, digestive, anthelmintic, astringent, and cardiotonic
Asparagus racemosus (Asparagaceae), root tuber	Steroidal saponins, essential oils, asparagine, arginine, tyrosine, flavonoids (kaempferol, quercetin, rutin)	4.13 ± 0.30	26.26 ± 0.71	32.44 ± 0.58	80 ± 1.26	Gastric ulcers and dyspepsia and as a galactogogue
Butea monosperma (Fabaceae), gum	Butrin, isobutrin, butin, palasitrin, and butein	426.66 ± 8.31	87.17 ± 1.39	80.53 ± 1.42	79.0 ± 1.26	Antimicrobial, wound healing, antifungal, antidiarrheal, hypoglycemic, hepatoprotective,

Table 3 (continued)

Plant species (family), part	Bioactive molecules	Biological activity				
		Total polyphenols (mg GAE/g)	DPPH% inhibition	SOD% inhibition	FRAP (mM Fe^{+2}/g)	Others/remarks
Mucuna pruriens (Fabaceae), seeds	L-Dopa	38.66 ± 1.15	89.85 ± 1.76	17.99 ± 0.42	868 ± 4.04	Male infertility, nervous disorders, and also as an aphrodisiac, antioxidant activity
Myrica esculenta (Moringaceae), bark	Myricanol, aproanthocyanidin, β-sitosterol, taraxerol, myricadiol	45.33 ± 2.04	81.27 ± 3.26	75.39 ± 0.98	800 ± 3.02	Antimicrobial, wound healing, antifungal, hepatoprotective, antioxidant, antihelminthic
Myristica fragrans (Myristicaceae), seeds	Trimyristin, myristic acid, myristicin, safrole, and elimicin	12.0 ± 1.04	89.99 ± 1.78	23.18 ± 0.46	633 ± 3.60	Aromatic, aphrodisiac, diarrhea, anticonvulsant, analgesic, anti-inflammatory, antidiabetic, antifungal antibacterial, antioxidant
Myristica fragrans (Myristicaceae), aril of fruits	Lignin(macelignan), flavonoids, phenolics, tannins, alkaloids, and saponins	40.66 ± 1.15	88.96 ± 1.32	14.2 ± 0.38	588 ± 3.51	Inhibits the enzyme xanthine oxidase
Ocimum basilicum (Lamiaceae), leaves	Terpenoids, alkaloids, flavonoids, tannins, saponin glycosides	9.00 ± 0.72	63.68 ± 1.80	5.04 ± 0.14	08 ± 0.53	Hepatoprotective, antitoxic, immunomodulatory, antihyperglycemic, antifungal, hypolipidemic, anti-inflammatory, antibacterial

Piper cubeba (Piperaceae), fruits	Diarylcyclobutane neolignans, dibenzylbutyrolactone lignan, *O*-ethyl cubebins, monoacetate of dihydrocubebin	15.53 ± 1.85	87.47 ± 0.92	9.72 ± 0.96	485 ± 6.80	Cough, swelling, indigestion, dysmenorrhea, erectile dysfunction
Piper longum (Piperaceae), roots	Alkaloids, tannins, flavonoids	4.13 ± 0.23	45.57 ± 0.12	37.13 ± 0.98	50 ± 0.96	Antioxidant, antibacterial activity
Piper nigrum (Piperaceae), fruits	Piperine	5.13 ± 0.61	57.22 ± 1.05	31.88 ± 0.73	19 ± 0.40	Stimulate digestive enzymes in the pancreas, antioxidant
Quercus infectoria (Fagaceae), galls	Gallic acid, tannic acid	645.33 ± 10.2	90.20 ± 2.4	90.34 ± 0.35	1115 ± 9.29	Astringent, diarrhea, leucorrhea, uterine prolapse, tightening the loose or sagging tissues
Rubia cordifolia (Rubiaceae), roots	Anthraquinone (munjistin, purpurin, and pseudopurpurin), rubiadin	9.60 ± 0.87	71.98 ± 2.21	49.32 ± 0.59	75 ± 1.10	Blood detoxifying, anti-inflammatory, hemostatic, antidysenteric, antipyretic, analgesic, anthelmintic
Solanum surattense (Solanaceae), roots	Alkaloids, sterols, saponins, flavonoids	4.86 ± 0.65	84.41 ± 1.21	24.9 ± 062	520 ± 2.29	Antiasthmatic, hypoglycemic, hepatoprotective antibacterial
Smilax chinensis (Liliaceae), roots	Kaempferol and its glycosides, rutin, engeletin	9.26 ± 0.81	87.36 ± 1.54	55.05 ± 0.83	55 ± 1.62	General health tonic, syphilis, skin diseases and women's health concerns
Solanum indicum (Solanaceae), roots	Flavonoids, steroid, tannin, saponins	14.13 ± 0.80	72.68 ± 1.27	25.11 ± 0.70	733 ± 3.60	Antioxidant, anticancer, anti-inflammatory, diuretic, diaphoretic

(*continued*)

Table 3 (continued)

Plant species (family), part	Bioactive molecules	Biological activity				
		Total polyphenols (mg GAE/g)	DPPH% inhibition	SOD% inhibition	FRAP (mM Fe^{+2}/g)	Others/remarks
						immunomodulatory, neuroprotective effects
Symplocos racemosa (Symplocaceae), bark	Phenolic glycosides (symplocoside), triterpenoids (betulinic acid, acetyloleanolic acid, oleanolic acid) flavonoids (quercetin)	86.0 ± 0.05	75.29 ± 0.10	63.33 ± 1.54	884 ± 4.50	Anticancer, hepatoprotective, antioxidant, antiandrogenic effect, anti-inflammatory, wound healing activity, antidiabetic effects
Syzygium aromaticum (Myrtaceae), flower bud	Clove oil (eugenol, trans-β-caryophyllene)	101.33 ± 0.23	88.13 ± 0.58	55.05 ± 1.05	675.33 ± 5.36	Antibacterial, antifungal, insecticidal, antioxidant, anticarcinogenic activities
Terminalia chebula (Combretaceae), fruits	Tannins (gallic acid, chebulagic acid, punicalagin, chebulanin, corilagin, neochebulinic acid, ellagic acid, chebulinic acid), chebulinic acid, ellagic acid, anthraquinones	166.0 ± 0.35	78.88 ± 0.85	84.66 ± 2.24	1009 ± 8.98	Antioxidant, antidiabetic, hepatoprotective, anti-inflammatory, antimutagenic, antiproliferative, radioprotective, cardioprotective, antiarthritic neuroprotective activities

Trachyspermum ammi (Apiaceae), seeds	Thymol, carvone, limonene, dillapiole	12.46 ± 0.98	88.39 ± 1.01	0.26 ± 0.02	955 ± 7.63	Stimulant, antispasmodic, and carminative
Tribulus terrestris (Zygophyllaceae), fruits	Flavonoids, flavonol glycosides, steroidal saponins, and alkaloids	10.2 ± 0.53	82.64 ± 0.98	1.10 ± 0.06	560 ± 2.80	Diuretic, aphrodisiac, antiurolithic, immunomodulatory, hypolipidemic, hepatoprotective, anti-inflammatory
Vitex negundo (Verbenaceae), seeds	Flavonoids, flavone glycosides, volatile oil, triterpenes, tannins, and lignin	5.46 ± 0.12	53.96 ± 0.96	4.25 ± 0.10	180 ± 1.26	Antinociceptive, anti-inflammatory, antitumor, antioxidant, antimicrobial, antiandrogenic, anti-osteoporotic, hepatoprotective, antihyperglycemic activities
Zingiber officinale (Zingiberaceae), rhizome	Flavonoids, alkaloids, saponins, steroids, terpenoids, tannin	11.4 ± 0.40	87.11 ± 0.61	33.78 ± 0.53	47 ± 0.65	Immunomodulatory, antitumorigenic, antioxidant, anti-inflammatory, antiapoptotic, antihyperglycemic, anti-lipidemic and antiemetic actions

period besides food fortified with fat and sugar to suppress bitter taste of herbs. Ginger is used in separate preparation as considered hot and lodh (*Symplocos racemosa*) in separate preparation being considered as cold. Hot and cold preparations are given separately, hot preferably first. All these preparations are divided into equal proportions to last 40–45 days. Increased milk drinking associated with galactogogue like *Asparagus racemosus* roots facilitates milk production. Bioactive molecules present in these herbal ingredients impart nutrition (high calories) and functional molecules which are helpful in developing immunological, antioxidative, and galactogogue effects. These plants contain a wide variety of free radical-scavenging molecules, such as phenolic compounds (e.g., phenolic acids, flavonoids, quinones, coumarins, lignans, stilbenes, tannins), nitrogen compounds (alkaloids, amines, betalains), vitamins, terpenoids (including carotenoids), and some related endogenous compounds, which have high antioxidant activity [129]. Most of the herbs and foods given during postpartum care in India showed strong antioxidant activity [130]. Other prominent biological activities include stimulant, improves digestion, blood purifier, progesterone production, balance of hormonal cycle, emotional balance, tonic for nerves and stress and wound healing activities. Some of them are well-established medicinal plants used in Ayurveda such as fruits of *Aegle marmelos* and *Terminalia chebula*; rhizome of *Curcuma longa* and *Zingiber officinale*; roots of *Asparagus racemosus*, *Rubia cordifolia*, *Smilax chinensis*, and *Desmodium gangeticum*; and seeds of *Mucuna pruriens* and *Vitex negundo*. Details of their active constituents are given in Table 3. Dried ginger is traditionally used in several food preparations including tea as well as major ingredient in postpartum food preparation. Ginger is known to impart antioxidant, antimicrobial, and anti-inflammatory effects, and modern tools of molecular targets validated these effects [131]. In all 38 plants are described in Table 3. These plants contain very diverse chemicals and their effects as an individual is neither known completely nor is possible to describe in this chapter. It is the combined effect of these herbs that is more important, and we know that such formulation imparts synergistic effect on human health.

Diet therapy includes preparations of medicinal herbs in the form of decoctions, infusions, and cold extracts. The herbs given during this period are traditionally known to strengthen the body and mind and prevent disorders such as postpartum depression (PPD), body aches, insomnia, indigestion, and oxidative stress [135].

Several reports describe the effect of maternal diet particularly rich in high fat on composition of human milk. Bioactive lipids in milk include triacylglycerides, diacylglycerides, saturated and polyunsaturated fatty acids, and phospholipids. Beneficial activities of milk lipids include anticancer, antimicrobial, anti-inflammatory, and immunosuppression properties. Fats are good media for solubility of many organic compounds and facilitate their absorption [136, 137]. Maternal diet has been shown to influence fatty acid composition of breast milk, with changes appearing within 8–10 h after a meal is consumed [138–140]. Fatty acids with a chain length greater than C14:0 originate from the maternal diet or body stores, while fatty acids up to C14:0 originate from de novo synthesis in the breast [138, 141].

The term conjugated linoleic acid (CLA) describes a mixture of positional and geometric isomers of linoleic acid (C18:2n-6) which contain a conjugated double-bond system instead of the more common isolated double bonds. Rumenic or cis-9, trans-11-octadecadienoic acid (cis9,trans11-C18:2) is the most regular CLA isomer and is frequently regarded as the biologically most pertinent one [142]. Humans receive CLA through diet (dairy products and ruminant meat), and it is presumed that the amount of CLA in the milk of breastfeeding women can be augmented by increasing the amount of organic dairy nutrients within their diet [143]. CLA content and both rumenic acid and TVA in human breast milk were increased in the milk of lactating mother consuming diet rich in organic products as compared to control (mothers) eating the same products obtained through conventional methods [144, 145].

Alternative to household preparations, several Ayurvedic formulations are also available for postpartum care such as shatavari kalpa granules (*A. racemosus*) for lactation and dashmool (ten roots, the combination of ten roots is used widely in Ayurveda for many health conditions related to anti-inflammatory, antirheumatic or antiarthritic, analgesic, antispasmodic, adaptogenic, antioxidant, neuroprotective, anti-paralytic, uterine tonic, uterine detoxifier). Out of these ten roots, five (*Aegle marmelos*, *Desmodium gangeticum*, *Gmelina arborea*, *Solanum surrentense*, *Tribulus terrestris*) are used in the household preparations. Besides, there are several herbal preparations that are also available for the newborn mainly for digestive system correction, gas, and flatulence.

6 Conclusions

It is increasingly clear that the regular consumption of traditional food has a long-lasting beneficial effect rather than changed diet regimen. Vegetarian diet has at least no harmful effect. Pulses are traditionally consumed all over India, and now we have new evidence that beneficial bioactive peptides are produced during processing and cooking; hence, the effect is nutraceutical besides nutritional. Similarly, coconut oil is consumed traditionally in almost all food preparations in Kerala state of India, while north Indian consumed sesame or mustard oil. Slight variation in food habits are due to what is produced in that area is preferably consumed in the area, irrespective of the general belief. There is no record of higher disease incidence in Kerala because of the consumption of saturated fat in high amount. Beneficial effects of mustard and sesame oil are being established now, whereas these are used since centuries and soybean or sunflower oil is of recent introduction.

In this review, we have tried to portrait the scenario prevailing in a country like India in relation to vegetarianism and postpartum care influencing the whole life of a newborn. In India, vegetarianism is centuries old and strictly followed by caste system and practiced by religion in well-to-do families. In contrast to this, those who are below poverty line families, they do not follow strict diet rules by caste and religion, and they have their own tribal rules or no rules, hence are not strictly vegetarian. Several herbal

ingredients used during postpartum care need to be evaluated scientifically using modern pharmacological techniques to ascertain their effects.

This will also provide information about necessary inputs required for better health of the mother and child. Recent studies demonstrated health beneficial effects of these centuries-old herbal preparations, and more insight into mode of action and mechanism of action using modern pharmacological tools will shed light on beneficial effects of these herbs and foods.

Abstract

It is an established fact that the plant-based food is known to provide several health benefits beyond basic nutrition to human. However, with increased demand for food, excessive use of pesticides, chemicals, and hormones to increase the yield and quantity has led to serious issues with use of plant-based diet. Additionally, dependency on few major crops, use of convenient, and ready

to eat type of food have also lead to excess of energy and high consumption of carbohydrates which resulted to unexpected increase in incidence of obesity, diabetics, and other metabolic syndromes, globally. In view of such issues with plant-based diet, recently a lot of emphasis is laid to the use of health promoting, low calorie and mixed variety of plant-based diet, and to have more benefits. Traditional indigenous and exotic plants are enriched with beneficial nutrients and are sold in today's market as functional food or nutraceuticals. Market value for this class of consumer market is close to 200 billion $ and is expected to grow at a rate of 7.5% compound annual growth rate. However, in this journey from food to nutrition and nutraceuticals, some key components have been neglected, which is critical to get optimum benefits. In this chapter, we would like to discuss some of the key challenges in achieving optimum concept of health promoting molecules from farm to fork. Often, we measure the content of these in plant either after harvesting or during storage and based on which we assume the surety of health benefits. Either due to lack of facility or collaborative efforts, we are not considering critical factors like the right time for harvest of commodity, right storage and processing technique, and right cooking and formulation protocol along with selection of right base and ingredients for food. Some of these aspects are discussed in detail along with problems in achieving the same. Additionally, the chapter also provides necessary information on how to test and ascertain the quality of nutrition and its delivery for optimal benefits.

1 Introduction

Bioactive molecules (BAM) in plants: Why and how they exist? Every creature in this universe has been provided with primary means of survival and existence. It is the immune system in human and animals, toxins, or other chemicals in microbes and in plants through secondary metabolites [1]. These secondary metabolites in addition to protecting plants against pest and diseases and abiotic stresses will also serve as metal transporting agents, as agents of symbiosis between microbes and plants, as sexual hormones, and as differentiation effectors. They have a wider variety of diverse chemical structure and biological functions that are species specific. In addition to structural reinforcement of tissue and tree, some of the secondary metabolites have special functions such as chemoattractants for pollinators, indication of ripening, indication of spoilage, etc.

Recent studies have also shown that plants have chemical and physical signal molecules to communicate to each other and sense the environmental alterations [2, 3]. Therefore, it is evident that secondary metabolites act as primary defense system in plants and protect them from both biotic and abiotic stresses. Since secondary metabolites are produced in very low concentration, for commercial application of

potent components, production of secondary metabolites will be induced by means of external factors like stress. Secondary metabolite content in most plants can be enhanced by biotic and abiotic elicitation technique, which is most commonly used in biotechnological route to producing plant metabolites. Some of the examples include production of vincristine and vinblastine by *C. roseus* cell cultures developed from shake flasks to scale up through bioreactor [4]. Other phytochemicals produced using such biotechnological route include medically important molecules like Taxol, berberine, podophyllotoxin, scopolamine, and nutraceuticals like anthocyanin, betacyanin, gingseng, geraniol, etc. [4, 5].

Formation of secondary metabolites: All the secondary metabolites are usually formed from conjugation and other reaction of primary metabolites, specifically amino acids, carbohydrates, and proteins. Among the biochemical pathways, shikimic acid, malonic acid, mevalonic acid, and methylerythritol phosphate (MEP) pathways are responsible of formation of secondary carbon-containing molecules. It is through photosynthesis and carbon source CO_2 compounds and through different pathways that compounds such as phenolics, nitrogen containing compounds, and terpenes are formed. For example, most of the terpenoids are formed from basic unit IPP (isopentenyl diphosphate) and a basic unit C_5H_8, either from mevalonic acid or methylerythritol phosphate (MEP) pathway from sequential combination of three acetyl CoA units to form 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) followed by mevalonic acid and finally isopentenyl diphosphate (IPP). This is formed by dephosphorization in the case of mevalonate pathway. In the case of MEP pathway, it is formed from combination of glyceraldehyde 3-phosphate and pyruvate, through 1-deoxy- D-xylulose 5-phosphate and methylerythritol phosphate (MEP). Similarly, most of the secondary metabolites are formed through established pathways (Table 1). Some of the high-value compounds are produced in plants by induction of stress, alteration in microenvironment, use of elicitors (biotic and abiotic), and genetic manipulation through biotechnological tools. Table 2 shown is the list of secondary metabolites produced through biotechnological routes.

Table 1 Formation of secondary metabolites in plant through different pathways and precursors for the same

Class of secondary metabolite	Initial precursor	Pathway
Purine alkaloids	Histidine and purine	
Imidazole alkaloids	Histidine	
Terpenoids, indole alkaloids, quinoline alkaloids, quinazolidine alkaloids, acridine alkaloids	Shikimate/ Shikimic aid	Shikimate pathway
Flavanoids, stilbenes, coumarins, tannins (condensed), lignans	Cinnamate, chalcone	Phenylpropanoid pathways (PPP)
Polyketides, saturated fatty acids	Acetyl CoA, mevalonate	Mevalonic acid pathways
Vitamin B_1, B_6, isoprenoid	Glucose	Deoxy xylulose pathway

Table 2 Secondary metabolites and bioactive compounds produced through biotechnological route

Name of the metabolite	Route of production	Application	Reference
β-Carboline alkaloids	Suspension culture	Administration of BCA is currently available experimental model to study essential tremor	[6, 7]
Gallotannins	Root culture	Prevention of gushing in beer and carbonated beverages	[8]
Withaferin A	Shoot culture	To study intermediate filament proteins	[9]
Berberine	Root culture	Antibacterial alkaloid	[10]
Vanillin	Genetically modified organism(*Pycnoporus cinnabarinus*)	Flavoring agent	[11]
Catechin	Hairy root culture	Antibacterial agent	[12]
Shikonin from *Lithospermum erythrorhizon*	Stirred tank bioreactor	Inhibit cancer cell glycolysis	[13]
Vinblastine from *Catharanthus roseus*	Air lift reactor	Chemotherapeutic agent	[14]
Capsaicin from *Capsicum*	Immobilized cell reactor + precursor isocapric acid	Digestive stimulant and for treatment of rheumatic disorders	[15]
Diosgenin from *Dioscorea doryophora*	Suspension cell culture	Precursor for medicinal steroids	[16]
Terpenoids	Metabolic engineering of mevalonate pathway	Flavor, fragrances, and cosmetics	[17]
Lycopene	Metabolic engineering of non-mevalonate isopentenyl synthesis pathway	Antioxidant, antitumor agent	[18]

Chemically, three major groups of secondary metabolites are produced in plants, namely, terpenes, phenolics, and N- and S-containing compounds. Terpenes composed of 5-C isopentanoid units are toxins and feeding deterrents to many herbivores. Phenolics synthesized primarily from products of the shikimic acid pathway have several important defensive roles in the plants as well as in humans. Members of the third major group, i.e., N- and S-containing compounds, are synthesized principally from common amino acids, and these have several biological properties in both plant and human [19].

Secondary metabolites role in plant: Unlike primary metabolite's presence, distribution of secondary metabolites within the species and plant part is very specific. They perform several functions in plant which includes protection of

plant against stress, pathogens, and interaction between plants and other organisms [20]. Defense is the primary role of these metabolites in plants, which is executed in multiple ways which includes being toxic to organisms (like pathogenic microbes, insects, and animals), formation of barrier for pathogens, production of enzymes that degrade pathogens, and acquiring immunity after first infection. Antimicrobial compounds which are released whenever there is an interaction from microbes are termed as phytoanticipins; these will be released from constitutively stored precursors during microbe attack [20]. Some of the compounds in this category are saponins, glucosinolates, cyanogenic glucosides, and benzoxazinone glucosides.

2 Alternation in Content of BAM

Bioactive molecules are meant for protection of plant under various stress and diseased conditions. Use of these for human health is one of the ancient systems of medicine which originated in Indian and other South Asian countries centuries back. The same has got great significance in the last few decades, due to established benefit in several diseases including chronic diseases. Although benefits from plant-based formulation is attributed to combined effect of multiple constituents, each of the plant is known to have a specific molecule known to be key ingredient for activity, and often they are termed as marker compound or active principles. As these are naturally produced or accumulated in plants, their concentration and distribution depend on several factors related to both plant and environment. These factors include processing of plant materials as food or formulation along with genetic factors of consumer and other factors including the bioavailability and bio-efficacy. Factors influencing the efficacy of bioactive molecules are summarized in Fig. 1.

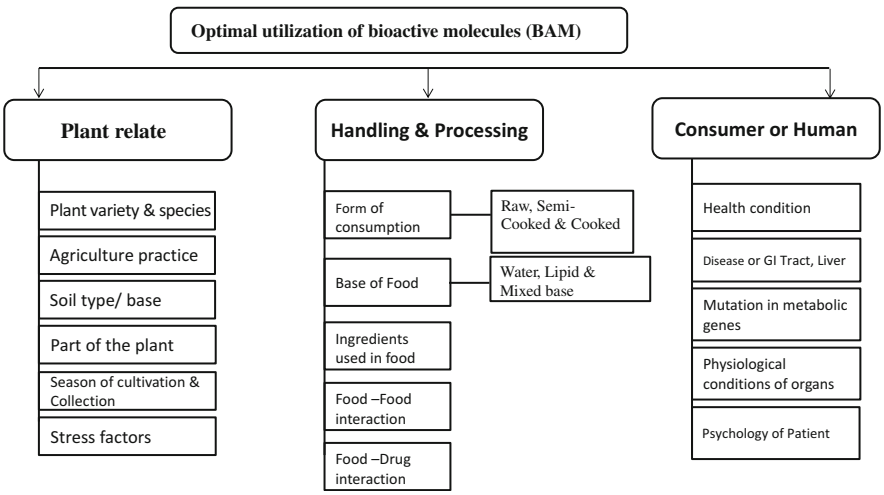

Fig. 1 Various factors affecting optimal utilization of bioactive molecules (BAMs) from food

2.1 Development and Agriculture: Growth of Plant, Season, Postharvest Handling

Accumulation of secondary metabolites at different stages of growth depends on both intrinsic and extrinsic factors. Accumulation of phenolic compounds increases with development, and the highest accumulation is observed during flowering stage. In the case of *Hypericum perforatum* L., increased content of naphthodianthrones at higher temperature and light intensity has been reported [21]. In the case of model plant *Arabidopsis thaliana,* it was observed that both content and composition of glucosinolate changed during different stages of development. Dormant and germinating seeds had the highest concentration (2.5–3.3% by dry weight) of glucosinolates, followed by inflorescences, siliques (fruits), leaves, and roots. Content of aliphatic glucosinolates predominated in most organs; indole glucosinolates make up nearly half of the total composition in roots and late-stage rosette leaves. Seeds possessed much higher concentrations of several types of aliphatic glucosinolates than other organs. Content of methylthioalkyl and hydroxyalkyl glucosinolates and compounds with benzoate esters was high in seed compared to other organs. Based on the age, older leaves had lower glucosinolate concentrations than younger leaves indicating maturity will enhance the secondary metabolites. Content of phytochemicals declined during seed germination and leaf senescence [22]. These results indicate that depending on role of secondary metabolites, accumulation varies with growth and quantity of accumulation will not be same in different parts. Therefore, selection of plant part and stage of development is critical to get optimum content for preparation of herb-based products.

Another important aspect of phytochemical variation is seasonal changes, as mentioned above; accumulation of secondary metabolites is greatly influenced by light, temperature, and length of day and night. These aspects are well established using model plants in laboratory studies; varied content of anthocyanin in grapes in different season and climate has been reported [23]. Accumulation of antimicrobial compounds in bulb and leaf extracts of *Tulbaghia violacea*, *Hypoxis hemerocallidea*, *Drimia robusta*, and *Merwilla plumbea* in different season has been reported by [24]. Results of the study suggest that accumulation of antimicrobial compound was highest in winter and autumn seasons. Total phenolics were found to be highest in spring compared to other seasons. Content of condensed tannin, gallotannin, and flavonoid levels, depending on the sample, was either higher in spring or winter except for *H. hemerocallidea* (corm) which had higher gallotannin levels in autumn. Total saponin content was highest in winter in all the plant studies [24]. Comparison of phytochemicals composition in different parts of commercial broccoli cultivars in spring and fall provided interesting findings in content of glucosinolates, vitamin C, total phenol, and total flavonoid contents and antioxidant activity. The highest total glucosinolate content was found in the florets of plants grown in both seasons. Phenols and flavonoids were highest in leaves, while vitamin C was highest in stems, suggesting that broccoli leaves and stems may be good sources of phytochemicals. All phytochemical contents were generally higher in florets in the spring than in the fall but were higher in leaves and stems during the fall than the spring

[25]. These results indicate that health benefits we get from the plant-based diet have some relation with season. This could be the reason for practice of seasonal plant-based diet in many cultures.

Similar to environment, nutrients supplemented to plants will also have great influence on the accumulation of secondary metabolites. Content of asiaticoside, asiatic acid, and quercetin 3-O-glucuronide was different in three cultivars of *Centella asiatica* grown under different soil nutrition condition. Salt stress is known to increase several secondary metabolites in plants; this includes sorbitol (*Lycopersicon esculentum*), flavonoids (*Hordeum vulgare*), jasmonic acid (*Lycopersicon esculentum*), tropane alkaloids (*Datura innoxia*), anthocyanins (*Grevillea* spec.), trigonelline (*Glycine max*), and glycine betaine (*Triticum aestivum*). Similarly draught stress which sometime occurs naturally is known to increase the accumulation of morphine alkaloids, glycosides, epicatechins, rutine, flavonoids, and anthocyanins, which are well known for the biological activity in human [26]. Under saline stress two cultivars of broccoli, namely, "Naxos" and "Parthenon" have shown accumulation of the highest phenolics [27]. Several plants have demonstrated varied accumulation of secondary metabolites when cultivated under different light and temperature, indicating direct effect from altered photosynthesis and several biosynthetic pathways. Accumulations of lycopene in tomato [28], carotenoids in Brassicaceae [29], and flavonoids and terpenoids in citrus [30] are some of the examples. The same approach is used in the case of plant cell culture to produce high-value secondary metabolites in reactors. These constitute the plant- and environment-associated factors that influence the accumulation of secondary metabolites.

Postharvest-associated factors also play major role in deciding the content of secondary metabolites in food ingredients. This is very important as most of the food ingredients will be stored (transported) under different conditions after harvest before consumed. This includes storage by producers, transportation, storage in market place, and household storage (refrigeration and room temperature). The time between the harvest and consumption of fruits and vegetables will be several weeks and the same is few weeks to months in the case of cereals and pulses. Hence, it is important to evaluate and understand changes in phytochemical content during postharvest handling and storage, which will have great impact on health beneficial activity of ingredients. Modified atmospheric packaging plays an important role in preserving the phytochemical content during postharvest and storage [31]. The level of phytochemicals present in fruit and vegetables may vary within and across cultivars. Available literature correlates the level of phytochemicals with many factors including cultivar type, environmental and agronomic conditions, harvest and food processing operations, and storage factors [32]. Postharvest storage of the vegetables and fruits in cold rooms increases the stress and upregulates the antioxidant pathway and antioxidant production; phytochemical content and also the weight of the vegetable commodities were observed to be significantly different from room temperature-stored vegetables/fruits and cold room-stored vegetables/plants [33]. Total phenolic content gets declined during curing and storage of fruits/vegetables due to anthocyanin degradation; anti-inflammatory factors and

antioxidant activity are reduced during the course of storage [34]. Further, studies also indicated that phytochemicals in fruits such as anthocyanins, phenolics levels changed during ripening and senescence [35]. The optimization of food processing and storage factors is an essential step to reduce the degradation of phytochemicals for potential health benefits.

Processing: Each of the plant food ingredients is subjected to one or the other processing before consumption. This may be cutting or size reduction, germination, drying in the case of those consumed fresh, steaming, boiling, frying, or cooking. These physical processes are known to greatly influence the fate of phytochemicals. One of the studies has shown variation in content of phenolic acids, isoflavones, flavones, and glucosinolates when analysis was done using fresh and fresh-cut samples including tomato, carrot, grape, eggplant, and broccoli. Content of phytochemicals reduced in cut tomato compared to fresh and similar results was observed in the case of eggplant. In other vegetables there was no significant variation between fresh and cut samples. Content of ascorbic acid, carotenoids, anthocyanins, and volatile principles (monoterpenes) decreases when fruit/vegetable is cut in to pieces and stored for a long time before use, irrespective of temperature as these are sensitive to light, temperature, and air [36]. Impact of different processing techniques on biological activity and phytochemicals composition is as shown in Table 3.

Three major medicinal plants, namely, *Ocimum basilicum*, *Senna petersiana*, and *Hypoxis hemerocallidea* have shown higher antimicrobial activity in fresh form compared to stored samples suggesting loss in either content or biological activity [60]. Another study has shown that heating and storage can greatly influence the phenolic content and biological (antioxidant) activity of blue berry extracts [61].

Cooking or formulation: This is another key factor in deciding quality and quantity of phytochemical content in food we finally consume. There are case-specific issues concerned with cooking, which essentially has three major processes, namely, shallow frying, deep frying, semi-boiling and pressure or complete cooking. In all these processes, using temperature-sensitive ingredients like ascorbic acid, some vitamins and enzymes are deactivated. On the other hand, cooking will also help in percolation of active compounds from peelings to edible parts as seen in the case of potato, cashew, and other crops. Content of glucosinolate and sulforaphane is greatly reduced in broccoli florets after cooking, and therefore it is recommended to be consumed raw for optimum health benefits [62]. In addition, cooking will also lead to alteration in chemical nature of phytochemicals like breakdown (pigments), complexation (glucosides), and polymerization (polyphenols). It is also important to consider the biological effects of converted compounds, which may be useful or sometimes harmful (formation of acrylamide is most common example).

3 Hurdles in Release of Bioactive Compounds

In addition to plant-related factors, other factors, which are known to limit or control the bioaccessibility of compounds, are complex nature of plant materials, food matrix, and other factors related to cooking and formulation of food [63]. These

Table 3 Impact of processing on component of food ingredients and biological benefits

Sl. No	Plant source/s	Bioactive molecule/s	Processing method/s used	Impact of processing (+) or (−) on bioactive molecule/s	Reference
1	Oranges and grape fruits	Phenolics	High temperatures or freezing	Affects the content of some polyphenols, including flavonoids, due to the extractability alteration by the rupture of the cell wall	[37]
2	Kale And red cabbage	Phenolics	Peeling, washing, chopping, boiling, frying, and baking (traditional oven or microwave)	Increase in levels of phenolics, as well as antioxidant activity after cooking	[38]
3	White cauliflower	Phenolics	Boiling, steam techniques and stir frying	- boiling results in a decrease of the total phenolic content - steam techniques and stir frying promoted an increase of these compounds	[39]
4	Tomatoes	Phenolics	Boiling, baking, and frying	Significant reduction in total phenolic content	[40]
5	Kale And red cabbage	Phenolics	Steam cooking	Higher contents of bioactive compounds and higher antioxidant activity	[38]
6	Potato "cultivar" (*Solanum tuberosum* L.)	Anthocyanin	Microwave cooking, steamed pressure cooking, boiling, and baking in a hot air oven	Preserves or causes a little increase in the anthocyanin content	[41]
7		Catechin	Heating	Reduction in bioactive compound by epimerization	[42]
8	Blueberry fruits	Anthocyanin	Blanching	Increase in the retention of Anthocyanin levels (23% instead of 12%) and the total anthocyanin content of juice from blanched blueberry is twice the nonblanched one	[43]

(*continued*)

Table 3 (continued)

Sl. No	Plant source/s	Bioactive molecule/s	Processing method/s used	Impact of processing (+) or (−) on bioactive molecule/s	Reference
9	Fruits and vegetables	Catechin, quercetin, and its glycosides	Blanching	Affects color, flavor, texture, and loss of the nutritional and functional quality by promoting the oxidation of phenolic compounds	[44]
10	Blackberry	Phenolics	Pasteurization	Phenolics is lost	[45]
11	Mushroom	Phenolics	Sanitizing using sodium hypochlorite	Disappearance of phenolics and the formation of their oxidation products	[46]
12	Red onion slices	Flavanols and anthocyanins	Sanitizing using sodium hypochlorite	Losses of flavonols (23%) and anthocyanins (13%) due to leaching.	[47]
13	Pineapple, banana, And guava	Phenolic content and flavanoids	Sanitizing using ozone (O_3)	Significant increase in total phenolics Whereas in bananas and pineapples, the flavonoid content increased in response to ozone treatment For guava fruits, the flavonoid content increased and total phenolic decreased inversely	[48]
14	Campbell grapes	Phenolics, flavonoids, and anthocyanin	Microwave heating, ultrasonication and blanching	- microwave heating and ultrasonication increased bioactive contents in non-cold stabilized grape juice than in cold stabilized juices - blanching decreased bioactive compounds both in non-cold stabilized and cold stabilized juice	[49]
15	Pumpkins	Phenols and carotenoids (lutein, a-carotene, and b-carotene)	High pressure processing	No differences in the total bioactive molecule contents	[50]

(*continued*)

Table 3 (continued)

Sl. No	Plant source/s	Bioactive molecule/s	Processing method/s used	Impact of processing (+) or (−) on bioactive molecule/s	Reference
16	Red bell Peppers	Vitamin C	Pulsed electric field treatment	Minimal loss of vitamin C due to improved mass transfer during drying	[51]
17	Beetroot tubers (*B. vulgaris*)	Betalain	Pulsed electric field treatment	90% recovery of metabolite	[52]
18	Oil tocopherol Polyphenol	Rapeseed	Pulsed electric field treatment	Increased content of polyphenols and tocopherols	[53]
19	Carrot	β-Carotene	Boiling	Increase in bioavailability	[54]
20	Kiwifruit puree	Lutein, neo-lutein, β-Carotene, Neoxanthin, Violaxanthin	Pasteurization by Conventional heat	No effect on bioaccessibility	[55]
21	Milk- and soy-based Fruit Beverages	α-Tocopherol, γ-Tocopherol, and δ-Tocopherol	High pressure processing	No effect (α-tocopherol) Decrease (γ- and δ-tocopherol)	[56]
22	Orange juice	Ascorbic acid, phenolics, flavanones, and Carotenoids	Pasteurization	Ascorbic acid, total flavanones, total carotenoids, and provitamin A values of pasteurized orange beverage were lower than those of fermented juice. Total phenolic remained unchanged and was similar to that of original juice	[57]
23	Fruits and vegetables	Anthocyanin	Thermal Processing	Anthocyanin pigments readily degrade during thermal processing which can have a dramatic impact on color quality and may also affect nutritional properties	[58]

(*continued*)

Table 3 (continued)

Sl. No	Plant source/s	Bioactive molecule/s	Processing method/s used	Impact of processing (+) or (−) on bioactive molecule/s	Reference
24	Orange juice	Vitamin C, carotenoids, and flavanones	High pasteurization	Losses in total vitamin C were < 9%, treatments with the higher temperatures tended to show the higher decrease in the content of both forms of vitamin C. Whereas increase in naringenin and hesperetin	[59]

are intermediate to plant- and human-related factors, and major ones include release of bioactive molecules from food matrix, nature of BAM from source, food-food interaction, and food-drug interactions.

Release of bioactive molecules from food matrix: Bioactive molecules are found in plants, fruits, and vegetables and include heterogeneous group of molecules such as polyphenols, carotenoids, tocopherols, phytosterols, and organosulfur compounds [63] with different chemical structures (hydrophilic, hydrophobic). These compounds vary in their distribution in nature (specific to particular vegetable or ubiquitous), concentration in food and human body, site and mode of action, efficiency against oxidative species, and their specificity.

There are many clinical evidences indicating the link between the chronic diseases such as cancer and cardiovascular diseases with diet, especially with plant-based food [64, 65]. Although the composition of the nutrients and other bioactive compounds in food will be mentioned on the labels printed on the package, the bioavailability of the bioactive molecules in human body differs. It is dependent on various factors, which include chemical nature of the nutrients, their release from food matrix, interaction with other food components, presence of suppressors and cofactors, formation of stable components from which nutrients are released, and so on. Recent evidence also suggests that the natural matrix of food and also the microstructure of processed food influence the bioavailability of bioactive molecules in vivo [66].

Food composition database (FCD) provides the information regarding the amount of energy, proteins, fats, vitamins, minerals, and other nutrients present in food. FCD provides the information which is the based on certain chemical assays performed. In the case of complex food, it is based on the nutrient composition of ingredients. FCDs have been methodically compiled over the years in many countries and provide information about the nutrients contained in most consumed foods [67]. FCDs are generally used to assess the nutrient content of diets and to derive nutrition guidelines. They are also often utilized in food policy recommendations and nutrition monitoring.

The FDA has defined bioavailability as the rate and extent to which the active substances or therapeutic moieties contained in a drug are absorbed and become available at the site of action [54]. This definition has to be also applied for the bioactive molecules present in food. Book on Indian nutrition that is known as *Indian Food composition Table* published by the National Institute of Nutrition, Hyderabad, on January 2017 provides extensive details on most of the food ingredients used in different regions of India.

Another term that is commonly used is bioaccessibility, which is defined as the amount of an ingested nutrient that is available for absorption in the gut after digestion [68]. If the amount of recovered nutrient is of relevance, then bioaccessibility term comes into use. However, bioavailability is measured in blood/plasma in vivo, and it will be affected by several factors such as physiological state, dosage, etc.

After consumption, the nutrients that are present in a food or drink will be released, absorbed into the bloodstream, and circulated in the body, and also few of the times, it is transported to their target tissues. Nutrients differ in their bioavailability, which is mainly decided by their solubility and affinity for binding with proteins and biological molecules either in blood or in different organs. Release of the nutrient from the food matrix, effect of digestive enzymes, binding and uptake by the intestinal mucosa, transfer across the gut wall to the blood or lymphatic circulation, systemic distribution and deposition, metabolic and functional use, and excretion can affect nutrient bioavailability. It is mediated by external (characteristics of the food matrix, chemical form of the nutrient, etc.) and consumer internal (gender, age, nutrient status, and life stage) factors. The bioavailability of macronutrients (carbohydrates, proteins, and fats) is usually very high, e.g., more than 90% of the amount ingested will get absorbed and utilized.

Bioaccessibility is the first step to make a nutrient bioavailable, which mainly depends on availability of nutrients for absorption. During this step, the nutrient is released from the food matrix and converted into a chemical form that can bind to and enter the gut cells or pass between them. Chewing, enzymatic digestion of the food in the mouth, mixing with acid and enzymes in the gastric juice, and releasing into the small intestine are the unit operations of the process by which the nutrients are rendered bio-accessible. The small intestine is the major site of nutrient absorption. Enzymes of the pancreatic juice continue breaking down the food matrix. Certain procedures involved in food preparation like cooking, chopping, or pureeing collaborate with mastication and enzymes to the digestibility of food matrices.

The oral bioavailability is limited due to the restricted release of the components from plant matrix, solubility of nutritional molecules in gastrointestinal fluid, the permeability across intestinal epithelial cells, as well as the enzymatic and chemical reactions occurring within the gastrointestinal tract. Following four essential steps are necessary for the effective absorption of bioactive compounds:

1. Release from food matrix
2. Incorporation into bile-salt micelles

3. Absorption by epithelial cells
4. Incorporation into the chylomicrons with secretion into lymphatic system

As mentioned in previous section, processing of food also has an impact on the chemical constituents, physical and sensory properties of the final product. In addition to cooking, industrial food processing technologies may influence the content of bioactive compounds leading to changes in their functional properties (e.g., bioavailability, bioaccessibility, and bioactivity) and potential health benefits. Loss of phytonutrients in foods becomes more significant as food is processed, stored, packaged, and transported. Some of the processes like frying, puffing, semi-cooking, and steaming are known to increase the bioavailability of compounds which are less sensitive to heat. Similarly, processing such as grinding, fermentation, and/or mild heating may improve bioavailability, most likely as a result of disruption of the cell walls of plant tissues, dissociation the nutrient-matrix complexes, or transformation into more active molecular structure. Therefore, attention should be given to the degree of disintegration of the initial tissue structure because of its impact on food quality, functionality, and deterioration. As the demand for functional food increases, intense research efforts for the development of new processing technologies is conducted with the goal of ensuring maximal nutritional and functional properties, as well as the overall quality of a product.

The bioavailability of nutrients and bioactive compounds present in plant products (fruits and vegetables) is presently an extremely important area of food and nutrition research. The objective of these studies is to determine the contribution of actual foods as sources of specific nutrients (e.g., antioxidants) and to establish processing conditions that maximize the health benefits. Although several photochemicals are known to be important in promoting human health, the bioavailability of these bioactive molecules will vary with respect to their microstructure. For example, food microstructure seems to be quite relevant in the bioavailability of several antioxidants. Some of the phytochemicals for which bioavailability has been established and extensively researched includes carotenoids, polyphenols, and folates.

Carotenoids are a family of fat-soluble plant pigments that provide red and orange colors to fruits and vegetables. Their function is to absorb light in photosynthesis, protecting plants against photosensitization. Dietary carotenoids are considered to be beneficial in the prevention of a variety of diseases, including certain cancers and eye disorders. The 5 principal carotenoids found in human plasma as a result of ingestion of plants are α-carotene, β-carotene, cryptoxanthin, lutein, and lycopene, but over 600 carotenoids have been identified to date in plant and marine organisms. Our research has demonstrated both radical scavenging and hepatoprotective activity of carotenoid-rich marine microalgae [69, 70]. Carotenoids present in a wide variety of plants are partially concentrated in chromoplasts or chloroplasts in different ways. The extent of release from the food matrix is highly variable depending on whether carotenoids are non-covalently bound to protein or fiber or not. In general, release of carotenoids from plant foods occurs only when the cells in the food matrix are disrupted, as is usually the case during food preparation,

processing, and/or mastication, but not during digestion, at least in the ileum of humans [71]. One of the studies suggests that size reduction in the case of carrot (pureed fresh carrot) has shown highest release of carotenoids and its isomers compared to raw or boiled carrot [72].

Lycopene, a carotenoid responsible for the distinctive red color of ripe tomatoes, is usually located within cell membranes, and its release is determinant on the bioavailability. Epidemiological studies have suggested that consumption of lycopene may protect against CVD and reduce the risk of several types of cancer, most notably those of the prostate, breast, lung, and digestive tract [73]. Food processing like cooking or heating may improve lycopene bioavailability by breaking down cell walls, which weakens the bonding forces between lycopene and the tissue matrix, thus making it more accessible. One of the studies indicate that bioavailability of lycopene is higher in tomato paste compared to consumption of fresh one [74]. Another clinical study suggests that severely homogenized (blending for 2.5 min using the same blender, followed by processing in a high-pressure homogenizer at 200 bar) tomato had shown the highest amount of lycopene and carotenoid content in serum along with increased antioxidant activity. This was in comparison with treatment of mild homogenization (blending for 2 min) and raw tomatoes to volunteers in food [75]. Clinical study has also shown that lycopene is more bioavailable in its cis form from tangerine compared to all trans form as in the case of tomato juice, which is more of chemical factor [76]. These results indicate that along with physical, chemical factors also plays critical role in deciding bioavailability of lycopene and other phytochemicals.

Xanthophylls are yellow pigments found in plants and are known for various biological effects, which includes lutein, zeaxanthin, capsanthin, canthaxanthin, astaxanthin, echionine, and β-cryptoxanthin. These are oxygenated carotenoids that are synthesized within the plastids. The xanthophylls lutein and zeaxanthin accumulate in the eye lens and macular region of the retina and have been implicated in helping to protect the eye against oxidative damage and cataracts. For optimal absorption of xanthophylls, they must be released from their food matrix and then transferred to lipid micelles in the small intestine. This requires the presence of dietary fat in the small intestine, which stimulates the gallbladder to release bile acids (i.e., emulsifiers). Therefore, fat or fat base is important for all nonpolar phytochemicals including fat-soluble vitamins.

Polyphenols represent a wide variety of compounds belonging to several classes, for example, hydroxybenzoic and hydroxycinnamic acids, anthocyanins, proanthocyanidins, flavonols, flavones, flavanols, flavanones, isoflavones, stilbenes, and lignans. These are ubiquitously found in all the plants used in diet and nutritional supplements. As mentioned before, phenolic compounds (or polyphenols) are secondary metabolites of the pentosephosphate, shikimate, and phenylpropanoid pathways in plants. Reported bioavailability of polyphenols is highly variable depending on their structure and conjugation. Among polyphenols, phenolic acids account for about one third of the total intake, and flavonoids account for the remaining two thirds. The most abundant flavonoids in the diet are flavanols (catechins plus proanthocyanidins), anthocyanins, and their oxidation products. Chemical structure

is the primary determinant of bioavailability of polyphenols. Studies in human have shown that excretion of polyphenols through urine varies from 0.5 to more than 50% depending the source and structure. Over 27% of caffeic acid was detected in urine after administration of 1000 mg, 24% in the case of hesperidin, 19.8% in the case of genistein from soy milk, and 6–8% of naringin from grapefruit. Most of the polyphenols takes 1–2 h to reach peak plasma concentration, except those absorbed after degradation. Based on the elimination rate and half-life of polyphenols, it is essential for repeated administration or consumption of sources preferably once in 24 h [77].

Folates and folic acid are forms of vitamin B that are necessary for the production and maintenance of new cells, especially important during periods of rapid cell division and growth, such as throughout infancy and pregnancy. Inadequate folate intake has been associated with development of birth defects [78]. Leafy green vegetables such as spinach and turnip greens, dry beans and peas, and some other fruits and vegetables are rich natural sources of folate in nature; folates are covalently bound to macromolecules. Bioavailability of folate from food source mainly depends on factors like nature of food matrix, extent of deconjugation of polyglutamyl folates in the intestine, and stability of certain folates during digestion and in presence of other dietary constituents which may either increase or reduce the stability. Apart from this, in the case of fortified supplements, stability of folate used is also a major concern toward optimum utilization. McNulty and Pentieva from the University of Ulster, UK, have discussed details of these factors along with experimental details in estimating folate bioavailability and bio-efficacy in acute and chronic model [79]. They have concluded that chronic studies on food supplementation can give better understanding on the bioavailability of folate, and this needs to be conducted using robust and highly controlled experiments which can ensure controlled source and delivery of folate equivalent to folic acid. It was also pointed that stability of folate and its analogues in plant sources (green leafy vegetables) after cooking is another major limiting factor.

3.1 Food-Food Interactions

Humans consume verity of food to meet daily needs of energy depending on the ethnicity and region. Additionally different types of foods are consumed on different occasions, which generally consist of several verities made out of multiple ingredients originating from either plant, animal, or microbial source and several chemicals; processed or semi-processed ingredients are also used in the food preparation. As each of the ingredients will have multiple phytochemicals, there will be a good chance of interaction between two or more molecules resulting in useful or deleterious outcome. The classical example of useful interaction is enhancement in iron bioavailability in the presence of ascorbic acid or vitamin C. Conversely, interference of phytic acid in absorption of essential minerals and nutrition is the established example for negative outcome.

Food supplements (e.g., nutrients, vitamins, hormones, amino acids, antioxidants) and functional food (e.g., phytosterols or omega-3 fatty acids enriched

food) occupy a position between food and drugs. Botanical materials represent a large segment of this class of products (e.g., tulsi, *Withania*, soy isoflavones, yam, or hop extracts). In addition to food-food interactions, the interaction between phytochemicals of food and toxic contaminants is another less studied concept. A team of toxicologists made an attempt to study this concept in order to understand the interactions which can lead to additive or subtractive or even synergistic effects, under a project named FOODINTER in Belgium. The communication between scientists and stakeholders (authorities, producers, and consumers) plays an important role in this particular regard. This will help to ensure the safety from food-food interaction and food-contaminants interactions, which accidentally get in to food during storage of food ingredients and processing or preparation of food. Therefore, it is necessary to conduct risk assessment of chemicals, natural compounds, and environmental contaminants present in food supplements which could interact between them or with micro- or macronutrients of normal human diet.

Interaction studies have been performed using existing in vitro models (based on culture of various cell types, prokaryotes and eukaryotes) with mixture of active substances at different concentrations. The project selected Ginkgo biloba, St John's wort, maca, black radish, garlic, and soy isoflavones, which are most commonly used as health supplements to understand the interactions. They studied several key phytochemicals from each of these commodities along with seventeen trace elements As, Ba, Bi, Cd, Co, Cr, Cu, Mn, Mo, Ni, Pb, Sb, Se, Sr, Ti, Tl, Zn, and Hg, over 23 mycotoxins, more than 15 PHAs, organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs), and of polybrominated diphenyl ethers (PBDEs), and dioxins were also analyzed in the selected samples. Evaluation parameters like cytotoxicity, inhibition of metabolizing enzymes, and results provided very specific information regarding various contaminants that needs to be considered for limitation in all the products containing selected plants/extracts derived from them. There is a need to create such database on all the major food ingredients used globally. Parameters for analysis and study interactions should be based on the location of cultivation, agriculture and postharvest practices, processing technique used, and method of food preparation [80].

3.2 Food-Drug Interactions

Food-drug interaction is defined as the alteration in the pharmacodynamic, pharmacokinetic properties of the drug due to the interaction with the nutrients present in the food or change in the nutritional composition in of food (in vivo) due to its interaction with drug. Food-drug interactions can result in two main clinical effects: either a decreased bioavailability of a drug, which predisposes to treatment failure, or an increased bioavailability, which increases the risk of adverse events and may even precipitate toxicities [81]. For example, grapefruit juice is a selective intestinal CYP3A4 inhibitor, cytochrome P-450 3A4, in the small intestine, resulting in a significant reduction of drug pre-systemic metabolism [82]. The overall exposure of some drugs can be increased by more than fivefold when consumed with grapefruit

juice and increases the risk of adverse effects. The use of certain drugs may affect GI tract function and may lead to a loss of bodily electrolytes and fluids. People in risk due to the food-drug interactions are usually elderly people, cancer patients, and people with malnutrition, who are more prone for mutation in related to metabolism. However, elderly people are exposed to the highest risk as 30% of the prescribed drugs are consumed by them due to the decrease in physiological function with age [83]. Pharmacokinetic particularities associated with aging are absorption (changes in gastric pH, decreased gastrointestinal blood flow), distribution (decreased lean body mass, water, serum albumin concentration, and binding serum proteins), and elimination (reduced renal function). Therefore, drug bioavailability, volume of distribution, clearance, and half-life of drugs are modified with aging. Water-soluble drugs become more concentrated, and fat-soluble drugs will have longer shelf life due to slow release of the drugs from fat tissue. Food-drug interaction is a serious issue in drugs with very narrow therapeutic window, like chemotherapeutic, immunomodulators, and drugs acting on CNS.

3.3 Types of Drug-Nutrient Interactions

Based on nature and mechanisms, drug-nutrient interactions are classified into four types:

Type I interactions are ex vivo bio-inactivation, which refer to interactions between the drug and the nutritional element or formulation through biochemical or physical reactions, such as hydrolysis, oxidation, neutralization, precipitation, or complexation. They usually occur in the delivery device or outside the body.

Type II interactions affect absorption. They cause either an increase or decrease of the oral bioavailability. The precipitant agents may modify the function of enzymes (type A interactions) or transport mechanisms (type B interactions) that are responsible for biotransformation. Complexation, binding, and/or other deactivating processes occur in the gastrointestinal tract as a result of interaction between drug/food ingredients (type C interaction) and reduce absorption.

Type III interactions affect the systemic or physiologic disposition and occur after the drug or the nutritional element has been absorbed from the gastrointestinal tract and entered the systemic circulation. Changes of the cellular or tissue distribution, systemic transport, or penetration to specific organs or tissues can occur.

Type IV interactions refer to the elimination or clearance of drugs or nutrients, which may involve the antagonism, impairment, or modulation of renal and/or enterohepatic elimination.

Predicting drug interactions during drug development is a challenge for pharmaceutical industries and regulatory agencies. Since the publication of the US Food and Drug Administration's (FDA's) first in vitro and in vivo drug interaction guidance documents in 1997 and 1999, researchers and clinicians have gained a better

understanding of drug interactions [84]. This knowledge has enabled the FDA and the industry to progress and begin to overcome these challenges. The FDA has continued its efforts to evaluate methodologies to study drug interactions and communicate recommendations regarding the conduct of drug interaction studies, particularly for CYP-based and transporter-based drug interactions, to the pharmaceutical industry. A drug interaction website was established to document the FDA's current understanding of drug interactions [http://www.fda.gov/cder/drug/druginteractions/default.htm].

Host factors (includes genetic factors) include genetic and pathological factors that are associated with adverse, toxic effect of selected food ingredients in individuals. Pathological conditions associated with malabsorption mainly associated with mucosal layer. This can be classified as premucosal, which includes impaired digestion and bile acid/enzyme deficiencies; mucosal-associated factors like reduced absorption, bowel resection, and diseases affecting absorption; postmucosal-associated factors including altered nutrient transport and vascular or lymphatic abnormalities. Factors affecting the bioavaibality in human is also depicted in Fig. 2 for better understanding. These conditions can be treated with altering the nutrition in terms of the use of high protein diet, parenteral feeding and designer food with easily digestible and absorbable nutrients [85]. Genetic factors include mutation in metabolization genes such as P450 (CYP2D6), methylene tetrahydrofolate reductase

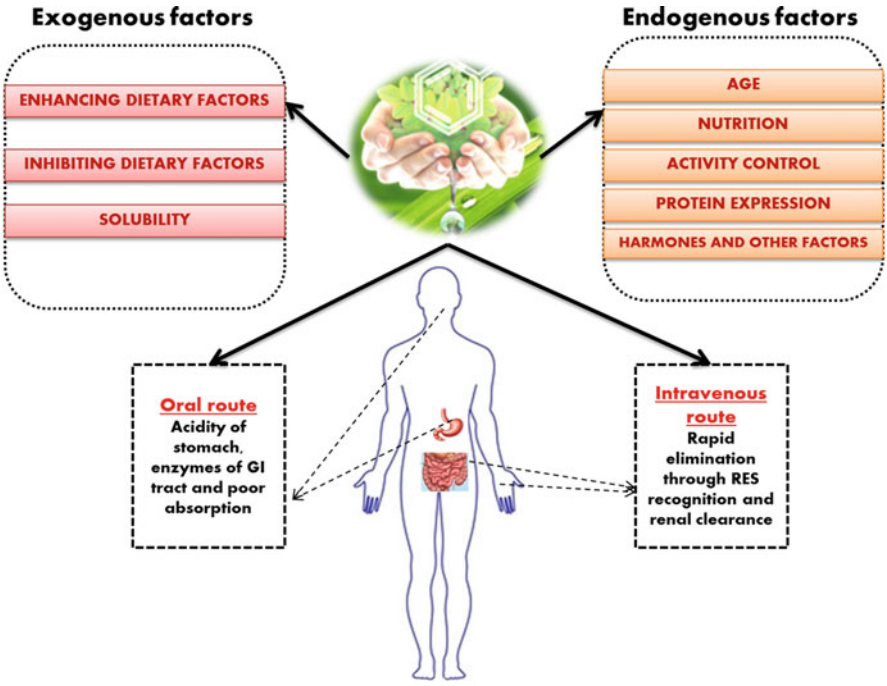

Fig. 2 Factors affecting/influencing bio-availability in human

gene, GST, N-Acetyl transferase, and so on [86]. Impact of metabolizing enzymes on the activity and content of biologically active compounds are shown in Table 4.

4 Models Used to Study Utilization of BAM

There are several in vitro and in vivo models available to understand the utilization of bioactive molecules from food ingredients. Prerequisite for bioavailability study is that we need to identify one or two marker compounds and its metabolites for which there should be very sensitive quantification or analytical method available. Flavonoids, polyphenols, terpenoids, and coumarins are some of the compounds extensively subjected for bioavailability studies in various models.

Among in vitro models, digestion of samples using gastric and intestinal enzymes at both gastric and intestinal pH is most widely used for both food and phytochemicals. It is commonly referred as "in vitro digestion model" [98]. Enzymes of porcine, rabbit, or human origin are used for this study, and some models have shown that the use of minor components such as bile salt, phospholipids, gastric lipase, and emulsifier is also considered for better results [99]. Simulated salivary fluid (SSF, pH 7.0), simulated gastric fluid (SGF, pH 3.0), and simulated intestinal fluid (SIF, pH 7.0) are used in these experiments, which give good indication of release of absorbable form of compound of interest. Use of artificial permeable membrane (also referred as artificial immobilized membrane-AIM), which simulates the permeability of intestinal lining is other model used commonly to estamale bioavailability of natural molecules. This is prepared by covalently binding membrane-forming lipids to an amorphous silica substrate which mimics both hydrophobic and hydrophilic nature of absorbing cells. Another model used is reconstituted or isolated cell membrane, which is more useful to understand specific type of molecular transport across the membrane. Compartment model is a commonly used model, which has two or more compartments connected through semipermeable membrane and movement of molecule from one chamber to another [100].

Common cell-based model used for bioavailability study is CaCo2 cell line, which is a colon adenocarcinoma cell. This cell line is generated to represent mucosal cells, which is primary site of absorption for GI tract. Primarily CaCo2 cells are used to understand the ability of nutrients to cross the intestinal barrier, as well as to study their transport mechanisms. Advantage with this model is it is quick and can provide good idea on permeation and absorption across the intestinal membrane, and it does not require ethical clearance [101]. Other ex vivo models include ligation of the intestine of animals like rat, rabbit, porcine, and pig. In this model, the intestine is ligated on one end, and solution containing food is added inside, and it is immersed in solution mimicking biological fluids [98, 100].

In situ model includes intestinal perfusion in animal, which is mainly done through microsurgery. It this done by cannulation of desired region of the intestine (proximal) after anesthetizing animals and collecting the sample flowing in the intestine at distal end. In this model any region of the small and large intestine can be studied [102]. In vivo animal and human models are the most realistic

Table 4 Major metabolizing enzymes known to interfere with bioactive molecules and their effects (+) or (−) on the bioactive molecules

Sl. No	Metabolizing enzyme/s	Bioactive molecule/s	Effect (+) or (−) on bioactive molecule/s	Reference
1	Transporter enzyme of intestinal or liver cells (e.g., P-glycoproteins	Bioactive molecules	Reduces oral bioavailability	[87]
2	Clearance enzymes	Bioactive molecules	Inhibitory potency against the target	[88]
3	β-Glucuronidase, β-glucosidase, β-galactosidase, mucinase, and nitroreductase	Resveratrol	Significantly reduced activities of these fecal and host colonic mucosal enzymes compared to control animals (21%, 45%, 37%, 41%, and 26%, respectively). The reduced bacterial enzyme activity was associated with a significant reduction in colonic tumor incidence in the resveratrol-fed rats compared to control rats	[89]
4	COX-2, NF-κB, AP-1, TNF-α, IL6, and VEGF (vascular endothelial growth factor)	Resveratrol	Inhibition of enzymes	[90]
5	GSTT2 and COX-2	Quercetin	Modulation of enzymes involved in detoxification and inflammation in LT97 human adenoma cells that could contribute to the chemopreventive potential of polyphenols after degradation in the gut	[91]
6	β -glucuronidase, β -glucosidase, β -galactosidase, mucinase, nitroreductase	Resveratrol	Modulating activity of bacterial enzymes and inhibitory effect on DMH-induced colon carcinogenesis in rats	[92]
7	Cytochromes P450	Flavanoids	Induce the expression of several CYPs and modulate (inhibit or stimulate) their metabolic activity. In addition, some CYPs participate in metabolism of flavonoids. Flavonoids enhance activation of carcinogens and/or influence the metabolism of drugs via induction of specific CYPs	[93]
8	Lipoxygenase, phospholipase, and cyclooxygenase.	Flavanoids	Inhibition of key enzymes involved in the prostaglandin biosynthesis	[94]

(*continued*)

Table 4 (continued)

Sl. No	Metabolizing enzyme/s	Bioactive molecule/s	Effect (+) or (−) on bioactive molecule/s	Reference
9	Kinases	Flavanoids	Inhibit these enzymes by competing with ATP for the binding to the catalytic site. These modes of inhibition provide an explanation for a molecular basis of flavonoid anti-inflammatory effects	[95]
10	Cytochrome P450 monooxygenases	Quercetin	Inhibition of gene expression of CYP1 family enzymes through blocking aryl hydrocarbon receptor which plays an important role in the cancer chemopreventive properties	[96]
11	Cytochrome P450 monooxygenases	Kaempferol	Prevents CYP1A1 gene transcription induced by prototypical aryl hydrocarbon receptor ligand	[97]

models, which involves repeated collection of blood and urine sample at regular intervals to understand the concentration of free-circulating compounds. Based on the loading concentration, both bound and organ absorbed concentrations can be calculated [103].

5 Challenges in Optimizing Mode of Delivery of BAM

As explained in previous sections, phytochemicals or BAM is present in different cellular compartments, which needs to be released from plant cell in to food matrix from where it needs to be released to GI tract for absorption. In this journey, BAM should be stable and withstand the conditions of postharvest, food processing and finally resist gastric pH and microenvironment to successfully be available for absorption. Some of the major challenges in this journey are as follows:

- Good agriculture practices to produce optimum BAM concentration.
- Best postharvest practices to protect or enhance the content of BAM.
- Best food processing methods to retain the quality and quantity of BAM.
- Minimizing the anti-nutritional or inhibitors of BAM activity through physical (soaking, grinding, etc.) or biological (fermentation, germination, etc.) process.
- Avoiding the combination of ingredients or food, those are known to interfere with either absorption or biological activity.
- Use of combination of ingredients or nutrients, which are known to synergize the activity or absorption of each other.

- Finally, to understand the genetic variation (metabolizing, transporting, and cell signaling genes) in individual who have problem in absorption and utilization of specific BAM.

6 Summary

It is a well-established fact that plant-based food can provide more benefits beyond primary nutrition to human. Often we give more importance to primary nutrition and focus on providing food security through agriculture and food industry practices. With increase in incidence of chronic disease, it is essential to provide more quality food which can provide good content of phytochemicals to support key biological functions like enhanced immunity, increase radicals scavenging ability, detoxify xenobiotics, and avoid infections. To achieve this, it needs integral efforts of agriculturist, food processing industry, food scientists, cook, and finally smart consumer. Often, aspects related to safe and efficient delivery of BAM is neglected due to lack of evidences, integration of experts and also complexity of processes involved. Therefore, it is essential to integrate the interdisciplinary expertise to achieve optimum outcome. This can greatly help in achieving good health through nutrition and can greatly help to reduce the burden of chronic diseases globally.

Acknowledgment Authors would like to acknowledge the support of the management of Gokula Education Foundation (medical) for their constant support and encouragement for research and also would like to acknowledge the help of research collaborators Prof. Bhimanagouda S Patil and Dr. G. K. Jayaprakasha, at VFIC, Texas A&M University for their support for research.

Bioactive Food Components in the Prevention of Cardiovascular Diseases

6

Arti Parihar and Mordhwaj S. Parihar

Contents

Abstract

Cardiovascular diseases (CVDs) remain one of the leading causes of death globally. The risk factors such as lipids, lipoproteins, and inflammation play a critical role in CVD. Lifestyle factors directly influence the risk of CVD. Understanding of the risk factors and the disease-causing mechanisms will lead to novel therapeutic treatments. Emerging data have explored the utility of natural food-based strategies in the management of diseases. Increasing interest has been grown up in recent years on the health-related products of food industry and to understand how foods products can help and maintain the individual cardiovascular health. Plant extracts rich in bioactive components could be used as the

functional ingredients for providing many health benefits. The recent advances in health benefits of bioactive components provide novel therapeutic approaches, which have played an important role in the reductions of CVD worldwide. This chapter presents a critical review of the potential benefits of bioactive foods consumed through diet to reduce the incidence of cardiovascular disease.

Cardiovascular disease · Coronary heart disease · Atherogenesis · Dyslipidemia · Inflammation · Active ingredients · Bioactive components of foods

1 Introduction

Cardiovascular diseases (CVDs) cover a wide group of disorders that involve the cardiac muscles and the vascular system. CVDs are regarded as the most common human health problem throughout the world. The mortality rates differ considerably from country to country with Japan and other Mediterranean countries having the lowest rates [1]. CVD is the major cause of the death increasing day by day in developed and developing countries [2, 3]. Heart failure is more common in countries with lower socioeconomic status and with those who tend to adopt unhealthier lifestyle, such as smoking and careless dietary habits [4–6]. CVD alone is responsible for taking 17.7 million lives every year, and atherosclerosis has been recognized as the prominent symptomatic anomaly responsible for CVD-related deaths [7]. The most important CVDs includes coronary heart disease, cerebrovascular disease, peripheral arterial disease, heart failure, rheumatic heart disease, congenital heart disease, deep vein thrombosis, and pulmonary embolism. Heart attacks and strokes that usually caused by a blockage of blood flow to the heart or brain are the most important acute manifestations of CVD in human. The causes of this global epidemic have been largely explained to originate from lifestyle factors which directly impact the novel pathways of CVD risk [8]. The increased lipids in the blood and build-up of fatty deposits on the inner walls have been strongly correlated with the increased incidence of CVD. Usually, combinations of risk factors are involved in causing the heart attacks and strokes. The most important factors associated with the incidence of CVD are lack of physical activity, drinking alcohol, use of tobacco, unhealthy diet, obesity, hypertension and hyperlipidemia. Diabetes mellitus is regarded as another epidemiological factor associated with an increasing prevalence of CVD [9, 10].

Atherosclerosis, mainly located in the intima of middle sized and large arteries, is the major cause of myocardial infarction, heart failure, and stroke. Dyslipidemias in vascular endothelium [11] and cholesterol deposition are the major contributors of atherosclerosis. Low-density lipoprotein (LDL) cholesterol when oxidized is pro-inflammatory and immunogenic and acts as an independent risk factor for CVD. The increase in oxidized LDL cholesterol results in endothelial dysfunction and directly influences the development of atherosclerosis. The decline in high-density lipoprotein (HDL) cholesterol increases the susceptibility to atherosclerosis substantially while the increase in the HDL cholesterol may reduce the incidence of coronary

heart disease (CHD) [12] and reduces the risk of CVD [13]. Appropriate levels of HDL cholesterol may also be responsible for clearing oxidized LDL cholesterol from the tissue by obstructing the monocytes attachment to the endothelium layer of blood vessels. Maintaining the HDL cholesterol level may also initiate the nitric oxide release that stops vascular bed atherogenesis [14]. Since the built up of atherosclerosis lesions require a long period of time, therefore, initiation of early lipid management may help prevention of atherosclerotic vascular diseases [15]. To manage the lipid level in patients with dyslipidemia, alternatives therapies have been designed in recent years [16]. Lifestyle modifications have been suggested as the primary prevention strategy in managing cardiovascular risk whereas food supplements were prescribed to patients to reduce the risk factors and symptomatic relief from CVD. The natural foods obtained from medicinal plants have been tried that might confer some benefit on some patient. However, more research is required that may include clinical trials with long follow-up outcomes to conclude their effectiveness against CVD illnesses.

The past few years have witnessed the extensive expansion of research on the association between dietary food and CVD. Certain foods have been recognized showing the effectiveness in reducing the risk of chronic diseases. These specific foods and food components appear as therapeutic strategies in the reduction and prevention of the risk of CVD. In recent years, a considerable importance has been given to functional foods. Apart from their basic nutritional effects, the functional foods exhibit an important role in disease prevention, or slowing the progression of many chronic illnesses. These functional foods work on two basic principles either possess a component with positive health benefits or remove a component with negative effects on the body functions. The relationship between the nutritional value of food components and the prevention of several chronic diseases led to increase in their demand in the market. However, to sustain in the market these foods must be safe, healthy, and delicious. They may be composed of a single compound that physiologically active or may include the addition of other food components to make them functional including omega fatty acids, prebiotics, phytochemicals, and bioactive peptides.

Bioactive food components are physiologically active constituents that are present in minute quantities in plant products and lipid-rich foods [17]. They are being extensively studied to evaluate their beneficial effects on health. These compounds vary widely in chemical structure and function and are grouped accordingly. Scientific evidence indicates that those certain bioactive food components participate in the prevention of CVD [17, 18]. Oral supplements of bioactive food components when taken along with the routine diet may increase the absorption of nutrients that will have clinical benefit in some diseases. Usually, bioactive components of foods are taken in addition to a healthy diet but they do not serve as the substitution to conventional food [19]. Their consumption as part of basic nutrition exerts useful physiologic effects in reducing the risk of diseases [20]. They may act at the different metabolic pathways that control various metabolism including lipid disorders in humans. By virtue of their targeted actions on various metabolic pathways, they are believed to have the therapeutic advantages for reducing the risk of CVD by combating the inflammation and dyslipidemias [21]. They have well-illustrative

beneficial biological effects such as antilipidemic, antihypertensive, antiglycemic, antithrombotic, and antiatherogenic. With the perceptible health benefits of bioactive components against various diseases, a wide array of the metabolomics and physiological relevance of these compounds were established [22]. A recent study in the United States, adults showed the associations of suboptimal intakes of dietary factors with mortality due to CVDs [4]. These functional foods, apart from providing basic nutritions, provide therapeutic benefits in the management of chronic diseases [23]. In this chapter, we thoroughly examined the beneficial effects of bioactive food components in reducing the risk factors of CVD including hypertension, dyslipidemias, oxidative stress, and inflammation.

2 Risk Factors of Cardiovascular Disease

A number of risk factors such as changes in lifestyle, age, physical inactivity, blood pressure, smoking, alcohol, obesity, hyperlipidemia, and diabetes have been listed for the pathogenesis of CVD [24–26]. Inflammation has been regarded as the principal molecular mechanisms responsible for atherogenesis [27–29]. During inflammation nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), a family of transcription factors that regulate varied processes in immune cells, initiates encoding of a number of genes responsible for cytokines and chemokines production [30]. The NF-κB signaling and cytokine secretion are found increased in atherosclerosis [31]. The IkappaB kinase/NF-kappaB (IKK/NF-κB) signaling pathway plays an important role in inflammation. In addition, this signaling pathway also regulates many other biological functions, including growth and survival of cells. These authors further elaborated that the activation of IKK/NF-κB pathway, which is an important regulator of inflammation, in cardiovascular tissues produce an excessive inflammatory response that causes cardiomyopathy leading to heart failure. Oxidative stress is another risk factor affecting the cardiovascular tissue in many ways. Oxidative stress can influence the functioning of endothelial layer of blood vessels, thereby leading to cardiovascular disease [32]. Reactive oxygen species (ROS) can have a direct effect on cardiac cells by oxidizing cellular constituents and disrupting the functions of proteins and enzymes [33]. The increase in ROS during the myocardial ischemia, hypoxia, and reoxygenation is the principal causes of reperfusion injury in cardiac tissues. During reoxygenation, increase in ROS cause direct oxidative damage to cellular components [34]. The obesity has been extensively correlated with the incidence of CVD, particularly among women [35]. Studies have shown an important connection between the obesity and dyslipidemia and the metabolic syndrome [36]. Dyslipidemia is mainly characterized by elevated levels of LDL-cholesterol and decline in HDL-cholesterol [37]. Hypercholesterolemia with total cholesterol level above 190 mg/L is the major form of dislipidemia and considered as one of the major risk factors for the CVD.

Hypertension is one of the major risk factors for cardiovascular-related illness. It is believed that hypertension is the single greatest contributor to cardiovascular disease [38]. With aging population throughout the world, the prevalence of

hypertension has a steep increase [39]. In addition to its detrimental effects on cardiovascular tissues, the hypertension is also associated with other cardiovascular risk factors, such as metabolic syndrome [40] and renal disease [41]. Changes in lifestyle, lowering sodium intake, reducing alcohol consumption, and weight reduction or physical exercise may lower blood pressure and thus reduce CVD [42]. Cigarette smoking is another important risk factor for CVD. An estimated 34.7% of all deaths resulting from cigarette smoking is related to CVD. Tobacco use cause impairment in endothelium-dependent vasodilation in the coronary microcirculation. The vasodilation response which was partly initiated by the release of nitric oxide (NO) was reduced in individuals who smoked [43]. Sera from smokers contain a reduced expression of endothelial nitric oxide synthase (eNOS) [44], whereas a brief exposure to tobacco smoke has caused the production of peroxynitrite ($ONOO^-$) [45]. Consumption of tobacco has been linked with the increase in the oxidation of LDL cholesterol, platelet aggregation, and impairment of endothelial layer [46]. Smoking for long-term increases the prevalence of hypertension, stroke, and atherosclerosis. Alcohol consumption is also associated with CVD. Although moderate consumption of alcohol cause lower risk of coronary heart disease, excess consumption of alcohol is detrimental to cardiovascular tissue [47]. These studies suggest that lifestyle changes such as physical inactivity, tobacco smoking, and heavy alcohol consumption are the risk factors contribute to CVD. The oxidizing chemicals, nicotine, carbon monooxide, and other particulate matters are believed to be accountable for cardiovascular disease.

3 Diet and Cardiovascular Disease

The life style and dietary patterns are often directly related with the development of hypertension, diabetes, and CVD. The nutritional diets may have a direct impact on the functioning of circulatory system physiology, thus affecting the occurrences of these diseases [48]. The metabolic abnormalities and the risk factors for CVD including dyslipidemia, central obesity, and hypertension are mostly depend upon the intake of an excess of total energy such as consuming high calorie or fatty meal [49, 50]. Individuals with dyslipidemia and high cholesterol levels were advised to take a diet rich in bioactive substances, fiber, and antioxidants and minimize the consumption of saturated and *trans* fatty acids. The dietary interventions that interfere with the reduction of plasma cholesterol and triglyceride levels may be effective in the prevention and management of CVD [51]. The diet consisting of nutritionally poor foods with high calorie and highly processed with deficiency of functional foods has been found to enhance systemic inflammation [52]. Food rich in fruits and vegetables along with moderate amounts poultry, fish, and meat has been associated with the reduction of inflammation thus prevent the occurrence of CVD. The direct correlation between serum total cholesterol and the heart attack and stroke was known since long time. Similarly, the importance of the Mediterranean diet in reducing the risk of coronary heart disease (CHD) [53–58] was also known since many years ago. Several studies were conducted describing the lifestyle and diets of

a population in the Mediterranean region and their relation to the rates of heart diseases [59, 60]. The traditional Mediterranean diet consisting of cereals, olive oil, fish, legumes, fruits, vegetables, dairy and meat products and moderate quantity of wine is quite beneficial for the heart. Consuming such diet provides a low risk of CHD and prevents the heart disease. Studies in individuals who opted for Mediterranean food [61] have shown a reduction in the incidence of CHD. Similarly, the choice of the Mediterranean diet with extra-virgin olive oil or nuts among individuals who are at high cardiovascular risk showed a reduction in CVD [62]. The studies performed on the composition of diet that should be useful for the prevention of CVD is limited. Thus, there is an urgent need to undertake such meticulously designed studies on the dietary food components that may be useful in reducing the lifestyle generated cardiovascular risk.

4 Types of Food Components Used for Prevention of Cardiovascular Disease

A critical role of lifestyle and diet in the prevention and treatment of CVD has become widely accepted. Besides classical food components, i.e., carbohydrates, proteins, fats, vitamins, and minerals, the diet prescribed to promote health and prevent diseases also includes the foods derived from medicinal plants known by various terms such as medicinal foods, bioactive foods, functional foods, or therapeutic foods [63], the consumption of which is believed to reduce the risk of many diseases including CVD [64]. The functional food refers to products with certain health benefit and reduced the risk of diseases. Foods such as fruits vegetables, cereals, fish, and red wine can be considered as functional foods that can prevent or cure several diseases. Medicinal food refers food product that can be considered to have therapeutic value in treating or preventing certain diseases and plays beneficial effects on physiological functions of a specific tissue. Medicinal foods are considered important in reducing the risk of certain diseases. Bioactive food components refer to constituents in foods supply with the basic human nutritional needs and taken with diet or as supplements. These food components exhibit the power to regulate one or more processes of metabolism that exerts the health benefits in reducing the risk of chronic human diseases [65]. These food components taken in appropriate quantities must be a part of the standard diet and consumed on a regular basis in order to beneficially affecting at various metabolic targets.

5 Bioactive Food Components in the Prevention of Cardiovascular Disease

One of the most favorite topics in the modern world is how to keep healthy and reduce the diseases caused by aging or changes in lifestyle. The most efficient ways to decrease the risk of common diseases, including CVD and cancer, are by limiting intake of carbohydrate/fat enriched food, limiting consumption of alcohol, limiting

salt intake, and adding the plant-derived food items, including vegetables, fruits, whole grains, legumes, nuts, and oils in the routine diet. Generally, bioactive foods are referred to those compounds that have potent antioxidative, anti-inflammatory, antithrombotic and immunomodulatory properties. These compounds possess the property to protect the body against the inflammation, cholesterol accumulation in the cardiovascular tissues, and protect against the oxidative stress, thus prevent the development of cardiovascular diseases and cancer as well as other pathological conditions such as neurodegenerative diseases [18]. Some of the most important bioactive components found in fruits and vegetables that possess the potential for promoting a healthy metabolism and in the prevention of diseases are flavonoids, carotenoids, organosulfur compounds, phytoestrogens, tocopherols, and L-ascorbic acid (Table 1). Figure 1 shows the schematic presentation of source and effects of some of the important bioactive compounds. The detailed account of occurrences and biological effects of these bioactive compounds and their role in the prevention of CVD are described individually in the following sections.

5.1 Carotenoids (Lycopene)

Carotenoids belong to a class of natural fat-soluble pigments found mainly in plants. The dietary carotenoids including lycopene, beta-carotene, lutein, beta-cryptoxanthin, zeaxanthin, and astaxanthin provide health benefits in decreasing the risk of many chronic diseases. Lycopene, the major carotenoid obtained from plants such as tomatoes, watermelon, and pink or red grapefruit, is very important in attenuating the risk of CVD. Lycopene extracted from plant sources predominantly exists in an all-*trans* isomer; however, *cis*-lycopene is the more bioavailable form [66]. The isomerization of *trans-cis* isoforms occurs with exposure to light of heat or in the gastric cavity under acid conditions [67]. Heat generated during cooking and processing converts some of the *trans*-lycopene to *cis*-lycopene increasing its bioavailability in the tissue [68, 69]. Thus the bioavailability of lycopene is greater in tomato paste and tomato puree than from fresh tomatoes [70, 71]. Thus the bioavailability of dietary lycopene is greater after cooking or when consumed with oil and other dietary fats [72, 73]. In addition, other nutrition present in tomatoes such as carotenes and lutein would also be absorbed by cells. Thus consuming whole processed tomato products will have more advantages than consuming lycopene alone. Although some studies concluded that consumption of a carotenoid-rich diet have no positive effect on plasma antioxidant status or markers of oxidative stress [74], but the majority of epidemiological and clinical studies have shown beneficial effects of lycopene or tomato-based food preparation in cardiovascular health. Lycopene supplementation has been shown to improve biomarkers associated with CVD. Studies involving a large group of people reported the association of higher intake of tomato with a reduced risk of CVD and myocardial infarction [75]. Lycopene level in the blood serum also improved the common carotid artery intima-media thickness which is an indicator of early atherosclerosis [76]. The intake of lycopene caused the reduction in cholesterol synthesis and enhanced the

Table 1 List of important bioactive food components that may influence cardiovascular diseases

Category	Bioactive components	Source	Cardiovascular effects	References
Carotenoids	Lycopene (carotenoid)	Tomatoes, watermelon, and pink or red grapefruit	Hypolipemic, inhibitor of proinflammatory and prothrombotic factors	[77–80]
Flavonoids	Genistein (Isoflavone)	Soybean, soy products	Antiatherosclerotic by inhibiting the expression of ICAM-1 and VCAM-1 and NFk-B on human endothelial cells	[105]
	Sulforaphane (isothiocyanate)	Cruciferae Family	Anti-inflammatory and antioxidant by stimulating Nrf2	[119]
	Apigenin (flavone)	Celery, parsley, and chamomile	Myocardial ischemia/ reperfusion injury reduction, inhibition of lymphocyte proliferation, and proinflammatory cytokine expression	[110, 112, 113]
	Quercetin (Flavanols)	Onions and shallots	Antiplatelet aggregation activity, reduction of mycocardial infarction	[121, 122]
	Resveratrol (polyphenolic compound)	Grapes, red wine	Reduction in LDL oxidation, vasorelaxation, reduction of platelet aggregation, antiatherosclerotic,	106–109
	Anthocyanins (glycosides of anthocyanidins)	Fruits and vegetables	Antiatherosclerotic, reduction in CVD mortality, protect DNA damage	[131–141]
	Hesperetin (flavanone)	Citrus plants	Block oxidized LDL-induced endothelial apoptosis	[94]
	Catechins (Flavanol)	Green tea	Reduction in blood cholesterol; antihypertensive; triglyceride, total cholesterol and low-density lipoprotein cholesterol	[91, 93]
Vitamins	Ascorbic acid	Fruits and vegetables	Prevent HDL from lipid oxidation	[144]
	Alpha-tocopherol	Oils, nuts, and leafy green vegetables	Prevent HDL from lipid oxidation	[147–150]

Fig. 1 Schematic diagram illustrating the role of bioactive components of food in the prevention of cardiovascular diseases (CVDs). As shown, bioactive components act on cells or tissue by targeting many physiological and metabolic processes. Together regulating multiple processes, these components of food prevent or cure cardiovascular diseases

degradation of LDL [77]. Oxidative damage related parameter such as lipid peroxidation and LDL oxidation were significantly declined in the subjects who were prescribed lycopene supplementation [78]. Similarly, individuals who were treated with lycopene (40 mg/day) for 6 weeks showed decline in triglyceride levels and LDL cholesterol levels whereas the HDL cholesterol was significantly increased [79]. The increase in HDL cholesterol and decline in total cholesterol/HDL cholesterol ratio was also reported in a study comprised of healthy men and women consuming the soy-tomato beverage that contain 21 mg lycopene/day on an average daily [80]. These studies suggest that lycopene or tomato-based products with a significant amount of lycopene improves the cardiovascular health by reducing the triglycerides, scavenging LDL, and maintaining HDL level thus reducing the risk of CVD.

5.2 Phenolic Acids and Flavonoids

Flavonoids are a group of polyphenolic compounds found in significant amount in many fruits, vegetables, grains, and beverages. They are classified as flavonols, flavones, flavanones, flavan-3-ols, anthocyanidins, and isoflavones. The flavonols

include compounds namely isorhamnetin, kaempferol, myricetin, and quercetin. Apigenin and luteolin compounds are grouped under flavones. Flavanones include compounds eriocitrin, hesperetin, and naringenin whereas flavan-3-ols include compounds such as catechin, epicatechin, epigallocatechin, epicatechin gallate, epigallocatechin gallate, and gallocatechin. Anthocyanidins include compounds such as cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin, whereas compounds daidzein and genistein are grouped under isoflavones. These compounds have varied chemical structure and biological functions and are grouped accordingly. The isoflavones genistein, daidzein, and glycitein occur predominantly in legumes. Genistein and daidzein found in soy, and resveratrol occurs in grape skin and red wine, are nonsteroidal polyphenolic compounds and considered as a phytoestrogen. The flavonoids contain sulfur are grouped under organosulfur compounds, prominent among are sulforaphane found in crucifer plants and γ-glutamyl-S-allyl-L-cysteines and S-allyl-L-cysteine sulfoxides found in garlic (Allium sativum L., family Liliaceae). Anthocyanins are a group of most studied flavonoid occurs in a wide variety of plant kingdom. Anthocyanins are providing the bright red-orange to blue-violet colors in many fruits and vegetables. Their consumption has been estimated to be up to ninefold higher than that of other dietary flavonoids [81].

Phenolic acid and flavonoids have three most important health benefit effects on the prevention of cardiovascular tissue. The most important effect is attributed to their antioxidant activity [82]. Secondly they have prominent effects on the prevention of atherosclerosis [83], and lastly, they have a significant effect on the platelet aggregation [84]. In vitro studies indicate that flavonoids inhibit the oxidation of LDL and decrease the thrombotic tendencies [85]. They delay the development of atherosclerotic plaque and prevent the development of atherosclerosis by reducing the endothelial dysfunction. Another mechanism by which flavonoids help prevent CVD is through their effect on platelet aggregation. Flavonoids interact with membrane lipids and modifying the membrane fluidity [86], which is partly responsible for the antiaggregatory and disaggregatory effects on human platelets.

Catechins are polyphenolic compounds found in food and in all kinds of tea with cardioprotective properties [87]. Catechins have an important role in the prevention of cardiovascular disease [88, 89]. Catechins have been shown to reduce the accumulation of cholesterol and its oxidation products in the walls of arteries, thus help in smooth blood circulation [90]. Supplementation of catechins may reduce the serum triglyceride, total cholesterol, and low-density lipoprotein cholesterol, thus preventing atherosclerosis [91]. Catechins may improve the vascular endothelial environment by eliminating ROS [92]. In addition, catechins exhibit very strong antihypertensive activity [93]. Both (−)epigallocatechin gallate and hesperetin flavonoids block oxidized LDL-induced endothelial apoptosis thus may function as antiatherogenic agents [94]. However, there is no clear evidence to suggest a beneficial effect of tea catechins on the prevention of CVD.

Phytoestrogens are polyphenolic compounds occur in many legumes, beans, nuts, soybeans, seeds of sesame and so on, and mimic the properties of estrogens. These compounds include certain isoflavonoids, flavonoids, stilbenes, and lignans [95]. The best-studied dietary phytoestrogens are the soy isoflavones and the flaxseed

lignans. Isoflavones, such as genistein and daidzein, occur in soybeans, legumes, lentils, and chickpeas. Lignans are the most abundant nonflavonoids occur in most cereals, linseed, fruits, and vegetables. The phytoestrogens are the most intensively studied bioactive components of food with regard to their health benefits. Isoflavone content of foods such as soybeans is sold as nutritional supplements. Good scientific evidence supports the observation that phytoestrogens may play a beneficial role in reducing the risk of cardiovascular disease [18]. Diet is the chief source of phytoestrogens in human. The bioavailability of phytoestrogens in body organs may be dependent on the metabolism of intestinal bacteria. After ingestion in their *beta*-glycosidic forms, most of these phytoestrogens are hydrolyzed in the intestine to their aglycones. Then in the intestinal wall and liver aglycones are absorbed and glucuronidated [96, 97].

Isoflavones have beneficial biological effects in the cardiovascular system. They exert antiestrogenic effects by competitive inhibition at the estrogen receptor and help maintain cellular proliferation, vascular reactivity, lipid profiles, and thrombosis [98]. Epidemiologic studies reported that consumption of dietary isoflavones from soy products protects women not only from cardiovascular disease but also from breast and uterine cancer [99–102]. The lipid-lowering functions of isoflavones will have profound effects on cardiovascular protection. Although very little evidence presented to show the protective roles of phytoestrogens for cardiovascular disease, clinical studies involving Japanese women concluded that intake of high isoflavone was correlated with the reduced risk of cerebral and myocardial infarctions [103]. Phytoestrogens intake could delay the progression of atherosclerosis in vascular tissue by their pathophysiologic effects on lipid profile, reactive oxygen species production, inflammation, and tissue damage [104]. Atherosclerosis is initiated when monocytes bind to the endothelium layer of blood vessel, migrate into the tunica intima, and later develop into the foam cells. Lipid-induced and oxidant-sensitive transcription of adhesion molecules and chemokines promote the monocyte binding to endothelium. Genistein has been reported to be capable of inhibiting the expression of intercellular adhesion molecules-1 and vascular cell adhesion molecule-1 (ICAM-1 and VCAM-1) on human endothelial cells cocultured with monocytes [105], thus protecting against atherosclerosis. Resveratrol, a phytoestrogen found in high concentration in red wine, has been proposed to be the agent responsible for cardiovascular protection [106]. Its protective role in the cardiovascular system occurs by mechanisms of stimulation of reduction of low-density lipoprotein oxidation, vasorelaxation, suppression of platelet aggregation, anti-atherosclerotic properties, and also providing defense against ischemic-reperfusion injury [107]. This compound has the ability to stimulate Ca^{++}-activated K^{+} channels so as to increase endothelium nitric oxide signaling, thus exerting vasorelaxant activity [108, 109].

Apigenin, a flavonoid found in many vegetables such as celery (Apium graveolens), parsley and chamomile have demonstrated to possess the cardio-protective effects. Apigenin ameliorates myocardial ischemia/reperfusion injury via the inactivation of p38 mitogen-activated protein kinase [110]. In a cardiac hypertrophy model, the supplementation of apigenin reduces hypertension,

cardiomyocyte cross-sectional area, and serum angiotensin II [111]. Similarly, in an autoimmune myocarditis mice model, dietary apigenin cause inhibition of lymphocyte proliferation thus mediating the protection of cardiac tissue [112]. Apigenin caused reduction of LPS-induced mortality in mice by inhibiting proinflammatory cytokine expression [113] and decrease heart injury by suppressing sphingosine kinase 1/sphingosine 1-phosphate signaling pathway [114]. In a recent study, Li et al. [115] demonstrated that apigenin protects cardiac tissue damage, cardiac injury, cardiomyocyte cell death, and cardiac dysfunction against LPS- induced toxicity by its anti-inflammatory and antioxidant effect.

Organosulfur compounds are chiefly found in cruciferous vegetables, as well as in garlic and onions. Vegetables belong to Cruciferae family such as cabbage, broccoli, and kale contain rich amount of sulfur-containing compounds known as glucosinolates. Isothiocyanates are biologically active breakdown products of glucosinolates. Different types of glucosinolates are found in different cruciferous vegetables, each of which upon hydrolysis forms a different isothiocyanate [116]. For example, glucosinolate glucoraphanin, most abundantly present in 3-day-old broccoli sprouts, is converted to the isothiocyanate sulforaphane by the endogenous enzyme, myrosinase. Sulforaphane protects the chronic diseases by upregulating the "phase 2 response" known as Kelch-like ECH-associated protein 1- nuclear factor erythroid 2 p45-related factor 2-antioxidant responsive element (Keap1-Nrf2-ARE) pathway. Sulforaphane has been regarded as one of the most potent known naturally occurring inducers of cytoprotective phase 2 enzymes [117]. Glucosinolates are rapidly hydrolyzed by myrosinase, generating metabolites when raw cruciferous vegetables are cut while processing the food. While cooked vegetables inactivate myrosinase, so as to prevent the glucosinolates breakdown. Light steam cooking for about 5 min will preserve some of the myrosinase and thus allow the conversion of isothiocyanate. Most of the absorption of glucosinolates occurs in the small intestine, however, a large proportion of it reaches the colon [118] where it generates a broad range of metabolites depending on the pH and the presence of cofactors. The sulforaphane has been shown to target pro-inflammatory pathways by stimulating Nrf2 induced antioxidant enzymes [119] and downregulating the expression of NF-κB target genes which code for proinflammatory mediators, such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1β), and IL-6 [119].

Allium vegetables are recognized to be a good source of organosulfur compounds [120] and its supplementation in human exhibits antiplatelet aggregation activity. Similarly, the quercetin, the main polyphenol found in onions and shallots, also inhibited platelet aggregation in vivo [121] and in vitro [122]. Higher intake of cruciferous and allium vegetables (per serving 75 g/d) were associated with lower risk of atherosclerotic vascular disease mortality [120]. This study was conducted in older Australian women with 15 years of follow-up and concluded that higher cruciferous and allium vegetables intakes render lower risk of atherosclerotic vascular disease (ASVD) mortality in old individuals and protect vascular health. Resveratrol has recently become a well-known potent antioxidant and is found in red grapes, blueberries, cranberries, and other types of Vaccinium berries [123].

It is also known for its antithrombotic, anti-inflammatory, anticarcinogenic, and lifespan elongation effects, as well as its positive role in protection against insulin resistance [18, 124–126].

Anthocyanins are the polyphenolic compounds, possessing a characteristic C3–C6–C3 carbon structure and present in fruits, vegetables, berries, and red wine [127]. Anthocyanins are readily absorbed and metabolized in the tissue. These phenolic compounds found in the circulation and urine as intact, methylated, glucuronide derivatives, and/or sulfoconjugated forms [128–130]. Their anti-inflammatory and antioxidative properties show beneficial effects in the cardiovascular system. Compounds containing anthocyanin have been shown to reduce atherosclerosis in rodents [131]. Epidemiological studies have examined the relationship between total anthocyanin intake and risk of developing CVD. In a 16-year follow-up study period of consuming strawberry daily (intake of 0.2 mg/d of anthocyanins), the postmenopausal women participating in the Iowa Women's Health Study showed a significant reduction in CVD mortality [132]. Intake of blueberries also showed a significant decrease in coronary heart disease mortality. Moderate consumption of red wine will have a preventive effect in CVD-related mortality [133, 134]. The beneficial effects of anthocyanins in the prevention of CVD are strongly linked to the protection against reactive oxygen species-induced oxidative stress. Other mechanisms of anthocyanin beneficial role on cardiovascular tissues may be via providing protection from DNA damage, inhibiting enzyme, regulating immune responses through increased cytokine production, and exhibiting anti-inflammatory activity [135–139]. There is a significant reduction in ischemia in patients with vascular diseases who were consuming anthocyanin [140]. Inhibition of platelet activity and experimental coronary thrombosis in vivo was significantly achieved by commercial grape juice (10 mL/kg) [141]. These studies suggest that anthocyanins have a wide range of protective effects against CVD. However, epidemiological studies are insufficient to provide comprehensive information about their usefulness in CVD.

5.3 Vitamins

A substantial body of evidence has presented describing the possible role of several vitamins in the reduction of CVD risk. L-ascorbic acid or vitamin C found in a wide variety of fruits and vegetables has received a considerable attention in the past two decades as a powerful dietary antioxidant with a possible role in heart health. It is well known that HDL participates in the removal of cholesterol from sites of atherosclerotic lesion. In addition, the HDL also performs other functions that potentially have cardioprotective properties. Some of the beneficial functions of HDL include the inhibition of platelet activation, anticoagulant and profibrinolytic activities, preservation of vascular endothelial function, and protection of LDL from oxidation [142]. However, HDL is also vulnerable to lipid oxidation with ensuing loss of some cardioprotective properties [143]. Vitamin C has been shown to prevent the lipid oxidation in HDL and thus conserving the cardioprotective properties

of this lipoprotein [144]. Vitamin C also has been found to inhibit the oxidation of LDL-protein, thereby contributing to reduce atherosclerosis [145]. Although the cardiovascular other functions of vitamin C in cardiovascular diseases are not fully understood, it has been linked to improve the lipid profiles, protect arteries from arterial stiffness, and improve the endothelial function [145]. Vitamin E that includes tocopherols and tocotrienols was found in many types of oils, nuts, and leafy green vegetables and exhibit cardiovascular protective property [146]. Several studies have demonstrated the protective role of vitamin E in preventing HDL from lipid oxidation with subsequent cardioprotective benefits [147–150]. Initial studies found no correlation between serum or plasma vitamin E concentrations and death from cardiovascular diseases [151, 152]. Epidemiological studies in Finnish men found no association between serum vitamin E level and a coronary end point [153]. An extensive study on vitamin E supplementation was carried out in the USA involving 87,425 female nurses [154]. Their findings concluded that the benefit function of vitamin E supplementation was only apparent with the continued consumption for greater than 2 years. The benefit of vitamin E intake appeared to occur with both supplemental and dietary vitamin E. Overall studies suggest that there exists a relationship between consumption of vitamin E and the incidence of CVD [146].

6 Conclusion

Changes in lifestyle, dietary habits, and environmental and physiological factors directly influence the risk factors of CVD. The health benefits of fruits and vegetables are known since ancient times. However, investigations on their bioactive components and their physiological and metabolic targets attracted the significance of these compounds in preventing or treating certain chronic human diseases. Studies have shown that fruitful changes in lifestyle and regular consumption of recommended bioactive food components will help prevent chronic cardiovascular-related illness. Bioactive components of food are a challenging area in terms of its ability to regulate the metabolic process and control chronic diseases. Exact mechanism of their effects and appropriate doses on various signaling pathways needs to work out. The appropriate human dose and the risk of side effects of most of the bioactive food components are not known. Awareness among people and confidence among physicians on dietary recommendations to patients to prevent or to treat the disease are warranted. The key is to encourage people to make habit of consuming bioactive food components as part of their daily diet so as to prevent or eliminate lifestyle or age-related chronic diseases.

Abstract

Capsicum annum L. commonly known as bell pepper exhibits proven health as well as medicinal significance. It can be consumed either in fresh or processed form and is rich source of vitamin C, provitamin A, and calcium. Array of bioactive compounds especially antioxidants in its phytochemical profile make it an ideal choice for preventing cell damage, cancer insurgence, diabetes prevalence, cardiovascular disorders, cataracts, Alzheimer's, and Parkinson's disease. Major antioxidant compounds in capsicum are carotenoids, tocopherols, and capsaicinoids (capsacicin). Their anticancer role is attributed to their ability to act as scavengers of singlet molecular oxygen, reactive oxygen species (ROS), peroxyl radicals, and reactive nitrogen species (RNS). Capsaicinoids intake effectively reduced the triacyclglycerols, plasma total cholesterol (PTC), and non-high-density lipoprotein cholesterol, and thereby helps in the prevention of cardiovascular ailments. It also exhibit effective and proactive contribution against age-related ailments. Capsaicin exposure expressively repressed the initial adipogenic differentiation, maturation, and lipogenesis of adipocytes. Capsaicin also has ability to target the TRPV1 receptors in the C-fibers lead to their stimulation followed by desensitization that helps to improve the neurogenic bladder. So, it may serve as a potential emerging treatment for patients who are nonrespondent to conventional therapy especially those with neurogenic bladder.

Keywords

Bell pepper · Capsaicinoids · Antioxidant · Neurogenic bladder

List of Abbreviations

18α-GA	18 alpha-glycyrrhetinic acid
ABCA1	ATP-binding cassette transporter
ABCG1	ATP-binding cassette transporter-G1
ABCG5	ATP-binding cassette transporter-G-5
AdipoR2	Adiponectin gene/protein and its receptor
ADP	Adenosine diphosphate
ALCAM	Activated leukocyte cell adhesion molecule
AMPK	Activation of activated protein kinase
Apo-A1	Apolipoprotein-A1
apoM	Apolipoprotein M
ATP	Adenosine triphosphate
BAT	Brown adipose tissue
BCC	Basal carcinoma cells
BUN	Blood urea nitrogen
C/EBPα	C-enhancer-binding proteins
Ca^{2+}	Calcium
CaMK-II	Calmodulin-dependent protein kinase II
Capz	Capsazepine
CCMSs	Capsaicin-chitosan microspheres

CD36	Cluster of differentiation-36
COX-2	Cyclooxygenase-2
CRP	C-reactive protein levels
CRT	Calreticulin
Cx43	Connexin 43
DCs	Dendritic cells
DHC	Dihydrocapsaicin
DNA	Deoxyribonucleic acid
EC-LPS	Lipopolysaccharide from *Escherichia coli*
EMT	Epithelial mesenchymal transition
eNOS	Endothelial nitric oxide synthase
ERK	Extracellular signal-regulated kinases
FABP4	Fatty acid binding protein-4
FADD	Fas-associated protein with death domain
FAK	Focal adhesion kinase
GC	Gastric cancer
GDM	Gestational diabetes mellitus
Glu	Glutamate
GSH	Glutathione
GSSG	Oxidized glutathione
HDL-C	High density lipoprotein
HMGCR	3-hydroxy-3-methylglutaryl-CoA reductase
HO-1	Heme oxygenase-1
HSL	Hormone sensitive lipase
HUVECs	Human umbilical vein endothelial cells
ICD	Immunogenic cell death
IL-1β	Interleukin-1 beta
IL-6	Interleukin-6
KA	Kainic acid
Klf2	Kruppel-like factor 2
LDL-C	Low-density lipoprotein-cholesterol
LDL-R	Low-density lipoprotein receptor
LPS	Lipopolysaccharide
MDA	Malondialdehyde
MS–MS	Mass spectrometry
NDO	Eurogenic detrusor overactive
NET	Neuroendocrine tumor cells
NF-κB	Nuclear factor-kappa B
NOD/SCID	Nonobese diabetic/severe combined immunodeficiency
NPC1	Niemann-Pick C1 protein
OH	Hydroxyl
PC-3	Pancreatic cancer
p-CaM	Adhesion molecule
PCR	Polymerase chain reaction
PPARdelta	Peroxisome proliferator-activated receptor delta

PPARgamma	Peroxisome proliferator-activated receptor gamma
PPARα	Peroxisome proliferator-activated receptor-alpha
PPARγ	Peroxisome proliferator-activated receptor gamma
PPARγ	Peroxisome proliferator-activated receptor-gamma
PTPϵ	Protein-tyrosine phosphatase ϵ
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SOD	Superoxide dismutase
SRA-1	Steroid receptor RNA activator 1
SRB1	Scavenger receptor class B member 1
TG	Triglycerides
TIMP-1	Tissue inhibitors of metalloproteinases-1
TNF-α	Tumor necrosis factor-alpha
TRP	Transient receptor potential
TRPV1	Transient receptor potential vanilloid subtype 1
UCP2	Uncoupling protein 2
UV	Ultraviolet
VEGFA	Vascular endothelial growth factor-A
VLDL-C	Very low-density lipoprotein- cholesterol
WT	Wild-type

1 Introduction

The bell pepper (*Capsicum annum* L.), a member of *Solanaceae* family, is most commonly consumed fruity vegetable and well known for its antioxidant significance [1]. *Solanaceae* family include over 90 genera and 2000 species, among them *Capsicum annum*, *Capsicum chinense*, *Capsicum baccatum*, *Capsicum pubescens*, and *Capsicum frutescens* are most common. Bell pepper exhibits medicinal as well as food value in all over the world, and both warm and dry climate are considered suitable for its cultivation [2]. About 30 species are included in the genus *Capsicum*, out of which only five are domesticated while rest of these are considered as wild. Major cultivars include *C. baccatum*, *C. chinense*, *C. frutescens*, *C. annuum*, and *C. pubescens. Capsicum chinense* is known as pungent fruit among the domesticated species [3]. These are also a rich source of neutral phenolic compounds, especially luteolin, quercetin, and capsaicinoids [4]. The utilization of bioactive compounds plays key health-promoting functions such as provide protection against oxidative damage to cells, cancer insurgence, diabetes prevalence, cardiovascular disorders, cataracts, Alzheimer's, and Parkinson's disease [1]. These chemical compounds also prevent oxidation of structural lipids of brain cells and are vital for their proper functioning [4].

Different consumable forms of pepper are fresh, processed (sauces), or preserves (dehydrated powder). Its industrial utilization is mainly due to its unique composition and aromatic properties. *Capsicum annuum* has worldwide existence [5] and has different types of peppers such as sweet bell and hot peppers, cherry, serrano, and

cayenne [6, 7]. These serve as a domineering nutrient source in human diet [8, 9]. It has a significant source of ascorbic acid (vitamin C) and carotene (provitamin A). As per estimates, about 60% and 100% recommended daily amounts (RDA) for vitamin A and C can be achieved by the intake of 50–100 g fresh pepper. Ripened pepper fruit contain phytochemicals with antioxidant and anticancer functions [10]. Among the different antioxidants found in pepper, chlorophyll, carotenoids, tocopherols, and capsaicinoids are most important constituents [8].

The pungent values of chili fruit are due to the presence of alkaloids compound, i.e., capsaicinoids, which is in capsicum placenta during its early maturity and can be used in the human diet as food, medicine, and pharmaceutics. Capsaicin along with dihydrocapsaicin collectively constitute about 90% of the capsicum capsaicinoids, while the rest include nordihydrocapsaicin, homodihydrocapsaicin, homocapsaicin, norcapsaicin, and nornorcapsaicin [11].

Carotenoids a colored pigment found in peppers impart yellow to red color. It also exhibits antioxidant properties and prevents tissues damage by acting as singlet molecular oxygen, reactive oxygen species (ROS), peroxyl radicals, and reactive nitrogen species (RNS) scavenger [12] (Table 1).

2 Chemistry of Capsicum

Flavonoids along with some other polyphenols are pervasive phytochemicals and considered as essential functional ingredients found in different types of peppers (green, sweet, and hot). So far various attempts have been made to detect, quantify, and characterize different types of flavonoid in peppers [14, 15]. They are also rich in glycosides as well as aglycones of quercetin, myricetin, luteolin, kaempferol, and apigenin. Structural studies of flavonoids showed that position and numbers of hydroxyl groups along with a double bond at the C2-C3 position are mainly responsible for their strong antioxidant and anticancer activities. Role of structure in determining antioxidant potential confirms the myricetin as one of the most potent flavonoids found in pepper [16, 17]. Mass spectrometry (MS–MS) fragmentation and ultraviolet (UV) spectra-based structural study was carried out to identify C- and O-glycosides in peppers. Results showed that the pericarp of pepper fruit contains four quercetin (3-*O*-rhamnoside, 3-*O*-rhamnoside-7-*O*-glucoside, 3-*O*-glucoside-7-*O*-rhamnoside, and quercetin glycosylated), two luteolin *O*-glycosides (apiosyl-acetyl-glucoside and 7-*O*-2-apiosyl-glucoside), five luteolin C-glycosides (6-C-hexoside, 8-C-hexoside, 6-C-pentoside-8-C-hexoside, 6-C-hexoside-8-C-pentoside, and 6,8-di-C-hexoside) along with two apigenin C-glycosides (6-C-pentoside-8-C-hexoside and 6, 8-di-C-hexoside) [18].

Flavonoid levels vary and mainly depend on genetics, developmental stage, and ecological situations. Such as red fruits of most cultivars have shown highest quantities of flavonoids. On the other hand, green fruits were found to be rich in quercetin 3-*O*-R-L-rhamnopyranoside whose level decreased during ripening [19]. Bioactive compounds include both essential and nonessential substances of natural occurrence in food and are well known for their impact human health.

Table 1 Nutritional composition of *Capsicum annum* [13]

Nutrient	1.80 g of capsicum
Water	0.145 g.
Energy	5.724 kcal
Carbohydrate	1.019 g
Fiber, total dietary	0.490 g
Protein	0.216 g
Fat (Total lipid)	0.311 g
Ash	0.109 g
Calcium	2.664 mg
Iron (Fe)	0.140 mg
Sodium (Na)	0.540 mg
Copper (Cu)	0.007 mg
Phosphorus (P)	5.274 mg
Selenium (Se)	0.158 mcg
Manganese (Mn)	0.036 mg
Magnesium (Mg)	2.736 mg
Zinc (Zn)	0.045 mg
Potassium (K)	36.252 mg
Saturated fatty acids (SFA)	0.059 g
Monounsaturated fatty acids (MUFA)	0.050 g
Thiamin	0.006 mg
Vitamin B6	0.037 mg
Niacin	0.157 mg
Riboflavin	0.017 mg

These are usually present in insignificant amounts in various foods and influence many cellular and physiological functions [20]. The bell pepper exhibits excellent antioxidant activity due to the presence of phytochemicals, such as flavonoids, capsaicinoids, phenolic compounds, carotenes, and ascorbic acid [21, 22]. Presence of these valuable micronutrients in bell pepper increases its significance against emerging diseases, especially dementia, diarrhea, and dysentery, along with many other ailments [23, 24]. However, quantities of these bioactive components in bell pepper depends on their farming conditions, state of maturity at harvesting, and varietal purity, and postharvest management [21, 24]. In red pepper, capsanthin, cryptocapsin, and capsorubin represent oxygenated carotenoids and exhibit strong antioxidant activity [25]. These phytochemicals pose generous ability to counteract free radicals involved in lipids oxidation, proteins, and cell deoxyribonucleic acid (DNA) damage and chronic human ailments [26]. In addition to capsaicinoids and carotenoids, flavonoids also exhibit antioxidants, anti-inflammatory, antiallergic, and antibacterial significance [14, 27, 28] (Table 2).

Table 2 Bioactive compounds and their potential metabolic roles

Name	Chemical structure	Metabolic role	References
Capsaicin		Anticancer	[29, 30]
Luteolin		Antidiabetic	[4]
Dihydrocapsaicin		Cardiopreventive	[31]
Capsaicin		Antirheumatoid and antiosteoarthritis	[32]
Capsazepine		Anticancer	[33]
β-Carotene		Antitumorigenesis	[34]

3 Health Perspectives

3.1 Anticancer and Antimalignant Activities

Meticulous in vitro and in vivo probing in mice demonstrated that capsaicin suppresses basal carcinoma cells (BCC) (5637 and T24) and nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mouse by inhibiting their proliferation, persuading cell cycle detention at G0/G1 phase, and diminishing ROS production. It also enhanced the Forkhead box O3 also known as FOXO3a and enhanced the catalase and superoxide dismutase concentration [29, 35]. Capsaicin stimulates autophagic process in BC cells by altering redox homeostasis, changing adenosine diphosphate/adenosine diphosphate (ADP/ATP) ratio, and inducing mitochondrial depolarization along with activation of activated protein kinase (AMPK) pathway. This enhanced capsaicin-prompted cell decrease in BC cells, proving that capsaicin promoted autophagy serves as a prosubsistence progression. Furthermore, BC cells showed distinctive mesenchymal properties of the epithelial-mesenchymal transition (EMT), such as overextended appearance and enhanced expression of the integrin-like kinase, anti-apoptotic Bcl-2 proteins, vimentin, and α5 and β1 integrin subunits

on capsaicin treatment. It rises CD24 and vascular endothelial growth factor-A (VEGFA), promotes the expression of Dhh/Ptch2/Zeb2 members of the Hedgehog signaling pathway and tissue inhibitors of metalloproteinases-1 (TIMP-1), and decreases CD44 and activated leukocyte cell adhesion molecule (ALCAM) mRNA expression levels. Amantini et al. [36] reported the involvement of the Hedgehog signaling pathway in the CPS-influenced autophagy and EMT phenotype. While increased resistance to commonly used BC curing drugs such as mitomycin C, gemcitabine, and doxorubicine was observed in capsaicin-resilient EMT-positive BC cells.

Capsaicin administration at the rate of 200 μM significantly inhibited the colon cancer cells proliferation; repressed TNF-α, IL-1β, IFN-γ, IL-10, and IL-1ra synthesis and exudation in a dose-dependent manner; and stimulated the IL-6 in human peripheral blood mononuclear cells (PBMCs) and HT-29 or RKO cells [37]. In addition its intake effectively reduce the proliferation of renal carcinoma cells, attenuation of transient receptor potential vanilloid type 1 (TRPV1) representative opponent capsazepine (CPZ), induction of apoptosis, upregulation of proapoptotic genes (Fas-associated protein with death domain (FADD), c-myc, Bax and cleaved-caspase-3, -8, and -9), and downregulation of antiapoptotic gene Bcl2. It also stimulated the p-38 and the Jun N-terminal kinase (JNK)-MAPK pathways [38]. Capsaicin in gastric cancer (GC) cell lines exerts its effect via significantly suppressing cell progression, but in GC cell lines, it causes change in histone acetylation. Subsequent investigations confirmed the vital role of hMOF, i.e., a major histone acetyltransferase for H4K16 in capsaicin-tempted epigenetic vicissitudes. Reduction in hMOF activity was noticed in GC tissues, which could be reinstated by capsaicin both in vivo and in vitro [39].

Immunogenic cell death (ICD) is due to early calreticulin (CRT) surface exposure. Cisplantin and capsaicin can persuade the cell apoptosis in human osteosarcoma cells (MG-63). Capsaicin treatment causes CRT translocation from the intracellular space to the cell surface which increased the MG-63 cells phagocytosis and IFN-γ secretion stimulation [40], induces apoptosis, lowers the bladder cancer lines growth, and downregulates the tNOX expression. Moreover, capsaicin effectively decreases the expressions of various protein involved in cell cycle progression, thereby enhanced the phenomenon of cell cycle arrest, repressed the extracellular signal-regulated kinases (ERK) activation, reduced paxillin and focal adhesion kinase (FAK) phosphorylation, and cell migration [41].

Capsazepine (Capz) is a synthetic analog of capsaicin having anticancer effects. The mode of action of the capsaicin against prostate cancer cells involves; inhibition of signal transducer and activator of transcription-3 (both constitutive and induced) activation, suppression of the upstream janus kinases (JAK1/2) and c-Src activation and low concentration level of oncogenes protein products, which in turn induce apoptosis is, minimize proliferation and invasion. The phosphatase inhibitor pervanadate overturned the Capz-induced STAT3 inhibition, representing that the consequence of Capz based on a protein tyrosine phosphatase. Moreover, siRNA-mediated knockdown of protein-tyrosine phosphatase ϵ (PTPϵ) reversed the Capz-induced initiation of PTPε and reticence of STAT3 activation, indicating that PTPε is

crucial for Capz-dependent STAT3 dephosphorylation. Finally, intraperitoneal Capz administration decreased tumor growth in a xenograft mouse prostate cancer model and reduced p-STAT3 and Ki-67 expression [42].

Capsaicin treatment of U251 cells decreased cell viability and altered the punctate patterns of LC3. In U251 human glioma cells, dihydrocapsaicin (DHC) exerts its effect by inducing apoptosis in a dose- and time-dependent manner and through decreased cell viability. The apoptosis effect of capsaicin is mainly attributed to mitochondrial depolarization, caspase-9 and -3, and enhanced ROS synthesis along with increase in calcium (Ca^{2+}) level [42].

3.2 Cardiovascular Role

Different body organs such as brain, gut, bladder, dorsal root ganglia, and sensory nerves contain transient receptor potential vanilloid subtype 1 (TRPV1), which serves as a receptor for capsaicin. TRPV1 activation results in increased intracellular calcium signaling which in turn induce various physiological effects. It is also involved in swelling, oxidation trauma, and associated discomfort [38, 43].

Capsaicinoids intake significantly reduced the plasma total cholesterol, non-high-density lipoprotein cholesterol, and triacyclglycerols but not cause any change in high-density lipoprotein cholesterol level. Fecal excretion of total acidic sterols is increased by dietary capsaicinoids possibly by increasing cholesterol 7-alpha-hydroxylase and decreasing liver X receptor α. Capsaicinoids reduced the cholesterol absorption by decreasing plasma campesterol/cholesterol ratio as confirmed by plasma sterol analysis. Capsaicinoids impede cyclooxygenase-2 (COX-2) expression, thereby positively influence the endothelium-dependent relaxations but negatively affect the endothelium-dependent contractions.

In atherosclerotic plaque mice, dihydrocapsaicin (DHC) treatment expressively reduced the cellular cholesterol content but increased the apoA1-mediated cholesterol efflux. Results also showed decreased in plasma triglycerides (TG), low-density lipoprotein (LDL-C), very low-density lipoprotein (VLDL-C), interleukin-beta (IL-1β), interleukin-6 (IL-6), tumor necrosis factor (TNF-α), and C-reactive protein (CRP) levels while apoA1 and high-density lipoprotein (HDL-C) levels in plasma were significantly increased. Results of another study reported a significant reduction in atherosclerotic lesion in $apoE^{-/-}$ mice when treated with DHC. Moreover, combined treatment with liver X receptor alpha (LXR-alpha) siRNA and peroxisome proliferator-activated receptor gamma (PPARγ) siRNA induces the upregulation of DHC on ATP-binding cassette transporter (ABCA1), ATP-binding cassette transporter-G1, ATP-binding cassette transporter-G-5 (ABCG5), scavenger receptor class B member 1 (SRB1), Niemann-Pick C1 protein (NPC1), cluster of differentiation-36 (CD36), low-density lipoprotein receptor (LDL-R), 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR), apolipoprotein-A1 (Apo-A1), and apo-E expression markedly stopped but decreased the DHC regulation on steroid receptor RNA activator 1 (SRA-1) expression distinctly compensated. LXRα siRNA treatment

demonstrated nonsignificantly affect the DHC-induced PPARγ expression but with significantly decreased DHC-based LXRα expression [31].

3.3 Antidiabetic Role

Peripheral neuropathy is a chronic diabetes complication mellitus and is characterized by severe pain. Antidepressants and antiepileptic administration serves as effective drug treatment options. Nociceptive sensory neurons, as well as other tissues containing transient receptor potential vanilloid 1 (TRPV1), are triggered via capsaicin-regulated modulation. TRPV1 activation induces calcium influx and promotes Kruppel-like factor 2 (Klf2), uncoupling protein 2 (UCP2), LXRα, endothelial nitric oxide synthase (eNOS), peroxisome proliferator-activated receptor delta (PPAR delta), and gamma (PPAR gamma) expression. In addition, TRPV1 activation provokes Ca influx which minimizes shear stress and stimulates eNOS, COX-2, thrombomodulin, and NRF2-responsive antioxidant enzymes expression along with decreased expression of proinflammatory proteins. LXRα activation via TRPV1-mediation validates effective cholesterol transfer thereby prevent plaque buildup. In gastrointestinal (GI) tract, capsaicin-based stimulation of TRPV1 increases metabolic rate via compassionately promoted activation of brown fat. TRPV1 activation demonstrated defensive antioxidant property through the improved expression of uncoupling protein-2 (UCP2) in the liver and vascular endothelium during nonalcoholic fatty liver disease and hyperglycemia perspective, respectively [44, 45]. Capsaicin supplementation effectively decreased the fasting lipid metabolic syndromes and postprandial hyperglycemia as well as hyperinsulinemia in women with gestational diabetes mellitus (GDM) and also reduced the prevalence of large-for-gestational-age newborns [46].

Capsaicin reduces viability and propagation, and induces apoptotic death in pancreatic neuroendocrine tumor (NET) cells. In addition, it also causes loss of mitochondrial membrane potential; minimizes ATP, reactive oxygen species (ROS), and mitochondrial Bcl-2 protein synthesis; and increases cytochrome c levels [47]. In male KKAy mice, 0.015% capsaicin supplementation significantly reduced the plasma and/or liver fasting glucose/insulin and triglyceride concentrations, along with decreased macrophage intrusion and inflammatory adipocytokine genes expression (e.g., monocyte chemoattractant protein-1 and interleukin-6). In addition, it also causes increase in adiponectin gene/protein and its receptor (AdipoR2) expression as well as activation of hepatic AMP-motivated protein kinase, i.e., a marker of fatty acid oxidation. It decreases metabolic dysregulation in diabetic and/or obese KKAy mice through improved adiponectin and its receptor expression [48].

Apolipoprotein M (apoM), mainly found in kidney and liver tissues, is linked with increased prevalence and development of diabetes and atherosclerosis complications. Dihydrocapsaicin (DHC) induction significantly decreased the atherosclerotic plaque formation in apoE$^{-/-}$ mice. Treatment of HepG2 cells with 0, 25, 50, and 100 μM DHC for 24 h effectively decreased apoM expression at both protein and mRNA level in HepG2 cells in a dosage- and time-dependent way. DHC

treatment negatively influences the Foxa2 expression but positively affects the LXRα expression in HepG2 cells. In addition, overexpression of Foxa2 markedly recompensed the inhibition effect induced by DHC on apoM expression. Treatment of C57BL/6 mice liver with DHC had significantly lower expression of apoM and Foxa2 while had higher expression of LXRα [49].

3.4 Antiobesity

Brown fat-specific thermogenic uncoupling protein-1 and bone morphogenetic protein-8b expression in white adipose tissue (WAT) are stimulated by capsaicin. Browning of WAT is triggered by capsaicin as it promotes expression and activity of sirtuin-1 through TRPV1 channel-based raise of intracellular Ca^{2+} and protein kinase II and AMP-stimulated kinase phosphorylation. Meanwhile, it also improved PPARγ 1 coactivator α expression along with increased metabolic and ambulatory activity. Another possible mechanism involved in WAT browning may include capsaicin-based stimulation of sirtuin-1-dependent deacetylation of PPARγ and the transcription factor PRDM-16 and assisted PPARγ-PRDM-16 interaction [50].

Brown adipose tissue (BAT) is involved in energy balance and body fatness regulation because this is the site of sympathetically activated adaptive nonshivering thermogenesis. Acute cold exposure activates the BAT in humans which in turn causes cold-induced increase in whole-body energy expenditure. BAT metabolic activity was found to be lower in old and obese peoples. BAT serves as energy dissipating activity in the body therefore negatively correlated with body fatness and is considered as an effective proactive approach against body fat accumulation. Repeated exposure to cold induces stimulatory effects through the activation of transient receptor potential (TRP) channels, which are chemosensitive receptors for various naturally occurring herbal and food ingredients. Capsaicin and its analog capsinoids, demonstrative agonists of TRPV1, mimic the effects of cold to decrease body fatness through the activation and recruitment of BAT [51].

Capsainin treatment of bone marrow mesenchymal stem cells (BMSCs) for 6 days followed by 2 days of adipogenic induction demonstrated a significant decrease in the cell viability and proliferation in BMSCs. The capsaicin-treated cells were collected at 2nd, 4th, and 6th days for analysis. After capsaicin exposure, dose and time-dependent reduction in cell viability and proliferation was observed in BMSCs. Interestingly, capsaicin increased the production of reactive oxygen species (ROS) and reactive nitrogen species (RNS) in order to induce cell cycle arrest at G0-G1 along with increased apoptosis. Capsaicin exposure effectively reduced the initiation of adipogenic differentiation, lipogenesis and maturation with associated repression of PPARγ, C-enhancer-binding proteins (C/EBPα), fatty acid binding protein-4 (FABP4), and stearoyl-CoA desaturase-1 (SCD-1). Capsaicin-based stimulation for ROS and RNS synthesis hinders the adipogenic mesenchymal stem cells discrepancy through different possible mechanisms such as inhibit proliferation, induce apoptosis, or cell cycle arrest [52].

Previous studies reported the involvement of TRPV1 pathway in weight management via enhanced intracellular Ca^{2+} concentration, although the possible mechanism by which dietary capsaicin involved in controlling obesity is not known. Connexin43 (Cx43) molecules take part in adipocyte differentiation by facilitating Ca^{2+} transfer between coupled cells. Role of TRPV1-mediated changes in Cx43-facilitated adipocyte-adipocyte interaction is not completely understood. In a study, effort was made to explore either Cx43 take part in TRPV1-facilitated adipocyte lipid break down in cultured 3 T3-L1 preadipocytes and visceral adipose tissues from humans, wild-type (WT) and TRPV1-deficient ($TRPV1^{-/-}$) mice or not. Findings indicated that capsaicin treatment results in the TRPV1 and Cx43 coexpression along with increased Ca^{2+} influx in 3 T3-L1 preadipocytes and endorsed lipid breakdown in cell as revealed by Oil-red O staining. No effect was observed when capsazepine, a TRPV1 antagonist, and 18 alpha-glycyrrhetinic acid (18α-GA), a gap-junction inhibitor, were administered. Regular intake of capsaicin cause weight reduction of perirenal, mesenteric, and testicular adipose tissues in WT mice fed a high-fat diet. Capsaicin improved the expression levels of cell adhesion molecule (p-CaM), connexin 43 (Cx43), calmodulin-mediated protein kinase II (CaMK-II), PPARδ, and hormone-sensitive lipase (HSL) in mesenteric adipose tissues from WT mice fed a high-fat diet, db/db mice, as well as obese humans; however, these effects were not observed in $TRPV1^{-/-}$ mice. Continuing capsaicin consumption reduced the serum lipids level and body weights of WT mice, but not effect high-fat fed $TRPV1^{-/-}$ mice. These findings inveterate that capsaicin-mediated TRPV1 stimulation improved Ca^{2+} invasion in Cx43-assisted adipocyte-adipocyte interaction which in turn endorses lipolysis both in vitro and in vivo. Cx43 is upregulated by capsaicin intake through activation of TRPV1 to improve visceral fat remodeling [53].

In mice, capsinoids inhibited fat buildup in vivo and in vitro. Liver, a chief site for lipid breakdown, was exposed to capsinoids, and the result showed a significant decrease in HMG-CoA reductase, CPT-1, FAT/CD36, and GLUT4 levels which in turn increase lipid breakdown in both adipose tissues and liver. Moreover, Oil red O staining also demonstrated that capsinoids inhibit fat buildup in the adipocytes [54].

Tan et al. [55] develop capsaicin-chitosan microspheres (CCMSs) through ion-cross-linking and spray drying and exploit its antiobesity suitability in rats (obese). CCMSs impact on body mass, Lee's index, fat, and serum lipids levels were examined. Furthermore, mRNA expression of PPARα, PPARγ, leptin, UCP2, GPR120, FTO, and adiponectin in the liver was assessed by quantitative real-time polymerase chain reaction (PCR) while protein expression of adiponectin, leptin, PPARα, UCP2, and hepatic lipase in serum was assessed by enzyme-linked immunosorbent assay. CCMSs were prepared with 85.17% entrapment efficacy and 8.87% mean drug loading capability. CCMSs demonstrated to be more efficient in controlling body weight, body fat, body mass index (BMI), organ index, fat/body mass ratio, and serum lipids when compared with Orlistat, capsaicin, and chitosan microspheres. The CCMSs downregulated the leptin expression but improved the expression of UCP2, PPARγ, PPARα, and adiponectin. Results showed that total cholesterol, fasting glucose serum levels, and triglyceride levels were also decreased

by capsaicin treatment. Immunoblot exploration and reverse transcription-polymerase chain reaction (RT-PCR) indicated higher expression of adiponectin and other adipokines containing PPAR-α, PPAR-γ, visfatin, and adipsin, but decreased tumor necrosis factor-α and IL-6 expression [56].

Hydrogen peroxide (H_2O_2) at 300–1000 μM level favorably and effectively stimulated capsaicin-mediated high threshold afferents but not low threshold stretch-sensitive afferents, which were only stimulated by expressively greater H_2O_2 levels. The TRPV1 apponents, capsaicin motivated 86% of high threshold afferents. The transient receptor potential cation channel (TRPA1) antagonist, HC-030031, but not the TRPV1 antagonist, capsazepine or the TRPM8 antagonist, M8-B, significantly inhibited the H_2O_2-facilitated stimulation of high threshold afferents. Dimethylthiourea and deferoxamine not altered the H_2O_2 effect on high threshold afferents. The results illustrate that H_2O_2-induced enduring instigation of the most of capsaicin-sensitive high threshold afferents, while not effect threshold stretch-sensitive afferents, when used in the concentration range determined in swelling or reperfusion after ischemia [57].

Study was planned with BALB/c mice and they were subjected to ethanol (5 g/kg body weight) for 6 month to induce oxidative stress. Mice were distributed in four groups and provided with curcumin (0.016%) or capsaicin (0.014%) containing diets with or without ethanol. During this observation period, behavioral disorder was observed in one mouse fed on an alcohol-treated normal diet. Capsaicin treatment significantly decreased the amount of malondialdehyde and phosphatidylcholine hydroperoxide levels in the brain tissue extract but catalase and superoxide dismutase activity remain unaffected [58].

Different cellular processes especially inflammatory injury and antioxidant homeostasis depend on Heme oxygenase-1 (HO-1), i.e., rate-limiting enzyme in the heme metabolism. Use of capsaicin monitor serum creatinine and blood urea nitrogen (BUN) concentrations along with tissue histology improves cisplatin-induced renal dysfunction. Moreover, capsaicin treatment decreases the expression of inflammatory mediators and oxidative stress markers for renal injury. It also persuades HO-1 expression in HK-2 cells and kidney tissues. Shielding properties of capsaicin were entirely revoked by either knockdown in HK-2 cells or treatment with the HO inhibitor HO-1 or ZnPP IX [59].

Capsaicin hinders almost 2.5–9% and 5–20% of complex-I activity and 8–75% of complex-III activity in Bx-panreatic cancer (PC-3) and AsPC-1 cells respectively, which was mainly caused by superoxide dismutase, catalase, and EUK-134. While, in normal HPDE-6 cells, capsaicin treatment not effect complex-I or complex-III activities. Capsaicin treatment effectively reduced the adenosine triphosphate (ATP) concentration in BxPC-3 and AsPC-1 cells and mitigated by catalase or EUK-134 (synthetic superoxide dismutase). Oxidation of mitochondria-specific cardio lipid was considerably higher in capsaicin-treated cells. BxPC-3 derived ρ(0) cells lack mitochondrial DNA and were found to be entirely resilient to capsaicin facilitated ROS synthesis and apoptosis. Findings tell that cytochrome c release, as well as caspase-9 and caspase-3 cleavage caused by mitochondrial membrane potential disruption were effectively obstructed by EUK-134 and catalase in BxPC-3 cells.

The capsaicin treatment reduces glutathione level and decreases the enzymatic performance and expression. Transient transfection results in overexpression of catalase which provides protection against capsaicin-induced ROS production and apoptosis. Besides, reduced in SOD activity with an increase in GSSG/GSH levels was detected in capsaicin (2.5 mg/kg) treated mice tumors [60].

Capsicum oleoresin (75 mg/kg bw/day) is found to be deleteriously linked with serum cholesterol and triglycerides levels in hypercholesterolemic gerbils [61]. The red pepper or its active component capsaicin showed a significant reduction in liver cholesterol and is responsible for enhanced fecal excretion of both free cholesterol and bile acids in female albino rats. This hypocholesterolemic effect of capsaicin is likely to be responsible for the presence of common vanillyl moiety [62].

Reduced weight gain and ameliorated hypertrophy of the liver and adipose tissues were found in male mice treated with high-fat diet, red paprika, and capsanthin. Red paprika and capsanthin treatment also improved serum lipid profile and adipokine secretion, and ameliorated hepatic steatosis by hindering fatty acid oxidation and gluconeogenesis. In epididymal fatty tissue, red paprika and capsanthin inhibited adipogenesis and decreased lipid droplet size [63].

3.5 Antiaging

Redox status of the red blood cell is characterized by lower glutathione (GSH)/oxidized glutathione (GSSG) ratio. In all age groups, GSH level is significantly influenced by capsaicin treatment which in turn causes a major shift in GSH to GSSG ratio and changes the cell redox status. The results assertively prove the antioxidant efficacy of capsaicin and also highlight its ability to modulate the redox status of red blood cells. This result proposes that food components that serve as antioxidant increases GSH level and possibly exhibit effective and proactive contribution against age-related ailments [64, 65].

The glutamate (Glu) induced neurotoxic effect negatively affects the cell viability but capsaicin treatment improved the situation. Use of glutamate (Glu) with capsaicin effectively decreased the ROS synthesis and apoptotic neuronal death by a combined treatment with both phytochemicals. The lower mRNA concentration of cytoplasmic glutathione peroxidase, Cu/Zn and Mn superoxide dismutases, Bcl-x(L) and elevated mRNA contents of interleukin-1β, and tumor necrosis factor-α were successfully reinstated by after treatment with capsaicin and/or resveratrol [66].

Antioxidant activity in the brain and blood of kainic acid (KA) facilitated status epilepticus model (30 mg/kg) was increased by using capsaicin (0.33 mg/kg or 1 mg/kg). Moreover, capsaicin treatment effectively decreased the KA-mediated increase in cytokines IL-1β and TNF-α level in the brain. Results confirmed that combined use of KA and capsaicin (1 mg/kg) because more reduction in apoptotic cell death in the cornu ammonis sections of the hippocampus when compared with their individual use [67]. Acetone (80%) extracted free polyphenols in red *Capsicum annuum var. aviculare* (Tepin) induced lipid peroxidation in brain and liver as well as exhibited the higher Fe(II) chelating ability, hydroxyl (OH) radical scavenging ability than the

bound polyphenols. These free polyphenols caused a significantly higher inhibition in the malondialdehyde (MDA) production in the brain and liver homogenates in a dose-dependent manner [4].

3.6 Anti-inflammtory Role

Atherosclerosis refers to chronic vascular inflammation characterized by combination of endothelial malfunctioning, leukocyte stimulation, lipid accrual, excessive generation of inflammatory mediators, and ROS. Capsaicin plays protective role for human umbilical vein endothelial cells (HUVECs) against oxLDL-facilitated dysfunction. Apo B disintegration along with associated diene formation of the Cu-regulated LDL oxidation is responsible for antioxidant potential of capsaicin. In HUVECs, capsaicin causes collapse of mitochondrial membrane potential and obstructs oxLDL induced ROS synthesis, and caspase-3 stimulation. It also avoids foam cell synthesis in macrophage RAW 264.7 cells [32, 53, 68].

Escherichia coli–derived lipopolysaccharides (EC–LPS) were used at the level of 1 μg/ml to induce inflammation via stimulation of primary peripheral blood mononuclear cells (PBMCs) and U-937 macrophages. Magnetic bead kit analysis showed that nonivamide decreased the EC-LPS-induced release of IL-6 and TNF-α in PBMCs and U-937 macrophages. This anti-inflammatory mechanism may involve MAPK pathway but was independent of NF-κB pathway. In addition, use of trigeminally active compound and an antagonist of TRPV1 or TRPA1 in combination for treating U-937 eliminated the anti-inflammatory activity. Results confirmed that nonivamide exhibited similar anti-inflammatory activity as observed in capsaicin and t-pellitorine. In U-937 macrophages, the tested compounds demonstrated an antiprovocative effect by preventing the EC–LPS-induced activation of the MAPK pathway. In addition, the TRP channel activation performs a vital role in anti-inflammatory capacity of capsaicin and nonivamide [69].

Capsaicin limits lipopolysaccharide (LPS)-facilitated IL-1β, IL-6, and TNF-α formation in a time- and dose-dependent manner. Furthermore, it increases LXRα expression via PPARγ route. Control of LXRα stimulation by siRNA reduced the inhibitory effect of capsaicin on LPS-induced IL-1β, IL-6, and TNF-α synthesis. In addition, LXRα siRNA repealed the inhibitory effect of capsaicin on p65, nuclear factor (NF-κB) protein expression. So, anti-inflammatory effects of capsaicin are LXRα-based, as LXRα link the capsaicin facilitated PPARγ stimulation and NF-κB inactivation in LPS-motivated inflammatory reaction [70] (Table 3).

3.7 Capsaicin in Urological Disorders

Neurogenic bladder is a urological ailment that utterly disturbs the comfort of patient's life and is common in patients with severe sclerosis, spinal cord injury, and other neurological pathologies. Capsaicin has also been evaluated as substitute treatment of neurogenic bladder disorder [71]. Neurogenic bladder is characterized

Table 3 Health perspectives of *capsicum annum*

Disorders	Mechanisms	References
Anticancer	Induced cell cycle detention at G0/G1 phase Enhanced FOXO3a expression	[29, 35]
	Altered histone acetylation	[39]
	Inhibited the colon cancer cells proliferation Decreased the formation and secretion of IL-1β, TNF-α, IL-10, IFN-γ, and IL-1ra	[37]
	Stimulated the secretion of IFN-γ Induced apoptosis, and downregulated the tNOX expression	[40]
	Suppressed the activation of ERK Reduced the paxillin and FAK phosphorylation	[41]
	Enhanced regulation of Dhh/Ptch2/Zeb2 members of the Hedgehog signaling pathway, improve CD24, VEGFA and TIMP1 and lower CD44 and ALCAM mRNA expression	[36]
	Reduced the proliferation of renal carcinoma cells Attenuated transient receptor potential vanilloid type 1 (TRPV1) representative antagonist capsazepine (CPZ) Stimulated P-38 and JNK MAPK pathways	[38]
Cardiovascular	Reduced the triacyclglycerols, total cholesterol, non-high-density lipoprotein cholesterol, and in plasma Stimulated cholesterol 7α-hydroxylase expression but negatively influenced hepatic X receptor alpha	[53]
Antidiabetic	Mediated activation of TRPV1-expressing neurons hyperglycemia perspective	[44, 45]
	Reduced reduces mitochondrial Bcl-2 protein production Increased cytochrome c levels	[47]
	Reduced triglyceride and fasting glucose amounts Increased adiponectin gene/protein and its receptor (AdipoR2) expression Activated hepatic AMP-activated protein kinase	[48]
Antiobesity	Improved bone morphogenetic protein-8b and brown fat-specific thermogenic uncoupling protein-1 expression Triggered browning of WAT	[50]
	Repressed initiation of adipocytic differentiation, lipogenesis, and maturation Repressed PPARγ, C/EBPα, FABP4, and SCD-1	[52]
	Inhibited fat accumulation and significant decrease in HMG-CoA reductase, CPT-1, FAT/CD36 and GLUT4 levels	[54]
	Decreased the levels of malondialdehyde and phosphatidylcholine hydroperoxide levels Enhanced the concentrations of catalase and superoxide dismutase activity	[58]
Antiaging	Decreased the KA-facilitated rise in cytokines IL-1β level and TNF-α declined apoptotic cell death	[67]
Anti-inflammatory	Suppressed ROS production	[32, 53]
	Inhibited the EC-LPS-induced activation of the MAPK pathway	[69]

by two severe conditions namely neurogenic detrusor overactive (NDO) and detrusor hyperreflexia that results in urgency and rise in urinary frequency, and sometime more severe complications [71, 72]. Overactive bladder is a clinical disorder that looks like neurogenic bladder [73], but its causes are not linked with neurological or urogenital sicknesses [74, 75].

Results of the previous findings reported that use of an alcoholic solvent may cause annoyance and pelvic discomfort in more than half patients, thereby decreased the capsaicin effectiveness [76]. The capsaicin or resiniferatoxin (RTX) effect in urinary tract is related to the action on TRPV1 receptors in sensory fibers and urothelial cells [77]. In vitro study was conducted by using bladder urothelial cells from non-neurogenic overactive bladder patients as well as from healthy volunteers. Results showed significant improvement in TRPV1 expression and activation along with higher capsaicin sensitivity in nonneurogenic overactive bladder patients [29, 78]. Possible mechanism by which capsaicin exerts its beneficial effect on the bladder activity is its ability to target and activate the TRPV1 receptors in the C-fibers. The use of both capsaicin and RTX is still not a routine clinical practice clinical use of RTX, and capsaicin is not very common but it may serve as a potential substitute for neurogenic bladder patients who are nonrespondent to conventional treatment with oral antimuscarinic drugs [71].

4 Conclusion

Capsicum annuum is well known all over the world owing to its taste along with characteristic smell and taste. It is also a promising source of carotenoids, capsaicinoids, flavonoids, and vitamin precursors. There is also an emerging trend to use of *capsicum annum* polyphenols in food-based products to curtail the various human degenerative disorders due to its antioxidant and free radical scavenging properties. This fruit has been proven very effective as antioxidant, anticancer, cardioprotective role, oxidative stress prevention, antiobesity, antidiabetic, and antimicrobial activities. Capsaicin is another bioactive compound which is present in higher concentrations in this fruit as compared to other bioactive moieties. The composition of *capsicum annum* polyphenols is significantly varied with genotype, soil type, temperature, maturity stages, and processing conditions. Capsaicin markedly suppressed the production and secretion of TNF-α, IL-1β, IFN-γ, IL-10, and IL-1ra in human cancer cell lines. Additionally, capsaicin lowered the proliferation of renal carcinoma cells; induced apoptotic cell death; attenuated transient receptor potential vanilloid type 1 (TRPV1); upregulated the proapoptotic genes including c-myc, FADD, Bax, and cleaved-caspase-3, -8, and -9; and downregulated the Bcl-2 gene. Capsaicin has been proven effectual to reduce the higher glucose levels, cholesterol and triglycerides concentrations as well as significantly decreased the CPT-1, HMG-CoA reductase, FAT/CD36, and GLUT4 concentration. These compounds from *capsicum annum* markedly caused reduction in level of the cytokines IL-1β and TNF-α in the brain. Moreover, capsaicin also suppresses the

lipopolysaccharide (LPS)-facilitated IL-1β, IL-6, and TNF-α formation. Further, it also enhanced the expression through PPARγ pathway. The current book chapter summarizes the therapeutic role of *Capsicum annuum* polyphenols against human syndromes.

Sesame: Bioactive Compounds and Health Benefits

8

Niti Pathak, Asani Bhaduri, and Ashwani K. Rai

Contents

Abstract

Sesame is a valuable oilseed crop that contains various nutritionally rich bioactive compounds including lignans, tocopherol homologues, phytosterols, etc. Lignans are the product of oxidative coupling of β-hydroxyphenylpropane. Sesame has a

combination of glycosylated lignans and oil-dispersed lignans. Based on their medicinal and pharmacological properties, the most important lignans are sesamin, sesamol, sesamolin, and sesaminol. Tocopherols (vitamin E compounds) are the lipid-soluble free radicals and constitute a major part of human diet. In sesame seeds, α-, γ-, and δ-tocopherols are found as tocopherol homologues. In addition to lignans and tocopherols, sesame is an important source of phytosterols, phytates, polyunsaturated fatty acids, and bioactive peptides. However, utilization potential of many of these compounds has not yet been fully understood. This chapter delves into the presence of multifarious bioactive components in sesame seeds, their biosynthetic pathway, and functional importance.

Keywords
Bioactive compounds · Sesame · Sesamin · Sesamolin · Sesamol · Pinoresinol · Tocopherol · Phytosterols

Abbreviations

CYP81Q1	Sesamin synthase
DIR1	Dirigent protein
DMPQ	2,3-Dimethyl-5-phytyl-1,4-hydroquinol
VTE1	Tocopherol cyclase
γ-TMT	γ-Tocopherol methyltransferase

1 Introduction

Sesame (*Sesamum indicum*, family Pedaliaceae) is considered as one of the earliest domesticated crops and oilseed plants known to mankind with its multifarious uses. It is found in the tropics and subtropics but is most common in the narrower belt closer to the equator, mostly north of it [1]. Basically, sesame is a crop of the developing countries in more southern latitudes. For a long time, it is being used in religious rituals in India, Egypt, and Persian region [2, 3]. Sesame is regarded as "queen of oilseeds" because of its oil quality [4, 5], sterols, and antioxidative agents, i.e., methylenedioxyphenyl compounds, sesamin, sesamolin, and tocopherols that act as nutraceuticals and impart resistance to oil against oxidative deterioration. Further, the composition of dry decorticated sesame seed per 100 g includes edible portion, i.e., water (3.75 g), energy (2640 kJ; 631 kcal), protein (20.45 g), fat (61.21 g), carbohydrate (11.73 g), dietary fiber (11.6 g), high amounts of Ca (60 mg), Mg (345 mg), P (667 mg), K (370 mg), Fe (6.36 mg), Zn (6.73 mg), vitamin A (66 IU), thiamin (0.70 mg), riboflavin (0.09 mg), niacin (5.80 mg), folate (115 μg), alpha-tocopherol (1.68 mg), and no ascorbic acid [6]. The presence of oxalic acid in sesame seeds makes it little bitter in taste.

The sesame oil is comprised of 83–90% unsaturated fatty acids that contain glycerides of oleic acid (36–54%) and linoleic acid (38–49%). Other components are saturated fatty acids (myristic acid, 0.1% or less; palmitic acid, 8–12%; stearic acid, 3.5–7%; arachidonic acid, 0.5–1%). The unsaponifiable matter (1.2%) includes tocopherols and the lignans sesamin (0.1–0.6%), sesamolin (0.25–0.3%), sesamol,

Fig. 1 Seed color variation in two sesame species cultivated in India

and sesaminol, which give the oil its resistance to rancidity. Extracted sesame cake varies in color from light yellow to grayish black, depending on the dominant seed coat color. Its chemical composition also varies according to cultivar, method of oil extraction, and the presence of testa. The sesame cake has ample amount of calcium and phosphate; protein content ranges from 35% to 47% but is deficient in lysine.

Sesame seed color show variation in different species which could partly be attributed to changes in composition of bioactive phenolics i.e., lignans and tocopherols (Fig. 1). The present chapter provides detailed and updated information on the bioactive components present in sesame seeds, their importance, and health benefits. In particular, sesame lignans and tocopherols have been focused at length: the biosynthetic pathway, the gene regulation, and the biotechnological approaches to enhance the concentration of lignans and tocopherols in sesame crop.

2 Bioactive Compounds in Sesame

Bioactive compounds are beneficial components in food and are accountable for disease-preventing properties. They include a range of chemical compounds including phenolics, carotenoids, phytosterols, and polyunsaturated fatty acids. These compounds are often utilized as antioxidants and other purposes such as inhibiting cholesterol absorption, blocking the activity of bacterial toxins, etc. Our recent review on value addition in sesame crop has elaborated the production of value-added products such as sesame oil and meal, thereby enhancing its economic importance [7]. The target candidates for this study are bioactive compounds such as lignans, tocopherols, phytates, phytosterols, and polyunsaturated fatty acids (Fig. 2).

2.1 Phenolics

Natural phenolic compounds are secondary metabolites, which are widely distributed in the plant kingdom. Plant phenols are noted for their role in prevention of

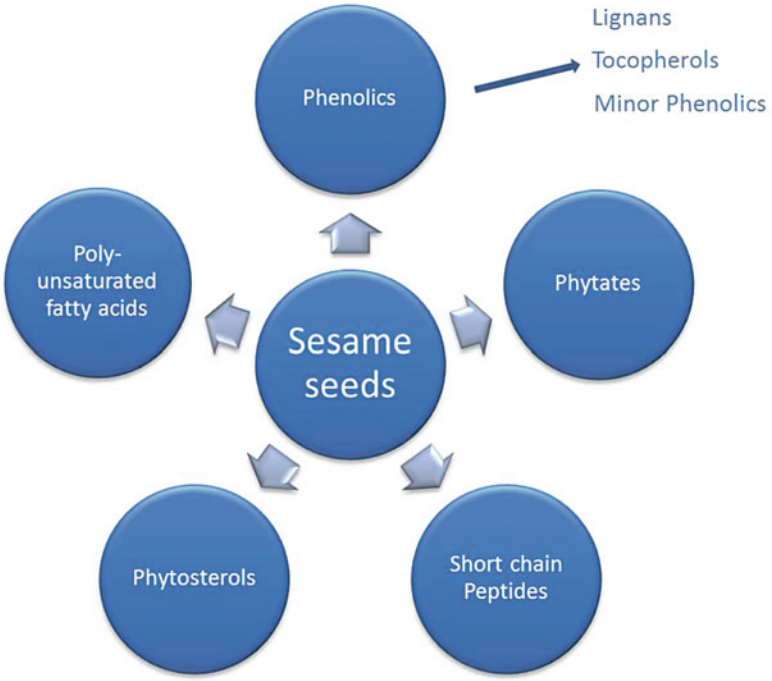

Fig. 2 Distribution of bioactive components in sesame seeds

various ailments associated with oxidative stress such as cardiovascular and neurodegenerative diseases and cancer [8]. Phenolics are characterized by the presence of aromatic ring (at least one) coupled with a few hydroxyl groups. The antioxidative potential of phenolics is very high as these compounds can produce stable radical intermediates utilizing electrons. Due to their antioxidative potential, they play an important role in the stabilization of edible oils and protection from off-flavor formation [8]. Recent findings suggest that phenolics could play an important role in conditions associated with oxidative stress [9, 10]. The antioxidant property of sesame seed and its oil along with various health properties is attributed to the presence of lignans such as sesamin, sesamolin, sesaminol, sesangolin, 2-episalatin, and tocopherol isomers [11]. Sesame oil is extremely resistant to oxidative rancidity due to the presence of chemically related compounds sesamol and sesamol dimer.

2.1.1 Lignans: Chemistry and Biosynthesis

The common feature of many natural products is recognized as a C_6C_3 unit, i.e., a propylbenzene or phenylpropanoid skeleton [12]. In a review of natural resins, Haworth was first to suggest (1936) [13] that the class of compounds derived from two C_6C_3 units having β,β′ linkage (8–8′ bond) should be called as lignans. Lignan is actually a constituent of lignin, a generic name for the compound resulting from two p-hydroxyphenylpropane molecules. Sesame seed contains two major groups of

lignans: (1) oil-soluble lignans (sesamin, sesamolin, sesaminol, sesamolinol, and pinoresinol) and (2) glycosylated water-soluble lignans (sesaminol triglucoside, pinoresinol triglucoside, sesaminol monoglucoside, pinoresinol monoglucoside, and two isomers of pinoresinol diglucoside and sesaminol diglucoside) [14–16]. The antioxidative property of sesame seed is associated with lignan components present in the oil and are unique to sesame. The lignans, sesamin, and sesamolin and their derivatives prevent oxidation of the oil and give it a long shelf life and stability [17]. Lignans and tocopherols are also reported to act in coordination resulting in enhanced vitamin E activity [18]. Namiki [19] suggested that the bioactive compounds present in sesame seed cannot individually describe the high oxidative stability of roasted sesame oil, but the cumulative effect of all the components of sesame oil protects the roasted sesame oil from oxidative deterioration.

The oil fraction of most oilseeds comprises mainly of triacylglycerols (95–99%) acting as a dispersing media for a wide range of lipophilic and amphiphilic secondary metabolites, together known as the unsaponifiable fraction of the seed. These unsaponifiable portions can be extracted with lipophilic solvents after saponification of acyl lipids [20] and are of importance as the presence of the lignans may be taken as marker for genuineness of the oil. Other constituents, tocopherols and tocotrienols, are strong antioxidants and provide stability to the oil. Also, lignans, especially sesamin, have currently been recognized for possessing interesting physiological bioactivities against chronic diseases.

Sesaminol, a water-soluble glycoside along with fat-soluble sesamin and sesamolin, constitutes the major lignans of sesame seeds. The isomer of sesamin called episesamin is generated in the process of refining sesame oil. The functional methylenedioxyphenyl group of most of these lignans especially sesamin, sesamolin, and sesangolin initiates the activities [21, 22], and these molecules in turn utilize their effect via inhibition of liver microsome oxidases [23].

Sesamin Biosynthesis

Phenylalanine and tyrosine are precursors for various plant substances such as tannins, polymeric lignin, and lignans. Phenylalanine is converted to cinnamic acid by the enzyme phenylalanine ammonia lyase (PAL). This is followed by a series of hydroxylation, methylation, and reduction leading to production of coumaric acid, caffeic acid, ferulic acid, and eventually E-coniferyl alcohol [24]. However, it has also been claimed that [^{14}C]-labeled tyrosine is incorporated into sesamin when administered to the cell suspension cultures of *Sesamum indicum* [25]. E-coniferyl alcohol has also been shown to undergo stereoselective coupling to synthesize (+)-pinoresinol in *Sesamum indicum* seeds (Fig. 3). (+)-Pinoresinol is then metabolized further, and methylenedioxyphenyl group is added in maturing sesame seeds which result in production of (+)-piperitol and (+)-sesamin and (+)-sesamolin [26]. A 78 kDa dirigent protein is known to assist in a stereoselective bimolecular coupling to produce (+)-pinoresinol [27]. Lignan synthesis is developmentally regulated and depends upon the stage of seed maturity. The most mature seeds of 8 weeks efficiently convert (+)-pinoresinol into (+)-piperitol and (+)-sesamin, while younger seeds have higher conversion to (+)-sesamolin [28].

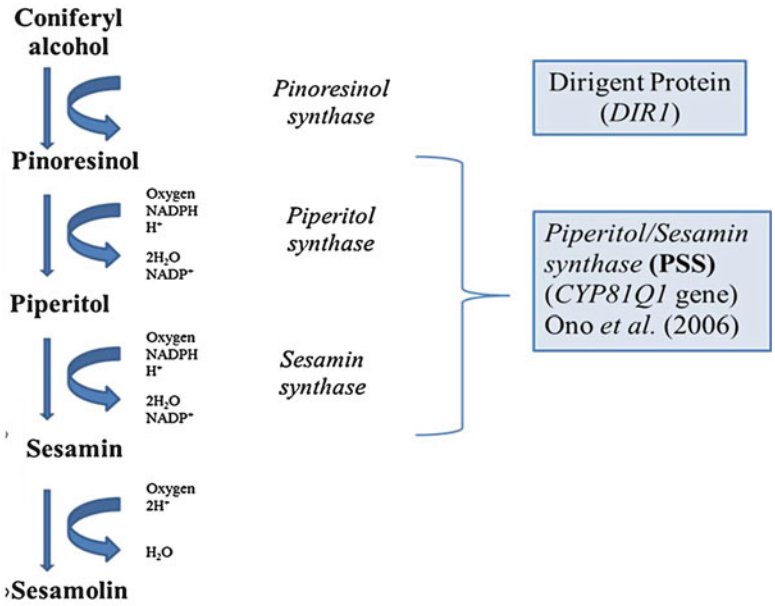

Fig. 3 Diagrammatic representation of sesamin biosynthetic pathway depicting conversion of coniferyl alcohol to pinoresinol with unstable intermediate piperitol followed by conversion to sesamin. Sesamin is further converted to sesamolin. Boxes indicate action of enzymes

Recently, it is shown that the synthesis of sesamin from pinoresinol is catalyzed by *CYP81Q1* in two steps [29].

2.1.2 Tocopherol Chemistry and Biosynthesis

Tocochromanols have both the hydrophobic and hydrophilic elements – these biomolecules generally have a lipophilic isoprenoid side chain linked to the membrane lipids and a polar chromanol ring toward the membrane surface. Tocochromanols inhibit membrane lipid peroxidation and scavenge reactive oxygen species. It is a well-known fact that antioxidants neutralize free radicals, thereby preventing DNA damage. Being scavenger of reactive oxygen species, tocopherols minimize free radical attack and interrupt lipid peroxidation. In this way, these molecules protect cell membranes, enable lipid repair and replacement, and are useful in preventing cancer and heart diseases [30]. Tocopherols are known to play a role in plant metabolism, for instance, sugar transport from leaves to phloem [31].

Tocopherols are an important group of plant phenolics that have antioxidative activity and nutritional values [32]. They belong to a family of molecules that have a chromanol ring (chroman ring with an alcoholic hydroxyl group) and a 12-carbon aliphatic side chain containing two methyl groups in the middle and two more methyl groups at the end. Plants synthesize eight different vitamin E forms, including α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols [33]. All tocopherols and tocotrienols consist of a chromanol ring and varying number of methyl

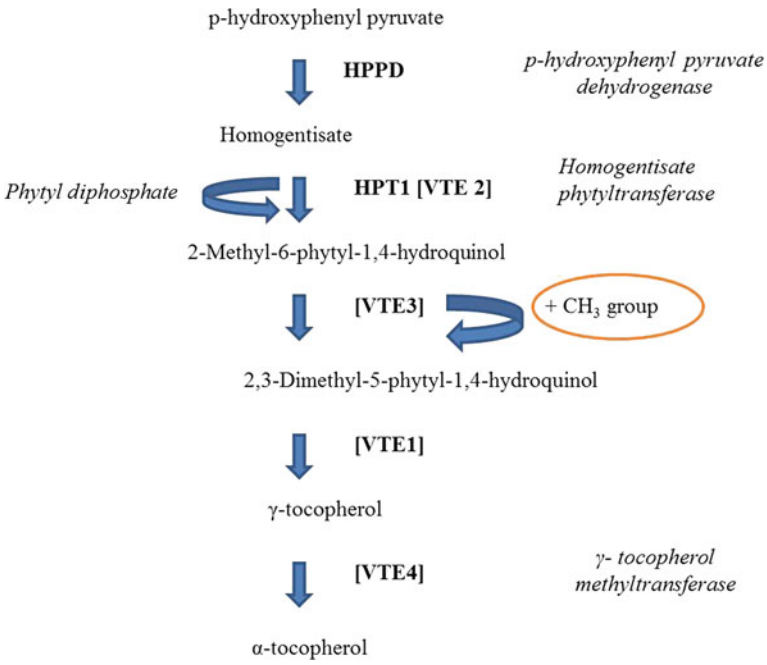

Fig. 4 Diagrammatic representation of tocopherol biosynthetic pathway depicting conversion of p-hydroxyphenylpyruvate to homogentisate, which gets converted to methylated hydroquinol and finally to tocopherol homologues

groups on the chromanol ring. Metabolic fate and biological activities of tocols depend upon their structural features. The entire isoforms act as lipid antioxidants, and α-tocopherol has the highest vitamin E activity [34, 35]. The difference between tocopherols and tocotrienols is that tocopherols have a saturated tail, while tocotrienols have an unsaturated tail.

Higher plants like dicots have tocopherols in almost all parts including roots, stems, leaves, flowers, fruits, and seeds [36, 37]. However, the total tocopherol content and different forms of tocopherols in these tissues differ considerably. Among the tocopherols, α-tocopherol is the predominant form in photosynthetic tissues such as stems and leaves. In most seed crops, α-tocopherol is present only in a minor form, and γ- and δ-tocopherols tend to predominate [38].

Tocopherol Biosynthesis

The hydroquinone ring of tocopherol is derived from the shikimate pathway of aromatic amino acid synthesis (Fig. 4). Biosynthesis of homogentisate, the precursor for tocopherol, tocotrienol, and plastoquinone, is catalyzed by p-hydroxyphenylpyruvate dioxygenase (*HPPD*) [39]. After attachment of the hydrophobic side chain by homogentisate phytyl transferase (*HPT1/VTE2*) [40, 41] and on methylation (*VTE3*) [42, 43], 2,3-dimethyl-5-phytyl-1,4-hydroquinol (DMPQ) is formed, which is converted to γ-tocopherol by tocopherol cyclase (*VTE1*) [44, 45].

Tocopherol cyclase is considered as a key enzyme in tocopherol biosynthesis. Final methylation by γ-tocopherol methyltransferase (γ-TMT, *VTE4*) results in the production of α-tocopherol.

2.1.3 Sesame Seed: Lignan and Tocopherol Bioactivities

Sesamin and sesamolin were initially considered as the major lignans in sesame seeds [46]. Sesaminol, another major lignan, was identified later from sesame seeds [47]. These seed components possess unique properties, and regular human consumption helps in lowering blood lipids [48] and arachidonic acid levels [49]. The sesame seed lignans are also known to reduce cholesterol level by inhibiting its absorption and synthesis simultaneously [50]. These lignans are anticarcinogenic [51] and anti-inflammatory [52] and are known to increase hepatic fatty acid oxidation [53]. They have immunomodulatory activities [54] and possess antihypertensive [55, 56] and neuroprotective effects against hypoxia or brain damage [57].

In addition to lignans, multiple tocopherol homologues [α-tocopherol (αT), δ-tocopherol (δT), and γ-tocopherol (γT), tocotrienols] are also present in sesame seeds, which possess antioxidative and health-promoting properties. Sesame lignans are found to exhibit synergistic effect with tocopherols on vitamin E activity and act as specific inhibitor of fatty acid metabolism in humans [58]. These nutritional properties of the sesame seeds contributed by the principal factors lignans and tocopherols have promoted their use in the daily diet worldwide.

Sesame lignans have antioxidant and tocopherol-sparing activities [59–62]. They are reported to reduce cholesterol level [48, 50, 63] and exhibit antihypertensive [64] and anti-inflammatory activities [65] as well as affect lipid metabolism by enhancing gene expression and hepatic enzyme (acyl CoA oxidase, carnitine palmitoyltransferase, bifunctional enzyme, and 3-ketoacyl-CoA-thiolase) activities involved in fatty acid oxidation [66, 67]. On the other hand, lignans reduce the activities of enzymes involved in lipogenesis (acetyl-CoA carboxylase, fatty acid synthase, ATP citrate lyase, glucose-6-phosphate dehydrogenase, and pyruvate kinase) by altering the gene expression [66]. Hence, sesame plays a crucial role in minimizing the vulnerability and increasing the safety against atherosclerosis, cancer, and cardiovascular diseases [48, 64, 68].

Thus, sesame has both preventive and therapeutic values in a variety of chronic diseases, owing to its rich lignan content and its antioxidative, anticholesterolemic, and antihypertensive properties. Sesame lignans, especially sesamin, are absorbed in human body, undergo enterohepatic circulation, and are converted into strong antioxidative metabolites. Intestinal bacteria metabolize them into other bioactive compounds such as mammalian lignans enterolactone and enterodiol compounds, which the role in breast, prostate, and colon cancers, bone health, and cardiovascular diseases is understudy [69–71].

In traditional Chinese and Indian systems of medicine like Ayurveda, sesame occupies an important position with diverse pharmaceutical application. In China, sesame oil is used in treatment of toothaches and gum diseases [72]. In India, it is being used as an antibacterial mouthwash to relieve anxiety and insomnia and in the treatment of blurred vision, dizziness, and headache [72]. Sesame oil is also noted for burn-healing effect [73]. Moist-exposed burn ointment (MEBO) a purely herbal

formulation from China contains sesame oil as an active ingredient along with β-sitosterol, berberine, and other plant extracts in trace amount [74] and is usually used in managing the burns of the face, neck, and hand [73].

The main antioxidant activity of α-tocopherol is to break the radical chain in membranes and lipoproteins [75]. Its antioxidant potential along with various functions at the molecular level mitigates the possibility of cardiovascular diseases and cancers [76, 77]. Other tocols that are present in lesser amount can also perform the antioxidative and biological activities. Gamma-tocopherol (γ-T), for instance, is more potent in decreasing platelet aggregation and LDL oxidation and delaying intra-arterial thrombus formation than that of α-tocopherol [78, 79]. Tocotrienols inhibit cholesterol biosynthesis [80] and are found effective in reducing the tendency of breast cancer [81]. Thus, tocopherols have high antioxidant, antitumor, and hypocholesterolemic potential. γ-Tocopherol is the major tocopherol in sesame, whereas α- and δ-tocopherols are present in very small amounts. It has been reported that γ-tocopherol is a more effective antioxidant compared to other tocopherols [82] but has poor vitamin E activity in biological systems [76].

Tocopherols terminate the recyclable chain reaction of polyunsaturated fatty acid (PUFA) radicals produced by oxidation of lipid [83]. The lipid peroxy radicals that are scavenged by tocopherols are converted into tocopheroxyl radicals, which with the help of ascorbate and other antioxidants are recycled back as the corresponding tocopherol [84]. In this manner, a tocopherol molecule can undergo in multiple lipid peroxidation chain-breaking events before it is finally degraded.

2.2 Minor Phenolics

In addition to tocopherols and lignans, sesame contains other phenolics like naphthoquinone and phenolic acids in trace amounts [85–88]. Sesamol, which is known as a strong free radical scavenger [89], is also present in sesame oil. It is a free phenol with methylenediphenoxy group.

2.3 Phytosterols

Phytosterols (sterols and stanols) are plant triterpenes with preventive functions in many diseases especially cancer. They have been shown to possess antioxidant [90], anti-inflammatory [91], and antibacterial properties [92]. Similar in structure to cholesterol (phytosterols have extra methyl group at C-24 position), these plant sterols, when digested, compete with cholesterol for small intestine absorption leading to lowering of the cholesterol level in blood [93]. The recommended functional foods usually contain phytosterols extracted from plant sources, or at times processed foods have phytosterols as supplement and are sold as cholesterol-lowering foods. Although corn and legumes are used to extract phytosterols, it is the sesame seeds that have the highest (400–413 mg 100 g^{-1}) amount of phytosterols [94].

In a recent study, Gharby et al. [95] noted that β-sitosterol constitutes a major portion of phytosterols in sesame seed and oil, and campesterol and stigmasterol are the other important sterols present. Compared to other phytosterols, β-sitosterol has been studied more extensively for its beneficial and physiological effect on human being. β-Sitosterol lowers cholesterol level [96], enhances immunity, and has anti-inflammatory properties [97]. The other major component is campesterol, which accounts for about 17.8% of the total sterols. Stigmasterol and Δ5-avenasterol measure about 6.4% and 10.2%, respectively, in sesame oil. Minor sterols present are Δ7-stigmasterol and Δ7-avenasterol. The total sterol content in sesame seed oil is approximately 540 mg/100 g oil.

2.4 Phytates

Phytic acid is a bioactive compound with wide distribution in plant foods. Due to its molecular structure, phytic acid has affinity to polyvalent cations such as minerals and trace elements. Phytic acid is one of the most important sources of phosphorus in plant seeds, and sesame is no exception. In fact, sesame seeds are richer in phytate than the commonly known legumes. In oil seeds such as sunflower, soybean, sesame, linseed, and rapeseed, the phytic acid content ranges from 1% to 5.4% compared to 0.2–2.9% in legumes. A defatted sesame meal has much higher phytate concentration than that of soybean meal [98]. Graf and Dintzis [99] have measured 5.36% phytic acid content in sesame seeds. Often, phytates are termed as anti-nutrient for preventing mineral absorption from meal, but it is also seen that phytates have anticancerous and hypocholesterolemic activities [100, 101].

2.5 Polyunsaturated Fatty Acids

Fatty acids are carboxylic acids with long-chain hydrocarbon side groups derived from or contained as esterified molecular form in lipids (fat, oil, or wax) of microbes, animals, and plants usually ranging from 1 to 30 carbon atoms in length attached to a terminal carboxyl group [102]. Polyunsaturated fatty acids (PUFAs) are long-chain fatty acids containing two or more double bonds introduced by specific desaturase enzymes. Over the years, vegetable oils rich in various PUFAs have emerged as potential dietary elements for normal growth and development of human beings with considerable biomedical significance. LC-x-3-PUFAs are important for human health in maintaining the cellular membrane by regulating cholesterol synthesis, transportation [103], and eicosanoid synthesis [104].

Sesame is a high-energy food containing approximately 50% oil. The fatty acid composition of sesame oil is highly desirable with about 80–85% unsaturated acids and only 15–20% of saturated acids. Sesame oil consists mainly of linoleic (35–50%) and oleic (35–50%) acids, with small amount of palmitic (7–12%) and stearic (3.5–6%) acids, but with only traces of linolenic acid [105, 106]. Studies indicate that a high intake of n-6 fatty acids shifts the physiologic state to one that is

pro-thrombotic and pro-aggregatory, characterized by increase in blood viscosity, vasospasm, and vasoconstriction and decrease in bleeding time. The n-3 fatty acids, however, have anti-inflammatory, antithrombic, hypolipidemic, and vasodilatory properties [103]. Sesame in combination with soybean oil increases the vitamin E activity along with nutritive value of the lipid [19, 107].

Sesame varieties differ greatly in fatty acid contents of their seeds, and this understanding could lead to crop engineering with an aim to develop better quality edible oil in future [108]. Indian sesame germplasms have lower level of saturated fatty acids compared to other sesame varieties with palmitic acid being the prominent one. C18:1 and C18:2 are the major unsaturated fatty acids present in Indian varieties [109]. In unsaturated fatty acids, while the content of C18:1 and C18:2 is quite high in sesame oil (38–49% and 17–43%, respectively), the C18:3 content is below par (<1%) [110]. A critical analysis of different cultivars is the need of hour, if we are assertive to improve the nutritional quality of oil by engineering the fatty acid biosynthetic pathway.

2.6 Short-Chain Peptides, Protein Hydrolysates, and Their Functional Properties

The bioactive polypeptides are amino acid chains joined by amide or peptide bonds, with molecular weight not exceeding beyond 20 kDa. These are protein fragments that have independent function in various biochemical, physiological, or cellular processes. While some of these peptides are formed naturally, it is the artificial protein hydrolysates that are much in use and are structurally and functionally a diverse group of peptides. Proteins can be digested by proteases, or specific fragment can be created in bio-fermenters utilizing microbes [111]. Sesame food preparation is also an important source of protein [112]. Protein hydrolysates are widely in use as nutritional supplement, functional ingredient, food flavor enhancer, pharmaceuticals, and cosmetics [113, 114]. They display hormone- or drug-like activities and based on the mode of action can be classified as antimicrobial, antithrombotic, antihypertensive, opioid, immunomodulatory, mineral binding, and antioxidative [115]. Use of papain for producing sesame protein hydrolysates having better functional properties, high storability, and emulsifying properties than that of the original sesame protein lysate has been studied by Bandyopadhyay and Ghosh [116].

3 Quantitative Insight in Lignan and Tocopherol Content: Interspecific and Intraspecific Variation

Sesame crops are of high nutritional value owing to the presence of antioxidants lignans (sesamin, sesamolin, and sesamol) and tocopherols (α-, γ-, and δ-forms). Separation of tocopherol homologues in sesame by RPLC on triacontyl (C_{30}) stationary phase has been successfully optimized. The reproducibility of the procedure is in the range 1.7–3.9%, and recovery ranged from 91% to 99% [117]. Lignans and tocopherol homologue contents in a wide collection of 143 sesame lines (wild species,

landraces, introgressed lines, and cultivars) collected from diverse agroecological zones of India have been determined by reverse-phase HPLC (RP-HPLC) [118]. Screening of sesame germplasm revealed an exploitable level of variation in major bioactive compounds. High levels of sesamin and γ-tocopherol suggested for the efficient introduction of these lines in the trait enhancement of other oilseed crops.

4 Biotechnological Approaches for Sesame

Sesame crop is relatively superior in oil quantity and quality compared to many major oil crops. The oil content varies from 35% to 60%, but mostly it is about 50% of seed weight [119]. Therefore, genetic engineering of sesame directed toward creation of sesame oil having diverse composition of lignans and tocopherols with high nutritional value is an important biotechnological aspect. With high genetic diversity, sesame becomes a promising oilseed crop for performing genetic manipulations to obtain high yield and quality oil [120].

4.1 Genome Sequencing of Sesame Crop: Unraveling the Oil Biosynthetic Pathway

Higher oil content compared to other oilseed crops, combined with small genome related to oil quality enhancement, makes sesame an invaluable model plant for studying oil biosynthesis. Wang et al. [121] have done de novo assembling of the genome, where a set of 12 transcriptomes and 29 resequenced accessions provided a large resource for exploring the mechanisms underlying different oil content between sesame and soybean, as well as among the sesame accessions. The results reveal the presence of whole genome duplication and absence of the Toll/interleukin-1 receptor domain in resistance genes. Genes and oil biosynthetic pathways responsible for high oil content were determined employing comparative genomic and transcriptomic analyses. That has indicated for the expansion of type 1 lipid transfer genes by tandem duplication, the contraction of lipid degradation genes, and the differential expression of essential genes in the triacylglycerol biosynthesis pathway in the early stage of seed development [121].

Resequencing data study in 29 sesame accessions from 12 countries suggests that the high genetic diversity of lipid-related genes is linked with the wide variation in oil content. Additionally, the results shed light on the pivotal stage of seed development, oil accumulation, and potential key genes for sesamin production, an important lignan with numerous health benefits. Recently, two more sesame landraces and the chloroplast genome have been sequenced [121, 122] enriching the sesame genome dataset. A recent genome-wide association study has identified *SiNST1* as the candidate gene for lignin and cellulose biosynthesis, and this gene could indirectly be associated with sesamin and sesamolin content [123]. Thankfully, a few

open access platform like Sinbase is also being maintained where all these datasets are managed for further analysis and utilization by sesame researchers [121].

4.2 Functional Gene Expression: "Lignan Biosynthetic Genes"

High-throughput sequencing technology has provided ample data on DNA sequences for the genomes of many plant species. Expressed sequence tags (EST) of many crop species have been generated, and thousands of sequences have been annotated as putative functional genes using powerful bioinformatics tools. Impact on breeding programs could be reached with this approach, because quality of crop plants is a direct function of their metabolite content [124] and quality of plant tissues determines their commercial value with respect to flavor, fragrance, shelf life, physical attributes, etc. [125].

Comparative analysis of expressed sequence tags from *Sesamum indicum* and *Arabidopsis thaliana* developing seeds has been done by Suh et al. [126]. The group could identify the genes involved in accumulation of seed storage products and in the biosynthesis of lignans, sesamin, and sesamolin. Their study could also identify the identical and different gene expression profiles during sesame and *Arabidopsis* seed development and the genes specific to sesame seeds [126]. Sirato-Yasumoto et al. [67] reported that sesamin content in sesame seeds was controlled by polygenes, because F2 populations originating from reciprocal crosses between high sesamin and normal sesamin varieties showed a continuous distribution in sesamin content, and correlation coefficients between F2 and F3 generations were positive and highly significant for sesamin content.

Ono et al. [29] reported that *CYP81Q1* is a single gene encoding (+)-piperitol/(+)-*sesamin synthase* in the *Sesamum indicum* genome, suggesting that *CYP81Q1* is a single enzyme, which catalyzes the formation of (+)-sesamin from (+)-pinoresinol. The *CYP81Q1* homologue (*CYP81Q3*) showed no activity of (+)-sesamin biosynthesis, due to (+)-sesamin deficiency in this species, whereas *S. radiatum* showed dual activity of the enzyme. Further, expression profile of *CYP81Q1* gene was temporally consistent with the accumulation pattern of (+)-sesamin during seed development. Hata et al. [127] detected sesamin (using ultra-performance liquid chromatography-fluorescence detection) in sesame leaves of two Japanese sesame varieties "Gomazou" and "Kin-goma," which differed in sesamin content of the seed, and probed genotypic differences. The higher sesamin content of "Gomazou" leaves correlated well with that of seeds and the expression of the sesamin biosynthetic gene *CYP81Q1*, indicating that genotypic difference of *CYP81Q1* gene expression affected leaf sesamin contents.

To comprehend sesame domestication, we examined the expression of sesamin synthase (*CYP81Q1*) during capsule maturation in three wild *Sesamum* spp. and four sesame cultivars [128]. Among the cultivars, only *S. indicum* (CO-1) exhibited transcript abundance of sesamin synthase and high sesamin content similar to *S. malabaricum*, whereas other cultivars had low expression, indicating that sesamin synthase was not favored during domestication.

5 Conclusions

Sesame is no more an "orphan" crop – the widespread collection of varieties and landraces coupled with extensive research in every aspect has made the crop as the perfect model system amidst other oilseeds. The superior quality of sesame seed oil containing a variety of lignans and tocochromanols merits a higher place among the oilseed crops being consumed worldwide. The diversity of sesame cultivars and their characterization has given sesame researchers enough impetus to create genetically engineered sesame varieties with high yield of secondary metabolites. Sesame seeds are microcapsules for health promotion and disease prevention in humans and an sustained effort in this area of oilseed research would be of immense value to the plant breeders as well as consumers.

Nutritional Quality of *Mangifera* Species

9

Luis M. Anaya-Esparza and Efigenia Montalvo-González

Contents

Abstract

Mango is known as the king of the fruits; its nutritional importance, unique flavor, and delicious taste impart this status as super fruit. Furthermore, it is commercially cultivated in different tropical and subtropical areas in the world. *Mangifera indica* is the most important fruit of this genus; over 60 different species of edible mangoes are grown worldwide; however, the most of them are not marketable

and underutilized and commonly are denominated as wild mango species, but they exhibit higher nutritional values. Mango species present morphological, physiological, sensorial, and nutritional differences among them. However, most of *Mangifera* species are characterized by their strong aroma, intense peel coloration, attractive fragrance, and delicious taste. Also, mango fruit is considered very healthy, good source of energy, and easily digestible.

Mango pulp and peel are a good source of carbohydrates, dietary fiber, vitamins (B, C, and E), minerals (Ca, P, Fe, Na, and K), and bioactive compounds (polyphenolic compounds, flavonoids, mangiferin, lupeol, and carotenoids). Most of *Mangifera* species have good nutrimental quality; their consumption may contribute nutrition. In general, the commercially (*M. indica*) and wild mango species can be considered for many purposes including for processing and for consumption because mango may be considered an excellent source for improving nutrition. However, enhanced knowledge of the status of such species and information on their health benefits is critical in efforts to promote these valuables mango species.

TSS	Total soluble solids

1 Introduction

Mango fruit has been recognized as the "king of the fruits," having socioeconomic importance in many countries and/or localities. Mango fruit is cultivated commercially in more than 87 countries around of the world, but also, mango ranks among major fruits worldwide [1, 2]. Furthermore, mango is a rich source of bioactive compounds and essential macro- and micronutrients; it is a powerful nutritive fruit, containing most of the essential substances needed by the human health. Its nutritional importance, unique flavor, and delicious taste impart this status as super fruit [3].

Mangifera is a genus that belongs to the Anacardiaceae family in the order of Sapindales, which is native to the Southeast Asia, in particular originated in India, Indo-Myanmar border, and Bangladesh [4]. Kostermans and Bompard [5] listed 58

species in the genus *Mangifera*, but today, this number is considerably increased [4]; majority of which were distributed in Asia. Currently, mango is cultivated in different tropical and subtropical areas worldwide [6, 7], and it has several species, varieties, and cultivars [8]. Around the world there are more than 150 mango varieties, and the main producers are India, China, Thailand, Indonesia, and Mexico [9]. Previous data are about the best-known species, *Mangifera indica*, a commercially important member of this genus, where the most representative varieties worldwide are "Tommy-Kent," "Tommy Atkins," "Haden," "Keitt," and "Ataulfo" varieties [10]. However, there are another consumable, but not marketable wild mango species in the genus *Mangifera* such as *M. casturi*, *M. zeylanica*, *M. odorata*, *M. lalijiwa*, *M. caesia*, *M. foetida*, *M. laurina*, and *M. pajang*, among others [11]; they represent a great potential for food, industrial, and pharmaceutical use. Unfortunately, the wild mangoes are vulnerable and in danger of extension [12–16].

2 Description of *M. species* Fruits

Mango is a tropical and exotic fruit with many species, varieties, and cultivars [1]. According to Hidayat et al. [6], the classification of *Mangifera* species is still labile; it is because of the complexity of the *Mangifera* genus. Furthermore, several mango fruit characterizations including pulp color (light, yellow, gold, and orange), pulp texture (soft, intermediate, or strong), fiber quantity in pulp, juiciness of pulp (slightly juicy, juicy, or very juicy), pulp aroma (absent, mild, intermediate, or strong), and eating quality (poor, good, very good, or excellent) have been developed [17]. For this reason, mangoes are grouped under two broad categories as wild and cultivated [18]. The fruit description of some edible *Mangifera* species is presented below.

Mangifera indica fruit is more or less compressed, oblong or sub-uniform, fibrous, highly variable in size, shape, weight, and peel coloration and has fleshy drupe with sweet juice and large and compressed seed. In the same way, fruits of *M. andamanica* are oval shaped and small in size and weight (11–15 g); their flesh is yellow, fibrous, and juicy with sweet taste (22 °Brix) [19]. Likewise, *M. caesia* fruit is an ovoid-oblong drupe, necked at base, and medium sized (12–20 cm), with whitish, yellowish, greenish, or pale brownish, smooth, thin skin (1 mm); the pulp is white, soft, juicy, and fibrous, with a peculiar sourish taste; it can be sweet, acidic, or both and has strong smell at maturity [20, 21]. Additionally, the fruits from *M. odorata* are obliquely ellipsoid-oblong or oblong drupe, are medium sized (10–13 cm), and have an average weight of about 200–320 g with a thin skin (3–4 mm) but also are characterized by their strong odor; the pulp is yellow to orange yellow, firm, fibrous, and juicy and has sweet to acidic, sweet taste (21 °Brix). The fruit peel has greenish purple color to canary yellow at maturity [19, 20, 22, 23].

With respect to *M. sylvatica*, the fruit is obliquely ovate, small (8–10 cm long; 27 g), and compressed; the pulp is yellow in color, has a sweet and sour taste, is very aromatic, and is almost fiberless. Their skin is very thin but has a big kernel (40% of its weight). The fruits look very much like that of the common mango (*M. indica*) [24–26]. *M. foetida* fruit is obliquely ovoid-oblong or almost globose drupe, small to

medium in size, dirty dark olive green or yellowish green in color with brown lenticels, fibrous, juicy, savory, and with strong smell and has skin of 5 mm thick and pale yellowish-white flesh when immature that turns into yellow or golden yellow when ripe [20, 21]. *M. laurina* fruit is a drupe-like small mango, obliquely oblong, small in size (5–7 cm), and medium green turning greenish yellow to yellow in color at maturity; flesh is yellow, watery, sweet, with a strong resinous taste, juicy, very acidic, and fibrous [20, 22, 23]. On the other hand, *M. pajang* fruit is a big drupe (2–3 kg), brownish, globose to broad-ovoid, 15–20 cm across, and roughish. Flesh is yellow, fibrous, acidic to acid-sweet, and middy fragrant [20, 21].

Furthermore, the fruits of *M. zeylanica* have an average weight of 150 g; they have a thin skin and are watery, sweet, and pleasant in flavor [22]. Also, the fruit of *M. casturi* is produced in large racemes of ten or more; fruits are small (50–84 g) compared to other mango species; immature fruits are green, and when ripe the color changes to brown or purple black, and it has a shiny surface. The flesh is orange with fiber; its taste is unique (slightly sweet) similar to lychee fruit [21, 22]. The fruits from *M. lalijiwa* exhibited a medium size of fruits (250 g) with green skin; the flesh is white pale yellow with particular brown honey pockets in the flesh. Fruits are very sweet and aromatic with a distinguish honey flavor [21].

In the last years, some research has demonstrated the relationship of some wild mango species, for example, *M. odorata* and *M. foetida* also have close relationship based on internal transcribed spacer nuclear ribosomal DNA [4]. Some authors have mentioned that *M. odorata* is a hybrid result from *M. indica* and *M. foetida* [27]. Also, a close relationship between *M. laurina* and *M. sylvatica* to *M. indica* was previously reported [8].

Mango species exhibited morphological, physiological, and sensorial differences among them. In general, the mango fruit is a simple, large, more or less compressed, fleshy, and resinous drupe. It varies in size, shape, color, taste, and nutritional value. However, most of the *Mangifera* species are characterized by their strong aroma, intense peel coloration, attractive fragrance, and delicious taste.

3 Traditional Uses and Health Importance

Mango fruits can be eaten immature green, mature green, or ripe [20] and usually are consumed fresh with or without peel; however, due to the excellent organoleptic attributes that it exhibits, the pulp is used as an ingredient to elaborate food and beverage products such as juices, nectars, puree, jam, jelly, yogurt, wine, and others [2]. On the other hand, in traditional folk medicine, mango pulp is consumed as an antiparasitic, laxative, and stomachic, among others [1, 28]. According to the World Health Organization, traditional medicine system based on the use of plants is an important source of health care [29]. In recent years, secondary metabolites with known pharmaceutical activities have been extensively investigated as a source of medical agents [30, 31]. In particular, *Mangifera* species exhibited several biological compounds as mangiferin, mangiferic acid, mangiferol, ellagic acid, steroids, alkaloids, terpenoids, saponins, tannins, and others [31, 32]. In this context, the intake of

Table 1 Physicochemical parameters of different flesh *Mangifera* species at green mature stage (GSM) and consumed mature stage (CMS)

Parameter	Maturity stage	pH	AT (% citric acid)	TSS (°Brix)
M. indica cv. Tommy-Kent	GSM	3.48	4.26	10.7
	CMS	4.07	2.39	15.1

Source: Barbosa-Gámez et al. [3]

mango pulp promotes strengthening of the body's defenses, mainly due to the presence of bioactive compounds in fruit pulp and peel as discussed below.

4 Postharvest Quality Parameters of *Mangifera* Species

It has been demonstrated that the majority changes related to the quality in mango fruit occur during its ripening [33, 34]. Barbosa-Gámez et al. [3] evaluated the changes in physiochemical parameters (pH, titratable acidity, and total soluble solids) of the pulp of *M. casturi*, *M. lalijiwa*, *M. odorata*, *M. zeylanica*, and *M. indica* cv. Tommy-Kent and Tommy Atkins, which are harvested in two maturity stages (green mature stage and consumed mature stage). In general, changes in pH, titratable acidity (TA), and total soluble solids (TSS) were observed in both maturity stages as shown in Table 1. In all *M. species* studied, an increase in pH and TSS content was reported when green to consumed mature stage, while TA decreases. Furthermore, numerous physical and physiological changes of mango ripening involving surface color, shape, size, shoulder growth, specific gravity, and firmness have been correlated with the fruit maturity stage [1].

5 Nutrimental Quality in *Mangifera* Species

Fruits play an important role in human nutrition by providing additional sources of energy and bioactive compounds, and their consumption is recommended by many health organizations [35]. Mango is a popular and economically important fruit worldwide mainly for its excellent organoleptic properties and nutritional value [32]. According to Masibo and He [36], mango fruit is unique because each of its parts

(pulp, peel, and kernel) is utilizable. In the literature, mango is described as a fruit with high amounts of water (72–86%) and carbohydrate (9–25%) and low protein (0.9–5.1%) and lipid (0.2–2.7%) content as presented in Table 2; these values are depending on each *Mangifera* species and can vary with the location of cultivation, variety, and stage of maturity.

In particular, differences in nutrimental contents were observed between *Mangifera* species. *M. zeylanica* exhibited the highest water (86%) and lipid content (2.7%). On the other hand, *M. foetida* exhibited the lowest water (72%) content but the highest carbohydrate (25%) content. With respect to the protein content, *M. lalijiwa* (4.7%), *M. odorata* (4.7%), and *M. casturi* (5.1%) showed similar values. Furthermore, some *Mangifera* species as *M. lalijiwa*, *M. odorata*, *M. casturi*, *M. zeylanica*, and *M. sylvatica* exhibited better nutrimental values compared to *M. indica* cv. "Tommy-Kent" and "Tommy Atkins." The nutrimental quality of the fruit is influenced by species, variety, nutritional status, and environmental conditions during growth of the parent plant [1].

The mango pulp is considered very healthy, good source of energy (63–92 kcal), and easily digestible (Table 2). Furthermore, mango fruit has been considered as a functional food because it is a source of dietary fiber [37]. The importance of dietary fiber (DF) content in fruit and its implications in human nutrition and health as prebiotic and regulating the glucose and lipid levels (cholesterol and triacylglycerols) in blood have been reported previously [38]. The total (TDF), soluble (SDF), and insoluble (IDF) dietary fiber values in some *Mangifera* species pulp at two maturity stages are shown in Table 3. In general, Barbosa-Gámez et al. [3] reported a decrease in total dietary fiber content when unripe to ripe mango fruit in all *Mangifera* species is evaluated. However, all mango species exhibited high amounts of dietary fiber, but *M. lalijiwa* showed the highest content in immature stage (41 g/100 g DW) and *M. zeylanica* in mature stage (20 g/100 g DW).

Vitamins and mineral contribute a major part of nutrimental content of fruits; these compounds are essential nutrients that are required for various biochemical and physiological processes in the body. In the case of mango, significant values of vitamin C, vitamin E, B vitamins (Table 4), calcium, phosphorous, iron, sodium, and potassium (Table 5) were found. Ascorbic acid (AA) or vitamin C is the most important water-soluble antioxidant, usually present and highly bioavailable in tropical fruits [39]. According to the Institute of Medicine's Food and Nutrition Board [40], the dietary reference intake (DRI) for vitamin C is 90 mg/day for males and 75 mg/day for females. In the case of mango, vitamin C content was dependent of each species and varies from 47 to 400 mg per 100 g of edible portion; the highest vitamin C content was found in wild mango species (*M. zeylanica*, *M. pentandra*, and *M. pajang*). Daily consumption of 100 g/day of mango (e.g., *M. indica* by popular) pulp could ensure an intake of 100% of the DRI. Furthermore, an interesting values of vitamin E (3.4–7.8 mg/100 g) and B vitamins as niacin (0.6–329 mg/100 g), niacinamide (8–149 mg/100 g), pyridoxine (4.7–86.2 mg/100 g), riboflavin (0.04–97.6 mg/100 g), and thiamine (0.05–8 mg/100 g) were found in different *Mangifera* species, which are another important vitamin groups for health care [41].

Table 2 Nutrimental composition and energy value (per 100 g of edible portion on fresh weight basis) of different *Mangifera* species

Mango species	Energy (kcal)	Moisture (g)	Ash (g)	Total protein (g)	Total fat (g)	Carbohydrates (g)	Total fiber (g)	References
M. indica cv. Tommy-Kent	66.3	83.5	3.4	4.04	1.5	9.2	–	[3]

Source: Barbosa-Gámez et al. [3]

Mango is a major source of carbohydrates, dietary fiber, vitamins, and minerals with high energy value but low in calorie. Fresh as well as processed form of mango fruit is an important part of people's diet. Furthermore, most of *Mangifera* species have good nutrimental quality; their consumption may contribute nutrition in many countries around the world. Also, some of these wild mango species have been domesticated for its use and commercialization.

6 Phytochemicals Present in *Mangifera* Species

In addition to their delicious taste, refreshing flavor, aroma, and nutritional value, mango fruit provides "bioactive compounds" to improve human health [34]. Bioactive compounds are defined as "inherent non-nutrient constituents of food plants with anticipated health promoting/beneficial and/or toxic effects when ingested" [42]. According to Raman et al. [7], the concentration of these compounds depends on many factors (e.g., varieties, maturity stage). In general, mango fruit has bioactive compounds in roots, leaves, bark, seeds, peel, and pulp. The types of compounds include β-carotene, isoflavones, vitamin C, mangiferin, gallic acid, lupeol, kaempferol, quercetin, and α-tocopherol, among others [43–45]. All these compounds have great potential for use in food and pharmaceutical industry (Raman et al. [7]). As mentioned above mango fruit is consumed with or without peel; for this reason we will focus on the bioactive compounds present in edible part (pulp and peel) of mango fruit.

6.1 Phytochemicals Present in Mango Pulp

Mango, like most fruits, is an important source of natural compounds considered as bioactives [34]. In the edible part of mango fruit, compounds as polyphenols,

phytosterols, isoflavones, and β-carotene, among others, have been identified as shown in Table 6.

Polyphenols are among the most extensive groups of phytochemicals present in fruits. Mango is an excellent source of dietary antioxidants as phenolic compounds. The concentration of phenolic compounds in mango pulp varies with species and/or variety, ranging from 200 to 3000 mg of gallic acid equivalents per 100 g of edible portion (Table 6), which exhibited a great antioxidant capacity [46] (Table 7). According to Palafox-Carlos et al. [34], the major phenolic compounds found in "Ataulfo" mango pulp are chlorogenic, gallic, protocatechuic, and vanillic acid. In addition, the authors mentioned that the gallic acid (39%) showed the highest contribution on antioxidant capacity followed by chlorogenic acid (21%), while major phenolic compounds in *M. indica* cv. Keitt pulp are gallic acid; mono-, tetra-, and penta-galloyl glucoside; hydroxybenzoic acid; and gallotannins [47]. The identified phenolic compounds coincide with those reported by Masibo and He [36] for mango pulp. Furthermore, Masibo and He [36] mentioned that the flavonoids are the most abundant polyphenols in our diet; unfortunately, information about flavonoid content in *Mangifera* species is scarce, and the values reported for some mango species ranged from 100 to 500 mg per 100 g of edible portion. Khoo and Ismail [48] have reported the presence of isoflavones as daidzein and genistein in *M. foetida*, *M. pajang*, and *M. odorata* pulps. These compounds can act as phytoestrogens, which may serve as health-promoting compounds in consumer's diet. *M. odorata* possessed the highest daidzein and genistein content (11.6 mg/100 g), followed by *M. pajang* (9.02 mg/100 g) and *M. foetida* (6.81 mg/100 g). In all cases daidzein content was higher than genistein content. According to the authors, the variability of the isoflavone content in mango fruits may be influenced by several internal and external factors [7]. Recently, López-Cobo et al. [49] in three mango cultivars (Keitt, Osteen, and Sensation) from *Mangifera indica* reported the presence of Alk(en)ylresorcinols and p-coumaric acid.

Mangiferin is a xanthone that exhibits great potential as antioxidant; it is a pharmacological active phytochemical and a natural polyphenolic antioxidant [50]. Mangiferin content of mango pulp ranged from 0.078 to 4 mg per 100 g. Furthermore, another phytochemical, lupeol, a well-known triterpene, is also found in several medicinal plants and fruits, including mango. The lupeol content in mango pulp from different mango species ranged from 0.006 to 0.181 mg per 100 g of edible portion. Some authors have mentioned that mangiferin and lupeol can act as an anti-inflammatory, antidiabetic, and cholesterol-lowering agent [50, 51].

[a]mmol kg^{-1} dry weight

The attractive color of mango pulp is mainly due to the presence of abundant β-carotene, but also, carotenoids are a potent antioxidant with several human health benefits [52]. Carotene content in *Mangifera* species ranged from 0.006 to 10.7 mg per 100 g of edible portion. *M. foetida* and *M. odorata* are *Mangifera* fruits which are considered as underutilized tropical fruits. But, the flesh of these mango species exhibited an important total carotene content as reported by Khoo et al. [45]; furthermore, carotene content of *M. foetida* (4.81 mg/100 g) and *M. odorata* (3.95 mg/100 g) is comparable to other commercial mangoes. Ajila et al. [53] mentioned that the yellow-orange flesh or ripened mango is attributable to the presence of carotenes. In this context, many of the wild mango species exhibited yellow-orange color pulp, indicating the possible presence of carotenes in their pulps [48].

Furthermore, Vilela et al. [54] mentioned that ripe mango pulp from *M. indica* cv. "Tommy Atkins" and other cultivars is a rich source of phytosterols and other lipophilic phytochemical (Table 8). The major groups of lipophilic compounds in mango pulp are sterols (947 mg/100 g DW) and fatty acids (949 mg/100 g DW), followed by the steryl glycosides (201 mg/100 g DW) [54]; some of these lipids have been termed as "bioactive lipids" because of their potential benefits for human health [55].

6.2 Phytochemicals Present in Mango Peel

Mango peel has been recognized as source for obtaining valuable components [56, 57] as phytochemicals (polyphenols, carotenoids) and vitamins (E and C) with different health-promoting properties [53], mainly by its antioxidant activity [34]. Moreover, mango peels are great source of proteins, carbohydrates, and dietary fiber [58–60], which make it suitable to be processed for value-added applications in functional foods

Table 8 Compounds identified in the lipophilic extracts of ripe mango pulp

Compound	*Mangifera indica* cv. Tommy Atkins (mg per 100 g db)
Fatty acids	940
Saturated	324

Stigmasterol	68
Steryl glucosides	201
Others	195
α-tocopherol	64

Source: Vilela et al. [54]

and nutraceuticals [61] as discussed below. Currently, mango peel flour is used as functional ingredient in food products, mainly in bakery products [62].

Ediriweera et al. [63] reported that major lipophilic compounds identified in *M. zeylanica* peel (chloroform extract) were 1H-cycloprop[e]azulen-7-ol-decahydro-1,1,7-trimethyl-4-methylene, β-sitosterol, 9,12-octadecadienoic acid, caryophyllene oxide, phenol-3-pentadecyl, and α-tocopherol, among others. Also, Kim et al. [47] informed about the presence of unsaturated fatty acids as oleic acid, linoleic acid, and ethyl linoleate in peels from *Mangifera indica* L. cv. "Irwin."

Hassan et al. [60] reported in *Mangifera pajang* K. a content of TDF of 72% (SDF: 33.4% and IDF: 38.8%). Ajila et al. [64] stated mango peel to be a rich source of fiber, and 30–50% SDF and 50–70% IDF can be considered as a well-balanced range for maximum health benefits, due to each fraction that has different

physiological effects [65]. Similar results were reported in mango peels by Ajila and Prasada Rao [66] in "Badami" and "Raspuri" varieties (TDF ranged from 40% to 72% in both cases). Furthermore, DF has been associated with polyphenol compounds and called "antioxidant dietary fiber" [66].

With respect to ascorbic acid, green and ripe mango (*Mangifera indica* var. "Chokanan") peel contained an ascorbic acid of 109 and 52 mg per 100 g (DW), respectively [62]. Previously, Ajila et al. [53] reported an AA content of 34 and 39 mg per 100 g (DW) in raw and ripe peel of mango "Raspuri" and "Badami" cultivars, respectively. Also, Sogi et al. [61] informed an AA value of 75 mg/100 g (DW) in mango (*Mangifera indica* cv. "Tommy Atkins") peel. According to Ayala-Zavala et al. [37], mango peel exhibits great agro-industrial potential for use as functional ingredient or as anti-browning additive in food processing due to high content level of AA in the samples that act as natural antioxidant.

Tocopherol species are present in foods; α-tocopherol is most important to human health [67]. Ajila et al. [56] reported the α-tocopherol content for raw (10.4 mg ATE per 100 g DW) and ripe (23 mg ATE) mango peels from *M. indica* var. Badami. Nonetheless, Abbasi et al. [67] reported a high amount of vitamin E in peels (ranged from 7 to 43 mg per 100 g DW) than in pulp (ranged from 0.87 to 4.12 mg) of nine "Chinese" mango (*M. indica*) varieties, and they mentioned that the variations in results indicate that phytochemical composition in fruits may greatly be affected by genetic diversity within/among the cultivars and other factors as maturity stage and harvesting time. These high values show that the consumption of mango peel can contribute at the dietary needs for intake of vitamin E.

Concerning with total soluble polyphenol (TSP) compounds, García-Magaña et al. [58] reported TSP of 6.8 and 4.2 g GAE (per 100 g db), respectively, in "Ataulfo" and "Tommy Atkins" mangoes. Hassan et al. [60] informed a concentration of 9.8 g GAE (per 100 g DW) in Bambangan (*M. pajang* K.) mango. Furthermore, Sáyago-Ayerdi et al. [68] characterized the hydrolyzable polyphenol profile in the peels of the "Ataulfo" mango; they reported that mango peel may contain series of gallotannins between 5 and 13 units that possess high antioxidant activity. This means that the peel of the mango species can be considered an excellent source of antioxidants. Shieber et al. [50] reported the presence of mangiferin, quercetin, and kaempferol and their related conjugates in mango peel from *M. indica* cv. "Tommy Atkins." Prasad et al. [69] identified six phenolic compounds (pyrogallic acid, gallic acid, catechin, epicatechin, mangiferin, and rutin) from *M. pajang* peels. Blancas-Benitez et al. [70] informed about the presence of chlorogenic acid (82%) and vanillin acid (17%) in "Ataulfo" mango peel (*M. indica*). On the other hand, Barreto et al. [71] studied 16 varieties of mango (*M. indica*) peel, and they reported minimal differences in the profiles between cultivars; however, there was considerable variation in the amounts of the major phenolic compounds. These findings demonstrated that every mango species is genetically different and unique, as has been pointed in this study.

7 Other *Mangifera* Species with Potential for Consumption

Other commercially valued species that produced edible fruits are *Mangifera similis*, *M. quadrifida*, *M. griffithii*, *M. altissima*, *M. gebede*, *M. macrocarpa*, *M. rufocostata*, *M. flava*, *M. applanata*, *M. macrocarpa*, *M. duperreana*, *M. oblongifolia*, *M. kashiana*, *M gracilipes*, *M. sclerophylla*, *M. merilli*, *M. rumphii*, *M. rigida*, *M. quemanga*, and *M. superba*, among others [72]. The ripe fruits are acid-sweet and have a pleasant flavor [20]. Additionally, there are many cultivars or varieties from *M. indica* that exhibit a great potential for their commercialization. According to many authors, *Mangifera* family includes many wild *Mangifera* species [1, 2]. Unfortunately, nutrimental information about these mango species are scarce. Naik et al. [73] opine that it is the large variability that has hindered the production of the commercial varieties on a large scale. However, it is true that this large biodiversity has not been exploited to the full potential [19].

8 Conclusion

Evidence showed that some of the wild *Mangifera* species such as *M. caesia*, *M. foetida*, *M. odorata*, *M. casturi*, *M. lalijiwa*, *M. zeylanica*, *M. sylvatica*, and others are healthy fruits to consume specially from the nutrimental viewpoint and are similar or better nutrimental source than the popular *M. indica*. In general, the commercially (*M. indica*) and wild mango species can be considered for many purposes including for processing and for consumption because mango may be considered an excellent source for improving nutrition. However, enhanced knowledge of the status of such species is necessary for the conservation of these valuable species. Also, this chapter offers a better understanding of the nutrimental and functional potential of these fruit species.

Abstract

Legumes are part of the human edible panel since prehistory times but the remains that reached our last centuries were all from a period posterior to fire domestication. In all parts of the world where human civilizations developed, pulses were associated with cereals and the combination of their proteins managed to cover the essential amino-acid requirements of Humans and animals. Legumes gathering more than 19,000 different species, all present high protein content due to specific symbiosis with *rhizobia* and arbuscular *mycorrhizae* present in the soils. These associations are thought to originate from first symbiotic events dating from more than 60 million years before present. They allow the plants to fix nitrogen that is used for protein biosynthesis. The nutritional value of actual pulses is generally higher than that of other crops especially since domestication and the genetic selection processes operated by humans. Beside proteins with suitable amino-acid profiles, legumes also contain digestible carbohydrates and some of them also contain fat. In some cases, these fat include polyunsaturated fatty acids that increase further the nutritional value of the corresponding legumes. However, if such valuable plants managed to survive along geological periods, it is because their evolution with their environmental pressure lead them to develop anti-nutritional substances to protect themselves from their predators. Here will be discussed some of these anti-nutritional substances, the so-called tannins, phytic acid, saponins, phytoestrogens, lipoxygenase, hemagglutinin, trypsin inhibitor, as well as allergens. Because all these substances are basically useful for the crops, it is only during processing that they should be removed. Therefore, a special focus is made on traditional versus modern recipes and industrial food processing. Their respective impacts on basic nutritional components (amino-acids, fats, carbohydrates, vitamins, and minerals) as well as on the anti-nutritional factors listed above are examined. Basically, wet processing which was most frequently developed in the past, associated orf not with fermentation or germination, is also the most efficient in removing all anti-nutritional factors.

1 Introduction

Legumes have been used for thousands of years in human nutrition and constitute one of the pillar bases of human civilization. Among other early domesticated pulses are lentils (*Lens culinaris*, L. Medic.), pea (*Pisum sativum*, L.), chickpea (*Cicer arietinum*), broad bean (*Vicia Faba*, L.), common bean (*Phaseolus vulgaris*, L.),

lupine (*Lupineus albus*, L.), peanut (*Arachis hypogaea*, L.), cowpea (*Vigna unguiculata*, L. Walp.), bambara groundnut (*Vigna subterranean*, L. Verdc), or soy (*Glycine max*, L. Merr). In all continents, pulses were domesticated although the archeological traces of these events are not always easy to show. The origin of high protein content and quality in legumes is the symbiotic nitrogen fixation by rhizobia and mycorrhizae in plant root nodules. This leads to increased production of protein and injects nitrogen into agricultural systems. Nitrogen from rhizobia symbiosis also provides residual soil nitrogen to subsequent non legume crops. Therefore, legumes have been used in crop rotations for thousands of years. The proteins of legumes are not only concentrated but also exhibit interesting amino-acid profiles that make them attractive for animals and humans. Therefore, and to allow plant survival to pest and predators, legumes progressively developed an arsenal of biochemical "weapons" to limit their palatability and digestibility. Thus beside excellent theoretical nutritional characteristics, legumes developed anti-nutritional factors such as tannins, phytic acid, saponins, oligosaccharides, hemagglutinins, lipoxygenases, protease inhibitors, or certain polyphenols. These substances help preventing large consumption of plants in raw and forced humans to invent cooking processes and specific recipes including fermentation or germination. These traditional processing practices have recently been renewed thanks to modernization of processing tools and industrialization of the food preparation. These new processes can act only partially on anti-nutritional agents. This may be a cause of increasing allergy prevalence among human consumers. Nowadays, modern recording tools allow to show that in all continents and with all legumes these allergic manifestation due to pulses consumption exist and possibly rise. This review tends to go through all these aspects giving perspective to the issue of plant proteins in human future.

2 History of Legumes Cultivation and Consumption

Domestication of a crop leads to the appearance of novel traits which can be favorable to harvest and to human uses. According to Caracuta et al. [1] experiments conducted on wild modern peas, chickpeas and lentils prove that neither harvesting of wild stands or cultivation of wild legumes results in profitable yields [2–4]. Therefore the added value got from the actual crops, directly comes from domestication. Among other traits, the seed-coat should be thinner and smoother in domesticated stocks to facilitate water penetration and germination [5]. However, using this mutation as a trait of domestication, while exploring antic farming sites, remains controversial, because several cultured legumes including lentils or grass pea do not exhibit great differences with their wild relatives [6, 7]. Oppositely, increase in seed size is considered to be one of the major domestication-traits even though this increase in seed-size does not occur at the early stage of domestication but rather later as a result of crop improvements [1]. Legumes have been associated to cereals as basic foodstuff in the human history for as long as agriculture and settlement started. The remains from excavations of the Neolithic period already, shows associations of wheat varieties and barley to lentils and peas in the Near East region

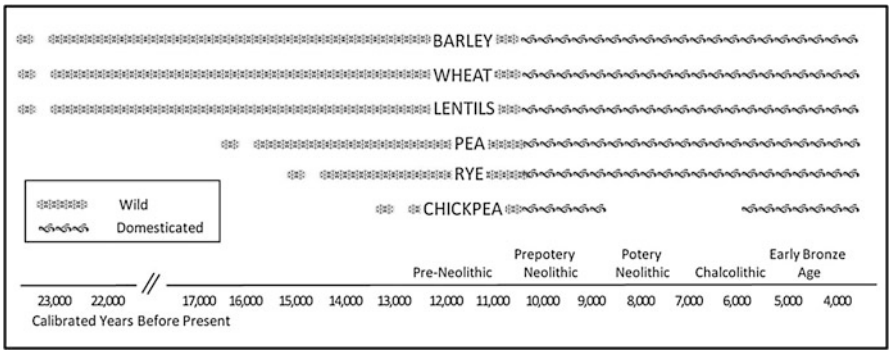

Fig. 1 Diagrammatic representation of the appearance of the main crops during human history as revealed by remains found in ancient human settlements

where cereal cultivation was shown to be first performed [8], then came chickpea (Fig. 1). The present chapter shows that all over the world and in all continents, legumes were domesticated to be part of human protein intake. They were always associated to cereals which allow the best amino-acid combination to fulfill human nutritional requirements.

2.1 Near East and Western Europe

2.1.1 Lentils

According to Zohary and Hopf [8], lentils (*Lens culinaris* L.) are found in remains which were determined to be as old as agriculture itself. Lentils seem to be closely associated with the start of wheat and barley cultivation in the Near East. The presence of small lentil-seeds was shown among remains retrieved from pre-farming zones of North Syria dated from 10,000 to 9,500 Cal BP (Calibrated Before Present). A few traces of the use of lentils are then found in Iraq, Iran, Anatolia, and Jordan. These traces are from the Neolithic period and more precisely from the ninth millennium Cal BP. and consist of small lentil-seeds (2.5–3.0 mm in diameter). This size does not allow to conclude on the wild or cultivated origin of the seeds. Larger amounts of lentil-seeds were also discovered in later phases of the Neolithic settlement in the Near East. According to Zohary and Hopf [8], they were found: in Syria (8,250 to 7,950 Cal BP) [9], in Turkey (7,800 to 7,000 Cal BP) [10], and in Iran (7,500 to 7,000 Cal BP) [11]. At that time, lentil-seeds had already attained 4.2 mm in diameter which is characteristic of a development under domestication. Lentils spread to East and then to Western Europe during the Bonze and the Iron ages, respectively. Because the remains of lentil-seeds in France seems to be less evident in early and late Bronze age than they are in Germany, Hungary, and Switzerland, it is assumed that the use of lentil-seeds spread from East to West during this particular period. However, only the seed-size of lentils can help to diagnose for domestication. Unfortunately this trait

evolves very slowly and is affected by environmental factors, and therefore, it is difficult to ascertain that we would be able to determine the one set of *Lens* domestication in the future.

2.1.2 Peas

Peas of the *Pisum* gender were found to be common in the Neolithic agriculture settlements in Europe. They were found to be closely associated with the wheat and barley products. According to Zohary and Hopf [8], remains of peas were discovered in early Neolithic farming villages of the Near East (9,000 to 8,000 Cal BP). Preserved, since they were carbonized, pea seeds were already present in aceramic jars of north Iraq, southeast Turkey, and in the prepottery B level in Jericho. According to the remains, the use of these legumes most probably spread over the Near East since remains dated from the eighth millennium Cal BP were found in this area. Remains dated from 7,400 to 7,000 Cal BP [12] show the smooth seed coat characteristic of domesticated peas. Genetic approaches show that the actual species *Pisum sativum* (L.) most probably derives from two main wild species *P. elatius* and *P. humile* which is smaller.

2.1.3 Cicer

Chickpea (*Cicer arietinum* L.) as other early European cultivated crop seems to originate from the Near East and deriving from a progenitor *C. reticulatum*. According to Garrard [13], remains of *C. arietinum* were found in Neolithic settlements of the Euphrate area and close to the natural distribution area of its putative progenitor. Later (10,000 Cal BP), it is recorded in Jericho far from its original region, and this is an indication of domestication. Establishment of the domesticated forms and replacement of the wild ancestral populations of European legumes is thought to have occurred in the Near East. This was performed within a relatively short time. Chickpea, however, appears as an exception among all other "founder crops." When all other crops including legumes are germinating in autumn, flowering in late winter/early spring and maturating in early summer, chickpea is a spring sown crop. Although the wild precursor was probably following the general cycle pattern, chickpea was deliberately sown in late winter (February) and this is considered to be a strong trait of domestication. As mentioned in [14], the winter cycle is found in all wild progenitors of the "founder crops" of Near Eastern agriculture without exception because their harvest yield is far better following winter germination. Plants are then able to use the winter rainfall for growing. It appears that chickpea sowing was delayed to avoid the *Ascochyta* disease whose pathogen agent is *Didymella rabiei*. This fungus has the potential to cause total yield loss on chickpea, and its occurrence is high since 9 fields over 10 can be attacked in a given area. In recent tests, only one out of ten actual varieties was able to resist to the fungal attacks when sowed in winter. The disease does not affect the legume sowed in late winter because of early dryness, and this allows maintaining lower (0.95 tons/ha rather than 3.0 tons/ha) but consistent yields.

2.1.4 Faba

Broad bean belongs to the section *Faba* of the genus *Vicia*. They appear today as big beans even though it is though that the progenitor of the actual broad bean was smaller and most probably derives from the *Vicia faba* var. *minor* [15]. Quite recently [1], reported the discovery of large amount of *Faba* seeds in sites located in the Galilee region of Israel. According to carbon duration, the seeds were collected 11,000–10,000 Cal BP and are the oldest *Faba* seeds ever found so far. The most ancient datation corresponds with a period when water supply was good enough for production and harvesting. The authors argue saying that these *Faba* seeds were most probably cultured under human input as early as the following millennium (10,000 Cal BP.) since seeds remains are still of good size indicating good water supply in a country where dryness was gaining. The earliest remains of broad beans found in Western Europe were from the Iberic peninsula and were dated from the late Neolithic times. In contrast, few carbonized remains of broad beans appear in several Bronze Age sites of the East Mediterranean and Aegean. All Bronze Age broad beans have relatively small seed and thus most probably belong to *Vicia faba* var. *minor*.

2.2 America

2.2.1 Phaseolus

The common bean *Phaseolus vulgaris* (L.) presents multiple variations of fresh and dried varieties. Those include string beans, green beans, French beans, kidney beans, or pinto beans. These varieties and others provide a third of daily dietary protein in some cultures of Africa and of Americas. *P. vulgaris* is originating from Mesoamerica and South America. Its domestication is much more recent than the European legumes since it is thought to start about 8,000 years before present time [16]. Plant domestication is often associated with a suite of morphological changes. In the case of common bean, domestication has led to increases in seed and leaf sizes, as well as to changes in growth habit and other features. Moreover, these morphological shifts occurred not once but twice, as common bean was domesticated independently in Mesoamerica (probably in what is now Mexico) and the Andes [17]. Currently, the domesticated gene pool of the species seems to be organized into four Mesoamerican and three Andean races [18, 19]. These two pools were domesticated independently. However, although the four Mesoamerican races Durango, Jalisco, Mesoamerica, and Guatemala differ in ecological adaptations, geographic ranges, morpho-agronomic traits, allozyme alleles, and random amplification of polymorphic DNA (RAPD) markers [18, 19], they probably all derive from a single domestication event. Indeed, they all present the same predominant phaseolin electrophoretic type S, and similar amplification fragment length polymorphism (AFLP) patterns [20, 21]. In parallel there are three Andean races: Nueva Granada, Peru, and Chile, which also differ in morpho-agronomic characters, allozymes, and phaseolin types [19]. This would support multiple domestications, but their geographic ranges overlap, and they seem to be similar in AFLP patterns [18]. This supports a single origin.

2.2.2 Lupineus

The discovery of the origin of lupine in South America is quite recent. According to Atchison et al. [22], *Lupineus mutabilis,* also called tarwi, was domesticated once and not in the putative south-central Andean core area of early agriculture, but rather in northern Peru, most likely in the Cajamarca region. This area is included, or close to, the distribution area of *L. piurensis*. Therefore, it can be assumed that *L. piurensis* is the most likely wild progenitor of the modern lupine *L. mutabilis*. Demographic analyses suggest that tarwi split from *L. piurensis* around 2,600 Cal BP. and suffered a classical domestication bottleneck. The earliest unequivocal archaeological evidence of domesticated tarwi seeds is from the Mantaro Valley, central Peru 1,800 Cal BP. According to the actual theory, lupine then spread North and South from the initial area of origin in Peru. Therefore, the pulse went south to Bolivia and north to Ecuador and Colombia. Lupine arrived then in Europe with Spanish conquistadores, *i.e.,* in the early fifteenth century.

2.2.3 Arachis

According to Bonavia [23], the geographic area of origin and domestication of the peanut would be the Huarmey valley, near the Peruvian coast. Most of the archeological records of fruits of *Arachis hypogaea* date from approximately 3,500–4,500 years BP. However, based on the distribution and biology of wild species and landraces of *Arachis,* the region of origin of the peanut may have been in the south of Bolivia and the northwest of Argentina [24]. According to Grabiele [25], radiocarbon-dated macro-botanical remains were dated from approximately Cal 7,840 year BP. They appeared as wild *Arachis* species or peanut fruits in early domestication stages. They were recovered in buried preceramic sites in the lower western slopes of the Andes in Northern Peru. However, since this region is not considered as a plant domestication center, the first *Arachis* species may have been first cultivated elsewhere in South America earlier than Cal 8,000 year BP. According to Grabiele *et al*. [25], *A. monticola* may be an intermediate tetraploid ancestor from which *A. hypogaea* has arisen upon domestication. In addition, *A monticola* was most probably obtained from the two diploid species: maternal (*A. duranensis*) and paternal (*A. ipaensis*) wild diploid species of *Arachis*.

2.3 Africa

2.3.1 Cowpea

The African *Vigna* studied here are cowpea [*V. unguiculata* (L.) Walp.] and bambara groundnut [*V. subterranea* (L.) Verdc.] [26]. *Vigna unguiculata* is most probably originating from sub-Saharan Africa. It was introduced in America during the seventeenth century by Spanish conquistadores and is now largely cultured and consumed as black eyed pea in USA and Brazil. According to Kongjaimun et al. [27], cowpea was domesticated from wild cowpea in Africa. In 2007, D'Andrea *et al*. [28] reported the discovery of cowpea remains in Kintampo settlements in Ghana. Kintampo is a Later Stone Age (LSA) tradition of West Africa dating to

3,600–3,200 Cal BP [29]. One seed collected in the B6B site in the Horizon 4 was submitted for radiocarbon dating by AMS. The resulting date was of 3,410 ± 60 Cal BP, at 95.5% c.i. (TO11883). This date confirms a Kintampo association and is consistent with other determinations obtained from the site. Although to date, the earliest remains are originating from Western Africa, a Northern or North-Eastern origin has been argued based on the absence of true ecologically wild cowpea in West Africa [30]. However, the paucity of available data from eastern African Countries has precluded a final assessment. Based on the botanical evidences, it is thought that *Vigna unguiculata* then spread in Asia. There, the cultivated cowpea or its weedy relative was subsequently selected for the vegetable crop, yardlong bean [*Vigna unguiculata* subsp. *sesquipedalis*]. The subspecies' main characteristic is the length of its pods which can range between 35 and 60 cm long. Nowadays, cowpea constitutes a major dietary source of protein for many sub-Saharan populations. When mixed with cereals, protein quality is significantly improved [31].

2.3.2 Bambara Groundnut

The main groundnut originating from Africa is Bambara *Vigna subterranean*. It is an important food legume grown widely in semi-arid Africa and closely related to cowpea (*V. unguiculata*). Bambara shares much of its area of cultivation and origins of genetic diversity with cowpea [32]. According to Philippson and Serge Bahuchet [33], the Bambara African name ⁎/jʊgʊ appeared in the Proto Bantu language probably incorporated thank to the immigration of people from Proto Benue Congo origin. This immigration is dated from a climate deterioration that scourged Sahara and Sahel and which is dated 7,100–6,900 Cal BP. Naming a plant does not mean that it was domesticated and cultured but at least recognized as a define plant probably because of human usage. Bambara groundnut appears as two botanical forms; var. *spontanea* which is most likely the wild forms and var. *subterranea* comprising the cultivated forms. *Vigna subterranean spontanea* is restricted to an area from Nigeria to Sudan, with a center of diversity around Cameroon. *Vigna subterranean subterranea* is found in many parts of the tropics and particularly in sub-Saharan Africa. Both the wild and cultivated forms bear 11 pairs of chromosomes [34]. As mentioned here, the use of this legume by human populations of West Africa probably dates from the early proto Bantu period which seems to coincide with Ceramic Late Stone Age but this still remains to be substantiated by archeobotany.

2.4 Asia

2.4.1 Glycine

The main legume in Asia is identified as soybean *Glycine max*. China is the country of origin of soybean. Deng in [35] reports that soybean was found to be present in the Neolithic site of Baligang in the Shijiahe period (Cal 4,500 BP). According to Hymowitz [36], it was domesticated and therefore cultivated in the Eastern half of North China 3,100 Cal BP. More precisely, soybean domestication probably started

in Liaoning province because the wild soybean grows everywhere and the stages of evolution are apparent [37]. *Glycine max* belongs to the subgenus *Soja*, which also contains *G. soja* and *G. gracilis*. *G. soja*, is a wild species of soybean, found in many different environments in many Asian countries [38]. According to cytological, morphological, and molecular traits, *G. soja* is most probably the ancestor of *G. max*. On the contrary, *G. gracilis* is most probably semi-wild form of *G. max*, which phenotypic traits place it as an intermediate in the speciation between *G. max* and *G. soja*. According to Willis [39], *G. max* ancestors produce tiny, hard seeds that are useless for food unless properly prepared. Therefore, the initial use of soya bean ancestors was essentially as green manure in crop culture rotations. Since then, and until 1915, Manchuria in North-Eastern China has been the heart of soybean production in China [40]. The ancient character for soybean (shu) seems to appear on Zhou dynasty bronze vessels dated around 3,020 Cal BP [36]. Confucius documents dated from 2,500 Cal BP mentioned soybean as one of the five staple grains of China. These were foxtail millet (*Setaria italica*), broomcorn millet (*Panicum miliaceum*), rice (*Oryza sativa*), wheat (*Triticum aestivum*), and legumes essentially soybeans (*Glycine max*).

3 Origin of Protein in Legumes

3.1 An Evolution Process

Legumes are particularly rich in proteins since they produce amino acid from ammonia. This NH_3 is supplied by rhizobia symbiotic organisms which produce it from aerial Nitrogen (N_2). Archeobiology established that the symbiosis between legumes (Fabaceae) and nitrogen-fixing bacteria, the so-called rhizobia, appeared Cal. 60 million years BP [41, 42]. This long association probably explains why adaptative processes gave rise to about 19,500 legume species [43]. Molecular and genetic studies suggest that rhizobia bacteria progressively associated to the more widespread and much older endo-mycorrhizal symbiosis [44]. The association between arbuscular mycoorhizal fungi and plants involve recognition factors generated by the fungus and named Myc factors [45]. As for mycorrhizal association, the plant-rhizobia interaction is most generally initiated by a mutual recognition of molecular signals released by both symbiotic partners. It is characterized by varying degrees of specificity pre-determined by the nature and profile of seed/root exudates from the legume, as well as nodulation factors from the rhizobia [46, 47]. The plant molecules involved in the recognition step are flavonoids [48, 49].

3.2 Adaptation for N_2 Fixation

Nowadays, the association between rhizobia bacteria and mycorrhizal fungi give birth to root nodules able to capture the aerial nitrogen and to inject it into the plant metabolism. Therefore, legumes receive the bulk of nitrogen fixed by rhizobia in the form of

ammonia, which is incorporated into organic form before being exported from nodules. The formation of effective root nodules with compatible soil rhizobia allow to reduce atmospheric N_2 into NH_3 for bacterial and plant use. The symbiosis requires the close association of the bacteria and the plant and the nitrogenase enzyme complex that reduces N_2 to NH_3 is oxygen labile. Rhizobia as other soil bacteria are obligate aerobes and require oxygen for respiration and metabolism. Therefore, they should combine two opposite situations under nitrogen-fixing conditions: oxygen for their own metabolic requirements and anaerobic conditions for nitrogen fixing. To achieve this paradox, the plant and the bacteria produce a micro-aerobic environment around nitrogen-fixing rhizobia in nodules. The outer cells of the nodules play as a barrier to gaseous diffusion limit the rate of oxygen into the central infected tissue. The outer cells, their bacteroids, and plant mitochondria consume oxygen as fast as it can enter the nodules. The oxygen is directly targeted to mitochondria and bacteroids via plant hemoglobins the so-called leghemoglobins. This insures a low oxygen ratio in the vicinity of the nitrogenase enzyme complex [50]. If leghemoglobin transcription is prevented (RNAi), this leads to a higher steady-state level of free oxygen locally a lower ATP/ADP ratio and a complete absence of nitrogenase activity [51].

3.3 The Nitrogen Uptake

The symbiosis between legumes and rhizobia, at its most basic level, results in the exchange of reduced carbon from the plant for reduced nitrogen from the bacteria. Thanks to its photosynthesis the plant produces sucrose which is the primary source of reduced carbon for nodule metabolism [52]. In nodules, phosphorenolpyruvate carboxylase and malate dehydrogenase activities divert carbon flux away from glycolysis to form malate. Malate is considered to be the primary source of carbon for rhizobia bacteroids. During nodule development, bacteroids are programmed to fix N_2 and not to assimilate NH_3 into an organic form. The assimilation of NH_3 is left to the plant, and during nodule development, genes such as those encoding glutamine synthase, glutamate synthase, and aspartate amino transferase are induced. These enzymes can incorporate NH_3 into amino acids for export from nodules [53]. Noteworthy, in legumes of tropical origin, like *Glycine max* and *Vigna unguiculata,* nitrogen is exported from nodules into the plant metabolism as ureides [54]. The nitrogen exportation from the bacteroids to the plant mainly occurs via ammonia rather than via any other more elaborated substance, i.e., amino acid. This transfer most probably occurs in a passive way. However, Glutamate, Asparate, or Glutathione may play a role in the active transport of nitrogenic molecules through the symbiotic membrane separating the bacteroids and the plant.

3.4 How to Explain the Efficiency of a Tripartite Symbiosis

A co-evolution process is generally put forward to explain the specificity of the association between legumes and their symbionts [55]. However, according to

Martínez-Romero [56], in some cases there may rather be a constant selection of micro-symbionts by the plant. The symbiont is selected for its large and fast capabilities for genetic change or of acquisition of symbiotic genes [57]. Rapid changes in symbiotic nucleic acid material could have enabled bacteria to adjust and adapt to the diversification burst of legumes that occurred during the earth evolution. Many studies have been conducted in order to decipher the mechanism of the tripartite association between the plant, the bacteria (rhizobium), and the fungus (mycorrhizae). According to Maillet et al. [58], mycorrhizal fungi of the genus *Glomus* and rhizobia secrete very similar lipo-chitooligosaccharide signal molecules, the so-called Nod factors in rhizobia and Myc factors lipo-chitooligosaccharides in arbuscular endo-mycorrhizal fungi. All Nod factors are lipo-chitooligosaccharides with a β-1,4-linked N-acetyl-D-glucosamine backbone of which the nonreducing sugar moiety is substituted with an acyl chain [59]. In legumes, rhizobial Nod factors are detected thanks to two different Lys-M-domain receptors to kinase. These proteins have an extracellular domain containing three Lys-M domains, a transmembrane domain, and an intracellular kinase domain. Mutations in either of the genes encoding for these receptors can block Nod factor induced responses, suggesting that these proteins operate in conjunction [60].

4 Protein Levels Compared to Other Plants

As mentioned previously, legumes are rich in proteins because they can use nitrogen fixed by their symbiotic nodules to produce endogenous proteins. Therefore when compared to other plant families, they tend to contain a higher rates of protein (Fig. 2). Legumes proteins are classified according to their solubility properties in water, salted water, or ethanol/water solutions. Albumins are soluble in water while globulins are soluble in salt water solutions, and prolamins are soluble in ethanol/water solutions.

4.1 Specific Proteins of Legumes

The most abundant proteins in grain legumes are globulins. These are classified as 2S, 7S, and 11S globulins according to their sedimentation coefficients (S) [61]. The two main storage proteins in soybean (*Glycin max*) are glycinin (11S) and β-conglycinin (7S) [62]. They can reach 41% of the total of grain weight. The glycinins are hexamers with molecular masses of 320,000 and 375,000 Da. The subunits are composed of specific acidic polypeptide chain which molecular mass is 40,000 Da linked by disulfide bonds. In lupine (*Lupinus alba*), the storage proteins are conglutin [63]. They have been classified into four groups: α, β, γ, and δ conglutins. The α–conglutin is a hexameric protein containing monomeric unit either acidic: (α) or basic: (β) subunits with molecular weight between 42,000 and 52,000 Da and between 20,000 and 22,000 Da, respectively. The α-conglutin (11S) may account for about 35–37% of the total seed storage proteins in white

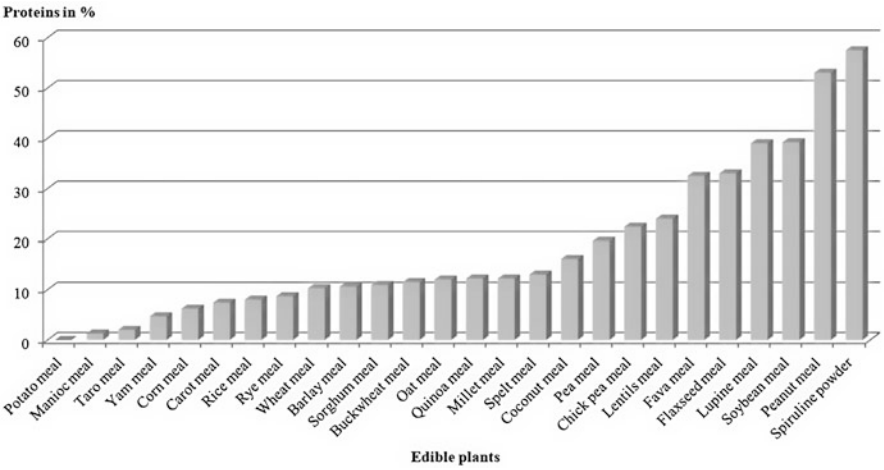

Fig. 2 Protein content of several plants used as human food

lupine seeds [64]. The most abundant lupine globulin is β-conglutin, also named vicilin, which represents about 44–45% of white lupine seed storage proteins [64]. The β-conglutin (7S) is a trimeric protein. Each of its monomer is formed by three polypeptides of low (17000–20,000 Da), medium (25,000–46,000 Da), and high (53,000–64,000 Da) molecular weight. The γ-conglutin accounts for about 5% of the amount of proteins in mature white lupine seeds [64]. The γ-conglutin (7S) is a tetrameric protein of about 50,000 Da composed of two subunits with molecular weight between 17,000 and 29,000 Da linked by disulfide bonds. Finally, δ-conglutin is the least abundant lupine conglutin, representing 3–4% only of total conglutin in white lupine [63]. δ-Conglutin (2S) is a monomeric protein consisting of two subunits of around 4,000 and 9,000 Da, respectively. These subunits are linked by two disulfide bonds. In pea (*Pisum sativum*), the globulin are named vicilin and convicilin (7S) and legumin (11S) [61]. Each group represents 4% and 3%, respectively, of the total weight of pea seeds. According to Barać et al. [65], vicilin appears as a globulin constituted from subunits with molecular weight of 47,300; 35,000; and 28,700 Da. Three minor subunits also appear in SDS-PAGE profiles of Tris-extracts with molecular weights of 37,000; 33,300; and 31,800 Da. Beside, two subunits of convicilin are identified with molecular weight of 77,900 and 72,400 Da. Legumin was identified as a trimer. Each monomer has a molecular weight of about 63,500 Da. These units associate acidic subunits of 40,890 Da and basic subunits of 22,300 and 23,100 Da. In broad bean (*Vicia faba*), the protein content accounts for 25–30% of the total weight, 75% of which are storage globulins legumin (11S) and vicilin (7S). The former is two- to threefold more abundant than the latter. Legumin is then the main storage proteins [66]. As in pea, legumin in *V. faba* is a polypeptide with a molecular weight of 60,000–61,000 Da, which is cleaved in vivo into two components: the α-subunit of 36,200 Da (acidic) and a β-subunit of 22,000 Da (basic). The native legumin molecule is composed of

six α-β units connected by disulfide bonds [66]. *V. faba* legumin in vivo is a hexamer of the basic polypeptide with a molecular weight of 328,000 Da [67]. Vicilin in *Vicia faba* has a molecular weight of 150,000 Da according to Derbyshire et al. [67], which is cleaved into subunits of molecular weight comprises between 55,500 and 33,100 Da (46,000, 43,100 and 33,300). In the common bean (*Phaseolus vulgaris*), the main globulin is called phaseolin (7S) and is a trimer formed from three subunits of 46,000; 49,000; and 50,500 Da [68, 69]. *P. vulgaris* also contains a legumin like globulin with a molecular weight of 340,000 Da. Immuno-determinations of the legume proteins show some cross-reactions between species like between peas and broad beans.

4.2 Absolute Nutritional Value

The nutritional value of different legumes can vary significantly as a result of their peculiar composition [70]. As examples, the quantity and variety of dietary fibers and starch, the protein composition, the rate of several anti-nutritional substances, and the phytochemical content of legumes can influence their dietary value. Legumes usually contain bioactive compounds, including enzyme inhibitors, hemagglutinins (lectins), phytoestrogens, oligosaccharides, saponins, and other phenolic compounds [70]. These substances can play metabolic roles in animals and humans who consume these foods frequently. The consumption of phytochemicals can be either beneficial or adverse and globally require additional investigations. They can also act synergistically or antagonistically with other components of the diet, and their mechanisms of action still have to be deciphered for health and diseases understanding. Some components are also known to improve their digestibility with food processing and this will be discussed later on. The absolute nutritional value of a legume takes into account its nutrient profiles as well as their digestibility.

4.2.1 Amino Acid Profiles

Leguminous proteins are globally low in the essential sulfur containing amino acids, methionine, cystine and cysteine, methionine, as well as in tryptophan (see Table 1) and are therefore considered to be an incomplete source of protein [80]. This is true either for humans or for domestic animal nutrition. Therefore, traditional associations are observed all around the world in human civilizations like *dhal* with rice in India, beans with corn tortillas in Mexico, tofu with rice in Asia, sorghum and cowpeas in Africa, Bambara groundnut and maize kernels in Zimbabwe, or rice and beans in Southern Africa and Latin America.

For domestic animals, the association is frequently corn with soybean or wheat and soybean [81]. For nutritional balance, legumes and cereals are to be consumed in the ratio 35:65 [82]. Although, this chapter is essentially focused on proteins from legumes, the traditional edible species also contain fibers, carbohydrates, and fat in different proportions (Table 2).

4.3 Digestibility (AntiNutritional Factors)

All legumes presenting high protein contents together with other valuable nutrients (polyunsaturated fatty acids, minerals, fibers) have a theoretical high nutritional value. However, if such plants get through the geological times until domestication, it is because despite their nutritional value they manage to limit their destruction by potential predators, by limiting their crude digestibility and appetence. Looking closely to their composition, it can be found that all legumes contain anti-nutritional factors that limit their digestibility and therefore their nutritional interest as crude matter for animal predators in the wild. As we will see further, the consumption of these legumes raise significantly when humans were able to apply basic cooking practices. The main anti-nutritional factors being inventoried here are tannins, phytic acids, oligosaccharides, lipoxygenases, hemaglutinins, anti-protease factors.

4.3.1 Tannins

Tannins (Fig. 3) mainly contained in the seed coats [83] are defined as water-soluble polymeric phenolic compounds exhibiting molecular weights from 500 to 3000 that can combine with proteins, cellulose, gelatin, and pectin to form insoluble complexes [84].

They currently protect the grains against insects, birds, and fungal attacks. The tannins content of legumes can be rather variable between species but also inside the same variety (Table 3).

In addition, it was shown that tannins affect the availability of amino acids, the utilization of protein, and they inhibit the activities of digestive enzymes [87]. Therefore, they tend to reduce the nutritional qualities of plants for their predators [88]. In domestic animals fed sorghum rich in tannins, it was shown that there were significant inverse relationships between tannin content and the mean digestibility of all AA [89]. When fava bean hulls tannins were added to casein diet, the apparent fecal digestibility of total and individual amino acids was decreased in rats [90]. The digestibility of proline, glycine, and glutamic acid were the most affected. It was thought to be due to the interactions of tannins with the proline-rich proteins secreted by the parotid gland since increasing amount of tannin-rich fava bean hulls caused a

linear increase in both the relative size of the parotid glands and in the quantity of proline-rich proteins in the rat's gland [90]. In addition, proline-rich proteins are secreted in the saliva and bind dietary tannins in the oral cavity. It was suggested that this phenomenon protects dietary and endogenous protein (digestive enzymes and proteins of the luminal side of the intestinal tract). However, if the salivary secretion is not sufficient, the tannins interactions with digestive enzymes can reduce protein and amino acid digestibility from tannin-containing diets [90, 91].

4.3.2 Phytic Acid

Cereals and legumes contain phytic acid (myoinositol 1,2,3,4,5,6-hexakisdihydrogen phosphate) at levels ranging from 0.4% to 6.4%, w/w. Phytic acid

Table 4 Phytic acid content in several legumes

(see Fig. 3) is the most preeminent form of phosphate storage form in most seeds. It accounts for 60–90% of total seed phosphorus [92]. In dicotyledonous seeds, such as legumes, nuts, and oilseeds, phytic acid is found associated with proteins. The amount of phytic acid in legumes can vary greatly (see Table 4).

Phytic acid has been reported to interfere with the action of pepsin on several vegetable and animal proteins *in vitro*. Its anti-proteolytic action probably goes through phytate:protein interaction that forms complexes at low pH [96]. Phytic acid was shown to inhibit trypsin activity in some but not all studies. Phytate was also shown to significantly (up to 25%) inhibit *in vitro* digestion of casein [97]. In addition, fermentation processes of millet, reducing phytate content by 23–26%, improved *in vitro* digestibility by 14–26%. Using microbial phytase, which metabolize phytate, in poultry or swine, improves phosphorous bioavailability and reduces the environmental impact of animal manure. Phytase also increased threonine and valine digestibility [98] and phytate concentration was negatively correlated with the inherent protein and amino acid digestibility of animal feed. From the animal studies, it seems that it is the ileal digestibility that is improved. The effects of phytase supplementation on protein and amino acid digestibility of proteins in several animal species may be explained by the release of protein from the protein-phytate complexes which are natural in feedstuffs. A second effect can be the prevention of formation of protein-phytate complexes directly in the gut. A third effect can be the reduction of the negative effect of phytic acid on pepsin and trypsin activities as well as to the reduction in endogenous amino acid losses [99].

4.3.3 Oligosaccharides

Legumes are classically rich in oligosaccharides of the raffinose family, namely, raffinose, stachyose, and verbascose (see Fig. 3 and Table 5).

According to Devindra *et al.* [106], raffinose family oligosaccharides are galacto-oligosaccharides that can account for more than 50% of the total soluble sugars in some cases. These carbohydrates cannot be hydrolyzed and absorbed, since the human small intestine does not exhibit the appropriate α-galactosidase activity. Therefore, these sugars are digested by the microorganisms present in the large

Means followed by the same letter within a column are not significantly different at $P < 0.05$.

intestine. This leads to flatus formation [107] because the indigestible raffinose family sugars are fermented anaerobically by the gut flora. This causes intestinal discomfort, nausea, abdominal rumbling, and diarrhea [108]. Therefore, these oligosaccharides which are important for the plant yields can be considered as anti-nutritional agents.

4.3.4 Hemagglutinins

Hemagglutinins are proteins belonging to the lectin family. These molecules are involved in the defense mechanisms of plants via their antifungal activities [109]. They can represent a large fraction of pulse seed proteins especially in beans. These proteins are known to bind carbohydrate moieties which can be present on cell membranes. As such, they can induce cell agglutination. Phytohemagglutinins (PHA-P) are tetrameric structures associating two types of polypeptide chains called PHA-E and PHA-L. These peptides bind preferentially either to erythrocytes or to leukocytes, respectively. Thus, five possible tetrameric isolectins of approximately 120 kDa can be formed, *i.e.,* E_4, E_3L_1, E_2L_2, E_1L_3, and L_4 randomly [110]. A large channel is present in the middle of the tetramer that may protect the protein from proteolytic degradation [111, 112]. The carbohydrate-binding sites of lectins can recognize not only monosaccharides but also oligo- and polysaccharides. Both PHA subunits ("E" and "L") contain an N-glycosylation binding sites. PHA-E is specific for bisected complex-type N-glycans with an outer Gal and bisecting GlcNAc, while PHA-L specifically binds tetra- and triantennary complex-type N-glycans with β6-branching [113, 114]. Close to the carbohydrate binding sites are located the divalent cations Ca^{2+} and Mn^{2+}, which maintain an active stable conformation with a great affinity for sugars [115]. Lectins are resistant to heat and to digestive enzymes, and they also can bind to the surface of enterocytes. This phenomenon can result in toxic reactions because of changes in intestinal permeability [116]. It was shown that PHA can strongly bind to the brush border membrane of the small intestine, and undigested PHA has a dose-dependent effect on hyperblastosis, and tissue growth [117]. High doses of dietary lectins also induce the abnormal development of intestinal microvilli in rats [118] as well as the disruption of enterocytes' plasma membrane repair. This effect usually results in necrotic death of the wounded cells [119]. Blood bioavailability of lectins is poor in normal situation, but it can increase when the intestine barrier is altered.

In their study [120], Putszai and co-workers shown that lectin from *Paseolus vulgaris* were able to decrease casein digestibility in rat. The net protein utilization of crude bean was 11 and that of casein could be reduced in a dose-dependent manner when adding increasing amount of lectin extracted from *Phaseolus vulgaris*. In humans, the oral acute toxicity of *Phaseolus vulgaris* lectins is characterized by nausea, vomiting, bloating, and diarrhea [121]. The legumes' lectins are not always as toxic, and several species express moderate agglutinating effects. Finally, oral administration of certain lectins such as those from *Phaseolus vulgaris* were found to induce immunoglobulin (Ig)E-mediated reactions, and sometimes simultaneously with IgG-mediated reactions [112, 122]. These phenomena take part into the allergic reactions observed in human with several edible pulses. This will be detailed later.

4.3.5 Lipoxygenase

Lipoxygenases are non-heme, iron-containing enzymes widely distributed in plants, fungi, and animals [123]. These enzymes catalyze the dioxygenation of polyunsaturated fatty acids PUFAs into cell signaling agents used as autocrine, paracrine, or endocrine signal molecules. Multiple lipoxygenase genes were identified in plants (at least eight in soybean, *Glycine max*), in animals (at least seven in the mouse), and in humans (five pseudogene characterized) [123]. Their importance is not correlated to their concentration, and cellular effects are now known to be crucial. In plants, lipoxygenases can be found in all organs. In plants, these substances have been shown to have a role in the vegetative growth, wounding, herbivore, and pathogen attack responses and also in mobilization of storage lipids during germination [124]. The role of lipoxygenases in plant defense mechanism was shown to be due to their implications in the synthetic metabolism of signal molecules such as Jasmonic Acid and their methylated parent compounds in sorghum [125], in arabidopsis attacked by aphids [126] or in the pulse *Pisum sativum* [127]. Lipoxygenase (Lox) enzymes play a role in the development of unpleasant flavors in foods containing legumes by oxidation of polyunsaturated fatty acids. This is particularly true for soybean which contains significant levels of these substances [128]. The action of lipoxygenase is thus deleterious to the palatability of legumes rich in fatty acid such as soy or peanut and these enzymes can therefore be considered as anti-nutritional factors.

4.3.6 Saponins

Saponins constitute a class of glycosides found essentially, but not exclusively, in plants. These substances include a steroidal or triterpene aglycone linked to one, two, or three saccharide chains. The carbohydrate chains can vary in size and complexity via ester and/or ether linkages (Fig. 4).

The most common sugars linked to the sapogenin moiety are galactose, arabinose, xylose, and glucose. Saponins express amphiphilic properties thanks to the lipophilic and lipophobic characteristics of the aglycone and carbohydrate moieties, respectively. Saponins occur in numerous edible plants, including legumes (soya, peas, and beans), root crops (potato, yams, asparagus, and alliums), or medicinal herbs (ginger). In grain legumes, saponin contents vary between 0.5% and 5% dry weight, with soybean exhibiting the highest rate (5.6%) [129]. *In vitro*, saponins were shown to inhibit, carrier-mediated galactose transport but not that of L-glucose [130]. Polyethylene glycol 4000, which transfer through the endothelial barrier is known to proceed via an extracellular mechanism, is also increased *in vitro* [130]. This indicates that saponins inhibit active transport and simultaneously increase the general permeability of the enterocyte barrier. This phenomenon is observed *in vitro* at saponins concentrations ranging from 0.3 to 8 mM. Not all saponins exhibit the same potency. Therefore, it appears that some saponins are able to increase the permeability of the small intestinal mucosal cells, facilitating the uptake of substances to which the gut would normally be impermeable. This effect, occurring at rather high concentration, is likely to have *in vivo* consequences when the saponins ingestion is recurrent. These consequences may be deleterious and justify the anti-

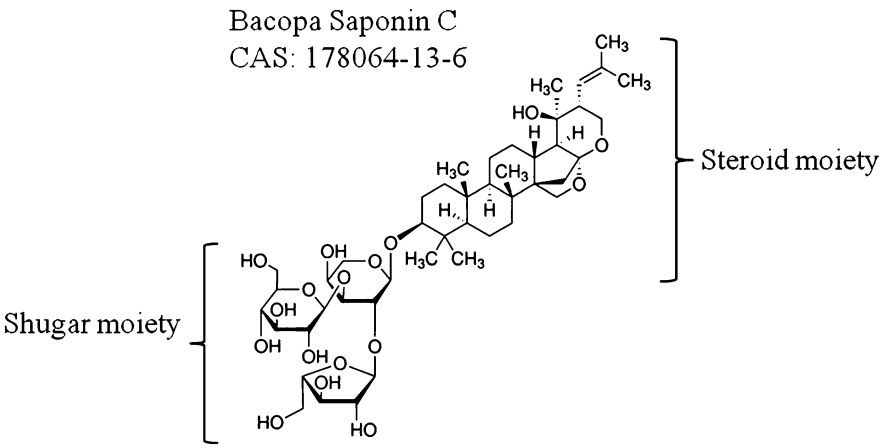

Fig. 4 An example of saponin. Here is Bacopa saponins C with its carbohydrate moiety and its steroidal moiety

nutritional status of saponins. However, saponins also exhibit anti-inflammatory, immunomodulatory and antifungal and antimicrobial activities and are protecting agents for the plants.

4.3.7 Anti-Protease Factors

Proteinase inhibitors are ubiquitously produced since their role is to regulate the proteolytic activity of their target proteinases. They are key factors in living organism interactions, and they appear essential looking at microorganisms and plants interactions, or examining microorganisms and animals interactions. They are also important in the plants and animals interactions. Therefore, many vegetables including legumes, cereals, potatoes, and tomatoes contain protease inhibitors that act on trypsin, chymotrypsin, or carboxypeptidases [92]. Maybe because of its high protein content, soybean is the richest source of dietary trypsin inhibitors and contains the Kunitz inhibitors (see Table 6) and the Bowman-Birk inhibitors [108].

The Kunitz inhibitors have a molecular weight of about 21.5 kDa with two disulfide bridges and act mainly against trypsin. The Bowman-Birk inhibitors have a molecular weight of about 8 kDa formed by 60–90 AA residues and numerous disulfide bonds. They mainly inhibit chymotrypsin and trypsin at independent binding sites. The Bowman-Birk inhibitor (BBI) family is the most widespread group in common bean (*Phaseolus vulgaris*) as well as in other legumes such as soybean (*Glycine max*) and pea (*Pisum sativum*). Variants of these two main types of inhibitors have been characterized with different amino acid sequences, electrophoretic mobility, specificity, and sensitivity to thermal inactivation. The actions of soybean inhibitors were reported to be similar in rat and humans on trypsin and chymotrypsin [129]. According to Lin *et al.* [136], Bowman-Birk inhibitors inhibit trypsin via binding with lysine or arginine at the P1 residue. Soybean, as one of the most concentrated legumes in anti-protease, has been largely studied and therefore the anti-nutritional effects of anti-

Table 6 Values of trypsin inhibitor activities in some legumes

Legumes	Trypsin inhibitor activity (mg/g)	Trypsin inhibitor activity (mg/g protein)	References
Soybean (*Glycine max*)	16.7–27.2	34.7–122.6	[131]
Pea (*Pisum sativum*)	2.7	11.9	[132]
Kidney beans (*Phaseolus vulgaris*)	4.6	13.5–62.3	[86, 133]
Chick pea (*Cicer ariterium*)	1.7–8.5	8–39.5	[134]
Cowpea (*Vigna sinensis*)	1.7	6.4	[135]

protease will be largely illustrated from data obtained on this legume. Many studies reported the deleterious effects of raw soy-protein compared to processed matters on protein digestibility and animal growth [137, 138]. Raw soybean protein preparations can cause pancreas hypertrophy and hyperplasia in susceptible animals since the exposure to soybean trypsin inhibitors results in the increased synthesis and secretion of proteases (such as trypsin, chymotrypsin, and elastase) [139]. Trypsin and chymotrypsin being rich in sulfur-containing amino acids such as methionine and cysteine, the result of this hyper-secretion is a diversion of these essential AA from the synthesis of body tissue proteins. This can result in an alteration of growth in domestic animals since soy protein is also deficient in these amino acids [140]. Direct infusion of the Bowman-Birk inhibitor purified from soybean into the duodenum of men significantly increased the pancreatic secretion of trypsin, chymotrypsin, and elastase. This effect was similar to that observed in rats [108]. Still according to Liener [108], the increased secretion of sulfur-AA-rich proteases would be due to the suppression of the negative feedback regulation of pancreatic secretion via an increased release of cholecystokinin from intestinal mucosa. This release is not only controlled by the protease secretion [141]. Because of their depressive effects on growth and protein digestibility, protease inhibitors from legumes can be considered as anti-nutritional factors. The studies earlier showed that heating and food processing can have beneficial effects on these anti-nutritional substances.

5 Food Processing

As seen above, legumes are at the same time rich in highly nutritive compounds and also in anti-nutritional factors. Their human consumption has been significantly detected during the Pre-neolithic and Neolithic periods when fire was already domesticated. Therefore, these pulses were likely to be cooked before consumption. Indeed, it can be easily demonstrated that the anti-nutritional factors detailed earlier can be partially or totally inactivated by food processing. Traditional heating, boiling, cooking, soaking, simmering, germinating, or fermenting all have been studied and were shown to improve the digestibility of the proteins in legumes. Modern practices including industrial defatting, roasting, extrusion, or

microwave cooking will be analyzed regarding their effect on anti-nutritional factors and bioactive polyphenols.

5.1 Traditional Processing

Legume seeds can be eaten raw as for chickpeas or broad beans when they are still green and at a tender stage (unripe stage) [132]. To improve conservation, legume seeds are traditionally dried to be consumed at distance of the harvest. Most farmers in developing countries naturally dry their mature beans under the sun [142]. Because seed coats contain tannins and other anti-nutritional factors, seeds are often dehulled [142]. Traditional dehulling was performed using a stone grinder and shaking the resulting grains over large flat baskets. More recently threshing, shelling, and grading of legume seeds were mechanically improved using machines [142]. After drying, seeds can be stored for several months before processing. Then two kinds of processes can be separated: the non-fermentation processes and the fermentation processes.

5.1.1 Traditional Non-fermentation Processes

These include sprouting of the fresh seeds and traditional soaking and cooking practices in boiling water. In [143], Khokhar and Chauhan studied domestic methods of processing and cooking the moth bean. Their studies included soaking in plain water, soaking in mineral salt solution, ordinary cooking of soaked seeds, sprouting, and ordinary cooking of sprouts. They described the soaking procedure as follow. After seed cleaning from broken seeds, dust, and other foreign materials, soaking was performed in tap water or mixed salt solution for 12 h at tropical temperature (24 °C). A seed to water ratio of 1:5 (w/v) was used. The unimbibed water was discarded. The soaked seeds were rinsed twice with water and then dried in air. The ordinary cooking procedure was described as follow. Presoaked seeds, after rinsing in water, were put in pans and tap water was added in a 3:1 v:w ratio. Cooking was performed for 60–90 min in water until seeds became soft when felt between fingers. Water was discarded before seeds were dried in air. Khokhar and Chauhan [143] also described the domestic sprouting procedure as follow. The soaked seeds were germinated in clean dishes lined with wet vegetal mesh for 60 h at 25 °C, with frequent watering. Sprouts were then rinsed in water and dried under the sun and cooked till soft like soaked samples mentioned above. For soybean [142], non-fermentation processes include the preparation of soy "milk," soy-cheese (*Tofu*), and soy-sheet (*Yuba*). In all cases, soybeans are cleaned and soaked in water for at least 6 h at room temperature. They can be dehulled before soaking or cooking. For soy-juice, the traditional practice usually includes a precooking step in water lasting 10–30 min. This step usually allows eliminating dust residues with the first water discard. Seeds are then crushed in the water before the final cooking step, lasting additional 10–30 min. Then the water is filtered to collect the juice. The filtered residue (Okara) can be kept for animal feeding. Tofu was traditionally prepared from the juice after cooling. Curdling agents are added to the juice. These can be calcium

chloride, calcium sulfate, magnesium chloride, magnesium sulfate, calcium acetate, or calcium lactate according to Prabhakaran *et al*. [144]. In China, calcium salts mined from mountain quarries have been used for over 2000 years [145]. In Japan, the traditional curdling agent was sea salt that contains small quantity of magnesium chloride ($MgCl_2$). The curd is then drained on a wooden frame with holes in the bottom and coated with fabric. The soybean curd is then pressed using a specific lead to squeeze out the water. This water constitutes the *tofu whey*. According to Maneepun [142], *Yuba* production is a domestic practice only performed at small scale. During thick soy "milk" prolonged cook, a film is formed at the surface. Boiling is prolonged until the sheet of film is thick enough, and then it is removed from the surface of soy "milk" by using a bamboo stick. The wet sheet is placed over a sheet of thick cloth, and air-dried by hanging. *Yuba* is used for wrapping meat and vegetable fillings in Chinese cuisine.

5.1.2 Nutritional Characteristics After Traditional Non-fermentation Processing

According to the study by El Adawi on chickpea [132], boiled chickpea seeds were not significantly different from raw peas in total protein, total amino acid, and total carbohydrate contents. Boiling significantly decreased the non-protein nitrogen, ash, and fat contents due to their diffusion into the cooking water. Crude fiber was significantly increased by boiling and or soaking associated to cooking. Water-soluble vitamins and minerals tend to leak into the water and significantly decrease in chickpeas on boiling [132]. Equally, Mubarak *et al*. [79] tested domestic processes on the anti-nutritional content of mung bean. Among them, they tested traditional cooking steps such as dehulling, soaking, boiling, and germination. They showed that the protein content was only slightly affected by soaking and boiling. All treatments significantly reduced the stachyose and raffinose content of mung bean and germination reduced it to nothing. Meanwhile, starch content was only reduced by germination. When considering the anti-nutritional factors, it appears that trypsin inhibitors and hemagglutinins were destroyed by boiling but only reduced by dehulling, soaking, or germination. Tannins and phytic acids were significantly reduced by all treatments, the most effective being germination. Polyphenols under their glycosylated form also leak into the soaking and cooking water [146] Germination of chickpea seeds resulted in a significant increase in crude protein, non-protein nitrogen, and crude fiber compared to raw seeds, while ash was not significantly affected. Germination also significantly decreased the fat and total carbohydrate contents. To be more precise, raffinose, stachyose, and verbascose were completely eliminated by germination and cooking in water for the latter. The same results were obtained on soybean sprouts [147]. According to El-Adaway [132], trypsin inhibitor activity was significantly decreased (−82%) by boiling. Sprouting was less efficient since it decreased trypsin inhibitor activity by only 34%. Hemagglutinin activity was completely destroyed by cooking and was drastically reduced (77%) by germination. This was also observed by Khalil & Mansour [148] on fava bean seeds. According to El-Adaway [132], tannins (−52%), phytic

acid (−71%), and saponins (−48%) in chickpeas were significantly reduced by simple boiling. Germination was less effective than boiling in reducing tannins and saponins but more effective in reducing phytic acid. This could be due to the phytase activity during germination. Polyphenols in legumes are generally present under their glycosylated forms and as such are soluble in water. Therefore, in all the preparation associating soaking, boiling, or simmering in water, these polyphenol concentrations can be reduced. For isoflavones, the longer the water contact the lower the remaining concentrations [149]. If the soy "milk," *Tofu,* and *Yuba* are considered, the successive soaking, cooking, and simmering in water classically included in their traditional recipes were most likely to reduce their isoflavone concentrations. This is sustained by the study by Liu et al. [150] showing that the vast majority of rural Chinese women were exposed to isoflavone levels lower than 15 mg/day when the actual exposure in modern Asian countries is usually over 20 mg/day and may go up to 120 mg/day. The estrogenic activities of isoflavones were observed at already 45 mg/day in American women [151].

5.1.3 Traditional Fermentation Processes

Legumes were fermented either traditionally or recently using several microbial strains from *Lactobacillus*, *Bacillus*, *Aspergillus*, *Rhyzopus*, *Actinomucor,* and *Saccharomyces* genders [152]. Traditionally fermented soy-food was quite numerous and still include *Natto*, *Miso*, *Tempeh,* fermented *Tofu* (*Sufu*), and soy-sauce (*Si-iu*). *Natto* is produced from soybeans cooked for 2–4 h in renewed water and dried after water discard. Beans are then wrapped in straw and seeded with *Bacillus subtillis natto*. Fermentation is prolonged for 24–48 h. Traditionally in Japan, *Miso* is made from soybean cooked in renewed water for 2 to 4 hours before grinding. Ground soy paste is then mixed with Koji (*Aspergilus oryzae*) developed on rice and/or wheat and other microbial strains together with salt and fermented in anaerobic conditions for 6–8 month. *Miso* tends to resemble the Chinese soy paste (*Tao-cheow*) [142]. *Tao-cheow* is made by incubating soybean paste with *Aspergillus oryzae* or other microbial strain like *Lactobacillus delbrulckii*, *Pediococcus halophilus*, *Saccharomyces* sp. for 3–4 months. After this first stage of *Koji* fermentation, a liquid is formed and separated for production of soy sauce. The resulting paste is packed and pasteurized and can be kept for several years with the best flavor after a year. *Tempeh* is an Indonesian soy-food prepared from soybeans rinsed and precooked 2–3 times in renewed water before being light dried and seeded with *Rhyzopus oligosporus*. Traditionally, precooked seed were packed in banana leaves and the fermentation was performed for 24–48 h at tropical temperature 24–26 °C, with high hygrometry [149]. *Si-iu* production as described in [142] includes two fermentation steps. The first stage is koji production using *Aspergillus orizae* in an aerobic solid-state fermentation for 3–4 months. The second stage is aromi fermentation by mixed cultures of halophilic yeast and lactic acid bacteria. This is an aerobic fermentation in 20–22 percent (w/v) brine solution leading to a bright reddish-brown colored sauce with pleasant aroma and salty taste [142].

5.1.4 Nutritional Characteristics After Traditional Fermentation Processing

Fermentation usually induces phytate hydrolysis because microorganisms possess phytase enzymes, which hydrolyze phytic acid into inositol phosphates [153]. This phenomenon is valuable because myoinositol phosphates with less than five phosphate groups (*i.e.*, IP-1–IP-4) do not inhibit zinc absorption [154], and those with less than three phosphate groups do not affect nonheme iron absorption [155, 156]. Microbial phytases originate either from the microflora present on the surface of legumes or from inoculates used for processing. The phytate reduction can vary and can reach −90% in soya beans, cowpeas, and lima beans. When tannins content are high, the phytase activity can be inhibited, and fermentation is less-effective. Fermentation also improves protein quality and digestibility as well as vitamin B content. Fermentation reduces adverse microbial development and improves food safety. Fermentation also produces small organic acids that improve iron and zinc absorption. This leads to lower pH and increases the activity of endogenous phytase from legume flours [157]. Ibrahim *et al*. [158] also showed in cowpea that fermentation with *Rhizopus oligosporus* dramatically reduced trypsin inhibitor activities. It was the same when fermentation was performed using a lactic acid bacteria *Lactobacillus plantarum* DSM 20205. Note that again in all recipes soya beans were traditionally cooked for long durations (2–4 h) in water and that the water was discarded. Therefore, glycosylated isoflavones were most likely eliminated with the water revealing that the isoflavone exposure probably raised dramatically in recent times in soy consuming countries where industrial processing were developed. Indeed, in industrial Asian countries, the modernization of human soy-food processing occurred 50 years ago, *i.e.*, about two human generations ago.

5.2 Modern Processing

Soy being widely used in industrial countries, either for animal or human feeding, is probably the legume which has been the most intensively processed to adapt to different people tasting and uses. New processes are still extensively developed to fit new demands [145]. As an example, food companies developed soy cakes, soy flakes, soy protein concentrates or isolates, meat substitutes proteins and extenders, and improved the quality of final products. Modern processes include high pressure cooking, autoclave cooking, microwave cooking, and extrusion. Solvent extractions are also modern processing.

5.2.1 Non-Fermented Modern Legume Products

According to Noguchi [145], modern *Tofu* is made from grade soybeans soaked overnight in water. After water discard, boiling water is poured on the beans which are pulverized into a mash. The paste is then ladled into boiling water and allowed to boil gently for about 10 min. Then the mixture is filtered to obtain “soy milk” and the residual material is called *Okara*. In Western countries, the process can be even simpler since after boiling for 1–2 min, softened soya beans are ground in cooking

water before being filtered to collect "soy milk" and *Okara*. In Japan, modern cooking of the beans were developed consisting in quick steaming at high temperature (45 seconds at 180 °C) before crushing and water addition. Subsequent filtration leads to the separation of "soy milk" and *Okara*. A small amount of either calcium sulfate ($CaSO_4$) or magnesium chloride ($MgCl_2$) from gypsum is added to coagulate "soy milk." The curds are then gently removed from the top of the whey and poured into molds lined with cloth. The containers have many draining holes in their bottom to evacuate whey. Other derivatives from "soy milk" or *Tofu* are *Yuba* (soymilk sheets) and *Shimi-tofu*. *Yuba* is made heating thick "soy milk" in pans to evaporate the water. The thin film formed on the surface of "soy milk" is then gently removed and dried. *Shimi-tofu* is prepared from soy protein curd cooled to below 0 °C. During this step, small ice crystals grow, before being thawed to expel excess water. A dried matter is then formed having a sponge-like texture named *Shimi-tofu*.

Beside these modern making of traditional products, new technologies allow producing new types of products based on legumes. The Fig. 5 summarizes the different ways followed to obtain different modern products from soy.

Soy cakes are essentially used for animal feeding. They are obtained from soy oil processing, after the oil extraction by pressing and/or using solvents like hexane. For human feeding, soy meal and oil are the most frequent soy-product, from which most other processed soy-based products derive [142]. New technologies have been introduced in the soybean industry that have and will have significant impact on farming methods, storage, and distribution of legume-based products. The industrial

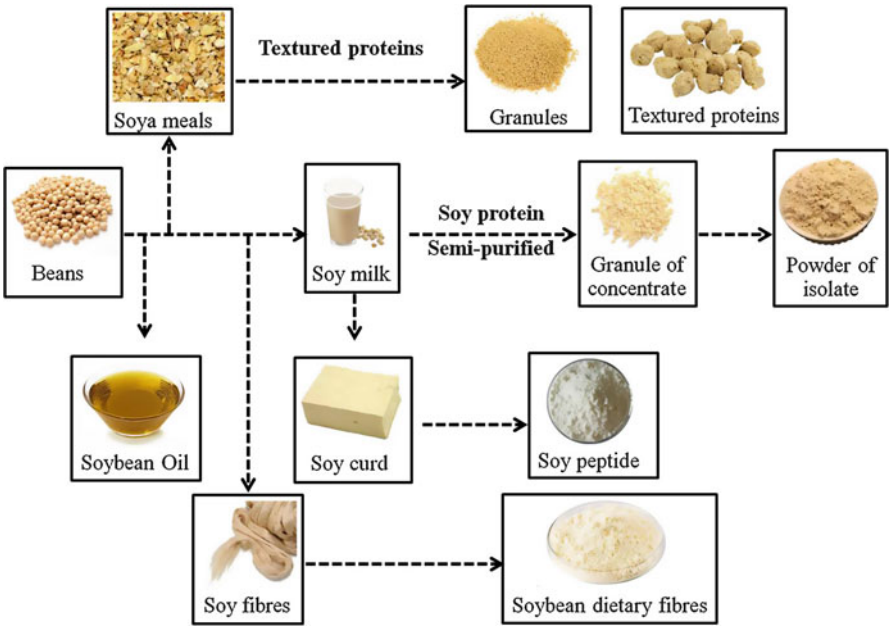

Fig. 5 Different soy-based products and their pathway of production following modern processing

processes always start with cleaning the seeds to remove foreign material. After drying and cracking into pieces, seeds are dehulled. They are heated and rolled into "flakes" before oil extraction. Oil is extracted from soybean flakes using hexane and then degummed and refined for edible and non-edible uses. The protein-rich flakes are toasted, dried, and ground in meal. Soybean meal can be mixed with corn for use in animal feeding. It is also processed into soy flour, soy concentrates, or soy protein isolates. The degumming process of soy oil gives lecithin, which is used in the candy and baking industries. Full fat soy flour from soybean is also used for baking, for soy-based beverages, snack foods, as well as for traditional foods (soy sauce, *Tofu*, and *Miso*). Texturized vegetable protein (TVP) obtained by extrusion of defatted soy flour can be found in different forms (granules, flakes, chunks, or slices). TVP has a long shelf life and can be kept at room temperature for several months. TVP should be re-hydrated with equal quantity of water and can be used as a meat substitute in processed foods (baked goods, meat products, protein drinks, soup bases, and gravies). Microwave and autoclave cooking also are modern processes which are used to prepare canned legumes.

5.2.2 Fermented Modern Legume Products

According to Nogushi [145], modern *Miso* is no more prepared from soya bean boiled for several hours in renewed water but rather from steamed beans. The process still implies long-term fermentation with *Koji* from soya, rice, or wheat and with other microorganisms. Although soy sauce still requires time to be brewed as it is for fine wines and cheeses, modern soy sauce is made from roasted wheat grains crushed and soybeans softened by steaming. A special seed starter is then added to the wheat and soybean mixture and incubated for 3 days. The resulting *Koji* is then combined with brine to form *Moromi*. *Moromi* is then fermented in large tanks until it reaches its full flavor and then pressed into fabrics to extract the raw soy sauce. The latter is then refined and pasteurized before its packaging in bottles.

5.2.3 Nutritional Quality of Legume Under Modern Processing

According to Siulapwa and Mwambungu [159], after oil solvent extraction, soybean seeds moisture is higher than that of row beans and that of extruded full-fat soy seeds. These have lower ash content when compared to raw seeds or to seed extracted with solvent. The extruded product exhibit lower fat and higher protein content than raw seeds and seeds extracted with solvent. Extrusion and solvent extraction reduce crude fibers, Ca^{++}, and phosphorous content. Both processes reduce significantly trypsin inhibitors activities. The processes increase arginine proportion while they decrease methionine. Raw seeds had lower amount of all the nonessential amino acids apart from tyrosine when compared to solvent extracted seeds and extruded seeds. In cowpea (*Vigna unguiculata*), Ibrahim and coworkers [158] showed that long-time soaking (16 h) in bicarbonate solution caused remarkable reduction in the anti-nutritional factors. Pressure cooking was more effective than ordinary cooking to remove phytates. This was confirmed by Khokhar *et al.* [143] on moth bean (*Vigna aconitifolia*) cooked under pressure after soaking in mineral salt solution. Finally, El Adawi [132] showed on chickpea (*Cicer arietinum*)

that microwave cooking reduced non-protein nitrogen, ashes, fibers, and oligosaccharides but had no significant effect on total protein and carbohydrate content including starch. In their study, they also show that this process also significantly reduced trypsin inhibitors and hemagglutinin activities as well as tannins, saponins, and phytic acid. Chickpea autoclaving led to the same reduction of anti-nutritional compounds except for trypsin inhibitors for which it was shown to be more efficient. However, both cooking processes significantly depressed the B vitamins content (Riboflavin, Thiamin, Niacin, and Pyridoxine) sometimes at rates over 50%. Minerals including Na, K, Ca, Mg, P, Mn, Zn, Cu, and Fe tend to leak into the water while boiling. However both microwave and autoclave cooking tend to better preserve their concentrations compared to other practices. These results were remarkably confirmed by Mubarak [79] while working on mung bean seeds (*Phaseolus aureus*). The effect of fermentation was studied in beans (*Phaseolus vulgaris*) [160]. The parameters followed were anti-nutritional factors (α-amylase inhibitor, chymotrypsin inhibitor, cyanogenetic glycosides and lectins) and also fibers (total dietary fiber -TDF-, insoluble -IDF- and soluble -SDF-). Beans were treated by natural and lactic acid fermentation. Autoclaving was added or not after the fermentation process. All treatments decreased the SDF content, while the IDF content were not modified in processed beans. Cellulose content was reduced by treatments and resistant starch increased in processed beans, except after lactic acid fermentation. Fermentation with *Lactobacillus plantarum* increased pectic polysaccharides and Klason lignin. Microorganisms reduced the solubility of dietary fibers. According to Noguchi [145], cooking soybean mash for *Tofu* and "soy milk" in water for at least 10 min before filtering "soy milk" is crucial since anti-nutritional enzymes of the beans are inactivated during boiling. This is confirmed by Chen and co-workers [161] who showed a progressive decrease of trypsin inhibitor activities (Kunitz and Bowman Birk factors) in "soy milk" with or without added salt. In their experiments, 10 min cooking approximately decreased TI activities between 40% and 30% of their initial value. One hour cooking reduces it between 20% and 15% of the initial value. However, not all modern processing of "soy milk" and *Tofu* especially those developed in the West include such step. Consequently, it has been shown in 1997 in Japan [162] that soybean products retain 2.5–12.5% of the initial trypsin inhibitor activity of the whole soybean and that "soy milk" is the food which is the most concentrated. Thus humans are consuming some active trypsin inhibitor in their daily lives. In [163], the phenolic composition of mung beans (*Vigna radiata*) and yellow soybeans (*Glycine max*) were followed under soaking and fermentation using *Lactobacillus plantarum* CECT 748 T. It was shown that soaking induced leaking of conjugated isoflavone for soybeans and increased apigenin derivatives in mung beans. On the other hand, fermentation converted glycosylated isoflavones of soybean into bioactive aglycones and increased the bioactive vitexin in green beans. These data are, in accordance with those from Fernandez-Lopez *et al.* [149], showing that glycosylated isoflavones tend to be progressively removed from soybean matrices during prolonged cooking and simmering in water. These steps were included in soybean traditional recipes. However, nowadays, modern processes tend to replace boiling in water by steaming and

cooking times and contacts of seeds with water were dramatically reduced in modern practices. In addition, extruded soy still contain high amount of isoflavones although they tend to be deglycosylated during the extrusion process [164]. This means that isoflavone exposure of soy-consumers was considerably lower in ancient times than it is nowadays when people consume modern processed soy-products. Because of their estrogenic effects, isoflavones tend to reduce the fertility of the soy consumers (animals and most probably humans) and can therefore be considered as anti-nutritional factors. In addition, the modern environment contains many other endocrine disruptors of anthropoid origin which can act synergistically with isoflavones on reproduction or estrogen-dependent tumor growth [165]. Isoflavone can also exert beneficial effects on several health end-points (bone preservation, prostate cancer protection, breast cancer occurrence, hot flashes relief...) and should be kept for specific health application for specific consumers [149, 166].

6 Allergy

Food allergies are adverse reactions to a harmless food that occur when the immune system reacts to proteins normally present in food without any incidence and that are recognized as foreign substances in some individuals. Then, the immune system triggers a response to neutralize them. Allergic responses vary from person to person and a protein may be allergenic in one individual but not in others. Nowadays, according to Verma *et al*. [167], eight foods or food groups account for over 90% of food allergies (peanuts, soybeans, cow's milk, hen's egg, fish, crustacean, wheat, and tree nuts). According to Maria John *et al*. [168], soybean is listed among the eight first allergenic diets for humans and animals due to the presence of many kinds of allergens whose action can be amplified by the presence of other anti-nutritional factors. Overall, allergenic events recorded after consumption of legumes in decreasing order of frequency may be peanut (*Arachis hypogaea*), soybean (*Glycine max*), lentil (*Lens culinaris*), chickpea (*Cicer arietinum*), pea (*Pisum sativum*), mung bean (*Vigna radiata*), pigeon pea (*Cajanus cajan*), and lupine (*Lupineus alba*). This takes into account both the allergenic power and the overall consumption at world scale. In Spain in 2015, [169] reported that among 455 adults, the prevalence of legumes allergy was 6.9% (77% women). Legumes involved were: lentil 27% of episodes; bean, 19%; peanut, 16%; soybean, 14%; chickpea, 13%; pea, 8%; and mungo bean, 3%. Anaphylaxis due to food allergies has a prevalence of about 6–8% in children and 4% in adults [167].

6.1 The Proteins of Food Allergies

Food reactions can be classified into three groups: the non-immunologic reactions and the immunologic reactions that can be subdivided again according to the type of reaction involved. The non-immunologic reactions include food intolerance or gluten sensitivity whereas immunologic reactions can either induce immunoglobulin

E (IgE)-mediated symptoms or non-IgE-mediated gastrointestinal symptoms. These phenomena mostly occur early in life, and food allergy frequency usually decreases with age. Legumes usually provoke IgE-mediated reactions. These reactions occur because foreign antigens have been able to stimulate the antigen-presenting cells at the gut level. This means that proteins were able to resist to food processing and then to gastric degradation by local acid and protease. The antigen presenting cells then process the antigens and present them to the Major Histocompatibility Complex (MHC). This activates naive CD_4^+ lymphocytes of the Th_2-type.

These immune cells secrete IL-4 and IL-13, which promote specific IgE secretion by plasma cells. This leads to the IgE antibodies to bind to mast cells. Re-exposure to the same food antigens causes the antigen-IgE antibodies complex to bind to mast cells. This directly provokes mast cells degranulation and release of histamine. Histamine and other mediators (prostaglandin D2, and cysteinyl leucotriene) can provoke vasodilatation, smooth muscle contraction, and mucus secretion that all lead to development of allergenic symptoms [170]. As mentioned earlier, allergenic proteins share common physicochemical and immunological properties. Class 1 food allergens such as legume allergens are stable in gastric fluid; their molecular mass range between 10 and 70 kDa; they are water soluble glycoproteins and can lead to sensitization via gastrointestinal tract [171]. Class 2 food allergens are sensitive to heat and to gastric acid and enzymes, thus sensitization does not occur via oral route. By means of IgE cross reactivity, they can cause allergenic response in people sensitized via inhalant allergens like pollen [172]. The dose of exposure does not seem to be related to either the sensitization process or to the allergenic susceptibility. Less than one microgram levels can induce an allergenic reaction [167] even if some authors report that the minimal level of exposure is over 500 μg of protein but not below this [173]. Glycosylation contributes in the allergenicity of a protein and it seems that the glycan moiety can also interact with IgE antibodies. The structural features of the proteins which are responsible for their allergenic properties are still difficult to predict. In the case of legumes, during digestion, allergens lose conformational form and exist as linear epitopes and sensitized individuals via gastrointestinal tract [67]. To summarize, the legume allergens resist to gastric fluid and proteases, they are heat stable and are glycosylated proteins. They present epitopes that bind to IgE. These can be linear epitopes remaining after food processing and gastric attack, they induce biologically active reactions.

6.2 Main Allergens from Legumes

Several classes of proteins have been involved into legume allergy. These are storage proteins which are considered to be stable to heat and to gut enzymes. Associated to anti-nutritional compounds such as saponins or hemagglutinins, they can cross the gut barrier and can induce immune response. Storage proteins presented earlier in this review are primarily localized in the seed, nut, or kernel. They are classified in Cupins, Prolamins, Pathogenesis Related proteins (PR-proteins), and Profilins.

6.2.1 Cupins Superfamily

The cupins superfamily share two conserved consensus sequence and a β-barrel core domain. Cupins include allergenic seed storage proteins of the vicilin and legumin family. These storage proteins are present in several legumes known for their allergenic properties, *i.e*., soybeans (Gly m5, Gly m6), peanuts (Ara h1, Ara h3), lupine (Lup a), pea (Pis s1), and broad bean (Vign r2, Vign r3).

6.2.2 Prolamin Superfamily

The prolamin superfamily is widely distributed among plants and not only in legumes. Prolamins include cereal seed storage proteins, several important types of allergens from legumes, tree nuts, cereals, fruits, and vegetables. This family includes chickpea allergens (Cic a2S Albumin), which is a 2S protein. It also includes the nonspecific lipid transfer proteins, the cereal alpha-amylase, and some protease inhibitors.

6.2.3 Pathogenesis Related Proteins (PR-Proteins)

PR-proteins stand for more than 10 different types of protein which increase in plants in response to environmental stresses or pathogens. PR-proteins are generally small in size, stable in acidic conditions, and resistant to proteolytic degradation. In legumes, some allergenic proteins were shown to belong to this category such as Vig r1 from mung bean, Ara h8 from peanut, and Gly m4 from soybean.

6.2.4 Profilins

Profilins are small proteins from 12 to 15 KDa. They are found in the cytoplasm of eukaryote cells and therefore they exhibit highly conserved sequences. Plant profilins are involved in a large proportion of cross-reactions between allergenic sources and especially in cross-reactions with pollens. As Class 2 allergens, they are considered to affect 10%–35% people in Europe. Some identified profilin-related legume allergens are Ara h5 from peanut and Gly m3 from soybean.

6.3 The Identified Allergens

In [167], Verma et al. gave a comprehensive table with the allergens from legumes which were known in 2012. In addition, main legumes are classified according to their decreasing importance of allergenic effects (frequency and severity) together with the number of known allergens in Fig. 6. In 2016, Bouakkadia et al. [174] completed the list that was increased to 15 allergens in peanuts, to 14 substances in soybean, and to 4 different compounds in lentils.

6.4 Effect of Food Processes on Allergen Proteins

Verma *et al*. in [175] published a comprehensive review and table showing the impact of different food processes on the inhibition of legume proteins playing as

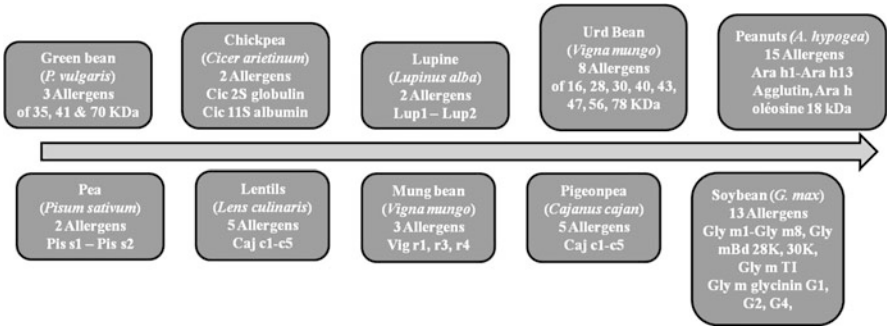

Fig. 6 Classification of the main legumes according to their increasing allergenic properties. The known allergens are mentioned for each pulse

food allergens. They classified the processes into four major categories: roasting, boiling, autoclaving, microwave heating. They reviewed the main allergens from peanuts (*Arachis hypogea*), soybean (*Glycine max*), lentils (*Lens culinaris*), lupine (*Lupinus alba*), pea (*Pisum sativum*), French bean (*Phaseolus vulgaris*), chickpea (*Cicer arietinum*), and mung bean (*Vigna mungo*). The effect of cooking has to be tested since it is not easy to predict. In some cases, cooking practices lead to elimination of the epitopes and to a reduction of the IgE reactivity. In that case, food processing affects the structural and allergenic properties of allergens by altering their stability or other physicochemical properties. On the opposite, in other cases, there is an increase of immunoreactivity of the antigens which leads to a higher IgE reactivity, a greater release of histamine and other mediators to finally increase the allergenic response. This can be explained since three-dimensional structures of proteins are generally correlated with their activity. Different temperature treatment can induce variable changes in protein structure. As an example, when heated at 70–80 °C, proteins lose their secondary structure whereas at 80–90 °C, new bonds and rearrangements of disulfide bonds can occur. At higher temperature (90–100 °C), protein aggregates can be formed [176]. Over 100 °C, new bonds between lysine residues and other substances may be created leading to the formation of adducts [177]. Protein digestibility and absorption usually increases with heat treatments. However, in some cases, thermal processing may also lead to formation of neoantigens that were not originally present and that can enhance the allergenic response. These neoantigens can result from the Maillard reaction, of protein with sugar residues upon heating. From the review of Verma *et al*. [175], it appears that boiling and autoclaving are overall good ways to reduce or to eliminate allergens although these procedures were not always efficient especially during short treatments on lentils, lupine, or French beans allergens. It should be noted that the traditional recipes which included prolonged cooking or simmering in water were empirically designed to get rid of anti-nutritional factors but can also be considered as efficient on allergens. Finally it can be summarized the following elements: Microwave heating is efficient in reducing soybean allergens but not lupine allergens. Autoclaving was reported to decrease the allergenicity of lentils, pea, chickpea,

lupine, and peanuts. Boiling is efficient in reducing the immune reactions of peanuts, mung bean, chickpea, and soybean antigens but the duration of the treatment is crucial and generally as to be prolonged for better efficiency. Roasting decreases mung bean allergenicity but increases that of peanut. As a consequence, food processing should be taken into account while comparing the prevalence of allergic reactions to various legumes over different world regions.

7 Conclusion

Proteins from legumes are undoubtedly of remarkable nutritional interest although they are better combined with cereal proteins to cover the animal food requirements. These combinations are known to exist since the domestication of crops anywhere human civilizations developed. Therefore, considering the actual expansion of the human population, pulses can be considered as a solution for future sustainable nutrition. Their ability to fix and enrich the soils in nitrogen as well as their capacity to produce protective and signal molecules to prevent or face pest attacks give them advantages when phytochemical treatments are due to be reduced. However, if these invaluable plants reached our modern times, it is because they also manage to protect themselves from their natural predators. Therefore, co-evolution of plants with microorganisms, insects, and herbivores along the geological times conducted to the intrinsic production of many different defensive substances some of which can be considered as anti-nutritional factors. These factors being essential for the plant growth and survival, genetic improvement should respect them for better field production rates. Therefore, the removal of these factors, which were developed by the plants to be detrimental for their consumers, can only be achieved at the transformation level. Future food processing methods will have to be imagined to reduce these anti-nutritional factors as economically as possible for both environment and market. Lessons should be taken from the ancient times and from the traditional practices and recipes used as early as the domestication of legumes started. Crossing different data obtained from modern practices or from those developed in the past, it appears that the traditional food processes, being essentially wet, managed empirically or not to eliminate most of the deleterious compounds including phytoestrogens, anti-nutritional substances, and allergens.

Contents

Abstract

Bioactive food components or functional foods have recently received significant attention because of their widely advertised positive effects on health beyond basic nutrition. Soybean, a leguminous crop native to East Asia, is renowned for

high protein and often used to replace the animal proteins in an individual's diet, due to fact that is only vegetable food contains all the essential amino acids. Therefore, FDA authorized a health claim for soy protein that 25 g of soy protein per day may reduce the risk of heart disease. Besides, soybean comprises isoflavones, phytosterols, saponins, and other basic nutritive constituents, such as lipids, vitamins, minerals, oligosaccharides, and biological active peptides, that are of strong therapeutic values. The potential health benefits of soybean/soy bioactive components include protect heart health, anticancer, reduce the effects of menopause, promotes bone health, improve metabolism, and decrease the risk of diabetes. Fermentation is considered as one of the best means to eliminate unpleasant beany flavors, which limit the wide consumption of soybean. Soy isoflavones appear to have estrogen-like activity because they structurally resemble to estrogen and bind to estrogen receptors. Daidzein, genistein, and glycitein are three major glycosidic forms of isoflavones found in soybeans responsible for most of health benefits. Soy bioactive peptides are specific fragments of major soy proteins β-conglycinin and glycinin, and they can be released by enzymatic hydrolysis, food processing, and/or fermentation. Apart from that, saponins derived from soybean appear to have strong cancer inhibitory properties. Moreover, several experimental trials revealed the ability of soy phytosterols to lower cholesterol. In spite of remarkable biological functions of soy bioactive compounds, their large-scale production and commercialization are limited. Therefore, there is much required need to emphasize large-scale production, mechanism of action, and bioavailability of these components. Henceforth, this chapter comprises the current scenario and future prospective of major soy bioactive compounds and their associated health benefits.

1 Introduction

Soybean (*Glycine max*) is considered one of the widely consumed legume crops in the world. Usually, soybean seeds consist of about 36.5% protein, 19.9% lipids, 30% carbohydrates, and 9.3% dietary fiber. Soybean has the highest Protein Digestibility Corrected Amino Acid Score (PDCAAS) among legumes, indicating that soy protein provides most of the amino acids required for human nutrition [1]. Soybean has been regarded as an important protein source for Eastern people. The recent knowledge of soy nutritional and functional properties has considerably increased the interest and consumption of soy products in the Western world. The consumer is looking for more nutritious and healthy products, concerning with the consequences of his/her food choices and life styles. Several studies have demonstrated the associated advantages of the use of soy products in preventing heart disease, obesity, blood cholesterol, cancer, diabetes, kidney disease, osteoporosis, blood pressure

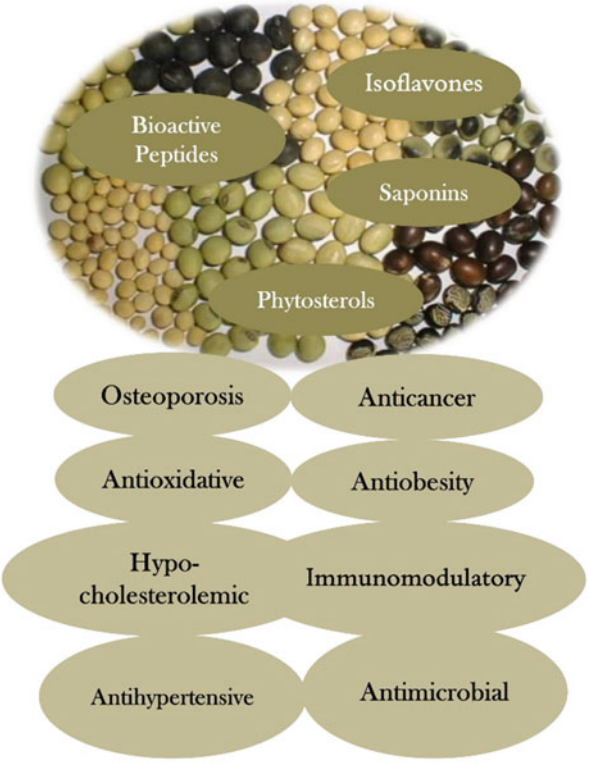

Fig. 1 Soybean bioactive components and associated health benefits

regulation, and menopause symptoms. Soybean and soy-based products contain phytochemicals such as isoflavones, saponins, phytosterols, and bioactive peptides that promote health (Fig. 1) [2]. Food and Drug Administration (FDA) authorized "Soy Protein Health Claim" on October 26, 1999, that 25 g of soy protein a day may reduce the risk of heart disease. Since then market is very much responsive to this health claim and soy foods had penetrated rapidly into Western cultures and diets [3]. Nutritional supplements based on soy (*Glycine max* L.) extract are a rapidly growing segment in the food and health care market [4]. Soy also benefits bone health, which is a concern for aging people [5]. The types of soy products available in market include soy-based cheeses, tofu, soy yoghurt, soy ice cream, soy sauce, and soy vegetable burgers. Also soybean flour, soybean concentrates, and isolated soy proteins are some of ingredients used in the food industry.

Although soy-based foods provide a range of health benefits to consumers, the consumption of soy milk or other soy-based products is hindered due to the presence of unpleasant off-flavors in soybeans. These characteristic flavors are caused by *n*-hexanal and pentanal, which occur in beans as a product of breakdown of unsaturated fatty acids [6]. In addition to these aldehydes, various oligosaccharides including raffinose and stachyose present in soybean may cause a gastrointestinal discomfort to consumers [6, 7]. Raffinose and stachyose are α-galactosides

comprising three and four monomeric units respectively, and are nondigestible in the gut due to the absence of α-galactosidase in the human intestinal mucosa. Consequently, intact oligosaccharides pass directly into the lower intestine where they are metabolized by bacteria that possess this enzyme, resulting in the production of gases [8]. Fermentation is one of the best ways to eliminate such problem and also to improve the acceptability. Fermentation improves the bioavailability of isoflavones, assists in digestion of protein, provides more soluble calcium, enhances intestinal health, and supports immune system. Moreover, nowadays, soy milk has been emerging as an interesting alternative to dairy products for lactose-intolerant population because it is free from lactose. Also, soybeans are less expensive and more abundant than bovine milk, and do not contain cholesterol [9].

Soybeans comprise the highest concentration of isoflavones among all plant foods. The associated health benefits of isoflavones include cancer prevention, reduced risk of osteoporosis, valuable role in chronic renal disease, and protection against cardiovascular disorders. Besides isoflavones, phytocompounds such as phytosterols and saponins have anticancer, hypocholesterolemic, and immunostimulatory activities in human beings. Soy bioactive peptides are specific fractions of soy proteins which have beneficial effect on living organisms. Usually, biological activities of soy peptides are encrypted in proteins, once they released from their parental proteins through hydrolysis, they may influence the major body systems such as cardiovascular, digestive, nervous, and immune. Henceforth, this chapter comprises the current scenario of major bioactive compounds of soybean and their potential health benefits. Future prospective in the field of soy bioactive molecules as technological and functional properties has also discussed.

2 Soy Isoflavones

Isoflavones are a group of naturally occurring heterocyclic polyphenols mostly found in soybean. They are present in soy and soy-derived products such as soy milk, meal, sauce, and tofu, both as free aglycones and as conjugates. Isoflavones are also known as phytoestrogens because they are found in plants and appear to have estrogen-like activity. They are structurally similar to estrogen and bind to estrogen receptors. Interest in soy isoflavones has increased in recent decades, due to their potential preventive activity against human chronic diseases, such as cardiovascular disease, cancer, osteoporosis, menopausal symptoms, and cognitive function [10–12]. Twelve isoflavones have been reported to be present in soybean, consisting of four chemical forms with each form having three compounds, such as malonyl-β-glucoside, acetyl-β-glucoside, and aglycones [13]. Three major groups of isoflavones found in soybeans are genistein, daidzein, and glycitein [14]. Isoflavones generally exist in soybeans and soy foods as aglycones (daidzein, genistein, and glycitein), β-glycosides (daidzin, genistin, and glycitin), acetylglycosides (6″-O-acetyldaidzin, 6″-O-acetylgenistin, and 6″-O-acetylglycitin), and malonylglycosides (6″-O-malonyldaidzin, 6″-O-malonylgenistin, and 6″-O-malonylglycitin) (Fig. 2) [15].

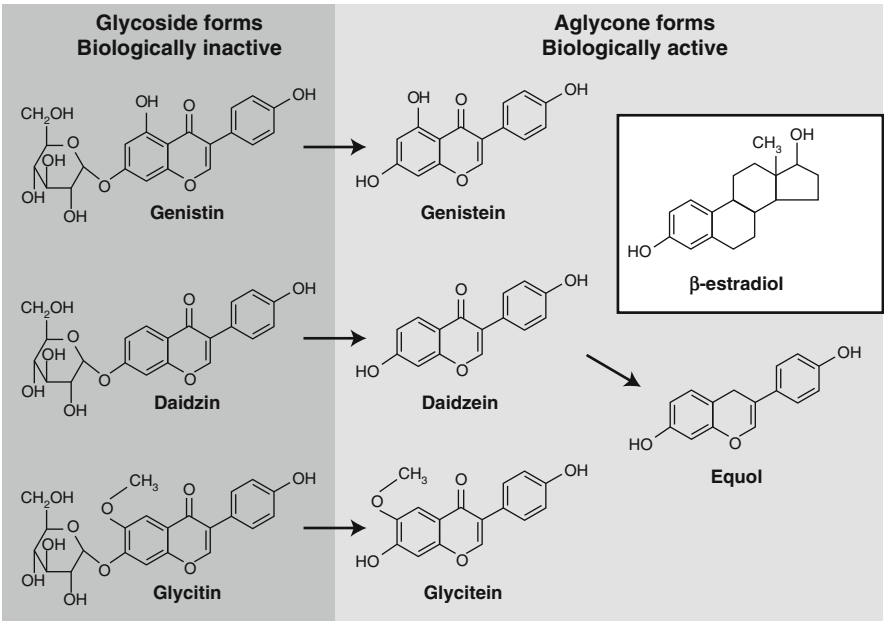

Fig. 2 Molecular structure of isoflavones. Isoflavones presents in a biologically inactive glycoside form (genistin, daidzin and glycitin) in soybean. β-Glucosidases cleave the glucosyl residue and generate biologically active aglycones form (genistein, daidzein, and glycitein) of isoflavones during digestion. Daidzein can be further metabolized into equol

The bioavailability of isoflavones can be influenced by their chemical form in foods and the susceptibility to degradation during heating [16]. Genistein and daidzein, in soybean, are mainly present in the form of their glycosides. Thereafter the consumption of soybeans or soy-based food products, intestinal microorganism's hydrolyzed isoflavones to its unconjugated form i.e., daidzein, genistein and glycitein which are more estrogenic and have better bioavailability [17]. Moreover, equol is a byproduct of bacterial metabolism of daidzein. Equol is reported to have more potent estrogenic activity, greater affinity for estrogen receptors, unique antiandrogenic, and antioxidant activity [18]. Earlier studies have documented that malonyl genistin is the most abundant form of isoflavones in soybean, followed by malonyl glycitin, daidzin, daidzein, genistein, and glycitin. It is generally believed that isoflavones hydrolyzed glycosides to their corresponding aglycones prior to gastrointestinal absorption. Isoflavones when ingested are metabolized extensively in the intestinal tract, absorbed, transported to the liver, and undergo enterohepatic recycling. Intestinal bacterial glucosidases cleave sugar moieties and release the biologically active isoflavones, daidzein, and genistein. These active isoflavones can be further biotransformed by bacteria to the specific metabolites, equol [19], desmethylangolensin, and p-ethylphenol [20]. All these phytoestrogens are then eliminated, mainly by the kidney, and therefore share the physiological features and behavior of endogenous estrogens [21].

2.1 Soy Isoflavones for Women Health

Ingestion of isoflavones containing soybean foods has reported as an alternative for hormone replacement therapy for post-menopausal women. Several epidemiological evidence suggest that isoflavones are beneficial for breast cancer and osteoporosis. Osteoporosis is an age-related disorder that affects most of the aged population in the world [22]. Osteoporosis most often occurs after menopause in women, when the ovaries stop producing estrogen. Soy isoflavones have the potential to overcome bone-specific effects, and evidence from epidemiologic studies supports that dietary isoflavones reduced osteoporotic bone loss induced by menopause through decreasing the bone resorption and stimulating the bone formation. Isoflavones can act as an antiresorptive and bone-sparing agent in preventing osteoporosis. The phenolic rings in their structures are critical structural elements to bind estrogen receptors (ERs) and exert estrogen-like effects [23]. Animal studies, as well as double-blind placebo-controlled trials in humans, suggest that genistein can help restore bone protection [24]. In contrary, the ingestion of high concentrations of isoflavones has reported to adversely affect the reproduction in several animal species. Daily ingestion of soy products has been reported to lengthen the menstrual cycle and suppress the usual midcycle surge in pituitary gonadotropins in premenopausal women [25].

2.2 Soy Isoflavones as Anticancer

The bioactive forms of isoflavones, especially the aglycones, have benefits against cardiovascular diseases and cancers and function by acting as antiestrogens [26]. Breast cancer is the one of most frequently diagnosed cancer in female worldwide and occurs as an interaction of genes and diet. It has been reported that the consumption of phytoestrogens enriched soy food/soy products is traditionally high in Japan, where the annual breast cancer incidence rate is only 0.033%, whereas this figure reached to 0.08% in Western European countries and in the USA, where people consumed less soybean [27]. Genistein and daidzein, two principal components in soy products, have been focused nowadays for their role in cancer prevention. Genistein is a well-known tyrosine kinase inhibitor [28] and inhibits topoisomerase and angiogenesis. Additionally, isoflavones have been thought to act as anticancer agents in part by their ability to scavenge oxidants involved in carcinogenesis. Genistein, which possesses weak estrogenic activity, has been shown to act in animal models as an antiestrogen and, therefore, may play a protective role in hormonally influenced cancers, such as breast cancer. Studies have shown that injection of the isoflavone daidzein reduced *N*-methyl-*N* nitrosourea-induced mammary carcinogenesis by approximately 20% [29]. These findings highlight the importance of daidzein as an anticancer agent and may offer therapeutic potential against colon cancer. Moreover, there are also many reports about the protective effect of soy against oxidative stress, which can also lead to numerous disorders, e.g., neurodegenerative conditions, chronic inflammation, and cancer [30]. An in vitro study on human intestinal Caco-2 cells revealed that

genistein, daidzein, and equol are able to reduce LPS-induced inflammatory responses from intestinal cells, interfering with NF-kB dependent molecular mechanisms [31].

2.3 Soy Isoflavones for Cardiovascular Disease (CVD)

In vitro investigations have demonstrated the hydrogen-donating abilities of isoflavones and metabolites, inhibition of lipid peroxidation, and the ability to interact with the oxidants such as hypochlorous acid and peroxynitrite [32]. Cell culture studies suggest that isoflavones may enhance the cellular antioxidant network by increasing metallothione in mRNA levels, inhibiting peroxynitrite-mediated LDL oxidation by delaying tyrosine nitration [33], and activating glutathione peroxidase [34] (thereby increasing levels of cellular reduced glutathione) or inhibiting superoxide production, and thus cell-mediated LDL modification [35]. A number of studies have shown that the consumption of soy is antiatherogenic, and the bioactive components in this regard are the isoflavones [36–38]. These polyphenols have the potential to scavenge lipid-based peroxyl radicals, and it is possible that the prevention of lipid peroxidation is an important mechanism underlying the protective effects of soy consumption. This contention is supported by the inhibition of copper-dependent LDL oxidation by addition of purified forms of the isoflavones, genistein, daidzein, and biochanin [39]. It has also been reported that genistein can inhibit LDL oxidation, which plays a potential role in atherosclerosis [40], by scavenging reactive oxygen species (ROS) or blocking generation of ROS involved in numerous pathological events. The shift of LDL particle size to a larger, less atherogenic pattern as a result of soy protein consumption and improvement in endothelial function independent of lipoprotein changes represent two other potential soy-mediated protective mechanisms [41, 42].

2.4 Soy Isoflavones for Diabetes Mellitus

Isoflavones content in soy foods possess antioxidant activity and α-glucosidase inhibitory activity, which have proved effective in the treatment of type 2 diabetes mellitus through lowering of the blood glucose level [43]. Similarly, Lee [44] reported that genistein and soy protein isolate contribute to alleviating the adverse effect of diabetes mellitus by enhancing the lipid metabolism as well as the hepatic antioxidant defense system. Genistein and soy protein isolate supplements may be beneficial for correcting the hyperglycemia and preventing diabetic complications. However, their mechanism of action is yet to be elucidated. A well-controlled study on 32 postmenopausal women with type 2 diabetes documented beneficial effect with high isoflavones soy protein supplement. The high isoflavones soy protein supplement has significantly reduced fasting insulin and insulin-resistance values in this population [45].

2.5 Soy Isoflavones as Antimicrobial Agent

The antibacterial activity of flavonoids against *S. aureus*, including antibiotic-resistant strains, and *S. epidermidis* has been reported by Harborne and Williams (2000), and there is an increasing interest in the use of plant flavonoids for treating human diseases [46]. The prokaryotic type II topoisomerases (DNA gyrase and topoisomerase IV) are targets for broad-spectrum antibiotics [47]. Genistein is a topoisomerase II inhibitor and has been shown to stimulate topoisomerase IV-mediated DNA cleavage in *E. coli* [48]. In addition, genistein inhibits the release of inflammatogenic substances by activated macrophages [49] and neutrophils [50], thereby contributing to the downregulation of inflammatory responses. According to Verdrengh and coworkers, genistein may represent a new type of antistaphylococcal agent, whose activity appears to involve the stabilization of the covalent topoisomerase II-DNA cleavage complex [51].

3 Soy Bioactive Peptides

Bioactive peptides can be defined as a specific fragments of proteins that have positive impact on body functions or conditions and may ultimately influence health [52, 53]. Mellander [54] was the first to suggest that casein-derived phosphorylated peptides enhanced vitamin D–independent bone calcification in rachitic infants [55]. Numerous bioactive peptides from different sources having various biological functions have been identified since the first observation of bioactive peptides. Soybean is economically the most important source of vegetable protein for millions of people and a potential source of bioactive peptides. Besides, bioactive peptides have been isolated and characterized from other food protein sources, including milk, egg, fish, oyster, cereal, and radish seeds [56–58]. Soybeans, an excellent source of dietary peptides, have antihypertensive, anticholesterolemic, and antioxidant activities, and appear to prevent cancer [59, 60]. Soybean contains around 40% of protein, and the major soy proteins are known as β-conglycinin and glycinin, which account for 65–80% of total proteins [61]. β-Conglycinin and glycinin are the precursor of most of the peptides isolated from soy bean [62]. Several peptides have been isolated, purified, and characterized from soybean having ACE-inhibitory, antioxidant, anticancer, immunomodulatory, hypocholesteromic, antibacterial, and insulin-modulating activities (Table 1) [67, 78–81].

It has well established now that bioactive peptides can be produced from different food proteins by enzymatic hydrolysis during gastrointestinal digestion and by fermentation of food [52]. Enzymatic hydrolysis has been recognized as one of the most common method for bioactive peptide production. Single and/or multiple specific or nonspecific proteases, i.e., pepsin, bromelain, trypsin, chymotrypsin, and papain, can be used efficiently for bioactive peptide production [82, 83]. Many bioactive peptides have been experimentally generated using various commercial proteases [84]. These enzymes are also used in combination to release more effective and stable bioactive peptides [85]. In addition, several enzymes of plant

Table 1 List of some potential bioactive peptides derived from soybean/ soy based products

Peptides sequences	Biological effects
Val-Pro-Pro	ACE inhibitory [63, 64]
Ile-Pro-Pro	ACE inhibitory [63, 64]
Thr-Pro	ACE inhibitory [63]
Ala-Phe-His	ACE inhibitory [55]
Ile-Phe-Leu	ACE inhibitory [65]
Trp-Leu	ACE inhibitory [65]
Ile-Ile	ACE inhibitory [66]
Ile-Phe-Tyr	ACE inhibitory [66]
Leu-Phe-Tyr	ACE inhibitory [66]
Phe-Phe-Tyr-Tyr	ACE inhibitory [66]
Tyr-Val-Val-Phe-Lys	ACE inhibitory [67]
lle-Pro-Pro-Gly-Val-Pro-Try-Trp-Thr	ACE inhibitory [67]
His-His-Leu	Antihypertensive [7]
Pro-Gly-Thr-Ala-Val-Phe-Lys	Antihypertensive [68]
Ala-Asp-Phe-Val-Leu-Asp-Asn-Glu-Gly-Asn-Phe-Leu-Glu-Asn-Gly-Gly-Thr-Tyr-Tyr-Ile	Antioxidant and ACE inhibitory [53]
Pro-Gly-Thr-Ala-Val-Phe-Lys	Antimicrobial [69]
Ile-Lys-Ala-Phe-Lys-Glu-Ala-Thr-Lys-Val-Asp-Lys-Val-Val-Val-Leu-Trp-Thr-Ala	Antimicrobial [69]
His-Thr-Ser-Lys-Ala-Leu-Leu-Asp-Met-Leu-Lys-Arg-Leu-Gly-Lys	Antimicrobial [70]
His-Cys-Gln-Arg-Pro-Arg and Gln-Arg-Pro-Arg	Immunomodulatory [71]
Gln-Arg-Pro-Arg	Immunomodulatory [71]
His-Cys-Gln-Arg-Pro-Arg	Immunomodulatory [72]
Gln-Arg-Pro-Arg	Immunomodulatory [72]
Leu-Pro-Tyr-Pro	Hypocholesterolemic [73, 74]
Leu-Pro-Tyr-Pro-Arg	Hypocholesterolemic [71]
Ile-Ala-Val-Pro-Gly-Glu-Val-Ala	Hypocholesterolemic [74]
Leu-Pro-Tyr-Pro-Arg	Antiobesity [75]
Pro-Gly-Pro	Antiobesity [75]
X-Met-Leu-Pro-Ser-Try-Ser-Pro-Try	Anticancer [76]
Ser-Lys-Trp-Gln-His-Gln-Gln-Asp-Ser-Cys-Arg-Lys-Gln-Lys-Gln-Gly-Val-Asn-Leu-The-Pro-Cys-Glu-Lys-His-Ile-Met-Glu-Lys-Ile-Glm-Gly-Arg-Gly-Asp-Asp-Asp-Asp-Asp-Asp-Asp-Asp-Asp	Anticancer (Lunasin) [77]

origin, papain and pronase, can be used for protein hydrolysis of soy flour and wheat flour [86]; soy protein hydrolysates have been enzymatically prepared by several commercially available proteases, alcalase, flavourzyme, trypsin, papain, protease, and peptidase [87]. Enzymatic digestion of β-conglycinin and glycinin hydrolyzed more active amino acid R groups that lead to increased antioxidant activity. It has been reported that additional advantage of hydrolysis can be the development of

hydrophobicity since proteolysis unfolds the protein chains. Moreover, hydrolysis leads to production of small bioactive peptides, and the bitterness of peptides of below 1000 Da is much less than fractions with a higher molecular mass [88].

Further, structural and chemical changes that occur during processing of food proteins may also lead to release of bioactive peptides [89]. Apart from that, fermentation is also an efficient way to produce bioactive peptides and food grade hydrolyzed proteins. Lactic acid bacteria (LAB), a large group of beneficial bacteria widespread in nature and also found in our digestive systems, are generally used for bioactive peptide production. They are best known for their role in the preparation of fermented products, not only because of their physiological significance but also because of their technological importance in texture and flavor development [90]. The proteolytic system of lactic acid bacteria, e.g., *Lactococcus (L.) lactis*, *Lactobacillus (Lb.) helveticus*, and *Lb. delbrueckii* ssp. *bulgaricus*, has proteinases that are capable of releasing a large number of different oligopeptides (4–8 amino acid). The oligopeptide transport system, main route for nitrogen entry into the cell and peptidases, located intracellularly is required for complete degradation of accumulated peptides [91, 92]. Lactic acid bacteria, possessing α-galactosidase enzyme, can hydrolyze the soy oligosaccharides (sucrose, raffinose, and stachyose) during fermentation and reduce its beany flavor and flatulence [6, 7, 93]. During fermentation of soy milk, proteins are degraded into simpler forms like oligopeptides, dipeptides, and tripeptides and serve as a good source of bioactive peptides. Comparatively microbial fermentation is the cheapest process instead of enzymatic hydrolysis for bioactive peptide production because microorganisms are a cheap source of proteases and are recognized as safe. Upon administration bioactive peptides may affect the major body systems, i.e., cardiovascular, digestive, immune, and nervous. The beneficial effects of bioactive peptides include antimicrobial, antioxidative, antithrombotic, antihypertensive, antidiabetic, anticancer, antiobesity, and immunomodulatory [94–97].

3.1 Effect of Soy Bioactive Peptides on Blood Pressure Regulation

Antihypertensive peptides are the greatly studied bioactive peptides in soy foods. Antihypertensive or angiotensin-converting enzyme (ACE) inhibitory peptides block the first step in the rennin-angiotensin system and interrupt the negative feedback effects of angiotensin II. The rennin-angiotensin system regulates blood pressure and fluid balance in body. ACE is a nonspecific dipeptidyl carboxy peptidase and converts the inactive decapeptide angiotensin I by cleaving dipeptide from the C-terminus into the potent vasoconstricting octapeptide angiotensin II in the rennin-angiotensin system (RAS), which has a tendency to increase blood pressure [98]. Besides, ACE also catalyzes the degradation of bradykinin, a blood pressure–lowering nonapeptide in the kallikrein-kinin system (Fig. 3) [99–101]. Inhibition of ACE is considered to be a useful therapeutic approach in the treatment of hypertension. Hypertension is also considered as a main cause of several risk factors, such as heart failure, stroke, coronary heart disease, and myocardial infarction.

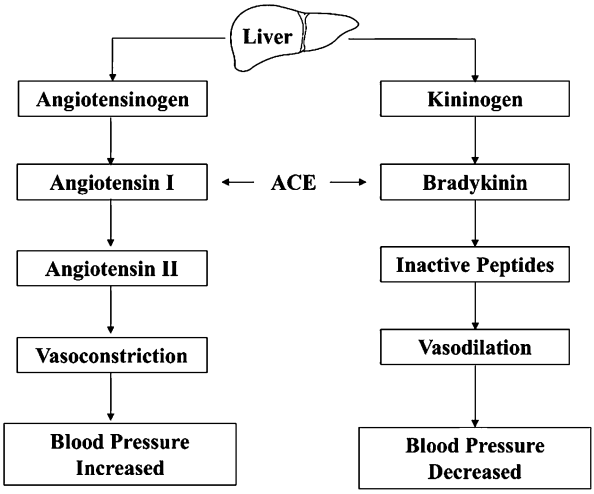

Fig. 3 Role of angiotensin-converting enzyme (ACE) in blood pressure regulation

Soy bioactive peptides, i.e., VPP (valyl-prolyl-proline), IPP (isoleucyl-prolyl-proline), and TP (Tyrosin-Proline), are known to have ACE-inhibitory activity and blood pressure lowering effect [63]. Similarly, bioactive peptides from fermented soy product (miso and doenjang) have been shown ACE-inhibitory activity in spontaneously hypertensive rats, mainly associated with tripeptides (VPP and IPP) [64]. Moreover, an ACE-inhibitory tripeptide Ala-Phe-His have been isolated from soybeans fermented by *Bacillus natto* and *Bacillus subtilis* [55]. It has also observed that peptides prepared from alcalase hydrolysis of soy protein significant decrease systolic blood pressure (SBP) in spontaneously hypertensive rats [102]. Fractionated whey from fermented soy milk with probiotics, *L. casei, L. acidophilus, L. bulgaricus, S. thermophilus*, and *B. longum*, has reported to exhibit antihypertensive activity [103]. Two ACE-inhibitory peptides have also been isolated having Ile-Phe-Leu and Trp-Leu amino acid sequence [65]. Fermented soybean extract were also used for the production of ACE-inhibitory peptide [104]. Shimakage and coworkers identified novel ACE-inhibitory peptides, such as Ile-Ile, Ile-Asp, Ile-Phe-Tyr, Leu-Phe-Tyr, Leu-Tyr-Tyr, Phe-Phe-Tyr-Tyr, and Trp-His-Pro, from protease-treated natto and soy milk [66]. Alauddin et al. [105] has recently identified the ACE-inhibitory peptide and studied its hypotensive effect from processed soy milk (PSM); the ingestion of PSM may lower high blood pressure and ameliorate cardiovascular diseases related to hypertension without causing adverse side effects in spontaneously hypertensive rat. Nakahara et al. [106] identified two antihypertensive peptide Seryl–tyrosine (Ser-Tyr) and glycyl–tyrosine (Gly-Tyr) from fermented soy sauce. Angiotensin-I converting enzyme (ACE-I) inhibitory activity of prepared soy whey proteins were fractionated into different fractions using ultrafiltration and found that unfractionated whey protein had the highest ACE-I inhibition activity. The study also indicated that soy–whey protein fraction (>50 kDa) had good solubility, emulsion activity, and stability, while the

unfractionated whey protein exhibited the strongest ACE-I inhibition percentage (19%) [107]. Recently, around 33 peptides were identified from soy milk fermented by a *Lactobacillus plantarum* strain, having ACE-inhibitory activity [53].

3.2 Effect of Soy Bioactive Peptides on Oxidative Stress

Antioxidants are recognized as a substances that can significantly decrease the unfavorable effects of reactive species. Reactive species can be formed during cellular metabolism of human system and plays important roles in cell signaling, apoptosis, gene expression, and ion transportation. However, when the production of these molecules is uncontrolled, poor cellular defenses lead to damaging of protein, lipid, and nucleic acids by the process called oxidative stress. However, human beings possess defense and repair systems for oxidative stress, but these innate antioxidative systems are usually not enough to prevent them from the oxidative stress [108]. Apart from several natural antioxidative compounds and vitamins, food-derived bioactive peptides have now been explored as an effective antioxidant agent. Antioxidant food supplements or bioactive peptides may be used to help the human body and animals to reduce the oxidative damage [109]. It has been noticed that several amino acid residues, i.e., histidine, tyrosine, tryptophan, phenylalanine, proline, and leucine, contribute for antioxidant capacity of peptides [110].

Antioxidative peptides can inhibit oxidation through multiple pathways, including inactivation of reactive oxygen species, scavenging free radicals, and chelation of pro-oxidative transition metals [111]. Several amino acids, such as Tyr, Met, His, Lys, and Trp, are generally accepted as antioxidants. On the same line, antioxidative peptide from β-conglycinin fraction of soy protein has been isolated by Chen et al. [112] using protease of microbial origin. Similarly, Coscueta et al. [113] reported that hydrolysis of soybean meal protein isolate has potentially enhanced ABTS and ORAC antioxidant capacity by treatment with corolase PP. Antioxidative peptides have been produced from soy protein isolate through hydrolysis with a food grade pancreatic trypsin/chymotrypsin with an antioxidative capacity of 113 mg TEAC/g [114].

In a recent study, *Lactobacillus plantarum* strain has been used as a starter to ferment soy whey in order to study antioxidative potential. The results demonstrated that fermented soy whey possessed more radical scavenging capacity as compared to unfermented, which is directly linked to generation of bioactive peptides during fermentation [115]. Similarly, Sanjukta et al. [116] reported 3.1–24 folds increment in total antioxidant activity of two soybean varieties of Sikkim Himalayan region of India by fermentation with *Bacillus subtilis.* Recently, we have also identified 35 antioxidative peptides from soy milk fermented by a *Lactobacillus plantarum* strain [53]. Bioactive peptides has also identified in soybean-based infant formulas having around 90% soy protein isolate. Around 120 antioxidant peptides were characterized by using ultrafiltration followed by HPLC-ESI-Q-ToF-MS/MS [117]. Antioxidant activity of lunasin (a soy peptide) has also been reported as a potent scavenger of peroxyl and superoxide radicals. The protective role of lunasin on cell viability and

antioxidant defenses of human Caco-2 cells has also been studied and found that direct antioxidant action of lunasin on enterocytes exposed to oxidizing species makes this peptide a promising agent to preserve the integrity of intestinal mucosa against oxidative damage–related diseases [118].

3.3 Antimicrobial Soy Bioactive Peptides

The growing problem of resistance to conventional antibiotics and the necessity for new antibiotics has stimulated an interest in the development of antimicrobial peptides (AMPs) as human therapeutics [119]. AMPs are peptides that can kill microorganisms, and they often exhibit a broad spectrum of activity against Gram Positive and Gram Negative bacteria [120]. Antimicrobial peptides are widely distributed in nature and are essential to the immune system. They are the organism's first line of defense against colonization by exogenous microorganisms, and they play a fundamental role in regulating bacterial populations on the mucosa and other epithelial surfaces. Therefore, using natural sources of antimicrobial compounds has enormous potential because they have characteristics such as low toxicity and high specificity. The mechanisms of these natural antimicrobial compounds can be better understood if we compare their modes of action against bacterial (unicellular) and animal (multicellular) cells. Bacterial cells have a layer rich in negatively charged phospholipids pointing toward the external environment, facilitating their interactions with peptides, most of which are positively charged. In contrast, animal cells are mainly composed of uncharged lipids in the outermost layer, and the negatively charged regions are pointed toward the cell interior (cytoplasm) [121, 122]. Soy proteins are excellent source of bioactive compounds. The biological activity of the glycinin and β-conglycinin hydrolysates was confirmed, and glycinin peptides were found to produce stronger antimicrobial effects than β-conglycinin peptides [123]. Antimicrobial peptides ranging from 15 to 40 amino acids in length, most of which are hydrophobic and cationic, are generally involved in innate immunity. These peptides include two or more positively charged residues provided by arginine, lysine, or, in acidic environments, histidine, and a large proportion of hydrophobic residues. They can exhibit an efficient role in the host defense against the most frequent pathogenic bacteria that interact directly with them and therefore scavenging them. Such peptides provide protection against bacteria, fungi, and viruses by acting on the cell membranes of the pathogens [124]. Recently, we have studied antimicrobial activity of bioactive peptide fractions derived from fermented soy milk. Five kilo dalton fraction has showed highest activity against most of the tested pathogens, among them highest activity has reported against *E.coli* (12 ± 0.57) followed by *S. dysenteriae* (11 ± 0.57), *L. monocytogenous* (10 ± 0.57), and *B. cereus* (10 ± 0.57 mm) [125]. Two soy peptides, i.e., PGTAVFK and IKAFKEATKVDKVVVLWTA, have tested against *Pseudomonas aeruginosa* and *Listeria monocytogenes* biofilms; both the peptides showed strong inhibitory activity against *Listeria monocytogenes* [69]. In a recent study, a soy meal fermented by a

Bacillus subtilis strain has found to produce antimicrobial peptides with great antimicrobial activity against *Vibrio alginolyticus* and *V. parahaemolyticus* [70].

3.4 Soy Bioactive Peptides as Immune System Modulator

Soy bioactive peptides have also been reported to enhance immune function. Two peptides from soy protein hydrolysate, i.e., His-Cys-Gln-Arg-Pro-Arg and Gln-Arg-Pro-Arg, have been found to exhibit phagocytosis stimulatory activity [72]. Usually, immunomodulatory peptides can enhance immune cell functions, such as lymphocyte proliferation, natural killer (NK) cell activity, antibody synthesis, and cytokine regulation. A soy protein hydrolysates prepared from insoluble soy protein has displayed highest immunomodulatory activity on proliferation of murine splenic lymphocytes and phagocytic effect of peritoneal macrophages [87]. Similarly, a phagocytic enhancing peptide has been isolated from trypsin digests of α-subunit of β-conglycinin soy proteins [61]. Lunasin, a soy peptide, exerts synergistic effects with cytokine Il-12 or Il-2 on modulating the expression of a number of genes in NK cells, resulting in strong NK activation with enhanced cytotoxicity, which is associated with higher levels of IFNγ and granzyme B expressed by both CD56 bright and dim populations [126]. Lunasin and other lunasin-like peptides, purified from defatted soybean flour, inhibited inflammation in LPS-induced macrophage by suppressing NFkB pathway. Out of three purified peptides (5, 8, and 14 kDa), the 5 kDa peptide inhibited most potently the proinflammatory markers including interleukin-6 production, nuclear factor-kappa B, cyclooxygenase-2 expression, nitric oxide production, inducible nitric oxide synthase, nuclear translocation, and p50 nuclear translocation [127]. Recently, Tung et al. [128] studied stimulatory effects of lunasin on innate immune cells by regulating expression of a number of genes that are important for immune responses. Lunasin-treated conventional DCs (cDCs) not only expressed elevated levels of costimulatory molecules (CD86, CD40) but also exhibited upregulation of cytokines (IL1B, IL6) and chemokines (CCL3, CCL4). Lunasin-treated cDCs induced higher proliferation of allogeneic CD4+ T cells when comparing with medium control treatment in the mixed leukocyte reaction (MLR).

3.5 Effect of Soy Bioactive Peptides on High Cholesterol

Hypercholesterolemia, also called high cholesterol, is the presence of high levels of cholesterol in the blood. It is a significant risk factor in the development of heart diseases and one of the major causes of deaths worldwide. Hypercholesterolemia is a state of high blood lipids and elevated levels of lipoproteins in the blood. Dietary proteins can modulate the effect of high serum cholesterol concentrations. The hypocholesterolemic activity of food protein and peptides involves stimulation of bile acids secretion, changes in cholesterol metabolism in the liver, hormonal effects, and regulation of cholesterol receptors [129, 130]. The effects of soy-based product

on cardiovascular diseases (CHD) have considered through its impact on blood cholesterol. It has been reported that the released bioactive peptides lower the cholesterol levels when soy protein was subjected to protease digestion in the digestive tract [131]. It has now been well established that the dietary intakes of 20 g of soy protein per day for 5 weeks would be effective in reducing the CHD risk among high-risk, middle-aged men [132]. Similarly, the effect of fermented soy milk on rats fed a high cholesterol diet was investigated to clarify the cholesterol-lowering function [133]. Wang et al. (2008) reported that soy protein reduced the level of circulating triglycerides and cholesterol in hypocholesterolemic subjects [134]. Similarly Sugano et al. [135] documented that soy protein hydrolysate of peptic digest has a stronger serum cholesterol lowering effect in comparison to intact soy protein in rats. Soy peptides may also bind to phospholipids and exert serum cholesterol lowering activity in humans [136]. Keeping the cholesterol lowering effect of soy protein in mind, Food and Drug Administration (FDA) approved a health claim linking foods that are naturally rich in soy protein reduce coronary heart disease [137].

LPYP, a tetrapeptide, has been isolated from soy protein glycinin with hypocholesterolemic effect [73]. Zhong and coworkers studied the in vivo hypocholesterolemic effect of soy peptides [138], and they found that cholesterol micellar solubility inhibitory rate of soy peptides was more than 45%. Similarly, Ferreira and coworkers (2010) reported cholesterol-lowering effect of β-conglycinin and glycinin soy proteins in rats fed a high-cholesterol diet [139]. A recent study showed effect of a symbiotic fermented soy product supplemented with okara (a by-product from soybean) on cardiovascular disease risk markers in healthy men. In a randomized two groups study, subjects consumed daily 100 g of soy-based product fermented with *Lactobacillus acidophilus* La-5, *Bifidobacterium animalis* subsp. *lactis* Bb-12, and *Streptococcus thermophilus* (starter culture), and LDL-C mean decreased significantly resulting in a significant improvement of the LDL-C/HDL-C ratio was observed [140]. Three peptides from soy glycinin, IAVPGEVA, IAVPTGVA, and LPYP, have been studied by Lammi et al. [74] for their hypocholesterolemic activity. HepG2 cells treated with these peptides interfere with the catalytic activity of 3-hydroxy-3-methylglutaryl CoA reductase (HMGCoAR) and modulate the cholesterol metabolism through the activation of the LDLR-SREBP2 pathway, increasing the ability of HepG2 cells to uptake the LDL.

3.6 Soy Bioactive Peptides for Weight Management

A condition when excess fat has accumulated in body to the extent that may have an adverse effect on health called obesity. Obesity has now been considered as a major health problem in most of the countries, which is associated with higher incidence of CVD, type 2 diabetes, obstructive sleep apnea, cancer, osteoarthritis, and depression [141]. Consumption of dietary proteins, i.e., soy, casein, and whey protein, has reported antiobesity effect. An in vitro study revealed that soy protein has greater antiobesity effect in comparison to casein and whey protein in obese rats/or mice

[142]. Soy protein may also lead to lower hepatic deposits of triglycerides [143]. Two peptides Leu-Pro-Tyr-Pro-Arg and Pro-Gly-Pro from soybean glycinin protein have strong antiobesity potential [75]. Several animal studies showed that soy protein ingestion lead to lipid-lowering effect by reducing hepatic cholesterol content and enhancing removal of LDL [144]. Soy proteins/peptides have directly affected the hepatic cholesterol metabolism and LDL receptor activity. Evidence from animal models suggested that soy protein has strongly influenced lipogenesis in the liver. Similarly, dietary soybean proteins have reported to reduce the concentrations of plasma triglycerides in rat liver. These effects have mainly associated with the reduction of hepatic lipogenic enzymes, such as glucose-6-phosphate dehydrogenase, malic enzyme, fatty acid synthetase, and acetyl-CoA carboxylase (ACC), which concluded that soy protein reduces liver triglycerides by inhibition of hepatic fatty acid synthesis in liver [145]. Soy protein can improve insulin resistance and lipid levels by activation of PPAR (peroxisome-proliferator activated receptors), which is the main transcription factor responsible for the regulation of expression of genes involved in glucose homeostasis, lipid metabolism, and fatty acid oxidation. On the same line, Jang and coworkers (2008) studied in vitro antiobesity effect of soy peptides derived from black soybean. They observed that the diet-induced obese mice fed a high-fat diet along with soy peptides gained less body weight in comparison to control [146].

3.7 Anticancer Soy Bioactive Peptides

Lunasin, a peptide isolated from soybean, is well known for their anticancer effect [77]. According to reports, lunasin can prevent cellular transformation induced by chemical carcinogens and the viral oncogenes RAS and E1A [147, 148]. Hsieh and coworkers (2010) reported that lunasin has been strongly inhibited cell proliferation and cancerous foci formation in cells treated with 7,12-dimethylbenz (a) anthracene (DMBA) and 3-methylcholanthrene-treated (MCA) [149]. Similarly, an in vivo study also documented anticancer effect of lunasin induced by DMBA [150]. As safety point of view reports claimed that lunasin does not affect the growth rate of normal and established cancer cell lines in spite of cancer-preventive properties. Soy proteins has several mechanisms for cancer prevention including increased mammary gland differentiation, decreased activation of procarcinogens to carcinogens, and regulation of genes in signal transduction pathways underlying tumor initiation, promotion, and/or progression [151]. Rayaprolu and coworkers [152] reported anticancer properties (more than 65%) of soy protein isolates against human colon (HCT-116, Caco-2), liver (HepG-2), and lung (NCL-H1299) cancer cell lines. Similarly, oral administration of lunasin has reported to reduce liver metastasis by 56–94% [153]. Downregulation of inflammation related genes was reported by Hwang et al. [154] when breast cancer MCF7 cells were treated with fermented soybean extracts. Similarly, Yang et al. [155] reported that lunasin can effectively suppress allergic airway inflammation.

4 Soy Saponins

Saponins are compounds containing a steroid or triterpenoid aglycone linked to one or more oligosaccharide moieties [156]. These high-molecular weight glycosides are found in many plant-derived drugs. Saponins, which derive their name from their ability to form stable, soap-like foams in aqueous solutions, constitute a complex and chemically diverse group of compounds [157]. Soy saponins are amphiphilic compounds and categorized as triterpenoic saponins [158]. Soybeans and soy-based products contain approximately 1–5% saponins. It has been estimated that there are at least 40 different saponins in soybeans. Most of the soy saponins identified till date have a soyasapogenol conjugated at the 3-position with a 2′-glycosylated glucuronic acid residue [159].

4.1 Health Effects of Soy Saponins

Soy saponins are well known for the inhibition of cancer cells [160]. Clinical studies have suggested that saponins affect the immune system in ways that help protect the human body against cancers [157]. At high concentrations, saponins cause cell damage by disrupting the cell membrane or inducing apoptosis [161]. The membranolytic activity of soybean saponins as indicated by their interaction with human colon carcinoma cells explains their role as anticarcinogens. Previous reports indicated that soybean saponins suppress the growth of colon tumor cells in vitro, and a 2% crude soybean saponins diet inhibited a carcinogen-induced colonic aberrant formation in rats. Soybean saponins have been shown to contain 2,3-dihydro-2,5-dihydroxy-6-methyl-4H-pyran-4-one (DDMP), and DDMP (1 mg/mL) possesses a strong radical scavenging activity equivalent to 17.1 units of superoxide dismutase [162]. Soybean saponins significantly inhibit the release of prostaglandin E2 (PGE2), nitric oxide (NO), tumor necrosis factor α (TNFα), and monocyte chemotactic protein- 1 (MCP-1) in a dose-dependent manner [163]. They also downregulate the expression of cyclooxygenase-2 (COX-2) or inducible nitric oxide synthase (iNOS) at mRNA/protein levels. The anti-inflammatory properties of soybean saponins are mediated by the necrosis factor-κB (NF-κB) signaling pathway, blocking the degradation of inhibitory proteins known as IκB-α. Kang et al. [163] concluded that the anti-inflammatory action of soybean saponins may be useful for developing preventive agents against inflammatory diseases as well as suppressing tumor progression. On the same line, Tsai and coworkers (2010) reported that soy saponins decreased the number of viable human colon cancer cells in a dose-dependent manner and suppressed 12-otetradecanol-phorbol-13-acetate-stimulated PKC activity. Cells treated with saponins developed cytoplasmic vesicles and the cell membrane became rougher and more irregular and eventually disassembled [158].

Apart from those other beneficial properties of soy saponins includes hypocholesterolemic, hemolytic, and immunostimulatory activities [11]. Moreover, soy saponins were reported to have antiviral and antioxidative activities. The blood

cholesterol-lowering properties of soybean saponins are also of particular interest in human nutrition. Saponins cause a depletion of body cholesterol by preventing its reabsorption, thus increasing its excretion. Studies on rats have shown soybean saponins to have an anabolic effect on bone components, suggesting its role as a nutritional factor in the prevention of osteoporosis [135]. Nishida and coworkers (1993) reported that the inhibition of radical-initiated lipid peroxidation by soy saponins was responsible for its anticarcinogenic properties [164].

5 Soy Phytosterols

Phytosterols are naturally occurring compounds which are found in all foods of plant origin. Phytosterols have the similar basic function in plants as cholesterol in animals, and they play a key role in cell membrane function. Therefore, they are best known for reducing blood cholesterol levels. Phytosterols comprise a wide variety of molecules that are structurally similar to cholesterol. They are naturally found in pulses, vegetable products, oils, and dried fruits [165]. Soybean phytosterols consist mainly of β-sitosterol, campesterol, and stigmasterol; β-sitosterol content being highest among them.

5.1 Health Effects of Soy Phytosterols

Several experimental trials revealed the ability of phytosterols to reduce LDL-cholesterol, without significantly altering HDL-cholesterol or triglycerides in general [165]. It was reported that phytosterols such as β-sitosterol offer anticancer effects [166], prostatic hyperplasia-lowering effects [167], and stimulation of a plasminogen activating factor [168]. In particular, there are many reviews on cholesterol-lowering activity of phytosterols. It has been demonstrated that soybean phytosterols are able to reduce serum cholesterol by inhibiting the absorption of cholesterol. Therefore, phytosterols are often supplemented into functional foods to improve human health. The FDA has also authorized a food claim for phytosterols: "Food containing at least 0.65 g per serving of plant sterol esters, eaten twice a day with meals for a daily total intake of at least 1.3 g, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease" [169–171]. Lerman and coworkers (2010) concluded that individuals at high CVD risk benefit from a soy phytosterol containing medical food; thereafter, conduction of a 12-week randomized trial for subjects received a phytochemical-enhanced diet [172]. Similarly, a diet program containing 30 g of soy protein and 4 g of phytosterols was subjected to 27 postmenopausal women per day for 12 week, and observed that total cholesterol, low-density lipoprotein cholesterol, and triacylglycerol have decreased significantly [173]. Moreover, mild-to-moderate hyperlipidemic patients were selected in a study and treated with placebo soy milk powder enriched with phytosterols. After 3 months of trail, the serum total cholesterol, low-density lipoprotein cholesterol, and non-high-density lipoprotein cholesterol levels decreased by 9.3%, 11.4%, and 12.6%, respectively [174].

6 Future Prospective

Over the last two decades, scientific research on soybean-derived bioactive compounds, such as isoflavones, peptides, and protein hydrolysates, has been detonated, which displays a broad scope of functions. However, these bioactive molecules are less potent in comparison to pharmaceutical drugs; conversely, they have minimum or no side effects because nature has provided the mechanism for their metabolism and utilization or excretion. Usually, bioactivity of compounds in vitro cannot be directly related to its in vivo effect because they may likely encounter degradation and modification in the intestine, vascular system, and liver. Therefore, they need to remain active during digestion and be transported through the intestinal wall into the blood. However, several differences are observed between in vitro models and in vivo studies [175, 176]. Therefore, bioavailability of bioactive compounds is one of the major areas of research which requires focus. It was evident that only a small portion of bioactive molecules are sufficient to exert the specific function at tissue level once they pass through the intestine barrier [177]. For instance, a numbers of mechanisms for absorption of peptides are available, such as paracellular route, passive diffusion, transport via carrier, and endocytosis. The lymphatic system is also a possible route of peptides absorption; here absorption of peptides is mainly affected by their permeability via the capillary of the portal circulation and lipid solubility [88]. The small peptides absorbed more readily instead of large peptides. They are able to cross the intestinal barrier and exert their biofunctionality at the specific target organs [178–180].

In spite of remarkable array of biological functions by soy bioactive molecules, it may be surprising that only a few have commercialized and reached to the market. Therefore, new strategies are needed to establish economical and efficient industrial scale production of bioactive compounds with different action. However, the high cost and multistep process limited the large-scale production of bioactive compounds. Therefore, advance and precise technologies are needed for hydrolysis, separation, and purification of bioactive molecules with high potency and yield. Also, downstream processing such as drying, cellular disruption, extraction, and production cost–related studies of bioactive molecules need specific attention. Moreover, bioinformatics approach should be explored for prediction and analysis of specific bioactivity of molecules. Molecular studies are also needed to examine the mechanisms by which these compounds exert their actions.

7 Conclusions

Soybean has a great potential of supplying bioactive compounds that are functionally significant. However, the raw beans itself are not accepted throughout because it contains some antinutrients that can disrupt digestion activities in the stomach, leading to cramping and associated discomfort. Therefore, these bioactive components can be incorporated in functional and fresh foods, dietary supplements, and even pharmaceuticals with the aim of delivering specific health benefits. Microbial

fermentation is also an effective way to increased bioactivity and acceptability of soybean. The effect of soybean/soy-derived bioactive components on emerging lifestyle complications, such as metabolic syndrome and cardiovascular disorders, has increased demands worldwide. Apart from that, soybean products can be good substitutes for animal products because, unlike some other beans, soybean offers a complete protein profile. Soybeans contain all the essential amino acids except methionine, which must be supplied in the diet because they cannot be synthesized by the human body. Besides the potential health effect of soybean-derived bioactive molecules, the bioavailability and safety of these products should be ensured as most priority. More definite clinical studies are needed to ensure any side effect. Advanced molecular and bioinformatics approaches should also be explored for target-specific studies of soy bioactive molecules.

Wheat Bran Proteins

12

René R. Balandrán-Quintana and Ana María Mendoza-Wilson

Contents

Abstract

Wheat pericarp, known as bran after milling, is the protective envelope of the grain. It is constituted by seven layers, grouped into three major sections: inner (aleurone), intermediate, and outer bran, respectively. Thousands of proteins are expressed during the wheat grain development, many of them in pericarp, so wheat bran protein content is 15%. Aleurone proteins are mostly storage and metabolic enzymes, while those of intermediate and outer bran layers are mainly involved in stress/defense. Bioactivity of wheat bran proteins has been scarcely explored. Some evidences suggest a role in regulating fat metabolism, which could be preventive of obesity and nonalcoholic fatty liver disease.

Antihypertensive peptides have been isolated from wheat bran, as well as soluble proteins of low molecular weight with antibacterial properties. Other uses for wheat bran protein extracts, such as enzyme inhibitors in food processing or as reservoirs of proteins for nanoparticle self-assembly, are discussed.

Keywords

Cereals · Bioactive peptides · Wheat bran proteomics · Wheat pericarp · Pericarp proteins · Wheat aleurone · Agro industrial by-products

Abbreviations

2-DE	Two-dimensional electrophoresis
ACE	Angiotensin I converting enzyme
AMP	Adenosine monophosphate
AMPK	AMP-activated protein kinase
Arg	Arginine
ATP	Adenosine triphosphate
CD	Degrees day after anthesis
DAA	Days after anthesis
DiFA (AT)	Dehydroferulic acid (aryltetralin form)
DiFA (BF)	Dehydrodiferulic acid (benzofuran form)
Gln	Glutamine
Ile	Isoleucine
Leu	Leucine
NASH	Nonalcoholic steatohepatitis
Phe	Phenylalanine
PPO	Polyphenol oxidase
Pro	Proline
ROS	Reactive oxygen species
Thr	Threonine
Tyr	Tyrosine
Val	Valine

1 Introduction

In this chapter, proteins from wheat bran are reviewed. Wheat is the third most important cereal world-wide, aside from rice and maize, in terms of production [1]. However, it represents the first supply of proteins and energy for human beings, either directly or indirectly, since it is processed to fabricate a variety of foods and also is used for livestock feed [2, 3].

The most common processing method for the wheat grain is milling, from which flour is obtained as the main product while bran and germ are major by-products [4]. Traditionally, most of the produced bran has been intended to animal consumption, whereas the remaining fraction has found applications in a few food groups as a source of dietary fiber [5]. In recent decades, an increasing interest for wheat bran

has arisen since many potential benefits to human health, derived from its consumption, have been discovered [5–7]. In this context, the wheat bran proteins, despite being of better quality than those of the flour, are underutilized because most are enclosed in cells, surrounded by a cell wall made up of cellulose and hemicelluloses, besides being complexed with polysaccharides, so their bioaccessibility is poor. This entrapment and/or complexation also make the extraction and isolation of proteins a difficult task [8].

Proteins from wheat endosperm have been well studied because of their technological importance [9], but not those of bran. The state of the art in this respect is that wheat bran proteins are distributed among the different layers, aleurone having the most part of them. The classes of proteins range from storage proteins to enzymes involved in cellular metabolism and stress/defense. Most of the proteins in aleurone are globulins, whereas those in middle and outer layers are mainly albumins with metabolic and defense activity [10]. Until now, with the assistance of mass spectrometry and bioinformatics, a great diversity of proteins have been identified from the thousands of spots revealed in two-dimensional electrophoresis (2-DE) gels from bran of mature and developing grains [11–16]. Distribution of proteins among the different layers that compose the bran has been possible to elucidate through proteomic studies assisted by electronic, fluorescence, and optical microscopies [10]. It is also known that pericarp proteins are under strict genetic control because no significant differences in their expression have been found between species or between growing conditions.

Although at the present time not all the proteins which are contained in the 2-DE Coomassie-stained spots have been identified, the available information has permitted to explain in some detail how the wheat bran proteome is interrelated to provide the grain with an arsenal of chemical compounds and enzymes. New evidences showing the advantages that could be taken from the properties of wheat bran proteins, highlighting those of importance to human health, are also discussed.

2 Overview on Wheat Grain

Common wheat (*Triticum aestivum*) is classified within the family of grasses *Poaceae*, subfamily *Pooideae*, and represents only one of the nine species of *Triticeae* tribe that conform to this subfamily, among which also are barley (*Hordeum vulgaris*), rye (*Secale cereale*), and triticale (*Triticosecale* sp.), as well as other wheat species known by their common name as Emmer or farro (*T. dicoccum*); hard Macaroni (*T. durum*); Einkorn the small spelt (*T. monococcum*); Spelt (*T. spelta*), and Rivet or cone (*T. turgidum*). The name *T. aestivum* comprises several forms of hexaploid wheat, although not necessarily all are common or have the necessary characteristics for the bread making. Within each species, there are also subspecies or varieties. The terms variety and cultivar are sometimes used interchangeably; however in a botanical sense, a variety (or subspecies) is the result of natural selection, whereas a cultivar is a plant that has been domesticated, i.e., is the product of a selection made by man, so it does not represent an evolutionary

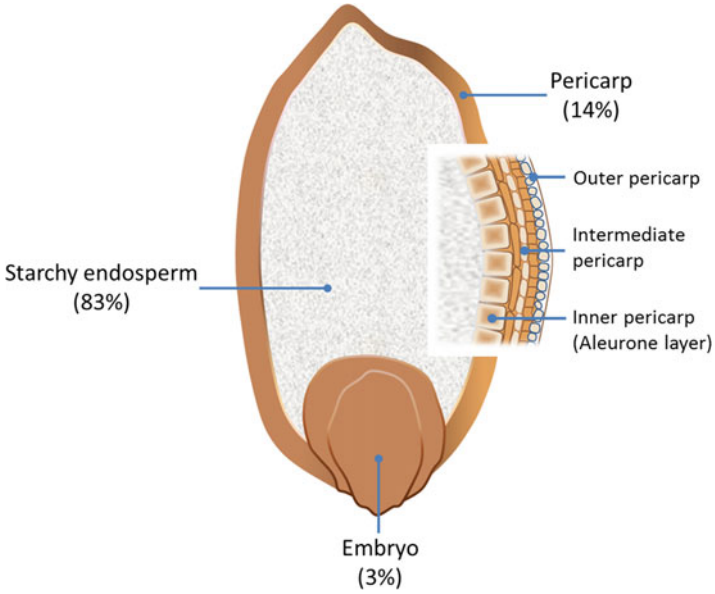

Fig. 1 Schematic representation of the major morphological components of the wheat caryopsis and their distribution by grain weight

status [17]. In this chapter, when reference is made to a cultivar, the taxonomic name will be written, followed by the name of the cultivar in quotation marks.

Wheat grain is a one-seeded fruit or caryopsis, which is constituted by three major morphological components [18] (Fig. 1):

1. Embryo
2. Starchy endosperm
3. Pericarp

The embryo is the reproductive organ from which a new plant is born after fertilization. Embryo represents the smallest percentage of the grain weight, only 3%, and its chemical composition is based on lipids and proteins. The starchy endosperm is the most voluminous part, representing approximately 83% of the grain weight, and is composed basically of starch and proteins. The proteins of the endosperm possess chemical characteristics that grant them the functionality required for the elaboration of bread. This quality makes wheat a unique cereal and is one of the main sources of energy and protein in human food [19]. Pericarp constitutes approximately 14% by weight of the caryopsis. It is an important source of dietary fiber and bioactive compounds, among which phenolic compounds stand out because of their antioxidant capacity [20, 21]. It also contains important amounts of vitamins, minerals, and proteins (Table 1).

Table 1 Chemical composition of wheat pericarp or bran

Component	Amount (per 100 g, unless otherwise indicated)	References
Water	9.9 g	[22]
Protein	15.6 g	[22]
Total lipid (fat)	4.25 g	[22]
n-Fatty acids	0.66 g	[23]

8-0-4′DiFA	≈1,000	[21]
8-8′DiFA (AT)	≈1,000	[21]

2.1 Protein Synthesis at Different Stages of Grain Development

As in any other biological system, cereal proteins are synthesized in response to an intricate molecular signaling system. In general terms, the ultimate aim of such a system is the formation of a new seed, which is equipped with the necessary to generate another plant and to defense itself against a hostile environment. Embryo, aleurone, and endosperm act in coordination and in a differentiated way after fertilization. From the

embryo, the new plant is born, while the endosperm and aleurone provide all the reserve substances and enzymes necessary for its development [12].

There are variations in literature regarding the number and duration of the stages through which the wheat grain develops. In order to give an overview of the proteins that are expressed along the wheat grain formation, here will be adopted the three-stage development [3, 16]. Duration of each stage is given in days after anthesis (DAA), i.e., days after the flowering period, and sometimes is also expressed as degrees day after anthesis (°CD), i.e., the accumulated daily average temperature, in Celsius degrees. These three stages are:

1. Early development (lag phase) [≈0–16 DAA; ≈ 0–250 °CD]
2. Accumulation of storage compounds (filling phase) [≈14–28 DAA]
3. Maturation-desiccation [≈28 DAA to maturity]

The events occurring in the early development stage and lasting of each one are:

A. Fertilization and development of coenocytic endosperm (0–1 DAA).
B. Cellularization (3–6 DAA; ≈50–100 °CD).
C. Differentiation (7–8 DAA; ≈115–135 °CD). In this event, the formation of main cell types occurs, such as transfer cells, aleurone, starchy endosperm, and cells surrounding the embryo.
D. Cell wall initiation and intense mitotic activity (8–10 DAA; ≈135–165 °CD).
E. End of cell division (at 16 DAA; ≈250 °CD).

Protein expression starts from the beginning of wheat grain formation, as evidenced by the 492 Coomassie-stained spots that have been observed in 2-DE gels from wheat grains in the early development stage (first 2 weeks, from ovary fertilization to 280 °CD) [16]. From these spots, 249 proteins were identified, 52.6% corresponding to enzymes involved in cellular and carbohydrate metabolism; 17.4% to environmental and information processing; 14.6% to genetic information processing; 13.4% to stress and defense responses, and 0.4% to cellular processes, whereas 1.6% were unknown. The most important changes in the proteome, which is defined as "the assortment of proteins produced at a specific time in a particular cell or tissue type" (https://www.nature.com/scitable/definition/proteome-297) at the early stage were observed at 125–195 °CD, when proteins with molecular mass 10–110 kDa were expressed and identified as storage proteins (glutenins and gliadins) [16].

Gliadins (prolamins) are not only the major storage proteins in the wheat grain but also determine the viscoelasticity of dough, so their study has been fundamental for targeting the quality of wheat [24]. Thus, proteome differences between wheat cultivars having different gluten quality properties have been studied. The analysis and identification of proteins in developing grains of *T. aestivum* "Jimai 20" and *T. aestivum* "Zhoumai 16" by 2-DE, assisted by MALDI-TOF/TOF-MS, resulted in variable patterns of protein expression. From 174 Coomassie-stained spots, 84 unique proteins were identified. Fourteen protein spots accumulated in higher abundance in "Jimai 20" than in "Zhoumai 16," the former having superior gluten

quality. Among proteins, the NAD-dependent isocitrate dehydrogenase, triticin precursor, LMW-s glutenin subunit, and replication factor C-like protein were identified, which are likely to be associated with superior gluten quality [24].

In general, proteins identified in the early stage are involved in the cellular metabolism, such as the enzymes of amino acid synthesis, energy production, cell wall initiation, etc., or in DNA repair and replication, cytoskeleton, and structure. At the beginning of the grain formation, also starch granules-associated proteins are expressed. Stable expression of many proteins involved in signal transduction, sugar metabolism, and stress-defense is carried out between 150–280 °CD. By the 195 °CD period, proteins responsible for folding and degradation are expressed, whereas the starch granule-associated proteins continue increasing constantly their expression up to 280 °CD. Heat shock proteins (HSP) are expressed in the early events [16]. In other study, 138 unique proteins were identified by 2-DE and tandem MALDI-TOF/TOF-MS in the 6–20 DAA development period of "Chinese spring" and "NIL-31" wheat cultivars. Proteins involved in carbohydrate metabolism were the most abundant (32.02%), followed by those of synthesis/assembly/degradation of proteins (13.16%), stress/defense (10.53%), and energy production and transport (9.65%) [25].

Nevertheless the resolution attained by 2-DE, it has limitations, as for example the difficulty for separating hydrophobic proteins. In this regard, other study has permitted the identification of up to 1762 proteins in the early stage, comprising from 4 to 12 DAA, by using isobaric tag for relative and absolute quantitation (iTRAQ) and LC–MS/MS methods [26]. Most of the proteins were involved in metabolism, including cell division, cytoskeleton, carbohydrate metabolism, lipid metabolism, nitrogen metabolism, protein synthesis, signal transduction, translation, and transport [26].

Thus, irrespective of the number of identified proteins, results obtained between distinct methodologies are consistent in that the early stage is characterized by an intense activity of enzymes involved in cellular metabolism, and this pattern is similar among wheat species [25–28].

In the middle and late stages of grain development (21–42 DAA), by means of 2-DE assisted by tandem MALDI-TOF/TOF-MS, 130 proteins have been identified in the Coomassie-stained spots. According to differential functions, proteins were classified and distributed as stress/defense (35.4%), carbohydrate metabolism (21.5%), protein synthesis/assembly/degradation (3.1%), storage proteins (6.9%), energy production and transportation (7.7%), photosynthesis (6.2%), transcription/translation (3.9%), signal transduction (4.6%), and unknown function groups (10.8%) [29].

Proteome characterization of the elite wheat *T. aestivum* L. "Shaan 253" in the filling stage (15–30 DAA) by using an iTRAQ approach, resulted in the identification of 859 differentially expressed proteins [30]. Results showed a down regulation over time of proteins involved in energy and starch metabolism. On the other hand, storage proteins (high and low molecular weight glutenins) were upregulated, especially at 25–30 DAA. Most of the stress/defense proteins showed upregulation during grain filling, with high expression levels at 30 DAA, i.e., alpha-amylase inhibitors, enzymes involved in the response to drought and oxidative stress, serpins, and xylanase inhibitors, whereas others, like some peroxidases and some HSP, were downregulated with age [30].

3 Wheat Bran

Bran is a slang word used for referring to cereal pericarp, the botanical tissue enveloping the grain and that gives mechanical support and protection to the endosperm [13] (Fig. 1). Wheat pericarp consists of seven layers, which together account for approximately 14% in weight of the grain. For simplicity, authors frequently group these layers to divide the pericarp into three great sections [31] (Fig. 1):

1. Inner pericarp. Consists of the aleurone, a monolayer of vegetative cells that surrounds the endosperm and the germ. Although aleurone botanically belongs to the endosperm, it is considered the innermost part of pericarp because it remains adhered to it after grain milling [32].
2. Intermediate pericarp. Comprises three layers, composed by the cross cells, tube cells, and testa, all of them made up from dead cells in the mature grain.
3. Outer pericarp. Also is composed of dead cells and comprise the hyaline layer, beeswing and the outer layer.

Pericarp layers are deposited at different developmental stages of the wheat grain, originally they were made up of living cells, each layer having a different function [33]. In the last stage of development, when grain is desiccated to reach the maturity, aleurone remains as a layer of vegetative cells. Aleurone constitutes an essential source of minerals, chemical compounds, and proteins, necessary for the growing of a new plant after fertilization [34]. On the other hand, the cells of the intermediate and outer pericarp layers undergo cell death, serving as mechanical support and protection for the mature grain [31]. However, they not only act as a physical shield but also are dynamic structures since contain a variety of enzymes intended to defend the grain against environmental stresses and pathogenic attacks [10]. Thus, through the development of the wheat grain, a great variety of proteins are expressed, many of them in the pericarp layers [13], resulting in that wheat bran has a total protein content of approximately 15% in weight [22].

After milling, the wheat endosperm is recovered as the main product (the flour) with an approximate yield of 72%, whereas pericarp and germ are obtained as by-products, with average yields of 15% and 2%, respectively [32]. As said before, once separated from endosperm and germ, in the miller's argot, the pericarp is called bran. Bran is obtained in the mill as flakes of 67 μm thick [35]. Mainly two classes of bran are obtained, which are graded as human or animal consumption. Animal consumption grade bran is mixed with impurities, such as straw and other classes of offal. Human consumption grade bran is the purest class of bran and is almost completely composed of bran flakes to which remainders of endosperm and some germ particles are adhered [32].

Traditionally, approximately 90% of the wheat bran is used for animal consumption, whereas the remaining 10% has found applications as ingredient in the elaboration of processed foods, mainly bread and cereal snacks [36, 37], or is used for its inclusion in healthy diets [5]. Wheat bran has been largely appreciated by its high content of dietary fiber and more recently by the benefits to human health which are

attributed to a diversity of bioactive compounds (Table 1). Among the chemical composition of wheat bran, proteins are highlighted, as these nutriments are present in a relatively high proportion (more than 14% DW) [22, 37]. Also is known that their essential amino acid composition is better than that of the flour [38]. However, wheat bran proteins have been largely ignored in terms of a rational use, probably because of the drawbacks arising during their extraction [8].

4 Wheat Bran Proteins

There is a copious literature on proteins from wheat endosperm. In fact, wheat endosperm is by far one of the most studied protein systems because of their technological and economical importance [9]. Wheat bran proteins have not been the subject of such an extensive study but, fortunately, plant biochemistry has been in charge of providing most of the information about it. Accumulated knowledge about classes, structures, properties, and distribution of proteins in the wheat bran is important as allows understanding their role in the grain. Finding explanations to phenomena related to their application, as well as predicting new uses, are also scope of interest in this subject.

It is worth mentioning the great impetus given by 2-DE to the large-scale study of the functions of proteins. In 2-DE, the protein separation is performed in two steps, by isoelectric focusing in the first one and then as a function of the molecular mass. After staining, usually with the Coomasie blue reagent, a number of spots are visualized on the gels, each one corresponding to a unique protein [39].

Proteins from the wheat pericarp or bran will be analyzed in this review in the context of grain development, as well as in terms of potential benefits and applications, at the light of the newest available information. Due to the space constraint, the analysis is not intended to be exhaustive but is expected to serve as a guide to awaken the interest to innovate in relation to the uses of these proteins.

4.1 Distribution of Proteins Among the Various Layers of the Wheat Bran

The methods used to prepare wheat bran for chemical characterization depends on the purpose of such characterization and this issue is very important when it comes to characterize proteins. Since bran has endosperm residues, if the purpose is to characterize the bran proteins in bulk, or fractioning them according to solubility, endosperm residues must be removed from samples by brushing [40] or by rapid washing while immersed in water [41]. Further defatting with solvent of the washed bran is also desirable. On the other hand, if bran will be used for technological purposes, where the presence of endosperm is irrelevant, preparation (if any) will probably consist in only homogenizing the particle size through sieving. In some other cases, stabilization to inhibit enzymatic activities, mainly lipases and proteases, is mandatory [42].

In proteomic studies, whole pericarp or its layers are invariably dissected by hand after imbibing the wheat grains in water. The latter has the objective of facilitating the manual dissection of individual layers. Manual separation of the bran into layers has permitted to analyze the histology and chemical composition of each one. This technique is advantageous because it permits to extract proteins from individual layers, so cross-contamination between layers is avoided; however, this is a laborious task.

The study of proteins from wheat bran dates from the 1920s and the details known until now have been gradually revealed. At that time, wheat bran was subjected to successive extraction steps with different solvents in order to obtain the Osborne fractions [43]. Wheat bran proteins were first classified as albumins, globulins, and prolamins, according to their solubility in water, dilute salt solution, and 70% alcohol, respectively [44]. In further studies, their amino acid content was reported [45], as well as their biological value, assayed in murine model [46]. Since proteins were obtained as a bulk, little or nothing was known about properties or functions of individual proteins. Gel electrophoresis and gel chromatography have helped to separate the proteins and elucidate their molecular masses [47]. In turn, separation has allowed testing some more specific properties, for example, those related to enzymatic activity [48].

Dissecting the bran in its layers and extracting proteins from each layer has been a good approach to study their distribution in the grain pericarp. Microscopic techniques have advanced to such an extent that it is now possible to observe the precise sites in which the different chemical components of cells and tissues are located. The high resolution of the current microscopes allows capturing in detail the cellular compartments. It is also taken advantage of the specific interaction of some cellular components with monoclonal antibodies and fluorescent molecules or with molecules which develop well-defined colors [49]. This makes possible the labeling of components of interest and, therefore, to identify their histological location by fluorescence microscopy or conventional optical microscopy, respectively [50].Intrinsic fluorescence of cellular components is exploited too, as is the case of phenolic compounds and proteins. It is also common to couple one or more microscopic techniques with the chemical labeling or the intrinsic fluorescence, to observe even more details. For example, in the particular case of wheat bran, the resolution of the scanning electron microscope coupled to the sensitivity of the confocal fluorescence microscopy, have allowed the fluorescence immunolocalization of defense proteins in bran cross-sections [10].

Identification and elucidation of protein functions has greatly advanced in recent decades thanks to proteomics, which relies on 2-DE, mass spectrometry, and nucleotide sequencing databases [51–53]. Proteomics is the study of all the proteins of a cell or tissue, rather than individual proteins, in order to integrate the information and thus respond to biological questions [53]. It is a tool which has permitted deepening on the knowledge on distribution and functions of the wheat bran proteins [11].

Proteins in wheat bran are distributed among their different layers [10]. Those of the outer layers are the most easily extracted because they are water soluble; these proteins are basically defense-stress enzymes. Those in the middle layer are a little more difficult to extract, most are oxidative-stress and defense-related proteins. On

the other hand, proteins from the aleurone layer are enclosed in the cells, so their extraction is invariably assisted by cell wall-disrupting methods, such as shear force and ultrasound, among others, or the use of hydrolytic enzymes [8]. Most of the aleurone proteins act as storage proteins, although some also have hydrolytic functions in protein and starch metabolism during germination and grain filling.

4.1.1 Proteins from the Outer Layers

The pericarp of the wheat grain represents the first line of defense against biotic and abiotic stresses, providing a series of protective barriers:

1. Gives mechanical resistance against invasive attempts by insects and pathogenic microorganisms;
2. Has a probable role in regulating the movement of water into dry grains, which is important to germination, preharvest sprouting, expression of dormancy, and conditioning for optimum milling performance [54];
3. Is sheltered with an arsenal of chemical compounds and enzymes, aimed at repelling biotic attacks if mechanical damage cannot be avoided.

The strength of the wheat grain pericarp is provided by the combination of individual mechanical properties of its layers [31]. In the caryopsis development, pericarp plays a key role because it performs photosynthesis and supplies oxygen to the endosperm, besides dissipating excessive energy during the grain-filling [55]. On the other hand, some of the chemical compounds acting against biotic stresses are structural constituents of the mature grain coat, such as the phenolics and some proteins [21]. Others, for example, many enzymes, are produced de novo or activated during one or more stages of the grain development. The components of this protective machinery act not necessarily in isolation, but sometimes they do it together or synchronously. Details on the complicated defense mechanisms of cereal grains are out of the scope of this chapter. Here, the functions of those proteins which are constitutive of layers of wheat bran will be reviewed.

Production of proteins in the course of caryopsis development obeys to gene expression. Such expression is space differentiated and responds to programmed events, which are necessary for the grain to reach a characteristic phenotype and to be equipped for repelling biotic and abiotic stresses [56]. Aleurone and peripheral layers are formed in the early stages of development of the wheat caryopsis [57]. Aleurone provides protection to the endosperm and acts as a reserve of plant hormones, minerals, vitamins, and other nutrients, including proteins. Eventually, these nutriments will be available in the mature grain to participate in the beginning of a new life cycle. Peripheral layers are those comprising the outer and middle pericarp, which, as said before, are the protective tissues of the grain. Some authors include aleurone within the peripheral layers. In this review, this detail if is considered appropriate will be noted.

Proteomic studies on the peripheral layers (including the internal pericarp, hyaline layer, testa, and aleurone) of hexaploid wheat grains, from anthesis to physiological maturity (0–700 °CD), have resulted in the identification of 207 proteins.

Classified in functional categories, the dominating proteins in peripheral layers are those involved in metabolism (32%), storage (25%), stress/defense (17%), and genetic information and processing (12%), whereas the remaining are unknown or hypothetical (6%), involved in environmental information and processing (3%), ATP interconversion proteins (3%), and proteins involved in biosynthesis of secondary metabolites (2%) [15].

The enzyme profiles are in good correlation to the cellular events associated to each development stage in cereal grains, with metabolic proteins having their maximum expression at the early stages (up to 397 °CD). Dominating proteins are those involved in energy metabolism, including photosynthesis and ROS (reactive oxygen species). At 204 °CD, a significant decrease of protein folding, PS, and signal transduction occurs, which is associated to the end of cell differentiation. The maximum functional diversity has been found at 295 °CD, in whose profile the largest category corresponds to the carbohydrate metabolism (enzymes of the citric acid cycle, glycolysis, and sucrose synthesis) as well as ribonucleoproteins, the latter involved in posttranscriptional changes. At the 397–455 °CD stage, when the grain color changes from green to pale yellow, a drastic decrease in the profile of proteins belonging to energy metabolism is observed, indicating that maturity is in progress [15].

In the late stages, proteins which indicate response to hypoxia, such as alcohol dehydrogenase and pyruvate decarboxylase, are identified, as well as enzymes involved in detoxification and oxidative stress. The two latter groups, which include ascorbate-peroxidase, glyoxalase, and thioredoxin peroxidase, are also identified in all stages of development. In the early stages, their presence is due to the production of ROS by photosynthesis in the green pericarp, whereas in the late stages probably help in maintaining the aleurone alive as this is the only tissue that remains alive in the grain after maturity. Finally, in the latter stages (700 °CD), the protein profile is dominated by oxidative stress proteins and by storage and defense-related proteins. Globulins 2, 3, 3B, and 3C have been identified, which are probably specific to aleurone. Xylanase inhibiting proteins, as well as chitinases and endo-chitinases are also dominating in the latter stages [15].

4.2 Proteins from Aleurone

The cereal grain aleurone is the main stock of phytic acid and minerals, besides to be a reservoir of hydrolytic enzymes that act on starch and endosperm proteins during the germination process [58]. Many of the nutrients and bioactive compounds present in the wheat grain are concentrated in the bran [59], especially in the aleurone layer. This layer is rich in B complex vitamins since 82% of all niacin, 61% of pyridoxine, and 37% of riboflavin are contained in it. Between 43% and 61% of the total minerals are also contained in wheat aleurone, being particularly abundant phosphorus, potassium and magnesium. Likewise, aleurone has 43.8% of hemicelluloses (pentosans). Its protein content of 30% represents 15.3% of the total protein content of the wheat grain, at the time that provides 30% of the total Lys, the limiting essential amino acid in wheat [60].

Proteome from wheat aleurone is strongly genetically controlled as significant differences between species have not been found in proteomic studies. Aleurone is the layer of wheat bran with the most abundant variety of proteins. The number of Coomassie-stained spots observed in 2-DE gels of wheat aleurone ranges from approximately 700 to 1300. Proteins from aleurone and peripheral layers of *T. aestivum* "Chinese Spring" and "Recital" did not show quantitative differences. 2-DE gels of the protein extracts revealed 518 to 754 Coomassie-stained spots in the range of 12.6–76 kDa, irrespective to the cultivar [9, 10].

The proteomic study of aleurone cells, isolated from *T. aestivum* "Babber," resulted in 672 Coomassie-stained spots in the 2-D electrophoresis gels. Among these spots, 387 (58% of the total) were identified as globulin-like storage proteins, whereas the remainder 285 corresponded to proteins involved in carbohydrate metabolism, protein synthesis, stress, and defense. The major proteins were 7S globulin storage protein; xylanase inhibitors (XIP-I, XIP-III, TAXI-I); chitinases (26 kDa endochitinase 1 precursor, chitinase class II); pathogenesis related-4 protein; secretory protein; alpha-amylase/subtisilin inhibitor; enolase; dehydrogenases (glucose-3-phosphate-, glucose ribulose- and formate-); cytosolic NADP malic enzyme; aldose reductase, and heat-shock protein 70 (HSP70) [10].

Variation in the number of expressed proteins in aleurone between wheat varieties is higher than that found between species. There have been observed 1258 Coomassie-stained spots in *T. aestivum* aleurone versus 1109 in *T. durum*, with a total of 339 spots differing between genotypes. Among these 339 spots, 30.8% differed within *T. aestivum* varieties and 56.5% within those of *T.durum*, whereas only 12.7% differed between *T.aestivum* and *T. durum* genotypes [14]. On the other hand, 1320 Coomassie-stained spots in 2-DE gels of aleurone from *T. monococcus* have been observed. Eighty eight (91.5% of total) spots were common between *T.aestivum* and *T. monococcus*, which indicates a highly conservated genome A of the hexaploid wheat. Among the 88 spots that differed significantly between species, 53 proteins were identified, 83% of which were storage proteins. Other proteins were lipoprotein, glyceraldehyde-3-phosphate dehydrogenase, and 1-*cis*-peroxiredoxin [61]. Puroindolines are other class of proteins found in aleurone and endosperm, which are products of the major locus that controls the wheat grain hardness. It has been suggested that the action mechanism of puroindolines in affecting the grain texture in soft wheat is by stabilizing the amyloplast membrane during desiccation and maturation. On the other hand, such stabilization does not occur in hard wheat or only to a smaller extent, resulting in a more direct contact between starch and the gluten protein matrix and so in a harder texture [62].

5 Bioactive Properties of Protein and Peptides Isolated from Wheat Bran

Wheat bran proteins are underutilized when wheat bran is consumed by either human or animals. This is because most of proteins are enclosed in the aleurone layer, whose polysaccharide-constituted cell walls (which are resistant to digestion

in the human small intestine) reduce their bioaccessibility [63]. In the commercial pig production, where the main diet consists in plant carbohydrates, a similar case occurs since the nondigestible fiber reduces nutrient and energy digestibility [64]. Since extraction methods for wheat bran proteins are not efficient and non-profitable [8], as far as is known at the present time there are no rationale use of them to take advantage of their functional and nutritive properties. However, scientific evidences regarding potential benefits of proteins or peptides from wheat bran to human health, as well as proposals for their use in fields other than food, could revert this scenario. Interesting discoveries on wheat bran proteins could impact or enhance the perception and interest of people in the consumption of wheat bran, or developing more efficient methods for protein extraction.

It is known that the regular consumption of wheat bran results in reduction of body weight, so it has been suggested as preventive of obesity. However, at the present time, the compounds of bran which are responsible for diminishing body weight have not been yet identified [65]. Fiber is a candidate, but other components could also have a role. It is known the relation of obesity with the lipid metabolism. Fat in excess, which is accumulated in adipose tissues, is further released as glycerol and fatty acids by action of the pancreatic lipase, so the latter is the target of inhibition for developing anti-obesity drugs [66]. In this regard, attention has been directed to search for possible lipase inhibitors as responsible for weight reduction associated to the uptake of wheat bran. The presence of a lipase-inhibitor component solubilized in the aqueous phase of wheat bran was deduced when a loss of 77–94% in the activity of porcine pancreatic lipase on triglyceride hydrolysis was observed when assaying wheat bran at 1% concentration [67]. Such inhibition was reported to occur only with the wheat bran and not when other fibers were assayed, like cellulose or hemicelluloses. Also it was demonstrated that inhibition was independent of adsorption effects on the fiber [67]. Later, it was reported that the lipolysis-inhibitor compound could be a soluble protein [68], which was further corroborated [69]. In fact, two proteins with molecular weights of 24.4 and 27.5 kDa, which inhibited the pancreatic lipase in vitro, were isolated from wheat bran and germ, [70]. The inhibition mechanism was attributed to the interaction between the proteins and the triglyceride substrate, hindering the adsorption of the enzyme on the interface.

In other study, the ability of wheat bran to inhibit the hydrolysis of tributyrin, a model lipid, by the calf pre-gastric lipase, has also been demonstrated in vitro [71]. Reductions in lipase activity up to 30.5% were observed with suspensions of wheat bran, which was soaked by 24 h. Components responsible for the inhibitory effects were not identified, but it was suggested that some low molecular weight compounds, such as polysaccharides or proteins, could be involved [71]. The physiological relevance of lipase inhibition by wheat bran in humans remains to be elucidated, but data suggest that wheat bran proteins likely play a role during fat digestion.

Wheat bran proteins also could be effective protectors against bacterial infections. Proteins with molecular weight $<$90 kDa, isolated from a soluble extract of wheat bran by size exclusion chromatography, may interfere in the attachment of

enterotoxigenic *E. coli* to intestinal porcine epithelial cells [72], the latter used as model of study. The identification of proteins by mass spectrometry resulted in several low molecular weight protease inhibitors, such as Serpin-Z2B, Class II chitinase, endogenous alpha-amylase/subtilisin inhibitor, and alpha-amylase/trypsin inhibitor CM3. Also, evidence suggesting that Globulin 3 (one of the 7S storage globulins of wheat) of 66 kDa could be one of the most firmly attached wheat bran proteins to *E. coli* cells was demonstrated. Although no details on the molecular events leading to the interfering process were studied, the information was placed in the context of developing innovative anti-adhesion therapeutic agents to prevent bacterial pathogenesis [72].

Other interesting fact about the wheat bran proteins is what has to do with bioactive peptides. Interest for bioactive peptides is recent because many sources of them have been identified, including cereals [73], in such a way that there are now in the marketplace several products with a variety of declared bioactivities, such as antihypertensive, antistress, immunomodulatory, among others [74]. By taking advantage of the presence of endogenous proteases, bioactive peptides have been generated by autolysis of wheat bran extracts (i.e., by stimulation of endogenous proteolytic activity through promoting suitable conditions). Studies performed both in vitro and with murine models have demonstrated several effects of these peptides, which could be beneficial to human health.

The autolysis of wheat bran and shorts, both by-products of milling, the shorts being constituted by a mixture of fine particles of bran, aleurone, and germ [32], has resulted in the production of peptides with potential antihypertensive effect [75].These peptides strongly inhibit the Angiotensin I converting enzyme (ACE), which is a key enzyme in the regulation of blood pressure so that is the target of inhibition for the development of antihypertensive drugs [76]. Shorts and bran hydrolysates have shown ACE inhibitory activity (IC_{50}) of 0.08 and 0.14 mg protein/mL, respectively. The highest effect obtained is by autolysis of a mixture of bran and shorts for 12 h, pH 3.2, 40 °C, from which six peptides with ACE inhibitory activity have been isolated: Leu-Arg-Pro, Leu-Gln-Pro, Ile-Gln-Pro, Val-Tyr, Ile-Tyr, and Thr-Phe. The first two peptides are of additional interest as they contain the branched amino acid Leu, which activates the pathway of AMP-activated protein kinase (AMPK) [77, 78]. AMPK is thought to be important for regulating fatty acid metabolism [79]. In this context, there is a pathological condition known as the metabolic syndrome, whose liver manifestation is the fatty liver disease of nonalcoholic origin [80, 81]. A progressive form of fatty liver disease is the nonalcoholic steatohepatitis (NASH), which has as secondary pathogenic factors the oxidative stress and the downregulation of AMPK [82, 83]. For these reasons, the effects of the Leu-Arg-Pro and Leu-Gln-Pro tri-peptides obtained by autolysis of wheat bran have been investigated in murine model on oxidative stress and the AMPK pathway [84].In general terms, the administration of both peptides for 10 days to mice in which NASH was induced by a high-fat diet resulted in a modulation of oxidative stress and overregulation of AMPK. In addition, a significant decrease in the severity of NASH disease was observed [84].

6 Potential of Wheat Bran Proteins for Other Uses

If using in bulk, wheat bran proteins could have some applications in food technology [85]. Since long time, wheat bran proteins have been proposed as enrichers for bread-making flour, because of their high digestibility, a well-balanced amino acid profile, and a protein efficiency ratio comparable to that casein [86–88]. Results have shown the feasibility of adding wheat bran protein-rich flour at levels up to 10% with no negative effects on bread volume. On the other hand, sensory evaluation of bread which was added with the protein-rich flour at levels between 15% and 25%, resulted in lower scores for texture, color crust, and flavor, but these were not objectionable [87].Wheat bran protein concentrates have also shown good water- and oil-holding capacities as well as high dispersibility, the latter related with good emulsification and foaming properties [40].

Inhibition of polyphenol oxidases (PPO) by proteins and peptides from several sources has been reported [89–93]. PPO enzymes are responsible for the oxidation of phenolic compounds, which eventually results in browning of fruits and vegetables [94], so are also target of inhibition for preventing enzymatic browning [95]. Under this scenario, hydrolysates obtained after proteolysis of aqueous extracts of wheat bran proteins (i.e., the albumin fraction) have been assayed on buffered extracts of apple. Kinetic data showed PPO inhibition up to 40% at hydrolysate concentration of 1% (w/v). On the other hand, Lineweaver-Burk plots showed a mixed-type inhibition, indicating that inhibitor or inhibitors interacted with both, the enzyme and the enzyme-substrate complex [41]. Inhibitor molecules were not identified, but authors reasoned about a possible role of proteins or peptides [41]. The globulin fraction of wheat bran proteins has also been tested as inhibitor of PPO, using the amino acid l-Tyr as substrate [96]. Tyrosinase is a PPO broadly distributed in organisms, including mushrooms [97], and is usually used as a model in PPO inhibition studies [98]. Competitive inhibition of the activity of mushroom tyrosinase by globulins from wheat bran, with an inhibition degree of 24% at 2 mM of l-Tyr, has been reported [96].

The great variety of proteins found in wheat bran has motivated some researches for finding alternative uses, beyond nutrition or the traditional food science applications. This is an interesting avenue in the context of an integral scheme for using wheat bran, even more when emerging technologies are involved. Such is the case of bionanotechnology, where proteins have shown to have a great potential for the development of nanostructures with a diversity of applications [99–101]. At this respect, the nanoencapsulation in order to protect or making drugs and bioactive compounds more bioavailable is a promising approach in both the pharmaceutics and food industries [102, 103]. Proteins from animal origin, like albumins, gelatin, elastin, and those from milk and whey, have been the most studied as raw material to fabricate protein nanoparticles by different methods [99]. Plant proteins have also been studied, mainly soy proteins, zein, and wheat gliadins [101].

Recently, there have been some proposals for utilizing aqueous extracts of wheat bran as source of water soluble proteins for nanoparticle formation. Nanotubes with 100 nm of internal diameter, outer diameter 200 nm, and more than 30 μm in length

have been obtained through the apparent self-assembly of peptides released after proteolysis of wheat bran albumins in presence of calcium ions [104]. Since aqueous extracts, once dialyzed and lyophilized, had a complex chemical composition (protein accounted 45% DW), the structure of nanotubes was difficult to be attributed only to proteins. Instead, with the assistance of infrared spectroscopy analysis, it was proposed a model in which polysaccharide-protein complexes, upon protease action, behaved as sheets which were then gradually curved themselves with the subsequent formation of a tubular nanostructure stabilized by calcium bridges [104]. On the other hand, it was reported that undialyzed wheat bran aqueous extracts subjected to cold gelation/desolvation results in formation of spherical structures [105]. Cold-set gelation/desolvation is a method for fabricating nanoparticles [106] which is based in the alkali cold gelation of proteins. Cold gelation consists in a first heating step, further cooling to room temperature and, finally, adding divalent ions [107, 108]. In another more detailed study, it was shown the protein nature of the nanoparticles and that these were formed during the heat treatment, long before the addition of calcium, which is advantageous because one step would be omitted during the process [109].

Protein-rich aqueous extracts of wheat bran are also investigated because of their potential feasibility for acting as scaffolds for biomineralization in vitro [105]. Preliminary results show that a variety of minerals can be formed by just adding calcium ions to aqueous extracts of wheat bran. Among the minerals, some which are biologically induced, like calcium phosphates, are highlighted. The latter indicates that phosphorus present in the extracts plays a role as precursor ion and that other components of the extracts could act as the scaffold matrix. Experiments are in progress to investigate the nature of the matrix and mechanisms of biomineralization.

In summary, in wheat bran there is a great diversity of proteins, which is derived from a differential genetic expression of them during the development of the grain. Most of these proteins are concentrated in the aleurone layer, where storage proteins are predominating. In the layers of the intermediate and external bran, there are proteins mainly involved in stress and defense. Although bioaccessibility of the proteins of the aleurone layer is poor, those of the outer and intermediate bran layers could be more accessible and present bioactivity related to the metabolism of lipids and against enteropathogenic bacteria. Wheat bran proteins are also a source of antihypertensive peptides, as well as peptides that activate the signaling pathway regulated by AMPK. The latter is involved in the prevention of steatohepatitis of nonalcoholic origin because of its involvement in the regulation of fatty acid metabolism. No less important are the applications that wheat bran proteins could have in food technology, as inhibitors of enzymatic darkening or for their functional and nutritional properties. Study of wheat bran proteins could also be the scope of disciplines which are related to emerging technologies, such as the bionanotechnology and biomimetics. In Fig. 2 a summary of all this potential is represented.

As final reflection, the great amount and diversity of proteins that have been identified in wheat bran suggest a variety of properties which are not exploited yet. The newest evidences are pointing in direction to innovation possibilities which are worth to be studied.

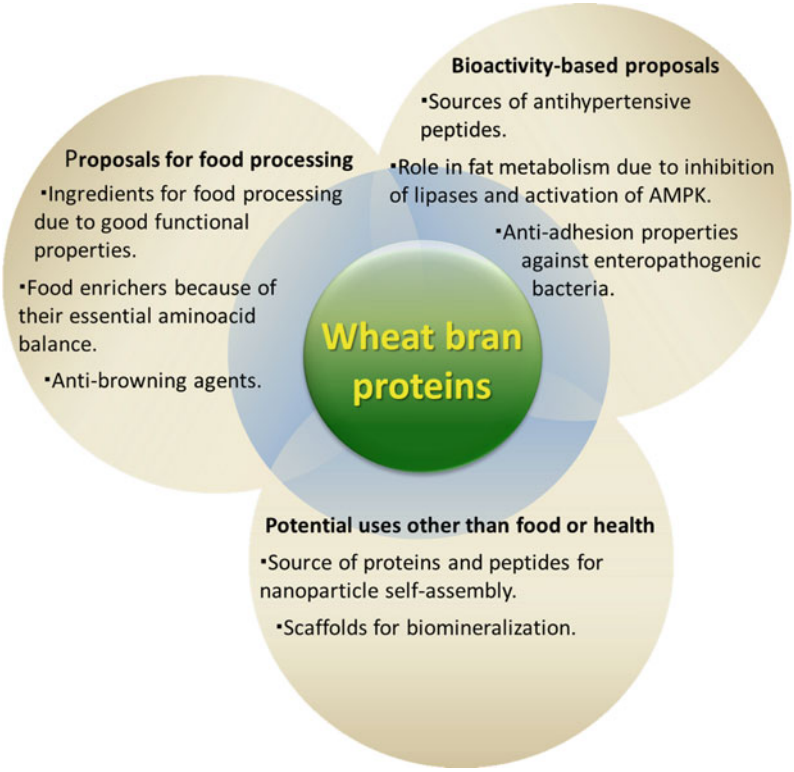

Fig. 2 Summary of the proposals for the use of wheat bran proteins

7 Conclusions

Underutilization of wheat bran proteins and the lack of proposals for their use make the search for innovative alternatives a good opportunity area. Studies showing the potential of wheat bran proteins or peptides in the prevention of hypertension and fat metabolism-related diseases could give some guideline. Also, technological uses of these proteins other than food, for example, in the fabrication of nanoparticles or biomineralization, could be explored in depth in order to add value to wheat bran.

Abstract

Hypertension is considered a major health problem throughout the world among adults, adolescents, as well as children and several preventive and therapeutic interventions are available. In addition to the pharmaceutical drugs and lifestyle changes, significant milestones have been achieved in the past decades in the identification of bioactive peptides from animal proteins with useful antihypertensive activities. The antihypertensive properties of these peptides are attributed to several mechanisms ranging from mineral-binding, opioid-like and antithrombotic properties to inhibition of ACE (angiotensin-converting enzyme). ACE-inhibitory peptides are the most widely studied bioactive peptides with promising potential in hypertension management. In addition to milk and dairy products, which are the major sources of antihypertensive peptides, a remarkable increase has been observed in the documentation of peptides from other animal proteins, such as meat, with demonstrated in vitro and in vivo antihypertensive properties. Numerous opportunities exist in the global market for the development of novel food products and additives based on these antihypertensive peptides for the dietary management of hypertension. This chapter reviews the antihypertensive peptides derived from meat proteins and examines their possible role as a functional ingredient in foods for the management of hypertension.

Antihypertensive peptides · ACE-inhibitory peptides · Muscle proteins · Connective tissue proteins · Aging · Meat products

1 Introduction

Being the largest cause of death and leading cause of disability worldwide, cardiovascular diseases are responsible for 17.3 million deaths per year globally [1] and by 2030 this toll is expected to increase to more than 23.6 million deaths worldwide [2]. Global deaths caused by cardiovascular diseases grew by 41% from 1990 to 2013 [3] and are considered to be the cause of one third of female deaths worldwide [4].

Despite of all prevention efforts and recent therapeutic advances, health issues associated with atherosclerotic cardiovascular diseases are increasing [5].

For all racial and ethnic groups, hypertension is a leading independent risk factor for cardiovascular diseases [6] and is thought to be the major preventable cause of premature death throughout the world [7]. Being the leading cause of mortality and morbidity among human adults globally [8, 9], epidemiologic data indicates that approximately 40% of the human population aged above 25 years are affected by hypertension [10] and has been held responsible for 10.4 million deaths per year worldwide [11]. It is the major cause of death among women compared with other metabolic and lifestyle risk factors [12]. Out of the annual 17 million deaths associated with cardiovascular diseases, more than half are caused by hypertension [13]. In the last few decades, childhood hypertension is constantly increasing and has become a major health problem in children [14].

With at least a diastolic blood pressure of 90 mm Hg and a systolic blood pressure of 140 mm Hg [15], the prevalence of hypertension is massive as more than 1 billion people have hypertension worldwide and 80 million people are affected in the USA alone [2, 16]. The number of the adult patients with hypertension has increased from 594 million in 1975 to 1.13 billion in 2015 [17]. Based on the definition used, the childhood hypertension has been recorded to exceed 30% in some reports [14]. Almost 90–95% of all the hypertensive patients belong to the most common class of high blood pressure known as "essential hypertension" which is recognized by an increase in a patient's blood pressure due to an unknown cause as no clear etiology is identified. It seems to be caused by a complex interaction between environmental factors and genetic predisposition. Essential hypertension is regarded as a controllable risk factor of cardiovascular disease as it can be improved with lifestyle choices like eating healthy foods, regular physical activity, decreasing sodium intake, quit smoking, reducing alcohol consumption, and reducing the stress level [18].

2 Management of Hypertension

2.1 Pharmacological Management

A range of pharmacologically active drugs are available on the market for the treatment of hypertension which include calcium channel blockers, ACE (angiotensin converting enzyme) inhibitors, adrenergic inhibitors (such as α- and β-blockers), diuretics, Ang II (angiotensin II) receptor blockers, direct vasodilators, renin inhibitors, and mineralocorticoid receptor antagonists. Drugs that inhibit renin-angiotensin system, which is a significant blood pressure regulator, are extensively used for pharmacological management of hypertension. Hypertension can be safely treated in most patients by using pharmacological drugs; however, these drugs have frequent side effects which may notably affect the quality of life and is a major burden on global healthcare costs.

2.2 Changes in Lifestyle

Lifestyle choices and dietary recommendations are considered utmost important in the management of hypertension. Unhealthy lifestyle and food eating habits are considered to contribute strongly to the persistence and onset of arterial hypertension [19]. The fast pace of modern times has increased preferences for processed and fast foods due to convenience that has contributed significantly to the spread of noncommunicable diseases like hypertension [20]. A substantial body of evidence has demonstrated that certain individual dietary elements and dietary patterns play a significant role in the development of hypertension [21]. Also, there is convincing scientific evidence that the consumption of food rich in both energy and dietary sodium is strongly associated with the development of hypertension [20, 22]. This has compelled many multinational food companies to reformulate their products towards healthier and better nutritional versions [23].

Several reports on hypertension recommend early intervention for pre-hypertension. In addition to the pharmacological drugs, changes in lifestyle including weight loss, reducing sodium intake, limiting alcohol consumption, increasing potassium intake, avoiding smoking, and regular physical activity are advised for both preventing the hypertension over the life span and for management of blood pressure in hypertensive subjects [21, 24, 25]. Dietary strategies to control the blood pressure in hypertensive patients and to lower the risk of hypertension in healthy persons include diets low in sodium and rich in vegetables, fruits, and low-fat milk products [21, 25].

2.3 Functional Foods and Food-Derived Peptides

Over the last few decades, efforts have been made consistently to produce designer and functional foods that contain certain components with blood pressure lowering properties. These foods are intended to supplement or provide an alternative to the pharmaceutical management of hypertension. Any food ingredient or additive with antihypertensive properties, including food-derived peptides, could contribute to the treatment or prevention of hypertension. Peptides with well-established in vitro ACE-inhibitory activities may exert in vivo hypotensive effects if they reach the target site in an active state [26, 27]. Fu et al. [28] suggested that daily consumption of aged beef with naturally developed antihypertensive peptides may play a vital role in maintaining normal blood pressure and indicated the possible use of these peptides for the development of functional beef products, like patties, with antihypertensive properties. Unlike synthetic ACE inhibitor drugs (such as captopril, benazepril, perindopril, enalapril, trandolapril, and quinapril) which have frequent side effects such as cough, hypotension, headaches, skin rashes, fatigue, fetal disorder and so on, food-derived ACE inhibitors are believed to be stable and have minimal side effects [29]. Very few studies have been conducted on the side effects of food-derived ACE-inhibitory peptides to date; however, it is believed if these natural peptides would cause any side effects, those would be milder [30, 31].

3 Antihypertensive Peptides

Latent within the parent protein, bioactive peptides are specific stretches or fragments of food proteins which can be released during food processing like enzymatic hydrolysis or fermentation or during digestion inside the gut and have some physiological benefits to human health beyond their nutritional capabilities. These short sequence fragments are characterized with a low molecular weight and approximately 2–30 amino acid residues in length [32]. Released in vivo or in vitro from food proteins, these peptides have the ability to affect various systems of body like cardiovascular, digestive, immune, endocrine, and nervous system and attribute various health effects including hypotensive, antimicrobial, cholesterol-lowering, opioid, antioxidant, antithrombotic, immunomodulatory, cytomodulatory, and antigenotoxic activity.

Among the various bioactivities, antihypertensive property is widely studied and several peptides from numerous sources have been reported. Proteins of animal origin like meat, milk, whey, egg, blood, and fish proteins have been reported to contain potential antihypertensive peptide sequences in their primary structure which could become active when released during enzymatic or microbial hydrolysis [33]. Table 1 presents some of the identified peptide sequences with antihypertensive properties from different animal proteins. Potentially bioactive ACE-inhibitory peptides are normally short di- or tri-peptides as sequence length plays an important role in the antihypertensive property of a peptide which could easily enter and bind the deep-seated active site of ACE [58, 59]. However, peptide sequences of up to 14 amino acids have been reported to possess antihypertensive properties [60]. These peptides usually contain aromatic or hydrophobic residues at their ultimate and penultimate positions, with proline being particularly favorable residue in both these positions [49, 59, 61, 62]. Besides the sequence length, the potency of the ACE-inhibitory peptides is also determined by the three C-terminal residues, with aromatic residues being most favored [62]. Several studies have suggested that ACE-inhibitory peptides may also possess antioxidant properties due to the shared requirements for both properties in terms of structure and length of peptide [63, 64]. The antihypertensive peptides have attracted global interest for the possible use of their therapeutic potential for the development of antihypertensive foods for dietary management of hypertension. Several new products have already struck the market with antihypertensive claims (such as Ameal S, Danaten, and Evolus) and several are under process of development and validation. Results of extensive in vivo clinical trials are used to support the health claims of these products.

4 Mechanisms of Antihypertensive and ACE-Inhibitory Peptides

Regulation of blood pressure in human body is a complex process involving several metabolic pathways that makes the pathophysiology of hypertension highly complex. It involves the interaction of genetic, environmental, and several other dietary

Table 1 Peptide sequences with antihypertensive properties from different animal proteins

and physiological factors such as long-term high sodium intake levels, increased sympathetic nervous system activity, increased RAS activity, low dietary calcium and potassium intake, endothelial dysfunction, altered cellular ion channel, vessel resistance variations due to vascular inflammation, and elevated activity of vascular growth factors [65, 66]. The most widely studied pathways, with regard to food-derived antihypertensive peptides, involve those reported to inhibit angiotensin converting enzyme (ACE) in vitro. ACE is a key enzyme that regulates the blood pressure of the body through the renin-angiotensin system. In addition to ACE-inhibitory mechanism, food-derived peptides may help in lowering the blood pressure through mechanisms that target rennin activity, calcium channels, arginine-nitric oxide pathway, endothelin system function, Angiotensin (Ang) receptors, vascular inflammation and oxidative stress, vascular remodeling, and sympathetic nervous system [65, 67, 68]. As the peptides can trigger signaling processes by binding the receptors in the gut, they may not need to be absorbed; however, many peptides exert their antihypertensive effects only when present in relevant amounts in the vascular system.

ACE inhibition is a better physiological target for treatment of clinical hypertension due to its association with two types of blood pressure systems, the rennin-angiotensin system (RAS) and kinin-nitric oxide system (KNOS). The angiotensin converting enzyme (ACE), a heavily glycosylated membrane-bound zinc metalloprotease, is a principle enzyme in RAS that controls the amount of fluids in the body and thus regulates the blood pressure. Angiotensinogen is a prohormone synthesized in liver which is cleaved by rennin produced by kidney to produce a decapeptide Ang I (angiotensin I). Ang I is further cleaved by ACE to produce octapeptide Ang II (angiotensin II) which is a potent vasoconstrictor and acts on vascular smooth muscles. Further, ACE also causes inactivation of bradykinin and kallidin, the vasodilatory peptides of KNOS. Therefore, by blocking the formation of Ang II and by reducing the degradation of bradykinin and kallidin, ACE inhibitors can exert antihypertensive effects. Although, ACE inhibitor pharmaceutical drugs are very much successful in reducing the blood pressure, food-derived antihypertensive peptides are free from any associated side effects and are believed to be safer than pharmaceutical drugs [65].

5 Production of Antihypertensive Peptides

Protein hydrolysates could be produced from protein sources by employing several methods like enzymatic hydrolysis by using proteolytic enzymes, chemical hydrolysis process, and microbial fermentation [69]. Hydrolysates with ACE-inhibitory properties have been generated from several kinds of proteins including proteins of animal origin, like fish protein [70], meat protein [71, 72], milk protein [73], egg protein [44], microbial proteins, like *Saccharomyces cerevisiae* protein [74], or plant proteins, like sorghum grain protein [75]. These peptide hydrolysates could be prepared economically from animal wastes and by-products that are rich in protein and are generally processed into low-cost end products like meat meal, blood meal, and so on [76].

5.1 Chemical Hydrolysis

Solutions of alkalis and acids could be used to cleave the peptide bonds of protein substrates to produce different peptides. There is less control over the hydrolysis which results into hydrolysates of different peptide profiles with reduced bioactivities and nutritional qualities. Higher variations in the end product and use of organic solvents limit the high-end use of these hydrolysates.

5.2 Enzymatic Hydrolysis

Exogenous proteolytic enzymes are widely used to produce peptides of several bioactivities by hydrolyzing various food protein substrates. Novel peptides with higher antihypertensive properties have been discovered by using proteases from various sources like alcalase, pepsin, flavourzyme, trypsin, actinidin, and papain which are commercially available or by using some noncommercially available proteases, such as *Virgibacillus halodenitrificans* SK1–3-7 protease [77]. Due to the milder conditions and better control over the hydrolysis, enzymatic hydrolysis is considered a better method for the production of bioactive peptides. The amino acid composition of the hydrolysates obtained is similar to that of the protein substrates with few modifications depending on the type of enzymes employed for the hydrolysis. This method is suitable for the production of hydrolysates for food and pharmaceutical industries due to noninvolvement of any toxic chemicals or organic solvents [78]. Protein hydrolysates of specific bioactivities could be produced by controlling the conditions using specific enzymes in comparison to chemical hydrolysis method. Protein hydrolysates of different peptide profiles could be obtained by using different enzymes and enzyme:substrate ratio.

5.3 Microbial Fermentation

Several microorganisms that are involved in the fermentation processes of foods have the proteolytic capabilities and could produce protein hydrolysates with bioactive peptides. The most common examples of these microorganisms are the ones involved in the fermentation of dairy products [79]. The best known hypotensive peptides IPP (Ile-Pro-Pr) and VPP (Val-Pro-Pro) were first isolated and identified from fermented milk [76]. Several studies have been conducted for the production of protein hydrolysates by utilization of microbial fermentation [80, 81]. Antioxidative and antimicrobial peptides were produced from tannery fleshings by fermentation using lactic acid bacteria [82]. *Bacillus pumilus* A1, a keratolytic bacterium, has been reported to produce wool waste protein hydrolysates with antioxidative properties [80]. *Bacillus subtilis* A26, another proteolytic bacterium, has been reported to produce protein hydrolysates through fermentation of several fish proteins [81].

5.4 Recombinant DNA Technology

Over the years, many novel genetic engineering-based techniques have been developed for the production of peptides at industrial scale. Recombinant DNA technology is a preferred choice for the production of relatively large peptides consisting of up to several hundred amino acids. This technology is well suited for the production of large quantities of peptides from very inexpensive starting materials; however, it typically requires a long and expensive research and development phase. There are certain challenges in the production of peptides by these methods like degradation of short hypotensive peptides by peptidases or proteases and the threat that expression products may be harmful to the host. These shortcomings have been taken care of by producing the peptides as a part of fusion proteins and afterwards separating the target peptides by using enzymes and purifying them, though that adds to the cost of production. Peptides with sequences FFVAPFPEVFGK, GHIATFQER, HVLPVP, and HHL with antihypertensive properties have been successfully expressed in E. coli [83]. A multimer, a precursor of 11 different hypotensive peptides, was expressed and shown to release peptides during simulated gastrointestinal digestion [84].

5.5 Synthetic Antihypertensive Peptides

Peptides with antihypertensive properties could be conveniently synthesized for therapeutic management of hypertension and is the most popular method of production of peptides in a laboratory [85, 86]. The choice of the method depends on the length and quantity of the desired product. While liquid-phase synthesis is a classical approach for large-scale production of peptides for industrial purposes, the solid-phase approach is now the standard method of production of peptides at the laboratory scale and is most powerful method for synthesis of peptides composed of about 10 to over 100 residues [85]. Peptides with several bioactivities have been synthesized for their therapeutic applications and are currently being used for their therapeutic contribution to the treatment of diabetes, obesity, immunosuppression and gastrointestinal, cardiovascular, osteoporotic, antibacterial, or oncologic diseases [87]. Synthesizing peptides or modifying peptides to improve their therapeutic value is a cost-effective and convenient method of production; however, use of synthetic peptides for the therapeutic purposes cause several and severe side effects [88] which reduces their superiority over therapeutic drugs.

6 Antihypertensive Peptides as Functional Food Ingredients

The search for functional foods with antihypertensive properties has increased as hypertension continues to increase worldwide. Several milk products like Calpis (Calpis Co., Tokyo, Japan), Evolus (Valio, Helsinki, Finland), Ameal (Calpis Co., Tokyo, Japan), and Danaten (Danone, Paris, France) with scientifically proven health

claims are available in the market and exclusive rights of these manufacturers to use these functional ingredients has proven to be a crucial factor in the ultimate success of these products in the market [89]. Table 2 presents some of the commercially available food products with antihypertensive claims. Using antihypertensive peptides as functional ingredients for the development of food products needs certain considerations including characterization of their physicochemical and sensorial properties. Figure 1 shows some of the essential steps in the development of meat peptide-based functional foods with antihypertensive properties. One of the challenges of using peptides as ingredients in food products is the bitter taste of these peptides composed mainly of hydrophobic amino acids which are responsible for both bitterness and antihypertensive properties [83]. However, several masking methods could preferably be used to improve the acceptability. An optimal method for the production of peptides by hydrolysis is required which could generate the output sufficient to meet the industrial scale. The peptides need to retain their antihypertensive properties during the entire stages of industrial level processing and remain stable during long-term storage. Little information is available in the literature about the effects of various processing methods on the activities of antihypertensive peptides. Research is required in some areas like analyzing the interaction of food components and peptides during processing, storage, and digestion.

Dehydration of peptides by using spray drying method has been reported to induce changes in peptide composition and causing nonenzymatic browning and a reduction in amino acid content [83]. Contreras et al. [90] studied the possibility of production of two antihypertensive peptides viz. Ala-Tyr-Phe-Tyr-Pro-Glu-Leu and Arg-Tyr-Leu-Gly-Tyr in a casein hydrolysate at an industrial scale. The peptides were also incorporated into yoghurt and evaluated for stability during various processing conditions and during storage under refrigerated conditions. The peptides retained their ACE-inhibitory properties in vivo in spontaneously hypertensive rats as well as under in vitro conditions. Four synthetic peptides (DFHINQ, GFHI, FHG, and GLSDGEWQ) with ACE-inhibitory properties have been reported to retain stability in water during heat treatment [91].

Another important challenge associated with antihypertensive food products is the bioavailability of peptides which is responsible for differences between in vitro and in vivo activities of peptides. The capacity of peptides to reach the target organ in active form determines the physiological effect of the peptides. The final desired activity of peptides depends on a series of processes involved in the oral administration of peptides. These include the effect of GIT enzymes, brush border peptidases, active intracellular peptidases during absorption through intestinal barrier, and enzymes in the blood once they make it to the circulation [92, 93]. These processes are more likely to affect the sequences which are responsible for the antihypertensive properties of the peptides before they will elicit their response in the target organ. Thus more scientists are interested in evaluating the different factors affecting the bioavailability of different sequences responsible for hypotensive properties. Different studies have been conducted on the effect of digestion on the hypotensive peptides by using in vitro gastrointestinal simulation models. Several studies have also analyzed the intestinal absorption by using in vitro intestinal epithelial

Table 2 Commercially available products with antihypertensive claims

Product	Company	Peptides	Product type
Ameal S 120, Ameal S, Ameal BP	Calpis Co. (Tokyo, Japan)	VPP, IPP	Cultured milk, tablets, capsules, component
Calpis	Calpis Co. (Tokyo, Japan)	VPP, IPP	Uncarbonated sweetened fermented milk beverage
Evolus	Valio (Helsinki, Finland)	VPP, IPP	Calcium-enriched fermented milk
Vasotensin	Metagenics, USA	LKPNM, LKP	Tablets (bonito protein hydrolyzate)
Peptide C12, C12 Peption	DMV International, The Netherlands	FFVAPFPEVFGK	Ingredient (casein protein hydrolyzate)
Tensiocontrol	Bioactor, The Netherlands	RADHPFL, IVF, YAEERYPIL	Ingredient (egg protein hydrolyzate)
Biozate	Davisco Foods International, USA	Whey peptides	Purified hydrolyzed whey protein (powder form)
Lowpept	Innaves Biotech, Spain	RYLGY, AYFYPEL	Tablets, ingredient (powdered casein hydrolyzate)
Casein DP Peptio	Kanebo, Japan	FFVAPFPEVFGK	Soft drink (casein protein hydrolyzate)
Danaten	Danone (Paris, France)	Tripeptides	Fermented milk drink (*Lactobacillus helveticus* DN-119 90)

simulations involving the use of monolayer of intestinal cell lines. While evaluating the effectiveness of hypotensive peptides, improvement in the bioavailability is considered as an important goal.

7 Antihypertensive Peptides from Meat Proteins

With increasing awareness and concern about the health and safety, the quest to replace synthetic drugs with natural compounds is of great interest. Antihypertensive peptides from food proteins could provide an excellent alternative to synthetic drugs [94] which is a major target for the treatment and prevention of clinical hypertension [48]. Several human and animal studies have demonstrated the blood pressure lowering capabilities of the food-derived peptides through ACE inhibition [95, 96]. Proteins from meat and meat by-products are considered as an excellent source of peptides (Fig. 2) with both in vitro and in vivo ACE-inhibitory properties [97]. In the last few decades, peptides derived from meat proteins from several sources, such as chicken muscle [98], porcine muscle [99], and beef muscle [100], have been found to reduce blood pressure through ACE inhibition [101]. Peptides with ACE-

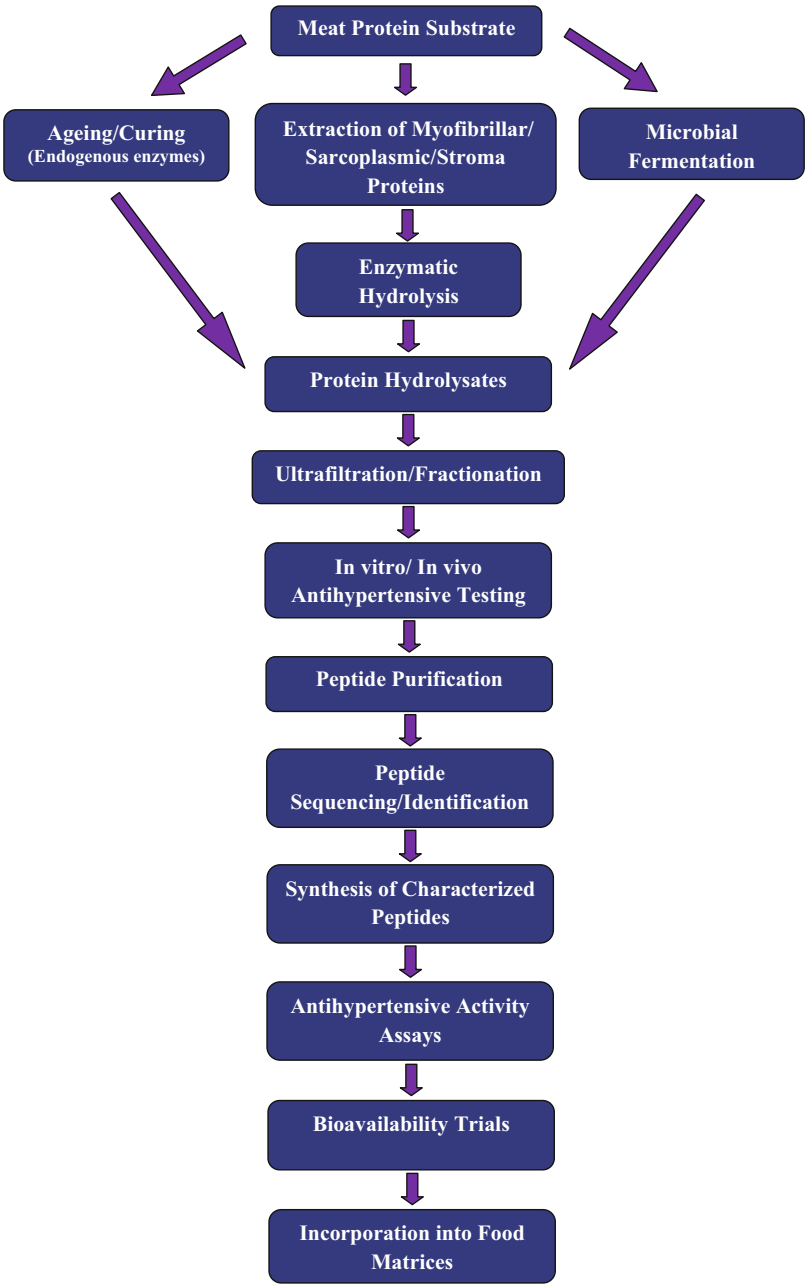

Fig. 1 Schematic diagram for the production of functional foods with antihypertensive properties

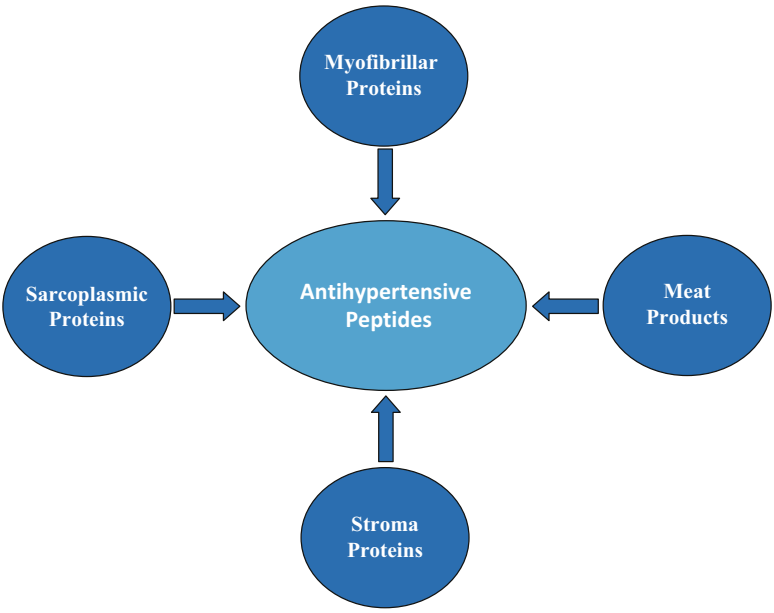

Fig. 2 Different meat protein substrates for the production of antihypertensive peptides

inhibitory properties have been reported from several skeletal muscle proteins namely myosin, actin, tropomyosin, troponin, and collagen [85]. ACE-inhibitory potential of these peptides is measured in vitro by IC_{50} value and in vivo by using spontaneously hypertensive rats as an accepted animal model for human essential hypertension [102–104]. Results from several studies have demonstrated that meat protein hydrolysates may represent the source of natural peptides capable to reduce ACE-I activity.

7.1 Myofibrillar Proteins

7.1.1 Contractile Proteins

Among all the meat protein-derived bioactive peptides, ACE-inhibitory peptides are most extensively studied [102, 105]. ACE-inhibitory peptides are commonly produced from hydrolysis of skeletal muscle and connective tissue proteins of farm animals like pig and poultry [106–108]. A large number of peptides with ACE-inhibitory properties have already been reported from the enzymatic hydrolysates of various meat proteins [27, 102, 105, 109]. Two ACE-inhibitory pentapeptides sequenced as MNPPK and ITTNP were identified from the hydrolysates of pig skeletal muscle proteins and were named as myopentapeptide A and B, respectively [108]. These pentapeptides, corresponding to position 79–83 and 306–310 on the myosin heavy chain, respectively, were shown to have ACE-inhibitory properties in

spontaneously hypertensive rats [110]. Six other peptides viz. PPK, MNP, NPP, ITT, TNP, and TTN sharing the sequence parts of these two myopentapeptides also showed the antihypertensive properties. An octapeptide VKKVLGNP corresponding to position 47–54 on myosin light chain with temporary ACE-inhibitory properties was identified from the myosin protein hydrolysates [99]. One more peptide sequenced as KRVITY isolated from pig skeletal myosin B treated with pepsin and VKAGF isolated from porcine actin were reported to have significant blood pressure lowering properties in vivo in rats [111, 112]. With IC_{50} value of 6.1 μM, KRVIQY was reported to retain its ACE-inhibitory activity after heating the myosin B at 98 °C for 10 min prior to hydrolysis by pepsin, suggesting the bioavailability of the peptide even after cooking.

Seven ACE-inhibitory peptides with sequence LKP, LKA, LAP, IKW, FKGRYYP, FQKPKR, and IVGRPRHQG were isolated from chicken muscle proteins by thermolysin treatment [98]. Although, IC_{50} value of these peptides ranged from 0.21 μM to 14 μM, however, the heptapeptide FKGRYYP with IC_{50} value of 0.55 μM failed to produce antihypertensive activity in vivo in spontaneously hypertensive rats. This indicated that in vitro ACE-inhibitory activity of the peptides may not necessarily correlate with their in vivo ACE-inhibitory activity. Intracellular peptidases or enzymes in the GIT or blood vascular system may have degraded the peptide affecting its antihypertensive properties in vivo. Further, modification of the peptides in the liver may also affect their in vivo antihypertensive potential [102]. ACE-inhibitory properties of chicken breast muscle extract were reported in vitro as well as in vivo in spontaneously hypertensive rats [104]. There was a significant increase in the ACE-inhibitory activity of the extracts treated with an Aspergillus protease and gastric proteases (trypsin, chymotrypsin, and intestinal juice). All the three peptides identified with ACE-inhibitory properties possessed a common sequence Gly-X-X-Gly-X-X-Gly-X-X, and the peptide with sequence Gly-Phe-Hyp-Gly-Thr-Hyp-Gly-Leu-Hyp-Gly-Phe showed the strongest ACE-inhibitory activity with IC_{50} value of 42.4 μM. This peptide had a high affinity for ACE and inhibited the enzyme in a noncompetitive manner. The Phe residue at the C-terminus position and an aromatic residue at the antepenultimate position were reported to play an important role in the inhibitory activity [113] supporting the theory of presence of three C-terminal hydrophobic residues for the ACE-inhibitory activity of a peptide. Binding of a peptide to ACE is strongly influenced by this C-terminal tripeptide sequence and is required for interaction with three hydrophobic subunits located on the active site of ACE [114]. Main inhibitors of the enzyme ACE show hydrophobic residues or proline, lysine, or arginine as C-terminal amino acids [115–117].

Two novel ACE-inhibitory peptides MNVKHWPWMK and VTVNPYKWLP corresponding to positions 825–834 and 125–135 of myosin heavy chain, respectively, were identified from chicken leg meat hydrolysate digested with pepsin. With IC_{50} values of 228 μM and 5.5 μM, respectively, the peptides were suggested to be a good starting substance for designing food supplements for hypertensive patients [118]. Gu et al. [119] studied the production of ACE-inhibitory peptides from muscles of black-bone silky fowl (*Gallus gallus domesticus Brisson*) hydrolyzed

with Alcalase 2.4 L (2.4 AU/g) and papain (320,000 U/g). A total of 29 peptide sequences were identified and based on the ACE-inhibitory properties of different fractions and prior literature, 11 peptide sequences with probable ACE-inhibitory properties were selected, synthesized, and further analyzed for ACE-inhibitory properties. Finally, two novel peptides Leu-Glu-Arg (IC_{50} = 45.62 ± 2.40 μM) and Gly-Ala-Gly-Pro (IC_{50} = 253.07 ± 6.66 μM) with strong ACE-inhibitory properties were found.

Beef myofibrillar protein extract was used to produce ACE-inhibitory peptides by using five commercially available food-grade microbial protease preparations viz. HT proteolytic (HT; 2 mg/mL) protease, acidic fungal protease (AFP; 20 mg/mL), fungal protease 31,000 (F31 K; 10 mg/mL), fungal protease 60,000 (F60 K 4 mg/mL), and fungal protease II (FPII; 4 mg/mL) [32]. The small peptide pool obtained from hydrolysate by using gel permeation chromatography (nominally <15 residue peptides) was reported to exhibit 89.0 ± 2.9% ACE-inhibitory activity. Castellano et al. [79] studied the production of ACE-inhibitory peptides from porcine myofibrillar proteins hydrolyzed by *Lactobacillus sakei* CRL1862 and *Lactobacillus curvatus* CRL705 isolated from traditional Argentinean sausages at 30 °C for 36 h. Meat-borne *Lactobacilli* were able to produce peptides with ACE-inhibitory properties and a total of 50 and 18 peptides were characterized from *L. curvatus* CRL705 and *L. sakei* CRL1862 protein hydrolysates, respectively.

7.1.2 Regulatory and Cytoskeletal Proteins

ACE-inhibitory peptides have been reported not only from muscle contractile proteins but also from regulatory and cytoskeletal proteins like troponin, tropomyosin, nebulin, and titin. An ACE-inhibitory peptide with sequence RMLGQTPTK was isolated from porcine troponin-C hydrolyzed with pepsin and showed high resistance to digestive enzymes, suggesting its possible in vivo ACE-inhibitory activity [120]. Two novel ACE-inhibitory peptides with sequence Lys-Arg-Gln-Lys-Tyr-Asp-Ile (KRQKYDI) and Glu-Lys-Glu-Arg-Glu-Arg-Gln (EKERERQ) were isolated from porcine skeletal muscle troponin treated with pepsin with proven in vivo antihypertensive properties in spontaneously hypertensive rats [103]. The IC_{50} value of KRQKYDI and EKERERQ was reported to be 26.2 μM and 552.5 μM, respectively, and the peptide KRQKYDI showed the strongest ACE-inhibitory activity among all previously reported troponin peptides.

Nearly 22 peptides, including the novel peptides MYPGIA and VIPEL, were reported from porcine *Longissimus dorsi* muscle hydrolyzed by sequential action of pepsin and pancreatin [121]. Among these, two pentapeptides with sequence KAPVA (IC_{50} 46.56 μM) and PTPVP (IC_{50} 256.41 μM) corresponding to position 4784–4788 and 4216–4220 on titin, respectively, and tripeptide RPR (IC_{50} 382 μM) corresponding to position 1263–1265 on nebulin were also reported. Strong ACE-inhibitory activity of these peptides (KAPVA, PTPVP, and RPR) was demonstrated in vivo in spontaneously hypertensive rats after oral administration [122]. Although, RPR showed far less ACE-inhibitory activity than KAPVA in vitro, it exhibited comparable ACE-inhibitory activity to that of KAPVA in vivo. Higher in vivo

activity of peptides which show weaker in vitro activity might be explained by their higher affinity to the target tissues or the possibility of involvement of a mechanism other than inhibition of ACE [102].

7.2 Sarcoplasmic Proteins

An ACE-inhibitory hexapeptide (VLAQYK) with an IC_{50} value of 32.06 μM was identified from enzymatic hydrolysates of sarcoplasmic protein extracts from beef *Biceps femoris* [123]. The peptide exhibited strong ACE-inhibitory properties in vivo in spontaneously hypertensive rats and also lowered blood total- and LDL-cholesterol concentrations [124]. Based on its strong ACE-inhibitory properties in vitro as well as in vivo, the authors proposed the use of this hexapeptide in clinical applications and for development of functional foods. Four ACE-inhibitory peptides identified as FHG, GFHI, DFHING, and GLSDGEWQ were produced from beef sarcoplasmic proteins hydrolyzed by incubating with commercial enzymes thermolysin + proteinase A (pH 7.5/37 °C), proteinase K (pH 7.5/37 °C), trypsin (pH 7.6/25 °C), tyrosinase (pH 6.5/25 °C), papain (pH 6.2/25 °C), pepsin (pH 3.0/37 °C), and protease (pH 7.5/37 °C) for 8 h [100]. The measured IC_{50} values of FHG, GFHI, DFHING, and GLSDGEWQ against ACE were 52.9, 117, 64.3, and 50.5 μg/ml, respectively.

Bernardini et al. [125] studied the possibility of production of ACE-inhibitory peptides from sarcoplasmic proteins hydrolyzed from beef low-value brisket cuts (*Pectoralis profundus*) with papain for 24 h. The 3 kDa peptidic fractions showed higher ACE-inhibitory activity than 10 kDa fractions which was in agreement with previous studies suggesting that peptide sequences with ACE-inhibitory properties are generally composed of small number of residues and are less than 3 kDa [50]. The authors suggested the possible use of these ACE-inhibitory brisket hydrolysates for the development of meat products, like patties, with antihypertensive properties. Hydrolysates from different sources like milk and soy have already been incorporated into the meat products like beef and pork patties [126–128]. A unique heptapeptide with sequence FISNHAY was generated from porcine sarcoplasmic proteins by *L. sakei* CRL1862 in fraction 27 which showed highest ACE-inhibitory activity. This peptide had, rather than a proline residue, aromatic (tyrosine) and aliphatic (alanine) residues at the ultimate and penultimate C-terminal positions, respectively [79].

7.3 Connective Tissue and Other Proteins

In comparison to other meat proteins, bovine elastin and collagen possess highest frequency of peptide sequences with different bioactivities [129]. Peptides derived from hydrolysis of bovine connective tissues have been reported to have strong ACE-inhibitory properties [130–132]. Peptides with strong ACE and renin-inhibitory activities were identified from collagen extracted from nuchal ligament of

bovine carcasses (GPRGF) and from cooked *semitendinosus* muscle (SPLPPPE, EGPQGPPGPVG, and PGLIGARGPPGP) [28, 132]. Two ACE-inhibitory peptides were produced and identified from collagen obtained from bovine Achilles tendon hydrolyzed with bacterial collagenase. Both the peptides sequenced as AKGANGAPGIAGAPGFPGARGPSGPQGPSGPP and PAGNPGADGQP-GAKGANGAP retained 80% of the ACE-inhibitory properties after treatment with common GIT enzymes [133]. Ryder et al. [32] studied the production of ACE-inhibitory peptides from beef connective tissue protein extract by using five microbial protease preparations. The small peptide fraction obtained from the hydrolysates showed 90.9 ± 1.0% ACE-inhibitory activity.

O'Keeffe et al. [134] studied the ACE-inhibitory activity of porcine skin gelatin hydrolyzed by *Aspergillus niger* prolyl endoproteinase for 4 h. Peptides were identified by using UPLC-ESI-MS/MS and 166 sequences were identified, Met-Gly-Pro being the most potent ACE-inhibitory peptide. Some of the peptides identified in the hydrolysate like Gln-Phe, Tyr-Pro, Leu-Ala, Val-Pro, Ile-Pro, Ile-Ala, and Gly-Pro were previously identified as strong ACE-inhibitors. Among these peptides Val-Pro, Ile-Pro, Ile-Ala, and Gly-Pro were suggested to be resistant to GIT enzymes following an in silico GI digest using PeptideCutter. The hydrolysate showed strong blood pressure lowering properties in spontaneously hypertensive rats which was attributed to the abundance of peptides with C-terminal Pro residue. The in vivo antihypertensive properties of hydrolysates obtained from gelatin from different sources have been reported by several workers [135–141]. Short peptides, such as Pro-Hyp, released from gelatin have been reported to cross the intestinal barrier and enter the blood vascular system after oral ingestion of hydrolysates by mice [142] and humans [143].

Inoue et al. [144] produced hydrolysates with ACE-inhibitory properties from porcine liver with in vivo blood pressure lowering properties in spontaneously hypertensive rats. Lafargaa et al. [72] studied the release of ACE-inhibitory peptides from porcine and bovine meat proteins including collagen, hemoglobin, and serum albumin, commonly found in meat by-products such as blood, bone, and low-value meat cuts, using enzymes papain, pepsin, bromelain, ficain, and thermolysin. PeptideCutter and BIOPEP were used for in silico cleavage of the proteins to predict the release of over 30,000 peptides. Four novel ACE-inhibitory peptides viz. Asp-Phe-Tyr, Ala-Pro-Pro-His, Ile-Ile-Tyr, and Ile-Phe-Tyr which were not present in existing databases were identified. Sequence Glu-Tyr, an ACE-inhibitory dipeptide corresponding to position 23–24 of bovine hemoglobin subunit alpha, was identified which was previously reported from shark meat [145] and several natural products including milk and fish [145, 146]. Fu et al. [131] identified two collagen peptides with sequence GPRGF and VGPV from bovine connective tissue and were demonstrated to be transported across Caco-2 cells, a monolayer of human intestinal cell lines, suggesting the possible bioavailability of the peptides and likelihood to exhibit the ACE-inhibition activity in vivo. Two peptides identified from the porcine hemoglobin with sequence GFPTTKTYFPHF, corresponding to 34–46 fragment of the α-chain, and VVYPWT, corresponding to 34–39 fragment of the β-chain, were reported to have ACE-inhibitory properties, showing IC_{50} values of 4.92 μM and 6.02 μM, respectively [147].

Saiga et al. [141] studied the ACE-inhibitory properties of hydrolysates obtained from collagen extracted from chicken legs. The hydrolysate produced with an *Aspergillus* species-derived enzyme showed the highest activity ($IC_{50} = 260$ μg/mL) with a strong antihypertensive effect observed in spontaneously hypertensive rats administered with low fraction. Peptides with a sequence Gly-Ala-Hyp-Gly-Leu-Hyp-Gly-Pro exhibited highest ACE-inhibitory activity ($IC_{50} = 29$ μM). Two ACE-inhibitory peptides with sequence GPL and GPV and IC_{50} values of 2.55 μM and 4.67 μM, respectively, were purified from bovine skin gelatin hydrolysate [148].

7.4 Effects of Aging and Cooking of Meat

Encrypted in the meat proteins are several ACE-I inhibitory sequences which are released during natural processes, like aging, dry curing, and fermentation, which naturally induce proteolysis of both sarcoplasmic and myofibrillar proteins in the muscles [149]. Fu et al. [28] studied the endogenous generation of peptides in beef *Longissimus thoracis* (LT) and s*emitendinosus* (ST) muscles during 20 days postmortem aging and reported the presence of a number of peptides with ACE-inhibitory properties. The activity was highest on day 10 in cooked ST (63 °C) which decreased at day 20, suggesting the presence of potent peptides on day 10 which became accessible by cooking. Highest ACE-inhibitory activity was exhibited by collagen-derived peptide sequences SPLPPPE, EGPQGPPGPVG, and PGLIGARGPPGP. After 20 days postmortem, more peptides were identified due to extensive degradation of proteins. Degradation of potent peptides by the endogenous enzymes may be the reason for the decrease in the ACE-inhibitory activity at day 20 [150]. The authors also reported for the first time the release of low molecular weight peptides (< 3 kDa) from aged beef with renin-inhibitory activity. The highest concentration of low molecular weight peptides was observed in cooked beef aged for 20 days and also exhibited highest renin-inhibitory properties. These results suggest that generation of peptides and their related bioactivities depends on aging time and cooking [151, 152] and may be ascribed to the release of certain active peptides during different phases of aged or cooked beef [28]. Although, calpains, which are mainly responsible for proteolysis, get inactivated at 55 °C [151], other endogenous proteases like cathepsins, metalloproteinase, and collagenase may still cause proteolysis in beef during cooking, increasing the concentration of small peptides [28, 153].

Liu et al. [154] studied the endogenous release of ACE-inhibitory peptides in duck meat during postmortem aging and reported that the small peptides (<5 kDa) produced due to the degradation of muscle proteins exhibited no ACE-inhibitory activity. Endogenous enzymes, unlike exogenous enzymes, work in uncontrollable manner and might only release a limited number of peptides [72] which might be produced in too little quantities to induce ACE-inhibitory activity [154].

Sangsawad et al. [155] studied the effect of cooking methods on the production of ACE-inhibitory peptides derived from simulated in vitro gastrointestinal digestion of *Korat* crossbred and commercial broiler chicken breast. The highest ACE-inhibitory

activity was exhibited by *Korat* crossbred chicken digestas heated at 70 °C for 0.5 h while the lowest inhibitory activity was shown by the digestas of *Korat* crossbred breast meat heated at 121 °C for 1 h. In general, ACE-inhibitory activity of the digestas also varied with the protein digestibility. The highest digestibility and ACE-inhibitory activity was reported in samples cooked by mild thermal treatment. The digestas heated at 70 °C for 0.5 h had highest proportion of small peptides (<1 kDa) whereas the digestas heated at 121 °C for 1 h had highest proportion of large peptides (>5 kDa). Peptide size has been reported to play an important role in ACE-inhibitory activity with most of the peptides possessing 2–20 amino acids [30, 156]. Larger peptides have difficulty in binding to the active site of ACE, resulting in decreased inhibitory activity [157]. This may partly explain the lower ACE-inhibitory activity of the digestas treated by high thermal treatment. High thermal treatment (>100 °C) has also been reported to induce several changes in proteins, like aggregation, cross-linking, and oxidative modifications [158, 159] which reduce their susceptibility to proteases, resulting in larger size peptides. Novel peptide sequences KPLLCS, ELFTT, and KPLL with potent ACE-inhibitory properties were identified with sequences homologous to that of myosin. The IC_{50} values of KPLLCS, ELFTT, and KPLL were 0.37, 6.35, and 11.98 μM, respectively. Peptides ELFTT and KPLL were reported to be resistant to in vitro plasmin hydrolysis for up to 60 min while KPLLCS was hydrolyzed by plasmin after 15 min, suggesting the resistance of these peptides to the blood proteases. Peptides need to resist the blood protease digestion after absorption to exert the ACE-inhibitory activity in vivo (Table 3).

7.5 Meat Products

Meat is considered as a good source of peptides with different bioactivities [120, 122, 162]; however, dry-cured ham was the only product among the processed meat products that was reported to be a natural source of peptides with antihypertensive properties [163, 164]. Table 4 presents the identified peptide sequences with antihypertensive properties from different meat products. Seven dipeptides sequenced as RP, KA, AA, GP, AR, GR, and RR with ACE-inhibitory properties were produced by the action of dipeptidyl peptidases purified from porcine skeletal muscle [169]. Since dipeptidyl peptidases remain active during the whole processing period of dry-cured meat products, or at least a great part of it, the authors hypothesized that their proteolytic action could contribute to the generation of peptides with ACE-inhibitory activity in cured meat products. Vaštag et al. [170] also suggested the possibility of production of meat protein hydrolysates with ACE-inhibitory properties during ripening process of *Petrovská Kolbása*, a traditional dry fermented sausage. Later three novel peptides possessing in vivo ACE-inhibitory properties were identified from Spanish dry-cured ham [153, 163] and were reported to be highly stable during in vitro gastrointestinal digestion and heat treatment [165]. AAATP was the identified peptide sequence with most potent ACE-inhibitory activity and effectively decreased systolic blood pressure in spontaneously hypertensive rats [153]. ASGPINFT and DVITGA were other sequences that yielded a moderate ACE

inhibition. Escudero et al. [165] studied the stability of ACE-inhibitory peptides from Spanish dry-cured ham and reported that almost the same activity was retained after applying diverse heating (50–117 °C), times of processing (3–60 min), and simulated in vitro digestion with gastrointestinal proteases. Peptides AAPLAP, KAAAAP, KPVAAP, KAAAATP, and IAGRP were reported to be the most potent ACE-inhibitory peptides. Gallego et al. [171] studied the stability of three ACE-inhibitory peptides (KPVAAP, AAATP, and AAPLAP) naturally generated in dry-cured ham during transepithelial transport in a Caco-2 cell monolayer. The results showed that the peptides degraded during the assay, although, some of the KPVAAP peptides remained intact and was also absorbed through the intestinal barrier, suggesting the possible absorption and bioavailability of dry-cured ham peptides in the blood stream to exert an antihypertensive action.

Production of peptides in dry-cured meat products depends on certain factors such as activity of muscle endogenous enzymes, which is very much influenced by genetics and muscle-type, and processing conditions including added ingredients and ripening time [162]. Paolella et al. [168] studied the effect of maturation time of dry-cured *Parma* hams on the peptide profile obtained upon simulated gastrointestinal digestion. *Parma* ham is a well-known dry-cured meat product obtained from heavy pig thighs, mildly salted and aged for a long period. A total of 81 peptide sequences were identified in digested samples and most of the sequences mainly

originated from myofibrillar proteins (myosin and actin) and sarcoplasmic proteins (such as pyruvate kinase, creatine kinase, fructose bisphosphate aldolase, etc.). A higher amount of short sequences were found in the digesta with a total of 21 dipeptides and 11 tripeptides among the identified sequences. Several of the identified sequences were already known in the literature with demonstrated ACE-inhibitory properties. Dellafiora et al. [167] used hybrid in silico/in vitro approach for the identification of ACE-inhibitory peptides from dry-cured *Parma* hams. Strong ACE-inhibitory sequences, like LGL and SFVTT, were identified for the first time in *Parma* dry-cured ham. On the basis of in silico results, a total of 25 peptides were predicted as active, and five ACE-inhibitory peptides with sequence LGL, SFVTT, GVVPL, ALM, and NSIM with IC_{50} values of 145, 395, 956, >1100, and >1100 μM, respectively, were identified.

Mora et al. [166] evaluated the antihypertensive peptides generated naturally in *Iberian* dry-cured ham and also studied the differences in the generated peptides between traditional Spanish dry-cured (14 months of ripening) and *Iberian* dry-cured ham (24 months of ripening). The extract obtained from *Iberian* dry-cured ham was analyzed in vitro showing up to 97.7% of ACE-inhibition in some of the fractions. A significant decrease of 12 mm Hg in systolic blood pressure of spontaneously hypertensive rats was also observed after 8 h of ingestion. Pro-Pro-Lys, Pro-Ala-Pro, and Ala-Ala-Pro with strong ACE-inhibitory activities were the most repeated sequences among 2632 peptides identified in *Iberian* dry-cured ham. These sequences appeared a total of 322, 302, and 119 times, respectively, and were mainly derived from the proteins troponin-T, myosin-heavy and myosin-light chains. Mora et al. [172] characterized the peptide profile of three European hams viz. Spanish *Teruel*, Italian *Parma*, and Belgian dry-cured hams. The peptides generated in these types of hams were identified and quantified using a label-free methodology to assess main differences in proteolysis between them. Peptide fractions from Spanish *Teruel* exhibited highest ACE-inhibitory activity of 93% while those from Belgian and *Parma* hams had ACE-inhibitory activity of 76% and 70%, respectively.

The *Bresaola della Valtellina*, produced by salting and naturally curing specific cuts of lean bovine hind quarters, is a Protected Geographical Indication from Valtellina, Italy. There are other similar products which are traditionally produced in other places such as *Viande des Grison* or *Bunder fleish* in Switzerland and *Cecina* in Spain. Both myofibrillar and sarcoplasmic protein fractions of *Bresaola* get extensively hydrolyzed by endogenous proteases during ripening, releasing a large variety of peptides which could exert several biological activities if they survive the digestive process. With this aim, Ferranti et al. [149] attempted to identify the bovine muscle-derived proteins and peptides from two different *Bresaola* samples (with and without the Protected Geographical Indication label) which could survive a static in vitro model of digestion that included the sequential oral, gastric, and duodenal phases. More than 170 peptides were identified which were released during in vitro digestion from the major structural and sarcoplasmic muscle proteins. Most of the identified peptides had reported antihypertensive properties or were precursors of potentially antihypertensive sequences.

Pastırma, a Turkish dry-cured meat product produced from whole beef muscles, was analyzed for antihypertensive activity and was reported to possess strong ACE-inhibitory properties [71]. ACE-inhibitory activity of more than 86% was shown from fractions corresponding to molecular masses between 900 Da and 1500 Da. ACE-inhibitory peptides were suggested to be generated due to the proteolysis caused by endogenous enzymes and the *çemen* paste used in production.

Recently, Fernández et al. [116] studied the possibility of generation of ACE-I inhibitory properties in the dry-fermented sausage *salchichón* by using purified proteolytic enzyme EPg222 and starter culture (P200S34) composed of *Pediococcus acidilactici* (MS200) and *Staphylococcus vitulus* (RS34), separately and together, followed by ripening for 90 days. EPg222 protease purified from *Penicillium chrysogenum* Pg222, isolated from dry-cured meat products, has been reported to have high proteolytic activity against myofibrillar proteins under the conditions normally present in dry-cured meat products [173]. Batches inoculated with EPg222 were reported to have highest ACE-inhibitory activities at 63 days of ripening. The ACE-inhibitory activities remained stable in most cases even after in vitro simulated gastrointestinal digestion, suggesting the significance of use of the enzyme EPg222 in association with the starter culture P200S34 for the production of functional meat products with antihypertensive properties. Mejri et al. [174] studied the effect of different starter cultures and ripening times on the size, concentration, and antihypertensive capacities of peptides in dry-fermented camel sausages. Sausages were inoculated with isolated strains of *S. xylosus* and *L. plantarum* (batch A), *S. xylosus* and *L. pentosus* (batch B), and *S. carnosus* and *L. sakei* (batch C) and were ripened up to 28 days. Both peptide size and concentration were reported to be affected by the ripening time and the inoculated bacteria. The ripening process resulted in an increased antihypertensive capacity with highest bioactivities in the fractions with <3 kDa peptides. Low molecular weight peptides (< 3 kDa) have been reported to contribute to the development of flavor as well as antihypertensive activities in fermented meat products [166].

8 Conclusions

A large number of peptides with demonstrated in vivo and in vitro antihypertensive activities have been reported from different meat proteins. Endogenous generation of peptides with antihypertensive properties has also been reported during natural aging process increasing the value of meat as a functional food. Cured meat products like dry-cured ham and *pastırma* might be considered as natural sources of peptides with strong antihypertensive properties. Several meat-derived antihypertensive peptides have been shown to retain their activity and bioavailability even after digestion and cooking. Thus peptides derived from meat proteins provide an exciting option for the

development of functional foods with antihypertensive properties for preventive and curative management of hypertension.

Bioactive Peptides from Fish Protein By-Products

14

Aurélien V. Le Gouic, Pádraigín A. Harnedy, and Richard J. FitzGerald

Contents

Abstract

The interest in fish processing by-products and underutilized catch for the production of biofunctional food ingredients has increased in the last number of decades. These marine-derived components contain a significant quantity of protein, which is normally processed into low-value products such as animal feed, fishmeal, and fertilizer. However, due to the global demand for high-quality protein and the need for sustainable production and processing of landed material, the valorization of proteins and other nutrients from fish processing by-products has significantly increased. Fish processing by-products contain significant

quantities of high-quality protein, which can be exploited as sources of essential nitrogenous nutrients and biologically active peptides. Bioactive peptides, including those from fish processing by-products, have been reported to possess the ability to beneficially modulate physiological processes associated with non-communicable diseases. These short peptides, which are encrypted within the primary sequence of the parent protein and are released during food processing or gastrointestinal digestion, could have a role in the prevention and management of these diseases. This chapter reviews the recent literature on the processing and utilization of proteins and protein hydrolysates from fish processing by-products and underutilized fish species with a particular focus on their bioactive properties and peptide sequences.

1 Introduction

The ocean covers about 70% of the total earth's surface and contains approximately 60% of all fish species. The other 40% are found in fresh water which comprises 1% of the earth's surface. The fishing industry represents an important economic activity for many countries around the world. In 2003, marine fisheries supported 260 million jobs directly and indirectly [1]. The demand for fish and shellfish has increased throughout the world. The amount of farmed fish doubled in the last decade while that of captured fish has tended to stabilize. According to the Food and Agriculture Organization (FAO), global fish production in 2016 was estimated to be 174.1 million tonnes (mt) by both capture and aquaculture with 152.8 mt being used for human food consumption and 21.3 mt for nonfood uses [2]. It has been estimated that greater than 60% (by weight) of the fish which are processed are represented by by-products, i.e., head, skin, bones, fins, trimmings, viscera, blood, and roe [3]. The large quantity of fish by-products generated represents a potentially significant source of pollution in developing and developed countries. Since 2014, the European Commission, under Directive No 1392/2014 [4], regulates the discard of all fish caught regardless of whether they are regulated by quota, smaller than the minimum size and either dead or alive, and now imposes an obligation to land all catch.

Fish processing by-products and underutilized catch contain a significant quantity of protein which is normally processed into low-value products such as animal feed, fish meal, and fertilizer [2]. However, given the increased global demand for high-quality protein and the requirement for sustainable production and processing, there is an increasing interest in the extraction and valorization of proteins and other nutrients from fish processing by-products. The proteins within fish processing by-products represent a source of high-quality protein which can be exploited for the provision of essential nitrogenous nutrients. Therefore, various biotechnological

approaches have, and are, being employed to extract valuable nutrients and bioactive compounds targeted at enhancing human health. Bioactive compounds have a role in the management and in the protection against a range of chronic noncommunicable diseases (NCDs). Furthermore, by-product proteins may be used to generate biologically active peptides (BAPs). BAPs have the ability to modulate physiological processes and thereby have a role in the prevention and management of disease.

Protein hydrolysates are obtained following the enzymatic conversion of intact proteins into peptides. These protein fragments usually contain no more than 20 amino acids. A large range of fish protein hydrolysates, generated using food-grade proteolytic preparations, such as trypsin, Alcalase® 2.4L, Flavourzyme® 500L/1000L, Corolase® PP, and Promod® 144MG, have been reported in the literature [5–7]. These hydrolysates, due to their physicochemical properties, are a source of amino acids [8] which have applications in human and animal nutrition, as well as in the pharmaceutical and cosmetic industries. Due to their good nutritional composition, amino acid profile, and bioactive properties, fish protein hydrolysates have many commercial applications [9].

This chapter reviews the recent literature on the processing and utilization of proteins and protein hydrolysates from fish processing by-products and underutilized fish species with a particular reference on their bioactive properties and peptide sequences.

2 Fish Protein Composition

Fish consumption is linked with many health benefits due to their high protein levels and also due to their content of unsaturated fatty acids, vitamins, and minerals [10]. Fish proteins are a particularly rich source of the essential amino acids valine and lysine [11].

The chemical composition of foods has an important role in the supply of essential nutrients for the maintenance of human health. The chemical composition of fish by-products, i.e., levels of protein, ash, and lipid, differs significantly between species.

Fish processing by-products are designated as parts of the fish which are not generally used for human consumption, e.g., head, skin, and viscera. However, the nutrients therein are recoverable and can be utilized after further processing. These components may represent between 30% and 60% by weight of the starting material. Consequently, these fish processing by-products represent a rich source of biofunctional materials such as vitamins, minerals, polysaccharides, polyunsaturated fatty acids (PUFA), enzymes, collagen, gelatin, and bioactive peptides with valuable nutraceutical, pharmaceutical, and cosmeceutical applications [12].

Proteins are characterized by their amino acid sequence and secondary structure and also by their tertiary structure, which may be highly ordered. Each type of protein has a unique structure that determines its function in the organism in addition to its technofunctional properties when utilized as a food source/ingredient [13]. The nutritional value of food proteins is determined on the basis of their essential amino

Table 1 Essential amino acid content of reference food proteins, fish proteins/protein hydrolysates, and human daily requirements

[c]Villamil et al. [15]

acid content. Table 1 summarized the essential amino acid content of foodstuffs compared to the daily requirement. In comparison to plant proteins, proteins derived from animal sources (because of their high content of essential amino acids) are considered nutritionally superior. Of these, egg white and milk proteins (casein) are usually used as reference proteins for determination of protein quality. Proteins derived from meat and poultry muscle are also considered as a source of high-quality protein. It has been shown that the nutritional value of most fish proteins is equal to or better than casein and the quality of fish proteins may exceed that of terrestrial animal meat [16].

Myofibrillar proteins are structural proteins responsible for movement by their capacity for contraction. They represent 65–75% of the total fish muscle, while sarcoplasmic proteins (soluble proteins) represent 20–35% [17]. Myofibrillar proteins are mainly composed of actin and myosin. The motility of fish is also stabilized and regulated by other structural proteins including titin, nebulin, α-actinin, tropomyosin, and troponin (T, I, and C). The proportion and presence of these structural proteins depend on the fish species. Myosin is the major protein in fish muscle (40%); however, it is a protein easily destabilized when heated, especially the myosin from cold-water fish species. It is a large protein, with a molecular mass of 470 kDa [18], and has an unusual structure as it has both fibrous and globular properties whereas most food protein ingredients, such as proteins from egg, soy, and milk, have globular structures and have a lower molecular mass. Myosin is composed of two heavy chains of 220 kDa and two pairs of different light chains (LCs), ranging from 17 to 22 kDa [19]. The myosin molecule is approximately 160 nm in length. The heavy chains interact via two domains: a globular domain called “head” and a fibrous domain called “tail.” Actin accounts for 15–30% of the myofibrillar proteins. The monomer form of actin is a globular protein (G-actin) of

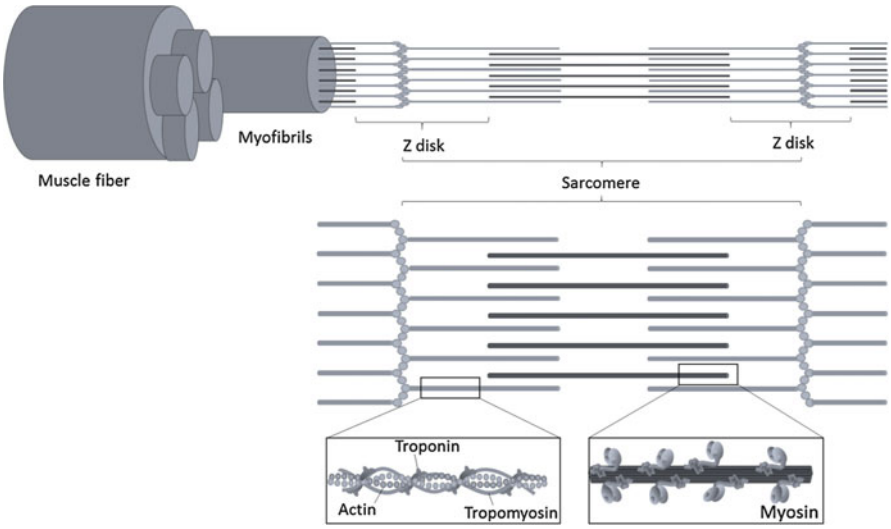

Fig. 1 Diagrammatic representation of the actin-myosin complex. (Modified from Gordon et al. [20])

43 kDa; however, globular actin monomers polymerize to form filaments of fibrous actin (F-actin). Other small proteins associated with either actin or myosin include titin, nebulin, tropomyosin, troponin, C-proteins, and M-proteins [18]. These proteins play an important role in the stabilization of the muscle myofibril basic structure termed the sarcomere (Fig. 1).

The denaturation of myofibrillar proteins by heat, chemical, and enzymatic treatment leads to the generation of a gel [21]. The gelation properties of fish myofibrillar proteins are exploited in the food industry to produce surimi or surimi-like products. The connective tissue proteins, or stromal proteins, provide the structural elements for connective tissue. The main protein in this group is collagen which in general represents approximatively 3% of the total protein in fish muscle and is present in the skin, bone, myocommata, and swim bladder [22]. However, some species, especially *Chondrichthyes* species, can contain a significantly higher amount of connective tissue (10%) compared with a value of 17% found in mammalian species [23].

3 Processing of Fish Proteins

3.1 Protein Extraction

To date, several methods have been used for the extraction of proteins from various fish species. The specifics of these methods vary depending on the parameters employed, e.g., pH, temperature, agitation time, homogenization,

weight-to-volume ratio, and the number of sequential extractions. The main approach used to recover proteins from fish is the so-called pH shift process. This technique employs homogenization of the fish sample in an acid (pH < 5.0) or alkaline (pH > 9.0) solution. The protein extract is then separated from the solid components by centrifugation where solids such as bones, scales, flesh, and skin are removed. Depending on the sample, a mechanical disruption process may also be employed prior to the homogenization step to disrupt the cells [24, 25]. The acid- or alkaline-solubilized protein is then precipitated by adjusting the pH to its isoelectric point. The precipitate is separated by centrifugation and a protein isolate is then obtained.

A second approach used for protein extraction is known as the surimi process. The production of surimi consists of protein recovery from fish mince by a series of sequential steps. Washing with cold water is essential to remove water-soluble, sarcoplasmic proteins and impurities such as the skin, bones, scales, and connective tissue which can reduce the gelation ability and ultimately reduce product quality. The number of successive washes and the volume of water required vary between fish species, the freshness of the starting fish mince, and the quality of the surimi required. It is common to use 0.1–0.3% (w/v) NaCl in the washing solution to facilitate removal of water during the subsequent processing steps. Before the dewatering step, the washed minced fish still contains a large quantity of impurities, which often consist of tissues from the skin and/or internal belly flap that need to be removed. A purification step is required to obtain a product with good organoleptic quality, appearance, and product safety. The water in the surimi base obtained can be removed by a screw press, and the water content is reduced from 91% to 80–84% (w/w) [26]. This method of extraction of proteins from fish is less successful than the pH shift method as sarcoplasmic proteins are lost during the process, leading to a reduced yield. A general flow diagram for these two processes is provided in Fig. 2.

Enzyme-assisted extraction of food proteins using food-grade proteolytic preparations relies on the intrinsic properties of enzymes, i.e., high specificity and selectivity. The disadvantages of enzyme-assisted extraction are the high cost which may be an issue in the case of production at commercial scale and the inability of some enzymes to disrupt the cell membrane which may lead to low extraction yield. A new approach to overcome these issues involves the use of microwave irradiation during enzyme-assisted extraction. The procedure known as microwave-assisted enzymatic extraction (MAEE) is recognized as having the potential to increase the yield of protein extracted and, in some cases, the bioactive properties of the resulting product. Nguyen et al. (2017) recently studied the generation of fish protein hydrolysates by MAEE and the pH shift method from rainbow trout (*Oncorhynchus mykiss*) using the proteolytic enzyme Alcalase 2.4L® [27]. The MAEE approach was reported to improve the technofunctional and bioactive properties of the hydrolysates when compared to those generated using the pH shift method.

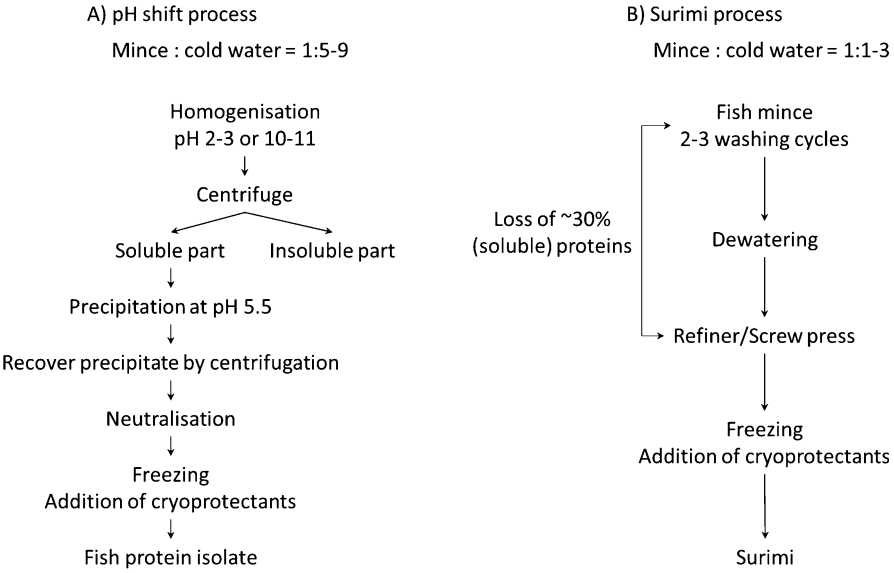

Fig. 2 Flow diagram representing the sequential steps involved in the pH shift (**a**) and surimi process (**b**) for the extraction of proteins from fish. (Modified from Kristinsson et al. [24])

3.2 Enzymatic Hydrolysis

Enzymatic modification is a method which has been used to treat food proteins to improve their technofunctional, physicochemical, bioactive, and organoleptic properties without alteration of their nutritive value [28]. As the degree of hydrolysis of the protein affects the bioavailability and the bioactivity of the peptides generated, the appropriate choice of the hydrolysis conditions (e.g., temperature, pH, enzyme preparation, and enzyme to substrate ratio) is critical [29, 30]. Proteolytic enzymes can be classified according to different characteristics, e.g., proteolytic enzymes can be endo- or exo-acting proteinases/peptidases. For example, endoproteinases cleave peptide bonds within the protein and release peptides or shorter fragments, while exopeptidases remove single amino acid residues or small peptides from either the C-terminus (carboxypeptidases) or N-terminus (aminopeptidases) by cleaving the terminal peptide bonds [31].

It has been shown that enzymatically modified food proteins have improved technofunctional as well as bioactive properties compared with intact proteins [6, 32]. The generation of lower molecular mass peptides with reduced secondary structures can improve the solubility, turbidity, gelling, emulsifying, and the foaming properties as well as heat and pH stability of proteins [33]. The use of fish protein hydrolysates for their technofunctional properties has been extensively reviewed [34–36]. The modification observed in the technofunctional properties of food

proteins following hydrolysis is highly dependent on the hydrolysis conditions, such as pH, incubation temperature, and duration of hydrolysis. Furthermore, the specificity of the enzyme used for the process and the operating parameters are responsible for the extent of hydrolysis and the peptide profile obtained. Control of the hydrolysis process is even more important when working with animal products since certain animal parts may contain endogenous proteinases [37] or even enzyme inhibitors [38]. These endogenous enzymes are mainly located in the gastrointestinal tract and are associated with the fish viscera; however, some hydrolytic enzymes, such as cathepsins, collagenases, alkaline proteases, and calcium-dependent proteinases, are located in the muscle tissue itself [39]. This endogenous proteolytic activity can increase the extent of hydrolysis independently from the exogenously added proteolytic preparations. Fortunately, the endogenous proteolytic activity in fish is generally not as high as that found in the muscle of terrestrial animals (bovine, porcine, and caprine).

A number of food-grade proteolytic preparations exist on the market. These arise from microbial, plant, and animal sources. Among the enzyme preparations available for the generation of protein hydrolysates from fish processing by-products, the most commonly used are Alcalase (*Bacillus licheniformis*), Neutrase (*Bacillus amyloliquefaciens*), Flavourzyme (*Aspergillus oryzae*), collagenase (*Clostridium histolyticum*), Pronase E (*Streptomyces griseus*), papain (*Carica papaya*), and bromelain (*Ananas comosus*) and digestive enzymes from bovine and porcine gastrointestinal tracts (e.g., pepsin, trypsin, and chymotrypsin). Moreover, fermentation and autolysis are processes which may be employed for the production of peptides by the action of the proteolytic enzymes from the product itself or from the action of the intrinsic microorganisms present. Furthermore, proteolytic enzymes have been purified from different fish species, especially from viscera for use during fish protein hydrolysate manufacture [15].

In some regions of the world, the endogenous enzymes from marine sources are used to improve the shelf life as well as the bioactive and technofunctional properties of proteins from fish and shellfish. Several examples of fermented fish, shellfish, and seafood exist for application as flavoring agents and food supplements with bioactive properties, such as Kapi, a fermented shrimp paste from Thailand, and Bakasang, a fermented fish sauce from Indonesia [40–44]. However, the high salt content and low pH and the presence of undesirable contaminants such as halophilic microorganisms and biogenic amines (histamine) represent some important issues for consumer safety linked to the consumption of these products. Therefore, the use of enzymatic hydrolysis with exogenously added food-grade proteolytic preparations when carried out in a controlled environment with the use of thermal treatment for enzyme inactivation and bacterial reduction represents a feasible approach for the generation of bioactive peptides from fish by-products for human consumption. Furthermore, it has been reported that the utilization of proteolytic enzymes releases a higher quantity of bioactive peptides with lower molecular masses than when fermentation processes are employed [45]. Additionally, enzymatic hydrolysis requires significantly less time to reach the desired degree of hydrolysis than fermentation processes. For example, the production of fish protein hydrolysates

takes between 4 and 6 h to reach the desired degree of hydrolysis [46], while it may take weeks or months for the fermentation process to reach the equivalent extent of hydrolysis [47].

4 Characterization of Fish Peptides

Fish proteins contain peptide sequences encrypted within their primary structure. Some of these peptides have the potential to beneficially modulate some metabolic pathways and consequently may play a role in disease prevention and health enhancement. Bioactive peptides are released from proteins during normal gastrointestinal digestion which occurs in the digestive tract or during food processing with the use of proteolytic enzymes (hydrolysis) or microorganisms (fermentation) [48]. The biological activity of food-derived peptides mainly depends on their structural properties such as molecular mass and the physicochemical characteristics of the amino acids within the sequence [49]. The biological activity of peptides present in protein hydrolysates is highly dependent on the hydrolysis conditions (pH, time, temperature), the enzymes used, and the enzyme-to-substrate ratio applied [50, 51]. Therefore, careful control of these conditions during the generation of bioactive peptides is essential to optimize bioactive properties and, therefore, their ability to enhance human health.

Type 2 diabetes mellitus (T2DM) and cardiovascular diseases are two of the main NCDs responsible for more than 0.6 and 3.9 million deaths, respectively, in Europe per annum [52]. Marine by-product-derived proteins represent a source of peptides that may have the ability to modulate specific biomarkers associated with these diseases, and therefore they have the potential for incorporation into functional food or nutraceutical products for the prevention and management of these conditions. Many studies have been conducted using several different food sources, such as bovine and camel milk, cereals, insects, and marine sources, to generate bioactive peptides with *in vitro* antioxidant, cardioprotective, antidiabetic, and appetite suppressant properties [53–58]. These include peptides with the ability to modulate specific pathways linked with blood pressure control and T2DM. This includes modulation of the renin-angiotensin system (inhibition of renin and angiotensin-converting enzyme (ACE)), stimulation of the incretin system (inhibition of dipeptidyl peptidase-IV (DPP-IV), and stimulation of the secretion of glucagon-like peptide (GLP-1)), as well as stimulation of the secretion of intestinal cholecystokinin, which is linked to appetite suppression *in vivo* [59–62]. Food protein-derived peptides have been shown to reduce oxidative stress associated with inflammation and tissue damage *in vivo*, which are complications generally linked to cardiovascular disease (ischemia), diabetes (diabetic food ulcer), and many other diseases such as neurodegenerative diseases and cancer [63]. The main bioactivities currently investigated for peptides from fish by-products are based on the regulation of oxidative stress and cardiovascular disease (Table 2). These include antioxidant, ACE inhibitory, renin inhibitory, and anticoagulant activities. Several reports suggest that protein hydrolysates generated from fish can modulate the immune response and inhibit

A one-letter notation was used for amino acid sequences
IC_{50}, inhibitor concentration that inhibits enzyme activity/activated coagulation factor 11 (FX11a) by 50%
EC_{50}, effective concentration causing 50% of antioxidant/antiviral activity
Antioxidant value expressed in μmol Trolox equivalent (TE)/μmol of dry weight (dw)
MIC, minimum inhibitory concentration
SBP_{6h}, systolic blood pressure after 6 h of oral peptide administration

cancer development, as well as having ACE inhibitory, antihypertensive, anticoagulant, ion chelating, antioxidant, antimicrobial, antiviral, and appetite suppressant activities [87, 94, 95]. These characteristics of peptides generated within marine-derived protein hydrolysates are linked to their potential as ingredients or nutraceutical products for the management of symptoms related to NCDs such as diabetes, cardiovascular diseases, cancer, and chronic allergic diseases. It has been previously reported that peptides with low molecular mass, mainly di- and tripeptides, have potent bioactive properties [96, 97], while longer peptides, with more than 20 amino acid residues, have been associated with technofunctional property improvements [98]. The most common method used to separate peptides within protein hydrolysates is reversed-phase high-performance liquid chromatography (RP-HPLC) [99]. The techniques mainly used to separate peptides on the basis of molecular weight include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and gel permeation high-performance liquid chromatography (GP-HPLC) [100]. Furthermore, characterization of the amino acid sequence of the peptides is generally carried out using liquid chromatography systems coupled with mass spectrometry (MS) or tandem mass spectrometry (MS/MS) [54, 97, 101].

5 Bioactive Properties

Globally, the total mortality linked to NCDs was 38 million in 2012 and is estimated to reach 52 million by 2030 [102]. As mentioned in previous sections, peptides derived from proteinaceous marine processing by-products have been shown to possess a range of bioactive properties. The potential health benefits of consuming fish protein hydrolysates/peptides for the control of NCDs and oxidative stress, allergenicity and inflammation, hypertension, and cancer will therefore be outlined.

5.1 Oxidative Stress

Oxidative stress is an important factor contributing to the development and the progression of NCDs. It is characterized by the generation of reactive oxygen species (ROS), including hydroxyl radicals ($^{\bullet}OH$), superoxide radicals ($O_2^{\bullet -}$), and non-radical hydrogen peroxides (H_2O_2). High ROS levels have been associated with the deleterious modification of nucleic acids (DNA and RNA), proteins, and lipids and have been implicated in accelerating cellular aging and several human conditions, such as atherosclerosis and neurodegenerative diseases [63]. In contrast, low ROS levels have beneficial physiological effects linked to the regulation of cell signaling, through the redox regulation of transcription factors, protein phosphorylation (kinase), and ion transfer [103]. The consumption of dietary components containing natural antioxidants (such as vitamin C, polyphenols, and carotenoids) has been shown to reduce oxidative stress by enhancing natural defenses [104]. On the other hand, oxidative stress can contribute to a reduction in the proliferation of cancer cells by inducing cell death. However, while cell death can be achieved by

radical-induced oxidative stress, some cancer cells have developed resistance which indicates that cells develop sophisticated adaptation responses to oxidative stress [105]. The peptides from fish processing by-product proteins having antioxidant activity have recently been reviewed [95]. For example, Glu-Leu-Phe-Glu-Pro-Arg, a hexapeptide generated by Alcalase hydrolysis of seabass (*Lates calcarifer*) skin gelatin, was shown to scavenge hydrogen peroxide [106]. Table 2 provides a list of fish protein by-product hydrolysates/peptides exhibiting antioxidant activity as reported in the literature.

The *in vitro* determination of antioxidant activity of peptides can be performed using various chemical reactions. The methods used to assess antioxidant capacity can be classified according to whether they assess the transfer of either hydrogen atoms (HAT) or electron (ET) [107]. The assays used to measure proton-donating ability are represented by the oxygen radical absorbance capacity (ORAC), hydroxyl radical, alkyl radical, and peroxide radical scavenging activity assays. The reported ORAC activity of peptides derived from fish processing by-products ranges from 5.47 to 19.74 μmol TE/μmol peptide (Table 2). Compared to milk protein-derived antioxidant peptides, the radical scavenging activity was approximately 2.1- to 7.5-fold higher than the hendecapeptide, Trp-Tyr-Ser-Leu-Ala-Met-Ala-Ala-Ser-Asp-Ile derived from a β-lactoglobulin A hydrolysate [108]. The ET-based assays used to determine the reducing capacity of an antioxidant are the Trolox equivalent antioxidant capacity (TEAC), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonate) radical cation ($ABTS^{\bullet+}$), FRAP (ferric reducing antioxidant power), and $DPPH^{\bullet}$ (2,2-diphenyl-1-(2,4,6-trinitrophenyl) hydrazyl radical) assays. The DPPH radical scavenging activity (EC_{50}, concentration causing 50% of antioxidant activity) of Phe-Ile-Gly-Pro, a peptide derived from a bluefin leatherjacket skin hydrolysate, was reported to be 0.118 mg/mL. Interestingly, Song et al. (2011) reported that a potent pepsin hydrolysate from half-fin anchovy (*Setipinna taty*) possessed a DPPH EC_{50} value of 4.46 μg/mL, while the synthetic antioxidant butylated hydroxytoluene (BHT) is reported to exhibit an EC_{50} value of 22.78 μg/mL [78]. The antioxidant potency of bioactive peptides has been attributed to the presence of specific amino acids therein especially histidine residues. This has been attributed to the chelating properties and the radical-trapping properties of the imidazole ring. Furthermore, the presence of hydrophobic amino acid residues in peptides has been associated with an increase in their accessibility to hydrophobic targets [109, 110].

5.2 Allergenicity and Inflammation

Allergy is a hypersensitivity response associated with an immune system reaction toward an allergen. The major types of allergies include life-threatening anaphylaxis; food, drug, and insect allergies; asthma; rhinitis; angioedema; eczema; urticaria; and eosinophilic disorders [111]. Allergic reactions/diseases can be caused by environmental factors, such as pollution, as well as genetic factors. The global prevalence of allergic diseases is increasing with 200–250 million people suffering from food allergy and about 300 million people suffering from asthma causing 250,000 deaths

annually [112]. The diagnosis of allergy is commonly performed using blood or cutaneous tests. The cutaneous (skin prick) test is carried out by introducing a series of punctures on a subject's skin which are loaded with different suspected allergens. The signs of inflammation, indicative of an allergenic response, are then observed. Inflammation is one of the first responses of the immune system to a challenge/infection [113]. The increase in blood flow into the tissue causes redness, swelling, heat, and pain. Inflammation occurs when damaged tissues or infected cells release eicosanoids and cytokines. Eicosanoids, which include prostaglandins, dilate blood vessels and increase the temperature locally, while leukotrienes recruit white blood cells (leukocytes). Cytokines, including interleukins and chemokines, are responsible for the recruitment and communication between leukocytes at the site of infection, while interferons shut down protein synthesis in infected cells [114]. Cytotoxic and growth factors can also be released by the damaged tissues. These molecules have the ability to recruit immune cells to the site of challenge/infection and contribute to the healing of damaged tissue following removal of the antigen [115].

The human immune system reacts against various chemical and biological threats by two separate but interconnected systems. The first defense system, called the innate immune system, consists of cells and proteins present in the circulation system, and it is activated in the presence of an exogenous threat. This system includes mucosal epithelial barriers, dendritic cells, and leukocytes [116]. The second system, called the adaptive immune system, is a specific system which involves B- and T-cells and the production of specific antibodies against the detected threat. The adaptive immune system is activated when the innate immune system is insufficiently effective or when it has been overcome [117]. Current treatments for allergies consist of the use of medication such as steroids, adrenalin, and antihistamines [118]. Immunotherapy is also available to treat some forms of allergy by injecting an inactive form of the allergen to stimulate the production of specific antibodies by the adaptive immune system [119]. Even though immunotherapy provides a longer-lasting effect, it also represents an expensive alternative to pharmacological solutions.

Immunomodulatory peptides can modulate immune functions by enhancing lymphocyte proliferation, antibody synthesis, and cytokine regulation [120]. Moreover, immunomodulatory peptides may have the ability to reduce allergic reactions and enhance the mucosal immune system in the gastrointestinal tract. Immunomodulatory peptides isolated from human milk, rice, and soybean tryptic hydrolysates act to stimulate the innate immune system [121–123]. A review of literature reveals that the mechanism of action of immunomodulatory peptides is relatively non-specific, and this may be the reason why the exact mechanism and the *in vivo* destination of these peptides are still unknown. Figure 3 depicts the main mechanisms of action of anti-inflammatory peptides. The details of the anti-inflammatory peptides isolated from fish by-products are reported in Table 2.

The main anti-inflammatory activity of bioactive peptides, as currently described in the literature, involves the up- and downregulation of signaling proteins (cytokines) such as interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α) and

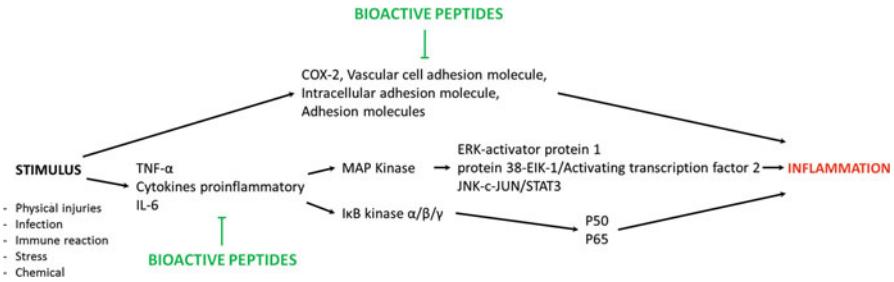

Fig. 3 Mechanisms of inflammation and potential sites of action of bioactive peptides. (Modified from Cicero et al. [124])

adhesion molecules. Modification of the expression and translation of these components has the ability to reduce inflammation. Chalamaiah et al. (2018) have recently reviewed the area of immunomodulatory peptides from food protein hydrolysates [125]. Subhan et al. (2017) demonstrated that peptides from fish scale collagen could downregulate the expression of pro-inflammatory cytokines *in vitro* [126]. This suggests that peptides isolated from fish scale collagen had a beneficial effect in the control of inflammatory diseases.

As shown in Table 2, a number of peptides/hydrolysates derived from fish processing by-products are reported to possess anti-inflammatory capacity. For example, the tripeptide Pro-Ala-Tyr derived from an Atlantic salmon (*Salmo salar*) pectoral fin peptic hydrolysate exhibits anti-inflammatory activity via the down-regulation of NO/iNOS and PGE_2/COX-2 pathways by 64–75% and 45–48%, respectively, compared to the control group. The inhibition of the production of pro-inflammatory cytokines, TNF-α, IL-6, and IL-1β, has been also reported (Table 2) by Anh et al. [67].

5.3 Hypertension

The literature reports that dietary protein intake can contribute to reducing high blood pressure, coronary heart disease, and other infarctions [127]. Blood pressure is determined by measuring two values: systolic blood pressure (SBP), which measures the pressure in blood vessels when the heart beats, and diastolic blood pressure, which measures the pressure in blood vessels when the heart is at rest. The normal values for systolic and diastolic blood pressures are 120 and 80 mmHg, respectively. A range of mechanisms are involved in the control of blood pressure, including the secretion of specific hormones, modulation of blood volume, and secretion of nitric oxide by endothelial cells and the renin-angiotensin-aldosterone system (Fig. 4). ACE, for example, catalyzes the conversion of angiotensin I to angiotensin II, a hormone which leads to vasoconstriction and an increase in blood pressure [128]. Furthermore, ACE degrades the vasodilator molecule bradykinin. Consequently,

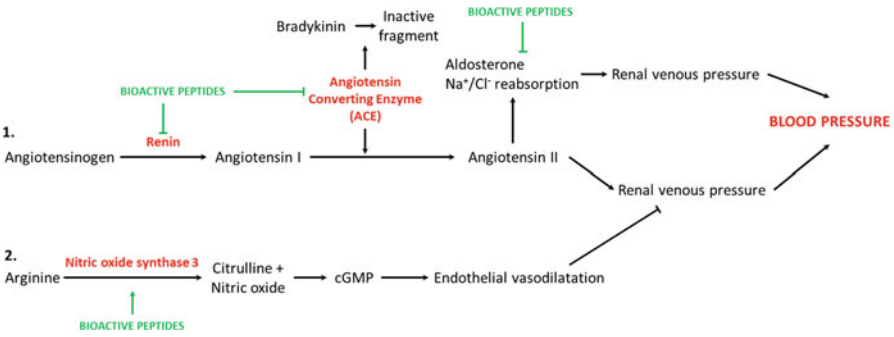

Fig. 4 Mechanisms of blood pressure control and the potential action of bioactive peptides. (Modified from Cicero et al. [124]) ⟞: direct inhibition, ⟶: direct stimulation

ACE inhibitory agents can lower hypertension. Many studies have focused on the ability of fish protein hydrolysates/peptides to inhibit ACE [66, 89]. ACE inhibitory peptides are generally short sequences. Moreover, structural studies of the ACE active site using X-ray crystallography show a lid-like extension formed by the amino-terminal helix (α 1-3) that partially covers the active channel and leaves an opening of almost 3 Å for substrate and inhibitor access [129]. Wu et al. (2006) performed an *in silico* analysis of the ACE inhibitory activity of long (4–10 amino acids) and short (2–3 amino acids) peptides. The importance of the type of amino acid residue in the peptide sequence for ACE inhibitory activity was predicted [130]. It was concluded that the optimum amino acid residues for potent ACE inhibition starting from the C-terminus were Tyr and Cys in the first position; Trp, Met, and His in the second position; Leu, Ile, Val, and Met in the third position; and Trp in the fourth position. Blood pressure is highly regulated *in vivo* and involves mechanisms other than modulation of ACE activity. It is likely that bioactive peptides derived from fish protein hydrolysates also beneficially modulate these systems.

Recently, research on nitric oxide synthase 3 (iNOS) suggested that stimulation of the production of nitric oxide (NO) in endothelial cells has a beneficial effect on blood pressure (Fig. 4) [131]. Ahn et al. (2015) isolated the tripeptide Pro-Ala-Tyr from an Atlantic salmon (*Salmo salar*) pectoral fin peptic hydrolysate and demonstrated that it possessed the ability to modulate the secretion of intracellular NO *in vitro* [67].

Several reports from *in vivo* studies using spontaneously hypertensive rats (SHRs) show hydrolysates/peptides derived from fish proteins having the ability to significantly reduce hypertension. Ko et al. (2016) identified ACE inhibitory peptides (Table 2) from hydrolysates of flounder fish (*Paralichthys olivaceus*) protein which were shown to have hypotensive effects *in vivo* [82]. The *in vitro* ACE IC_{50}'s for two identified hexapeptides, Met-Glu-Val-Phe-Val-Pro and Val-Ser-Gln-Leu-Thr-Arg, was 79 and 105 μM, respectively. These peptides were found to reduce SBP in SHRs after 6 h oral administration (Table 2). Interestingly, the reduction in SBP value obtained with the Val-Ser-Gln-Leu-Thr-Arg-treated group was similar to

the group treated with Captopril®, a synthetic drug inhibitor of ACE. As shown in Table 2, numerous peptides with ACE inhibitory activity have been derived from marine by-products. These include hydrolysates/peptides from Atlantic salmon, bluefin tuna, boarfish, leatherjacket, *Pangasius* catfish, rockfish, and skate.

5.4 Type 2 Diabetes Mellitus

Type 2 diabetes mellitus (T2DM) is characterized by insulin deficiency caused by pancreatic β-cell dysfunction and insulin resistance [132], which arises from the fact that the pancreatic cells produce and release insulin, but the quantity released is insufficient. All these complications lead to hyperglycemia and many side effects such as atherosclerosis leading to heart attack, stroke, and organ failure. Type 1 diabetes, also named "insulin-dependent diabetes," is a malfunction of the pancreatic cells that fail to produce and release insulin resulting from a cell-mediated autoimmune attack of pancreatic β-cells [133]. However, T2DM is the most common type of diabetes accounting for 90–95% of all diabetes cases [132]. The occurrence of T2DM has increased in developed countries and is associated with an unhealthy lifestyle and obesity which contributes to higher rates of morbidity as diabetic individuals generally have a higher risk of heart disease, kidney failure, blindness, and nerve and circulatory damage [132]. The global prevalence of diabetes was 415 million adults aged over 20 years in 2015 (8.8% of the adult population), and this is expected to increase to 642 million by 2040 (10.4% of the adult population) [134]. The countries with the highest incidences of diabetes in 2015 were China (109.6 million), India (69.2 million), the United States (29.3 million), Brazil (14.3 million), the Russian Federation (12.1 million), Mexico (11.5 million), Indonesia (10.0 million), Egypt (7.8 million), Japan (7.2 million), and Bangladesh (7.1 million). Several types of medication are currently employed for the management and control of T2DM. The most common treatments involve the use of Metformin® and Gliclazide® which decrease the release of hepatic glucose and increase insulin secretion, respectively. Both medications are on the World Health Organization list of essential medicines for the treatment of T2DM. Other treatments used in the management of the disease include the injection of glucagon-like peptide-1 analogues and the use of enzyme inhibitors which inhibit the activity of dipeptidyl peptidase-IV (DPP-IV), α-amylase, and α-glucosidase. These treatment approaches enhance the body's response to reduce postprandial serum glucose levels. The enzymes targeted for inhibition are linked to the reduction of glucagon release and the stimulation of insulin synthesis, glucose absorption, and metabolism, as well as appetite reduction [135–137]. DPP-IV degrades two incretin hormones, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1). In the presence of glucose, the incretin system stimulates pancreatic β-cells to secrete insulin. Therefore, by inhibiting the action of DPP-IV, the incretin hormones are maintained at a stable level in the circulation and continue to stimulate insulin production [138]. Human *in vivo* studies have shown that the inhibition of DPP-IV leads to a reduction in glycated hemoglobin (hemoglobin A1c) [139] as well as an

increase in circulating GLP-1 [140]. Consequently, this represents clear evidence of the blood glucose-lowering effect of DPP-IV inhibitors. Although DPP-IV inhibitors and GLP-1 analogues are interesting targets for blood glucose regulation, they represent distinct drug classes with different mechanisms of action, route of administration, and clinical efficiency. However, some synthetic drugs with DPP-IV inhibitory activity are now being used for the treatment of T2DM, such as sitagliptin (Merck & Co. as Januvia®, FDA approved in 2006), vildagliptin (Novartis as Galvus®, EU approved in 2007), and alogliptin (Takeda Pharmaceutical Company as Nesina®, FDA approved in 2013). While these drugs have proven to be efficient in the management of T2DM, side effects including postprandial hypoglycemia, nasopharyngitis, headache, nausea, heart failure, hypersensitivity, skin reaction, joint pain, and adverse cardiovascular effects have been associated with their use [141]. Therefore, the use of natural sources to produce DPP-IV inhibitors is being explored in order to reduce the side effects of antidiabetic drugs. Protein hydrolysates derived from fish processing by-products have been reported to have *in vitro* DPP-IV inhibitory activity, and numerous DPP-IV inhibitory peptides have been identified. These include Gly-Gly-Pro-Ala-Gly-Pro-Ala-Val (624.7 Da) and Gly-Pro-Val-Ala (342.4 Da) which can inhibit DPP-IV by 50% at a concentration (IC_{50} value) of 0.26 and 8.14 $mg.mL^{-1}$, respectively [64]. Recent *in vivo* studies on protein hydrolysates derived from the underutilized fish blue whiting (*Micromesistius poutassou*) have shown the ability to lower glucose and increase insulin level in mice [77]. Another approach to regulate blood glucose is to stimulate the production of cholecystokinin (CKK) by enteroendocrine cells in the duodenum. The secretion of CCK is linked to gastric emptying, the stimulation of pancreatic secretion, and satiety [142]. Several *in vitro* and *in vivo* studies testing intact proteins and their hydrolysates or corresponding amino acid mixtures demonstrate this phenomenon. Sharara et al. (1993) have shown that protein intake stimulates CKK secretion postprandially in rats, whereas free amino acid intake had no effect [143]. Furthermore, Cudennec et al. (2008) have shown that protein hydrolysates derived from blue whiting can enhance the secretion of CKK and GLP-1 *in vitro* [144]. *In vivo* studies with the same hydrolysates showed an increase in CKK and GLP-1 levels in the plasma of rat [145] and in human [62]. Greco et al. (2017) in reviewing the effect of protein intake on appetite have shown that the effect observed depends on the protein source [146]. Madani et al. (2015) showed that feeding obese rats with sardine proteins resulted in reduced plasma glucose and reduced insulin resistance as well as higher plasma GLP-1 levels compared to the group fed with casein [147]. A list of DPP-IV inhibitory peptides and CKK-stimulating hydrolysates obtained from fish processing by-products and underutilized fish species is provided in Table 2. The *in vitro* DPP-IV inhibitory activity of two peptides, Gly-Pro-Ala-Glu and Gly-Pro-Gly-Ala, identified from Atlantic salmon skin hydrolysates had IC_{50} values of 49.6 and 41.9 μM, respectively. Furthermore, Gly-Pro-Val-Ala identified from an Atlantic salmon trimming protein hydrolysate possessed a DPP-IV IC_{50} value of 264.74 μM. It was noted that the differences in amino acid residues in the peptide sequence had a major impact on DPP-IV inhibitory activity. The peptide Ile-Pro-Ile which is a known DPP-IV inhibitor and found in many dietary proteins was reported to have an IC_{50}

value of 3.2 μM [148]. It is possible that fish processing by-products could be a potential source of peptides with similar or higher levels of DPP-IV inhibitory activity.

5.5 Cancer

Cell division is a normal physiological event that occurs in tissues. Cell proliferation and cell death are highly regulated processes. Certain mutations in cellular DNA destabilize this process and can ultimately lead to cancer. The process that transforms normal cells into cancer cells is called carcinogenesis. It is characterized by a series of changes at cellular and genetic level that reprogram the cell into an uncontrolled division process leading to the formation of a tumor. This malignant mass can remain at a particular site or spread throughout the body via an angiogenesis process and metastasis diffusion.

Apoptosis is a form of programmed cell death and is one of the main mechanisms used in cancer treatment. As apoptosis does not enhance immune response or produce inflammation, it is a better method of treatment compared to classic chemical chemotherapies. Therefore, selective induction and modulation of apoptotic pathways in cancer cells represent a promising approach for cancer therapy [149]. In mammals, two major apoptosis signaling pathways are involved in the activation of cysteine proteases (caspases), the extrinsic death receptor, and the intrinsic mitochondrial pathways [150]. These interlinked pathways involve pro- and anti-apoptotic molecules that can trigger or regulate apoptosis. Therefore, the development of antiproliferative peptides that specifically target these pathways has become an interesting strategy for the development of anticancer therapies.

A large diversity of peptides with anticancer activity have been extracted from various marine organisms, mainly sessile animals, such as sponges, molluscs, and tunicates, which synthesize potent cytotoxic compounds to protect themselves against predators. These compounds are currently being exploited for cancer therapy. However, reports on the antiproliferative activity of peptides derived from fish protein hydrolysates are limited. Chalamaiah et al. (2018) reviewed the area of anticancer peptides from food protein hydrolysates [125]. Several studies have reported that free amino acids have diverse effects on different cancer cells [151, 152]. Cys promoted the proliferation of gastric and breast cancer cells. Asp and Arg stimulated the growth of breast cancer cells, while Glu induced apoptosis in gastric cancer cells. Ala showed an *in vitro* antiproliferative activity against gastric and breast cancer cells, while Pro and Lys showed an antiproliferative activity against prostate cancer cells. These reports suggest that the presence of specific amino acids in peptide sequences could modulate their activity against different cancer cell metabolic pathways. Furthermore, two peptides, Leu-Pro-His-Val-Leu-Thr-Pro-Glu-Ala-Gly-Ala-Thr and Pro-Thr-Ala-Glu-Gly-Gly-Val-Tyr-Met-Val-Thr, isolated from tuna protein hydrolysates possessed antiproliferative EC_{50} values of 8.1 and 8.8 μM on the human breast cancer cell line MCF-7 *in vitro*, respectively [80]. A list of the antiproliferative peptides obtained from half-fin anchovy, loach, and rohu by-products is provided in Table 2.

To date, Alemán et al. (2011) have reported the highest antiproliferative EC_{50} value (0.13 mg/mL) for a squid gelatin hydrolysate using Esperase® on MCF-7 cell line [153].

5.6 Other Bioactivities

Other biological activities involving peptides which possess antiviral and antimicrobial activity have been reported in the Antarctic fish (*Pleuronectes americanus*) and small red scorpionfish (*Scorpaena notate*), respectively (Table 2). Mineral-binding peptides have been identified from Alaska pollock and seabass. Mineral-binding capacities are important in many metabolic processes, including nutrient absorption, cellular proliferation, energy production, and oxygen transport [68, 70, 88]. Anticoagulant activity had been reported in peptides extracted from yellowfin sole frame [93] (Table 2).

6 Bioavailability

As already outlined, bioactive peptides can be released from food proteins during food processing by fermentation or enzymatic hydrolysis as well as during normal gastrointestinal digestion. Research has proven that fish processing by-products are a potential source of bioactive peptides for the production of functional food ingredients [154]. However, more studies on the stability of the bioactive properties need to be carried out. In order to be active at the target site in the human body, the peptides must maintain their biological activity after passing through the gastrointestinal tract, be resistant to extreme pH values and the action of gastrointestinal enzymes. An *in vitro* simulated gastrointestinal digestion (SGID) approach is often carried out to determine the stability of bioactive peptides following *in vitro* incubation with gastrointestinal enzymes. The enzymes used are salivary amylase at pH 7.0 for the oral phase, pepsin at pH 3.0 to simulate the gastric system, and a pancreatic enzyme preparation composed of trypsin, chymotrypsin, elastase, lipase, and amylase at pH 7.0 to mimic the intestinal phase [155]. Hydrolysis of proteins by these enzymes can release bioactive peptides. This has been shown when using the SGID approach for the generation of bioactive peptides from different food sources such as cereals, dairy products, and fish [156–159]. Moreover, *in vitro* SGID has shown that the hydrolytic action of gastrointestinal enzymes has the potential to modulate the bioactive properties of peptides generated following hydrolysis using non-mammalian food-grade enzyme preparations [160]. For this reason, bioactive peptides may be tested using *in vitro* gastrointestinal digestion to assess their potential stability and bioavailability after ingestion. However, some bioactive peptides have shown resistance to further digestion by gastrointestinal enzymes, such as the ACE inhibitory peptide Leu-Leu-Pro from tilapia, which maintained its activity following incubation with pepsin, pancreatin, and α-chymotrypsin [161]. The permeability of biological membranes, which allow bioactive peptides to reach the circulation,

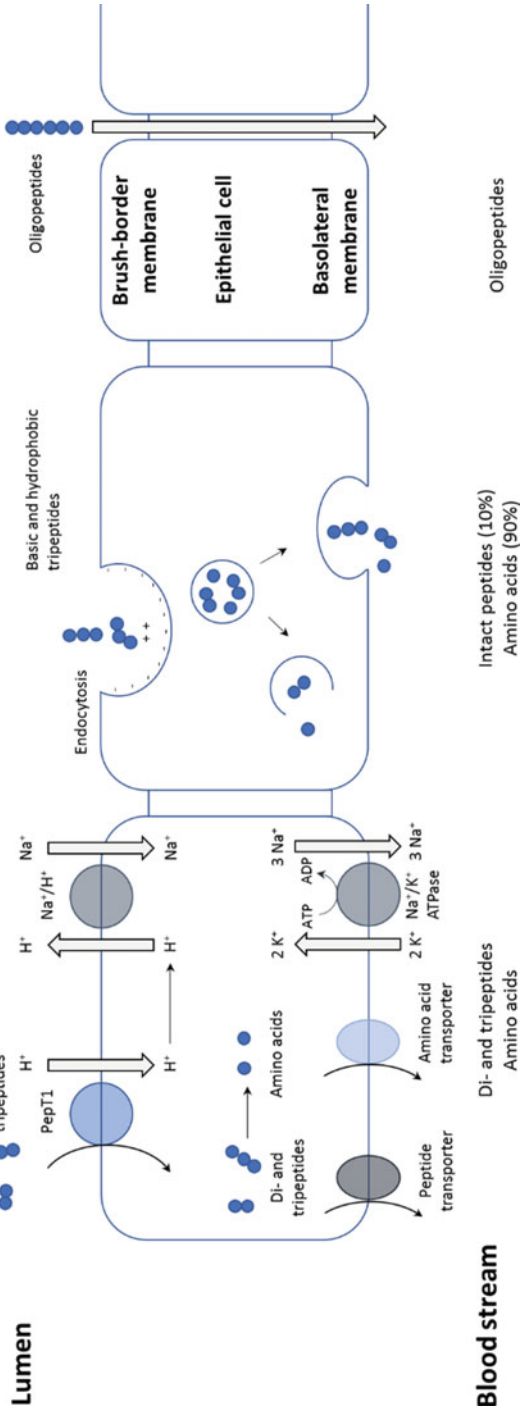

Fig. 5 Peptide transport mechanisms across intestinal cells. (Modified from Hamedy and FitzGerald [154])

depends on many factors such as peptide molecular mass and chemical stability and hydrophobicity. The transport of peptides through the gastrointestinal tract and the intestinal cell barrier is mediated via three main transport mechanisms. These mechanisms are schematically represented in Fig. 5. These consist of (A) active transport via the PepT1 carrier, which transports di- and tripeptides coupled with a proton pump, (B) endocytosis-exocytosis which transports basic and hydrophobic peptides via endocytosis vesicles, and (C) tight junction paracellular diffusion, which transports intact oligopeptides through tight junction pores [154]. However, active transport via PepT1 and passive paracellular diffusion are more efficient routes than endocytosis-exocytosis-mediated transport as peptides may be hydrolyzed after endocytosis by intracellular enzymes into amino acids before reaching the bloodstream. Furthermore, larger peptides and single amino acids have been shown to be less easily absorbed by gastrointestinal cells than short peptides (i.e., containing two to six amino acids) [162]. Transfer across the gastrointestinal membrane also depends on the amino acid sequence of the peptide [163]. Bioactive peptides isolated from fish have been reported to be resistant to the gastrointestinal digestion process and to be able to pass through intestinal membranes to reach the bloodstream. For example, *in vivo* studies in hypertensive rats have shown that the antihypertensive effects of bioactive peptides derived from fish, such as salmon, sardine, sole, tuna, and Alaska pollock, remain stable after passage through the digestion and assimilation processes. For example, Hou et al. (2016) showed that Pro-Thr-Gly-Ala-Asp-Tyr derived from tryptic hydrolysates of Alaska pollock frame could significantly enhance the humoral, cellular, and non-specific immune system in immunosuppressed mice [164]. This indicates that this peptide was resistant to digestion and was able to pass into the bloodstream. However, the stability of bioactive peptides can be enhanced via several strategies which have been developed by the pharmaceutical industry. Among these, encapsulation and structural modification of peptides at C- and/or N- terminal residues, including glycosylation and alkylation, have been shown to improve the bioavailability of peptides. Furthermore, peptides containing Thr, Glu, Phe, and His amino acids seem to be absorbed significantly faster compared to their free amino acid mixture equivalent [163]. The presence of a high percentage of Hyp and Pro amino acids also seems to improve resistance to hydrolysis by gastrointestinal enzymes [165]. Some of these approaches have been used to improve the bioavailability of fish-derived bioactive peptides. For example, the encapsulation of rainbow trout peptides in biopolymer-coated nanoliposomes was an efficient technique to maintain their antioxidant capacity [166].

7 Conclusion

The study of fish protein for the generation of bioactive peptides has increased in the last few years, and fish processing by-products as well as underutilized fish species have been identified as potential sources for bioactive peptides. However, even though several studies with regard to the extraction and hydrolysis of proteins

from fish and fish by-products, as well as the purification, characterization, and identification of bioactive peptides, have been carried out, more research is required to fully exploit and deliver their potential to consumers. While interesting studies on the use of fish processing by-products as functional food ingredients have been carried out, more research is needed in addressing the large-scale production of these products, their bioavailability, compatibility with different food matrices, long-term stability, and *in vivo* efficiency. Furthermore, it is necessary to determine the mechanisms by which peptides and hydrolysates can mediate their physiological effects. More nutrikinetic and metabolomic studies are required in order to understand the relationship between the dose administered and physiological effect. Marketing and economic studies are also required to establish consumer needs and preferences. Finally, *in vivo* validation studies are required to generate health promoting claims acceptable for international food safety agency approval.

Abstract

The potential of insects as a source of protein for future food and feed is the object of numerous studies. The nutritional value of edible insects is well established, and other aspects of consumption thereof are investigated. In this chapter, we aim to summarize the main features of insects as food. We briefly describe the history of the usage of insects as food for humans and refer to the current acceptance of insects by Europeans based on conducted surveys. We characterize the most common insect species with the biggest potential to be used as food and feed in the EU according to EFSA. We describe the nutritional value of insects and the possibility of application thereof in the food and feed industry, keeping in mind the safety of consumption. In addition, the ecological aspect of insect breeding is discussed. A review of the growing edible insect market in Europe and the USA is also provided. Moreover, we analyze the current legal status of insect intake in Europe. We aim to make this chapter a current conclusion about the consumption of insects.

Entomophagy · Edible insects · Protein · Environment · Nutritive value · Functional properties · Insect products · Bioactive peptides · Preferences of consumers

1 Introduction

The practice of eating insects is known as entomophagy. The term "entomophagy" itself is relatively new in English and some other European languages. The Google Ngram currently dates the first published mention of "entomophagy" to 1871, in a volume entitled "Sixth annual report on the noxious, beneficial and other insects of the state of Missouri" by Charles V. Riley. In French, the term "entomophagie" was found in data from 1810 [1]. Today, we can find "entomophagy" in Oxford Dictionaries online, which defines the term as "the practice of eating insects, especially by people." The greater interest in entomophagy is reflected in the increase in the number of publications. As reported by Evans et al. [1], the number of publications

in the Web of Science containing "entomophagy" amounted to 16 in 2001–2010 and as many as 49 in 2011–2015. In turn, 50 articles were published between 2016 and September 2017.

The rising interest in edible insects is reflected in the emergence of companies dealing with the production and processing of insects as well as the expanding scientific literature. The resulting publications present the use of insects in feeding farm animals, accompanying animals, and humans [2], whereas, research grants are focused on the use of insects in the food industry in various forms [3]. The consumption of insects as a whole can be difficult for Western consumers; therefore, the easiest way for processing insects is grinding them to flour [4]. It is also possible to isolate individual components of insects such as protein [5], fat [6], and chitin [7].

Eating insects by humans is not a new concept; it occurs globally [8] but is still rare in Europe [9]. Why not eat insects? Is it worth it? The answer is simple – definitely yes. Entomophagy has several advantages. First of all insects are a good source of protein, essential fats, and antioxidant peptides [10–13]. Many insects are rich in microelements such as iron, calcium, and zinc and in vitamins [14, 15]. Secondly, insect breeding is environmentally friendly. Insects emit significantly fewer greenhouse gases (GHGs) and ammonia than most livestock [16]. Moreover, insects require less space, feed, and water for breeding than livestock [17]. Economic factors are also important. Insect rearing can be low-tech or very sophisticated, depending on the level of investment [18]. For these three main reasons, insects have been highlighted as an important food source in response to the growing concerns about the future of world food security.

In this chapter, we describe the state of the knowledge of various aspects of insect consumption and their potential to be used in the food industry. We will also discuss the historical and cultural background of insect consumption, and we will focus on the biology of popular species.

2 History and Cultural Acceptance of Entomophagy

Despite the lack of tradition and the reluctance of some consumers, edible insects are increasingly becoming part of the diet of the people of not only Africa, Asia, and Latin America but also the USA, Australia, and Europe [18]. In many countries, they are considered not only as food providing nutrients but also as a delicacy. Although for many Europeans, insects are still associated with something unpleasant, it should be noted that in countries such as Thailand, Madagascar, and Mexico, they could only be consumed by the royal elites and the rich [19].

2.1 History and Tradition of Eating Insects by Humans

Habits, geographic regions, cultures, and religious beliefs have the main influence on food and diet practices. It is known that insects were consumed in ancient times, not only by animals but also by our primate ancestors [20]. Already in the fourth century

BCE, cicadas (nymphs, in particular) were described by Aristotle as a delicacy in Ancient Greece [21]. The first mention of insects as food ingredients can be found in the Old Testament (Leviticus 11.20–23), where we can read: "All winged insects moving on four feet you will regard as detestable for eating. Of all these winged insects you may eat only the following: those with the sort of legs above their feet which enable them to leap over the ground. These are the ones you may eat: the various kinds of migratory locust, the various kinds of solham locust, hargol locust and hagab locust. But all other winged insects on four feet you will regard as detestable for eating" [22]. Noteworthy is the fact that only some insect species were allowed to be eaten. Moreover, the New Testament (Matthew, 3, 4) mentions locusts as the food of John the Baptist [22]. Entomophagy was described in the early centuries AD in Greek literature by many philosophers; however, the approach to insect consumption was not unequivocal because many Greeks in the first century AD believed that cicadas should not be eaten because these insects were a swallow food and themselves were scary and musical [23]. In turn, in the first century AD, Roman historian Pliny the Elder (author of the encyclopedia – *Historia Naturalis*) mentioned that cicadas were eaten in the East [23] and the Cossus, i.e., an insect living on oak trees, was a meal valued by the Romans [23, 24]. In the early third century AD, in one of his works (*The Deipnosophistae* of Athenaeus), which is named the first cookbook, Athenaeus of Naucratis described grasshoppers and cicadas that were eaten as an incentive to appetite [25]. As shown by the abovementioned sources, the tradition of eating insects dates back several thousand years, and the mention of insect food can be found not only in the literature of the Christian religion but also in the Jewish and Islamic culture. As far as Christianity is concerned, we find already mentioned data on insect eating in the Bible, whereas species of kosher locusts were largely accepted in the Jewish culture in ancient times. In the following years, the tradition of consuming insects among the Jewish diaspora due to the lack of knowledge of the various types of insects known in the Torah as "winged swarming things" significantly decreased. Probably, also the influence of the Western culture was the reason for the disappearance of the tradition of eating insects by Jews [26]. In the Islamic tradition, we can also find several references to eating insects. El-Mallakh and El-Mallakh [27] find insects in the text of the Koran (e.g., gnat, locust, lice, bee, ant, and spider) that have played an important role in historical events or religious instructions. Only locusts, despite the association with plagues, could be designed to eat (Sahih Muslim, 21.4801). Moreover, insects were seen as low life forms (with the exception of bees) that had a negative influence on the daily life of humans. In the early literature of the Far East, especially in the Chinese literature, we can find information about insects as food. The *Compendium of Materia Medica*, i.e., a Chinese herbology and medicine book written by Li Shizhen during the Ming dynasty [28], provides information about the consumption of insect tea prepared from feces of moths, e.g., *Aglossa dimidiatus*, *Hydrillodes morosa*, and *Nodaria niphona*, which exhibited potential activity in treatment of otitis media [29]. The same source of interesting data about insects provides information that *Megachile* spp. China were used as medicine for cancer, *Endoclita sinensis* (grape tree borer) was used to enhance health, and larvae and adults of

Apriona germari japonica (mulberry longhorn, mulberry borer) were consumed [30] or used for treatment of cardiovascular diseases and brain fever [28]. As can be seen, insects are an important part of human nutrition history. They were very important sources of nutritional compounds not only for Africans, Asians, Americans, Latin Americans, and Indians in the west of North America. Some species were more important such as grasshoppers, caterpillars, beetle grubs and (sometimes) adults, winged termites (some of which are very large in the tropics), bee, wasp, and ant brood (larvae and pupae) as well as winged ants, cicadas, and a variety of aquatic insects. It should be noted that these insects were eaten not only during the periods of famine as the ultimate food, but they were also elements of the normal diet. Due to the tradition of nutrition, taste, and nutritional compounds among some people such as the Yukpa people of Colombia and Venezuela or the Pedi of South Africa, traditional insect dishes are more preferred than meat dishes [31]. It should be emphasized that insect consumption in many countries is not a new trend in nutrition and is part of the culture and tradition of the East and tropical countries. Moreover, the history of entomophagy is very old – from ants and larvae of beetles eaten in the tribes of Africa and Australia to maintain a balanced diet to fried locusts and beetles, which are popular also today in Thailand. It is estimated that insects are part of a diet of about two billion people worldwide, and 1900 species have been documented in the scientific literature as edible species. Similar to meat eaters who do not eat all kinds of meat, insect consumers do not eat all insect species. The most populous groups of insects include locusts, crickets, cicadas, beetles, wasps, caterpillars, leaf and plant hoppers, termites, scale insects, true bugs, dragonflies, flies, ants, grasshoppers, and bees [18]. In cultures where insects are regarded as food components, there are special local standards for the preparation thereof to make them suitable for consumption [32].

2.2 Do Europeans Already Eat Insects?

Although it may seem that Europeans do not eat insects, this is not exactly true. Even though many people claim that they would never eat insects, they actually consume them every day. Insects are everywhere. In spite of farmers' efforts, insects are found in cereals, spices, vegetables, and fruits, and despite the enforced limits on the specific insect content, they reach finished products such as flour, frozen food, chocolate, ketchup, coffee, fruit juice, and many other foods. Calculations indicate that each of us unknowingly consumes about 1 lb (500 g) of insects per year [33].

Furthermore, sometimes we eat insects consciously. The cochineal scale insect (*Dactylopius coccus*) produces a red dye called carmine (E120) when it is crushed. This dye is widely used in the food industry, e.g., in beverages, sauces, yogurt, and baked goods. In turn, cheese from sheep milk casu marzu (literally "rotten cheese") is a Sardinian delicacy. It is left to ripen for so long that it starts to rot. The rotting process attracts cheese flies that then lay their eggs on the cheese. The fly larvae eat their way into the cheese, digesting fats along the way and making the hard cheese soft and runny on the inside. The cheese is eaten with larvae, which are about 8 mm

long. However, the most popular and totally accepted product, although processed through an insect, is honey. People may not realize anymore that it comes from an insect and it is the vomit of some kind of larva [33]. Nevertheless, since honey is delicious, perhaps a chance should be given to other insects.

2.3 Preferences of Consumers in Western Countries

Although there are historical data on the use of insects for nutrition and insects are considered delicacies in many parts of the world, in most Western countries, eating insects is regarded as a disgusting practice arousing distaste and associated with primitive behavior [34]. In these cultures, insects are completely rejected as food ingredients, because they are unclean, unhealthy, and thus involved in the risk associated with food contamination and consuming insects [35]. The current growing scientists and consumers' interest in insects as food should be noted. It seems that there are three main barriers for the sector of edible insects: consumer acceptance, technology, and regulation. Hoverer, a study conducted in Switzerland has indicated nine main factors that have an influence on the willingness to consume insects. These are convenience orientation, discernibility of insects in food, food neophobia, expected food healthiness, perceived health benefits of meat, food technology neophobia, need for familiarity, and binary variables: gender and prior consumption. It is interesting that food neophobia does not play the most important role in the willingness to consume insects [36].

The current European Union policy on the food sector is cautious about new food sources. Classification of products as a "new food" and new food technologies as well as legislation of edible insects in human diet is still under consideration [37]. Nevertheless, according to Lensvelt and Steenbekkers [38] and Caparros Megido et al. [39], crickets and mealworms are most widely accepted as edible insects by people from Western countries. Factors that have an influence on this trend include increased interest in non-European cultures, developing ecology, environmental concern, and increased consumer awareness of technological issues in food production. In some countries, ten species of reared insects are mainly used as animal feed; however, some of these species have recently been sold as food in China, Thailand, the Netherlands, South Africa, Belgium, France, and the USA [40]. Commercial insect consumption in Western countries is currently limited to experimental restaurants where insects are served as a delicacy and something different or original [41] or to products that contain insecticides such as protein isolated as a nutrient ingredient for athletes. There are many studies on consumer preferences, relationships between human nutritional habits and entomophagy, or factors that have the strongest influence on consumer acceptance of insects as food. The results are not clear and depend on the countries and the awareness of participants in the experiments.

In recent years, the consumption of animal-based proteins, especially meat, aimed to maintain a well-balanced diet has been identified as one of the most important topics both for consumers and for food producers. It is known that the intensity of animal production generates climate change, has a strong influence on the environment, and is

expensive [42]. For this reason, studies mainly focus on determination of consumers' readiness to replace meat with other products in the diet [43]. Alternative nutritional approaches are vegetarian, macrobiotic, or anthroposophical diets, in which meat is either not eaten at all or very rarely and the protein is replaced by a vegetable healthy protein. Last but not least, insects are considered a potential source of protein [44]. The insects are not associated as food but as something nasty and food contamination. However, results of a study conducted in Belgium have shown that more than 65% of respondents disagree with the idea of including insects as food compounds [45]. Another study provided data from a representative survey of Dutch consumers on their habits in preparation of meat meals, meat substitution, and reduction of this ingredient in the diet, showing that the meal form, cooking skills, product familiarity, and preferences for plant-based foods had an influence on the consumer preferences. The most important factor that has an influence on acceptance of edible insects by consumers is their invisibility and the way of preparation of the meal [39, 46]. The results of the study with Dutch consumers, in which pictures of food with whole insects and with protein isolated from insects but used as an ingredient of the product, e.g., pizza, indicated that the photos with visible insects were rated much more negatively than those showing protein derived from insects and processed in the pizza. It seems that the pizza flavor has a positive effect on accepting insects as food, as chocolate-coated locusts were rated less negatively than fully visible insects [42]. The aim of another experiment was to determine how the product preparation, individual traits (e.g., food neophobia), and familiarity influence the acceptance of insects as food by consumers. The Dutch respondents rated eight pictures with four dishes (familiar foods). There was beef stew, curry, and brownie and spice cake in two variants: the mealworms were ground and not visible in the picture, and the insects were visible in the dishes. The results indicated that adding mealworms to familiar meals did not guarantee high product acceptability. Moreover, the products with edible insects were ranked lower, even if they were visually identical with products used as a control [47]. It would be worth exploring whether insects would be more readily accepted as a snack food than a part of the main meal. Since consumers have little experience with insects as food, it is difficult to conclude that the taste of dishes is based only on the presentation of the meal [48]. Hence, insects presented in various forms in a dish can cause different sensations and perceptions of taste, which affect the readiness of consumers to eat insects. In turn, a study conducted in Italy indicated that students engaged in a so-called bug banquet with cookies made with "insect flour" willingly tried the product and claimed that they would try other insects in the future. The main role in the decision to try a cookie made with cricket flour was played by curiosity, but negative opinions of family members and friends and the disgust factor prevented the consumers from eating the insects. In general, respondents consider insects as a rich source of protein and other nutrients, which may influence the desire to introduce them into the diet. This largely depends on the market availability and regulatory framework, food category (e.g., bakery product with insect flour), marketing strategies, methods of preparation, and culinary trends [49].

Another study provided some data about the sector of edible insects in the Netherlands, the progress of the sector, and limitations in the legitimacy process. Interviews were held with experts and stakeholders, including, e.g., industry experts,

researchers, government officials, and farmers in the emerging sector, about the strengths, weaknesses, opportunities, and threats of the edible insect industry. It should be noted that almost all respondents rated high the use of edible insects for economic and social purposes. Edible insects can also constitute a new business model in the Netherlands, be an alternative to soy and fishmeal, and provide a solution to global protein deficiency. However, the development of this sector should not be rushed and not limited to the feed market [37].

A study assessing the perception of entomophagy among the Belgian population was carried out by Caparros Megido et al. [39]. The results indicated slight neophobia, but consumers agreed to test insect preparations. Two species of edible insects were tested (house crickets and mealworms); they were prepared as a snack with known flavors and crispy texture. The results have suggested that people will be eating, preparing, and cooking insects in the near future. It has been shown that edible insects that are prepared as snacks with common flavors such as chocolate, chili, caramel, or curry arise curiosity and are more likely to be eaten than raw insects. It should be noted that, even in 2012, insects were not accepted as an alternative or replacement of meat in Belgium [43].

Determination of the acceptance of edible insects as food and an alternative source of protein was the aim of a study conducted by Gere et al. [50] in Hungary. The results showed that less than 11% of respondents did not regard insects, algae, soy, and whey as an alternative source of protein, but half of them knew algae and whey as this kind of protein source, and soy had the highest familiarity scores. Moreover, almost 60% of the respondents have heard about edible insects but do not know them. Interestingly, those who intended to reduce their meat intake in the coming year suggested insects as a replacement for fresh meat, but the general scores of food neophobia were significantly higher than the scores of food technology neophobia. The results confirm findings reported by other authors, i.e., in the case of European consumers, food neophobia is a barrier for the consumption of insects. Table 1 summarizes the acceptance of insects as alternative proteins among Western consumers.

We can conclude that edible insects may be introduced to the diet of the Western consumers in the future; yet, although the product design is important, it is insufficient to popularize insect consumption. Moreover, people's knowledge about the environment and positive aspects of edible insects as bioactive components of food should be increased. In the future, edible insects may become such a delicacy for European consumers as seafood, which in some European countries is a source of disgust.

3 Examples of Popular Insect Species for Human Consumption

The word insect derives from the Latin word "insectum," meaning "with a notched or divided body," literally "cut into sections." In the Online Etymological Dictionary [55], we can also find: "The Latin word is Pliny's loan-translation of Greek entomon

Table 1 Acceptance and methods of preparation of insects as alternative proteins among Western consumers

Country, year of study, and sample	Method of preparation	Main research question/intervention	Provided information
Hungary, 2016, 400 adult meat consumers [50]	No info	Have you ever heard about this alternative source of protein, and would you be prepared to eat insects as a meat substitute?	89% of the respondents know about the alternative protein sources. 60% of the respondents have heard about insect consumption and know what this means. Insects can be an alternative source of protein for people who want to reduce meat consumption, but neophobia is a barrier
Italy, 2015, 109 people (53% female and 47% male), aged between 18 and 25 years old [49]	Cookie with cricket flour	Would you like to taste an edible insect? The reasons for the decision	Almost all respondents tasted the cookie and are willing to try other insects in the future. The barriers include negative opinions of family members and friends and the disgust factor. Market availability (regulatory framework), food category (e.g., bakery product with insect flour) marketing strategies, gastronomy (preparation), culinary trends, and education have an influence on insect consumption in the future
German- and French-speaking parts of Switzerland, 2015, 379 cases [36]	No info	Predictors that are currently used to explain the willingness to consume insects	There are nine significant variables reliably predicting the willingness to consume insects: convenience orientation, discernibility of insects in food, expected food healthiness, need for

(*continued*)

Table 1 (continued)

Country, year of study, and sample	Method of preparation	Main research question/intervention	Provided information
			familiarity, perceived health benefits of meat, food technology neophobia, food neophobia, and binary variables: gender and prior consumption. Food neophobia was not found to be the key predictor of the willingness to consume insects but shares its rank with various predictors. Further, the analysis revealed one significant two-way interaction effect
Belgium, 2014, students interested in insect food, 79, 44% males, 56% females [39]	Burger with a mixture of beef, lentils, and mealworm	Overall liking of the hybrid burger in comparison with a beef burger	Females liked the beef burger better than the burger containing mealworms. Males perceived no significant difference between the beef burger and the mealworm burger. The major factors influencing the results were knowledge of entomophagy, previous experience with insect tasting, and gender
Denmark and Italy, no info, 136 students from Denmark (61 females), and 128 from Italy (71 females) [51]	Insects	Impact of individual and social benefits of eating insects on acceptance of insect-based food products. Effect of communication, also comparing messages based on individual versus societal benefits of insect	Communication has an influence on the intention and behavior and depends on the nation, gender, and knowledge of entomophagy Negative associations with insects have a strong

Country, year of study, and sample	Method of preparation	Main research question/intervention	Provided information
	crickets and mealworms, roasted crickets and roasted seasoned mealworms, and roasted mealworms garnishing rice crispy squares		effective way to change attitudes toward insects as food
Switzerland, 2015, 104, 55% men [54]	Tortilla chips: made with a traditional corn flour recipe and cricket flour as an additional ingredient	Could processed foods like cookies or chips made with a small amount of cricket flour be used to increase the general acceptance of insects as a food source?	The results have shown that the positive experience with a processed insect product can increase people's willingness to eat unprocessed insects. The products with edible insects as an ingredient can taste good, and processed insect food may be a first step to accept insects as food by western consumers

'insect,' which was Aristotle's term for this class of life, in reference to their 'notched' bodies. First in English in 1601 in Holland's translation of Pliny. In zoology, in reference to a class of animals, 1753."

Insects have a three-part body (head, thorax, and abdomen) with a chitinous exoskeleton, three pairs of jointed legs, compound eyes, and two antennae. They are among the most diverse groups of animals on the planet: there are more than one million described species, which is more than half of all known living organisms. Until recently, the total number of species is estimated at 6–10 million [56], but the current estimates are up to 30 million [57]. Among the millions of insect species living on earth, 2111 are considered as edible (Fig. 1) [58]. These facts show that insects are an important source of protein in our diet. Members of Lepidoptera, Hemiptera, Coleoptera, Diptera, Orthoptera, and Hymenoptera are the most commonly consumed insects. The popularity of edible species varies among regions or cultures [59]. In Europe, the consumption of insects is marginal, but the interest in insects is still growing. Therefore, the Scientific Committee of the European Food Safety Authority issued a scientific opinion "Risk profile related to production and consumption of insects as food and feed" [60]. The report contains a list of insect species that were found to have the biggest potential to be used as food and feed in the EU:

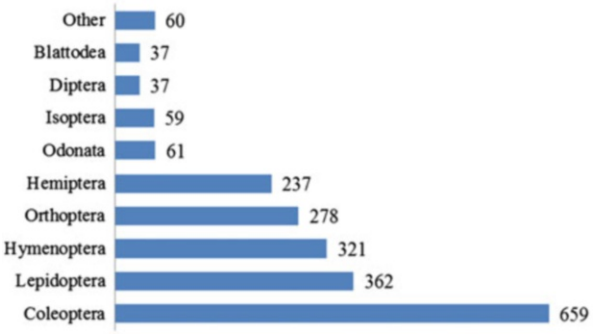

Fig. 1 Number of recorded edible insect species per group in the world [58]

Musca domestica: Common housefly
Hermetia illucens: Black soldier fly
Tenebrio molitor: Mealworm
Zophobas atratus: Giant mealworm
Alphitobius diaperinus: Lesser mealworm
Galleria mellonella: Greater wax moth
Achroia grisella: Lesser wax moth
Bombyx mori: Silkworm
Acheta domesticus: House cricket
Gryllodes sigillatus: Banded cricket
Locusta migratoria migratorioides: African migratory locust
Schistocerca americana: American grasshopper

At the same time, EFSA notes that this list does not need to be considered definitive or exhaustive. This selection is undoubtedly supported by the large number of scientific studies of these species.

3.1 Diptera

Flies (order Diptera) are a very popular insect order consumed by humans [58]. *Musca domestica* and *Hermetia illucens* are representatives of this order. They are probably characterized by the largest reproductive capacity, shortest life cycles, and rapid growth rates, which makes them one of the most attractive species of insects for human consumption [61]. The black soldier fly (*Hermetia illucens*) can be used commercially to solve a number of environmental problems associated with manure and other organic waste, such as reducing manure mass, moisture content, and offensive odors. At the same time, they provide high-value feedstuff for cattle, pig, poultry, and fish [62]. *H. illucens* has become an object of interest to researchers who work on the possibility of using this insect in animal feed [63–65]. It can also be used

in solving another problem: the increasing amount of food waste, which can cause environmental pollution if not managed properly [66]. The black soldier fly exhibits rapid food intake ranging from 25 to 500 mg of fresh matter/larva/day feeding on a wide range of decaying organic materials, such as rotting fruits and vegetables, fish offal, and animal manure and human excreta [67].

3.2 Coleoptera

Insects of this order are most commonly consumed in the world with 659 documented species being consumed (Fig. 1). Of the several edible groups within this order, the most interesting is probably the family Tenebrionidae. The *Tenebrio molitor*, *Zophobas atratus*, and *Alphitobius diaperinus* species listed by EFSA belong to this family. Tenebrionids have a bad reputation as pests of meal, flour, and other stored and packaged cereal foods, but, despite this, the yellow mealworm, *Tenebrio molitor*, has been reared by zoos, aquaria, and commercial dealers as food for animals since at least the eighteenth century [59]. Moreover, the mealworm (*T. molitor*) is the subject of many studies. Its properties and nutritional value are well known [4, 5, 14, 68–70]. The insect can be easily reared on many types of vegetables and grains in a small space. There are even special devices for breeding insects at home. A Livin Farms hive is a device that facilitates breeding of mealworms for the needs of your household. The system is divided into multiple vertically stacked chambers beginning with pupae, placed into the topmost pupation component, where they hatch into meal beetles (*T. molitor*). After the adult beetles mate, they lay eggs that fall through into the egg layer where the mealworms are hatched. Every week, the mealworms will be lowered into the next compartment until they reach the sixth drawer for the weekly harvest. The mealworms can survive on oats and vegetable scraps, while in-built smart systems help maintain ideal microclimates for growth and remove foul odors. The weekly full harvest process should take approximately 8–9 weeks for setup [71].

3.3 Lepidoptera

Caterpillars are the second most consumed insect order by humans, with 362 documented species being consumed (Fig. 1). *Galleria mellonella*, *Achroia grisella*, and *Bombyx mori* are representatives of the EFSA list. They are eaten in the larval form, and the largest size (up to about 60 mm) is reached by the silkworm *Bombyx mori*. They are very high in fat but also in microelements such as iron and zinc [68]. They are less popular for consumption in Europe, but they are massively reared for the animal feed industry. Moreover, these larvae are the subject of research on bioactive substances derived from their organism. Studies on the antihypertensive properties of peptides from *B. mori* are being conducted [72, 73]. *B. mori* and *G. mellonella* have been found to produce antimicrobial peptides [74–77].

3.4 Orthoptera

Insects of this order such as grasshoppers, locusts, and crickets are known to all insect-eating cultures. Two hundred seventy-eight species of crickets, grasshoppers, and katydids are recorded as being consumed by humans (Fig. 1). Acrididae, Gryllidae, and Tettigoniidae are the most commonly consumed insect families [61].

The house cricket *Acheta domesticus* is most readily available to Western consumers. Studies have shown that, when kept at temperatures of 30 °C or higher and fed diets equal in quality to those used in bringing conventional livestock to market condition, this cricket exhibits food conversion efficiency about twice as high as that of broiler chickens and pigs. In addition, female crickets have much higher fecundity than other animals. Each cricket lays 1200–1500 eggs over a period of 3–4 weeks [59]. Another cricket *Gryllodes sigillatus* is also well known in Europe, for example, as food for exotic pets. The tropical house cricket is probably native to Southwestern Asia but has been spread by commerce to tropical regions worldwide [78]. *Locusta migratoria migratorioides* and *Schistocerca americana* are members of the Acrididae family. Despite the extensive practice of farming insects, these species are more difficult in commercial breeding than the crickets mentioned above [18]. There is a prototype device for breeding crickets or grasshoppers at home. The Lepsis is a vessel that can be used to grow insects for food. The product consists of four individual units that are each designed to breed, grow, harvest, and kill grasshoppers, and they combine to form a decorative kitchen product [79].

4 Nutritional Value of Edible Insects

The nutrient compositions of many edible insects were compiled and published in numerous studies [80–85]. The nutritional values of insects are expressed as the content of proteins (amino acid profile), fat, fibers, dietary energy, minerals, and vitamins. The nutritional values of edible insects depend on many factors, e.g., the origin of the insect, stage of metamorphosis, diet, and environmental factors (temperature, humidity) [86]. Therefore, it is very difficult to generalize about the nutritional value of the 2000 edible insect species.

4.1 Energy Content

The energy content in most edible insects is considerable due to the high levels of protein and fat. The energy value depends on the stage of insects, i.e., larvae or pupae are usually richer in energy than adults. Ramos-Elorduy et al. [87] analyzed 78 species of insects and estimated their energy value in the range from 293 to 762 kcal/100 g. On the basis of 113 literature reports, Rumpold and Schlüter [70] have found that 79.65% of insects are characterized by energy content above 400 kcal/100 g and 40.94% above 500 kcal/100 g. The mean energy content in edible insects is in the range of 409.78–508.89 kcal/100 g (based on dry matter), with maximum energy

Table 2 Nutritional content of selected insect species compared with common protein commodities

Name (*Latin name*)	Protein content (% in dry mass)	Fat (%)	Fiber (%)	Energy content (KCAL/100G)
Banded cricket (*Gryllodes sigillatus*)	70.00 [14]	18.23 [14]	3.65 [14]	452.00 [14]
Black soldier fly (*Hermetia illucens*)	17.50–36.00 [81]	14.00 [80]	6.70 [89]	199.00 [80]
	17.50 [80]	32.60 [90]		
	47.00 [89]			
Common housefly (*Musca domestica*)	9.30 [89]	11.90 [89]	–	552.40 [70]
	63.10–63.99 [70]	15.50–24.31 [70]		
Giant mealworm (*Zophobas atratus*)	41.50 [90]	36.20 [90]	–	–
(*Zophobas morio*)	19.85–51.60 [81]	40.80–42.04 [70]	1.54–2.50 [81]	575.53 [70]
	43.13–46.79 [70]		9.26–13.0 [70]	
	46.80–55.16 [91]			
Greater wax moth (*Galleria mellonella*)	15.39 [81]	51.40–60.00 [70]	8.92–19.52 [70]	650.13 [70]
	33.98–41.25 [70]			
House cricket (*Acheta domesticus*)	7.50–23.70 [80]	2.41–6.71 [80]	1.18–4.03 [81]	135.10–170.90 [80]
	15.60–73.60 [81]	9.80–24.00 [70]	6.20–22.08 [70]	414.41–455.19 [70]
	55.00–70.75 [70]	14.40–22.10 [89]	9.60–10.20 [89]	
	66.60–67.20 [89]			
Lesser mealworm (*Alphitobius diaperinus*)	48.60–60.00 [81]	8.50 [3]	4.40–9.10 [81]	–
	61.70 [90]	24.30 [90]		
		29.00 [92]		
Locust (*Schistocerca americana*) (*Schistocerca gregaria*)	61.10 [70]	17.00 [70]	10.00 [70]	427.00 [70]
	76.00 [14]	12.97 [14]	2.53 [14]	432.00 [14]
Migratory locust (*Locusta migratoria*)	62.20 [91]	12.61	23.61	364.70
	13.00–28.00 f.m [18]

	10.14–25.66 [80]			
	17.90–22.89 [81]			
	48.70–69.84 [70]			
	53.80–64.70 [89]	8.09–37.10 [89]	6.40 [89]	389.60–555.00 [70]
Commonly consumed protein source				
Egg, whole, dried	12.56 [93]	9.51 [93]	–	592.00 [93]
Beef, grass-fed, ground, raw	19.42 [93]	12.73 [93]	–	198.00 [93]
Chicken ground, raw	17.44 [93]	8.10 [93]	–	143.00 [93]
Soybeans, mature seeds, raw (*Glycine max*)	28.70–50.10 [94]	19.94 [93]	9.30 [104] – 11.90 [94]	403.00–446.00 [93, 94]
Broad beans, mature seeds, raw (*Vicia faba*)	22.00–38.20 [94]	1.53 [93]	25.00 [93]	320.00–341.00 [93, 94]
Lentils/raw (*Lens culinaris*)	24.63 [93]	1.06 [93]	10.70 [93]	352.00 [93]
Wheat, durum (*Triticum durum*)	13.68 [93]	2.47 [93]	10.70 [93]	339.00 [93]

contents as high as 762.00–776.85 kcal/100 g in moth *Phassus triangularis* [70, 88]. Among the species of edible insects listed in Table 2, the maximum energy contents was found in the greater wax moth (650.13 kcal/100 g) [10], and the minimum value was estimated in the silkworm (*B. mori*) 128 ± 7.48 kcal/100 g [80]. Evidently, the energy content in most edible insects is high, even in comparison to meat.

4.2 Protein and Essential Amino Acid Profile

In recent years the protein content is a leading trend in the development of food products. Protein is a very important basic macronutrient for humans, as it plays many functions in the body and, above all, is a source of essential amino acids and energy. The growing desire for unconventional non-animal-based protein sources has led to an interest in pulses and insect-based protein. As a rich protein source, edible insects are alternatives to meats within international dietary guidelines. The total protein content of insect species is presented in Table 2.

The protein content of most edible insects has been shown in many studies to be within the range of 13–77% [81, 82] or 9.3–80% [89, 95]. The protein level in insects depends on many factors, e.g., their metamorphosis stages, feeding mixtures used, varying water content, methods of preparation and processing applied before consumption of insects (e.g., drying, boiling, or frying), and primarily methods used from protein determination (Dumas technique or Kjeldahl method) [89, 90, 95]. Many studies have reported analysis of the nutritional value of edible insects; however, these data are not always comparable due to the variations between insects and because of the varying methodologies employed to analyze the compounds. The Kjeldahl method is widely used for determination of the crude protein content in food [18]. Therefore, many scientists use this method in their studies devoted to insects. This procedure evaluates the total concentration of nitrogen (N), which is converted to protein by multiplying it by the nitrogen-to-protein conversion factor of 6.25. Because insects contain many N-rich compounds that are not digested by humans (chitin and proteins tightly embedded in its matrix), the Kjeldahl method can overestimate the content of digestible protein. In view of the above, Jonas-Levi and Martinez [81] proposed evaluation of digestible nitrogen by quantifying N in the cuticle and subtracting it from the total nitrogen content and calculation of a new N-conversion factor, which should be similar for all insect species and their development stages.

The highest percentage of protein (80%) was found in the adult stage of the gypsy moth (*Porthetria dispar*) and (78.8%) in the German cockroach (*Blattella germanica*) [88]. Among insects recommended by EFSA, the cricket (*Acheta domesticus*) was characterized by the highest protein content (73.60%) [81].

Comparison of the conventional protein source in human nutrition with insect protein demonstrates that the content of proteins in many insects is comparable to that in beef or chicken meat. As shown in Table 2, some insects are comparable to eggs, meat, and plants. Moreover, insects are richer in protein than cereals, e.g., wheat 13.68%, pseudocereals: buckwheat 13.1% and amaranth 13.5% [96] and legume seeds including dried peas (*Pisum sativum*) 14.2–36.1%, chickpeas (*Cicer arietinum*)19.1–31.2%, beans (*Phaseolus vulgaris*) 15.2–36.0%, and soybeans (*Glycine max*) 28.7–50.1% [94]. Finke et al. [97] investigated insects as a source of protein used for feeding rats. They observed that the amino acid composition in cricket protein (*Acheta domesticus* and *Anabrus simplex*) was equal or better than that in soy protein. By contrast, silkworm protein showed a significant lower quality than casein.

A major consideration with respect to the inclusion of insects in food products relates to the quality of their dietary protein. Protein quality depends on the kind of amino acids present in their sequence (essential or nonessential) and protein digestibility. However, the quality of insect proteins in comparison to other animal and plant proteins has to be assessed through the amino acid requirements in humans. The most important aspect and characteristic of protein from a nutritional standpoint is its amino acid composition. Phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, and lysine are classified as essential amino acids, and histidine is a semi-essential amino acid.

Cereal proteins that are major components in human diets and animal feed worldwide are rich in sulfur amino acids, but they are poor in lysine, tryptophan, and threonine (e.g., maize) [98–100]. Similar to cereals, legumes (soybean, pea, chickpea, lentil, beans) contain high amounts of essential amino acids such as arginine, leucine, and lysine but are poor in sulfur-containing amino acids (particularly methionine) and tryptophan [31].

The amino acid spectra in edible insect have been shown in many studies [70, 80, 89, 101–103]. Analysis of many edible insects has revealed that their essential amino acid content is 10–30%, covering 35–50% of all types of amino acids, which is close to the amino acid model proposed by the World Health Organization and FAO [89]. In some insect species, essential amino acids are very well represented [104], while in others they are limited. It was reported in literature that insect proteins were low in the Met + Cys [103] and high in Lys, Trp and Thr [31], or Phe [105]. As demonstrated by Williams et al. [89], Trp is a limited amino acid in ants, bee (*Apis mellifera*), and silkworm (*B. mori*), Ile in caterpillar, and Lys in termites. The essential amino acids (EAA) of selected insects compared to plant and animal protein sources are shown in Table 3. The giant mealworm (*Z. atratus*) protein is low in Met, silkworm (*B. mori*) in Met and Phe, and common housefly (*M. domestica*) in Ile.

Generally, proteins derived from animal foods (meats, milk, eggs) are complete, but protein malnutrition continues to be a problem in many countries around the world. Insects are a promising alternative source for nutritional and functional proteins. Insects are characterized by high protein quality with beneficial potential for human nutrition. The great number of investigations on the health benefits of edible insects associated with consumption thereof increase interest in developing innovative technologies to expand the use of insects in food or feed products. Apart from their nutritional properties, proteins from edible insects possess functional properties that play an important role in food formulation and processing [18].

4.3 Lipids and Essential Fatty Acid Profile

Fats are one of the three main macronutrients, along with carbohydrates and protein. Dietary consumption of fatty acids has an impact on human health. Some insects are rich in fat, in a wide range from 4.56% to 60% (Table 2). The fat content is higher in

Table 3 Essential amino acid (EAA) content of selected insect species compared with common protein commodities [70, 93]

EAA [mg/g protein]		Egg, whole, raw, fresh	Wheat, durum	Soybeans mature seeds. Raw	Silkworm (*Bombyx mori*)	House cricket (*Acheta domesticus*) (adults)	Mealworm (*Tenebrio molitor*)	Giant mealworm (*Zophobas morio*)	Common housefly (*Musca domestica*) (larvae)	Summary of the adult EAA requirements FAO/WHO/UNU (2017) [mg/g protein]
Essential amino acids	**His**	24.60	23.54	30.06	25.8–29.5	22.7–23.4	28.7–37.9	30.5	30.9	15

the larval stage than in the adult stage [82]. Larvae of the greater wax moth (~60%) and mealworm (~43%) exhibit the highest amounts of fat [10, 90, 98, 100].

Lipids are a source of not only energy but also essential fatty acids (FA). Many studies have found that replacing saturated fatty acids (SFA) with monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) in the diet reduces the risk of cardiovascular diseases. The evaluation of fat quality is a complex issue, since SFAs elevate the LDL cholesterol concentration in serum, while MUFAs and PUFAs (in particular, those from the n-6 family) have been shown to decrease LDL cholesterol concentrations. Therefore, it is recommended that SFA should be replaced with PUFA (n-3 and n-6) in the diet, and the total intake of SFA should not exceed 10% of energy [106]. The fatty acids of many insects contain more PUFA and are comparable to those of poultry and fish in their degree of unsaturation [70, 104]. In contrast, beef and pork contain very low levels of PUFA but high content of MUFA [107]. The highest MUFA proportion was found in beetle larvae, while PUFA levels were determined in adult crickets [102]. The ratio of fatty acids recommended for human nutrition is SFA/MUFA/PUFA 1.25:1.5:1. The ratio found in *Zophobas morio* by Kourimska et al. [105] was 1.9:1.4:1. The determined MUFA/PUFA ratio meets the requirements for human consumption (1.4:1), but the amount of SFA is significantly higher. Similar results were obtained by Zielińska et al. [14] (1.34:1.4:1.1) for *Schistocerca gregaria*. In turn, Tzompa-Sosa et al. [11] obtained a lower ratio (1.4:1.6:1) in the case of this species. The amount of SFA in the mealworm (*T. molitor*) was significantly lower. This is confirmed by the results obtained by Zielińska et al. (2015) (1:1.7:1.2). Tzompa-Sosa et al. [11] obtained a significant content of MUFA (1.1:2.3:1), whereas Bednářová et al. [91] reported a greater amount of PUFA (0.7:0.8:1). A greater amount of PUFA was determined by Zielińska et al. [14] in the case of *Gryllodes sigillatus* (1:1:1), but the amount of SFA and MUFA was considerably lower than recommended. The quality and quantity of fatty acids in foods are very important from the nutritional point of view. The fatty acid composition in edible insects has been summarized in many studies [14, 68, 70]. The differences between reported values of fat contents in many studies may have been associated with the variety of insects and with changing the insects' feed composition [70, 95, 108]. The main MUFA detected in edible insects are palmitoleic acid and oleic acid. The silkworm larva is a potential source of such fatty acids as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are important to support a healthy cardiovascular system [109]. The highest content of essential α-linolenic acid and oleic acid was determined in *T. molitor* larvae and *A. domesticus* [11, 102, 110]. Therefore, the mealworm could be the most suitable insect of all analyzed species for human consumption. PUFA that can be found in the fatty acid spectra of edible insects are represented by linoleic, linolenic, arachidonic, and eicosapentaenoic acids [70, 92, 103].

4.4 Fiber Content

The fiber content of edible insects was investigated in many studies and referred to as crude fiber (CF), acid detergent fiber (ADF), and neutral detergent fiber (NDF)

[111–113]. According to Rumpold and Schlüter [70], the average fiber content in edible insects ranges from 5.06% (termites) to 13.56% (true bugs). The average fiber content in the species of edible insects listed in Table 2 ranges from 2% (silkworm) to 22.08% (house cricket). The differences in the fiber content likely result from the presence of different compounds that are bound to chitin. The exoskeleton of edible insects contains a significant amount of different compounds, including chitin and substances that are bound to chitin (e.g., protein, lipids, and other compounds) [111, 114]. Moreover, Finke [111] suggests that insects with harder cuticles do not necessarily contain more chitin than softer-bodied insects, but rather they contain higher levels of cross-linking proteins that are essential for sclerotization. Chitin is considered as an indigestible fiber by humans, because chitinase found in human gastric juices is inactive [115]. However, it was found that this enzyme is active in the organisms of inhabitants of tropical countries where the consumption of insects has a long-term tradition [18, 89, 105]. Removal of chitin improves the digestibility of insect protein [111].

Chitin has been associated with defense against parasitic infections and some allergic conditions; it acts as an anticoagulant and protects against certain pathogens in the blood and skin. The positive activity of chitin involves significant reduction of serum cholesterol, functions as a hemostatic agent for tissue repair, enhancement of burn and wound healing, enhancement of pollutant removal from waste-water effluent, improvement of the washability and antistatic nature of textiles, inhibition of growth of pathogenic soil fungi and nematodes, and an increase in wheat, barley, oat, and pea yields by as much as 20% [116–118].

4.5 Microelements

Many edible insects are a good source of macro- and micronutrients that are necessary for a healthy organism [40, 119]. As shown in many studies, edible insects are a rich source of phosphorus (P), magnesium (Mg), potassium (K), sodium (Na), calcium (Ca), copper (Cu), iron (Fe), manganese (Mn), zinc (Zn), and selenium (Se). Therefore, edible insects can supply necessary nutritive elements for human body functions. Very important is the supply of Fe and Zn in the diet, given the worldwide deficiencies in these minerals among humans. There are nutritional studies on the use of insects (caterpillar cereal) in prevention of diseases associated with iron deficiency diseases such as anemia and stunting [120, 121]. Most edible insects have equal or higher iron contents than beef [104]. An excellent source of iron are mopane caterpillar (*Gonimbrasia belina*) (31–77 mg/100 g) and locusts (8–20 mg/100 g DM), while the iron content of the beef is 6 mg/100 g [122]. Zinc content in beef is on average 12.5 mg/100 g, while house cricket (*A. domesticus*), for example, contains 29.69 mg/100 g, chapulin (*Sphenarium histrio*) 78 mg/100 g, and house fly pupa (*M. domestica*) 85.8 mg/100 [70, 89]. Generally, edible insects are low in sodium (except caterpillar *Usta terpsichore*) and calcium (except *M. domestica* and *A. domesticus*) [70]. The composition of macro- and micronutrients largely depends on the food consumed by the insect. The macro- and microelements can be contained in the

consumed food present in the gastrointestinal tract or in components incorporated in the insect's body [89, 113, 123]. The levels of these nutrients vary considerably between species. Rumpold and Schlüter [70] concluded that edible insects generally lack sufficient amounts of Ca and K. In contrast, Gosh et al. [102] have shown that the calcium content in all studied insects was much higher than that in conventional foods of animal origin except chicken eggs. Edible insects have the potential to provide specific micronutrients such as Cu, Fe, Mg, Mn, P, Se, and Zn, and, in addition, they can be utilized in low-sodium diets. Nowak et al. [83] compared a high number of insect species and found that the mineral content in insects exhibited extreme variability within and between species. According to Oonincx and Dierenfeld [124], the high variability in microelements is a result of a small sample size, species-specific metabolism, varying accuracy of sampling and/or analytical techniques, and contamination.

4.6 Vitamins

Edible insects are also a source of vitamins, which are essential for normal growth and development of a living organism by stimulating metabolic processes and enhancing immune system functions. Due to the limited data about vitamins in insects, it cannot be indicated which insects are a good source of vitamins. Nevertheless, Bukkens [104] has shown that the level of vitamin B_1 in a whole range of insects is 0.1–4 mg/100 g and B_2 – 0.11–8.9 mg/100 g; in comparison, whole-meal bread provides 0.16 mg and 0.19 mg/100 g of these vitamins, respectively.

Rumpold and Schlüter [70] have demonstrated that edible insects contain a whole range of water-soluble vitamins, B_1 (thiamine), B_2 (riboflavin), B_3 (niacin), B_5 (pantothenic acid), B_6 (pyridoxine), B_7 (biotin), B_9 (folate), and C (ascorbic acid), and fat-soluble vitamins, A (retinol) and E (tocopherols). By comparison of the vitamin content in insects with the vitamin requirements in human nutrition of adults, Rumpold and Schlüter [70] noted that edible insects are generally rich in riboflavin, pantothenic acid, and biotin. In turn, Nowak et al. [83] collected 56 literature reports about vitamin content in edible insects and found that mealworm can be a good source of vitamin B_6 (pyridoxine), B_2 (riboflavin), B_3 (niacin), B_9 (folate), and B_{12} (cobalamin). Caterpillars are especially rich in B_1, B_2, and B_6 [82, 125].

Wakayama et al. [126] noted that many insect species were characterized by low levels of vitamin B_{12} (cyanocobalamin). It is present only in animal-origin food and is well represented in mealworm larvae (*T. molitor*) (0.47 μg/100 g) and house crickets (*A. domesticus*) (5.4 μg/100 g in adults and 8.7 μg/100 g in nymphs). According to van Huis [122], Williams et al. [89], and Rumpold and Schlüter [70], insects are generally a good source of some vitamins B but not A, C, B_3, and B_1. The content of vitamin A (as retinol or β-carotene) was less than 2 μg/100 g and less than 100 μg/100 g in yellow mealworm larvae, superworms, and house crickets [68, 104, 127]. Compared to commercially bred insects, those captured in the wild contain higher levels of carotenoids, such as astaxanthin, α- and β-carotene, lutein, or

zeaxanthin; this is associated with their diet, which is a richer source of these compounds. The high level of carotenoids in insects may be a promising source of vitamin A in human diet [122].

There are insufficient data on the content of vitamin E in insects. According to Bukkens [104], palm weevil larvae (*Rhynchophorus ferrugineus*) had 35 mg and 9 mg/100 g of α-tocopherol and β+γ tocopherol, respectively (the recommended daily intake – 15 mg). A relatively high level of vitamin E, 9.65 mg/100 g, was determined by Tong et al. [128] in freeze-dried silkworm powder (*B. mori*).

In conclusion, since the literature provides only a few data on insect vitamin content, more research is needed to identify edible insects as a source of vitamins. Moreover, Payene et al. [80] observed that the contents of minerals and vitamins varied greatly between insect species; this was suggested to be due to soil contamination of samples and variation in the diet of the insects.

Although significant variation was found in the data, many edible insects provide satisfactory amounts of energy and protein; they are also rich in monounsaturated and/or polyunsaturated fatty acids and amino acids, micronutrients (copper, iron, magnesium, manganese, phosphorous, selenium, and zinc), vitamins B_{2-12}, carotenoids, and bioactive substances, which are essential for humans.

4.7 Bioactive Substances

Insects and bioactive substances extracted from them have been used in unconventional medicine by human cultures all over the world. Insects constitute an almost inexhaustible source of compounds for scientific research. A wide range of edible insects is a source of many bioactive components (polyphenols, enzymes, peptides/proteins) [116, 129, 130].

Nongonierma and FitzGerald [131] focused on studies published between 2005 and 2017 and analyzed the literature on the generation of bioactive peptides (BAPs) from edible insect proteins following enzymatic hydrolysis. Different enzyme preparations (Alcalase™ 2.4 L, Flavourzyme™, Protamex™, papain, trypsin, and pepsin) were used during hydrolysis of insect proteins to obtain bioactive peptides. The authors suggested that silkworm (*B. mori*) is currently the most widely studied species. Generally, the peptides obtained by enzymatic hydrolysis of edible insect proteins showed angiotensin-converting enzyme (ACE) inhibitory activity and, hence, antioxidant and antidiabetic properties. Moreover, selected species of edible insects studied by Zielińska et al. [12, 13] have high antiradical activity and an ability to chelate iron ions. They can inhibit lipoxygenase and cyclooxygenase-2 activity after the digestion and absorption process. Moreover, the heat treatment process positively affects the antioxidant properties of peptides derived from these species.

A majority of studies were focused on insect protein-derived peptides with ACE inhibitory activity. Vercruysse et al. [132–134] were one of the first authors presenting on ACE inhibitory activity of protein hydrolyzates from insects (*B. mori*, *B. terrestris*, *S. gregaria*, and *S. littoralis*). Dai et al. [135] investigated an angiotensin I-converting enzyme (ACE) inhibitor peptide (Tyr-Ala-Asn) derived from *T. molitor*

larva protein hydrolyzate. Wang et al. [136–138] examined antihypertensive properties of a novel peptide (Ala-Ser-Leu) obtained from silkworm pupa protein on spontaneously hypertensive rats and the effect of these peptides on the fermentation and quality of yogurt. The peptides, Ala-Pro-Pro-Pro-Lys-Lys, Val-Glu-Ile-Ser, Lys-His-Val, and Gly-Asn-Pro-Trp-Met, were identified in *B. mori* protein hydrolyzed by Wang et al. [138], Li et al. [139], Jia [140], and Tao [141], respectively. In their study, Wu et al. [142] investigated a silkworm larvae protein isolate (SLPI) as a source of bioactive peptides. The SLPI hydrolyzate exhibited strong angiotensin I-converting enzyme (ACE) inhibitory activity and antioxidant activity. The second large group of peptides comprises antioxidant peptides obtained by proteolysis of insect proteins with the use of different enzymes [12, 13, 132]. There are only few investigations evaluating the α-glucosidase inhibitory activity of insect protein hydrolyzates. However, Zhang et al. [143] used a quantitative structure-activity relationship (QSAR) approach for prediction of α-glucosidase inhibitory activity of peptides from *B. mori* proteins. Moreover, alkaloids, flavonoids, anthraquinones, tannins, phlobatannins, steroids, triterpenoids, and cyanogen glycosides were detected in hydrophilic and lipophilic extracts from *Encosternum delegorguei* (Hemiptera: Tessaratomidae) hydrophilic and lipophilic extracts [130]. These extracts were characterized by high levels of flavonoids and free radical scavenging activity, but the potential trade-off from the elevated levels of cyanogen glycosides after processing needs further investigation.

Peptides obtained from insects (Fig. 2) also have antibacterial and antifungal properties. A few antifungal compounds have been found in insects, for example, termicin from termites, drosomycin from *Drosophila melanogaster*, heliomicin from the tobacco budworm (*Heliothis virescens*), and the gallerimycin peptide from greater wax moth (*G. mellonella*) larvae [144]. The extract from housefly larvae possesses broad antibacterial activity against both Gram-negative and Gram-positive bacteria [145]. *T. molitor* produces antimicrobial and antifungal tenecin 4 [146].

In turn, Chinese black ants contain compounds with anti-inflammatory, immunosuppressive, and renoprotective activities [147]. Protein fractions extracted and purified from housefly larvae have antiviral and antitumor activities [148]. Elpidina and Goptar [149] reported that proteinases from *T. molitor* presumably have potential for oral administration to treat celiac disease. This insect contains a wide spectrum of digestive proteinases operating in the midgut with a sharp pH gradient from acid to alkaline values. Two digestive peptidases from the acidic AM, i.e., cysteine cathepsin L and post-proline cleaving peptidase, readily hydrolyze bonds formed by the major amino acids of cereal gluten – proline and glutamine.

In summary, potentially bioactive peptides derived from insect proteins and phenolic compounds have been identified (Fig. 3). Many of these peptides had interesting activities (mainly antihypertensive) even in small animals. The bioactive potency of edible insect protein hydrolyzates/peptides has been shown by Nongonierma and FitzGerald [131] to be similar or higher than that of other dietary proteins (plants and animals).

5 Processing Edible Insects for Food

In tropical countries, whole insects are often consumed after a suitable thermal process. However, Western consumers may be reluctant to accept this form. Some consumers are not convinced to eat insects because of the bad associations with their appearance. It is easier to accept products where the insect additive is not visible [41, 45]. In typical western societies, consumers find insects more appealing when used as an ingredient of foods with familiar flavors and textures [150]. There are many possibilities of using insects in an invisible form, for example, grinding insects to so-called insect flour or extraction of the main insect ingredients such as protein, fat, and chitin (Fig. 4).

5.1 Insect Flour

Cricket flour is the most popular insect product in Europe because of its versatility [151]. The addition of the flour to traditionally eaten foods is a great way to introduce insects into our diet without altering our habits. The powder form seems to be ideal for use in the food industry as it can be used for all kinds of products without changing their textural or functional properties; moreover, this additive can improve the products [152, 153]. Furthermore, the process of flour production is not complicated and, hence, cost-effective.

The easiest way to make flour from insects is to dry them first because of their high moisture content [68]. Drying is important because it reduces not only moisture but also water activity in the product, which is important in microbiological terms. Insects can be dried in industrial driers or lyophilized, which is probably the best possible method for preserving the chemical and other properties of food (Fig. 5). Reduced water content in the finished product guarantees longer storage time, but this is not the only advantage of producing insect flour. Milling the whole insects retains all their components in the flour, i.e., micronutrients or chitin in addition to proteins.

Fig. 5 The process of freeze-drying edible insects

5.2 Extracted Insect Protein

Supplementation of food products (e.g., meat products) with legume protein is a known practice. Extraction of insect proteins to increase the protein content in a food product could be a useful way of increasing acceptability among wary consumers. In this case, a small step method is a good idea. The gradual introduction of insect food proteins will allow consumers to get acquainted with the new product that at first sight is not different from what is known to them. However, supplementation of food products with insect ingredients (e.g., proteins) requires extensive research of their properties. A good understanding of the properties of proteins will allow specific application in food production according to the potential shown. Proper use of extracted proteins will make it possible to create the desired properties of food without altering the taste or smell of products that are well known to consumers.

Extracted proteins may also be part of the diet of individuals with increased protein requirements such as sportsmen. Importantly, insect protein contains a set of essential amino acids and high content of BCAA (branched-chain amino acids) [83]. Protein isolates can be an ingredient of nutrition supplements or protein shakes – a process already being carried out [154, 155].

5.3 Extracted Fat

Fat can be extracted from insects during flour production. This treatment prevents unsaturated fatty acids from exposure to undesirable oxidation processes; however, fat is not an unnecessary by-product. Oils are essential to the food industry for many uses, and oils from insects are valuable due to the composition of fatty acids. Many species of insects are high in unsaturated fatty acids including omega-3 fatty acids with a desirable omega-6 to omega-3 fatty acid (n6/n3) ratio [14, 156]. Oils from different species, and species fed on different diets, can have different fatty acids profiles. By changing insects' diet, oils with the desired composition of fatty acids can be received [11]. Oils obtained from

insects can be widely used in the food industry: from production of salad dressings or supplements of traditionally consumed dishes to attempts at replacement of fats used conventionally in food technology.

5.4 Chitin

Chitin seems to be a by-product of flour production, but, in fact, it is a high-value product. Primarily, chitin acts as a dietary fiber but this is not the only function. Chitin and chitosan (produced commercially by deacetylation of chitin) are natural products that are compatible with plant and animal tissues, biologically functional, biodegradable, nontoxic, and eco-friendly [7, 157]. Due to these properties, chitin and its derivatives have many application areas including wastewater treatment, pharmacy, medicine, cosmetics, weight loss, edible biofilm production, and reduction of low-density lipoprotein (LDL) cholesterol levels in the blood. The vast majority of chitin currently used for these applications comes from unsustainable harvesting of shrimp which, like much of the ocean's other resources, is constantly being overharvested [151]. Moreover, chitin has shown antioxidant, antimicrobial, and antitumor potential [7, 158, 159]. The surface morphology, acetylation degree, and molecular weight are the three main criteria determining the industrial use of chitin and its derivatives [7, 157].

5.5 Functional Properties of Insect Protein

Supplementation of food products with insect flour or extracted ingredients requires extensive knowledge of their properties. In the case of proteins, these properties include, among others, solubility, thermal stability, and techno-functional properties such as water and oil holding capacity, gelling, foaming, and emulsifying capacity. These properties determine the strict application of insect flour or protein isolates in food products. Furthermore, enzymatic modification of proteins is a useful mechanism to improve the functionality compared with the native unhydrolyzed proteins [152].

Good solubility of proteins is important in many uses, mainly for formation of emulsions, foams, and gels in designed food products. Zhao et al. [160] observed that the lowest protein solubility for proteins from *T. molitor* was reached around the isoelectric point and increased with either increasing or decreasing pH. Good solubility of insect protein in a wide pH range ensures varied use thereof in food industry – as a food additive in acid and alkaline food. Yi et al. [3] investigated the techno-functional properties of proteins from five insect species: *Tenebrio molitor* (larvae), *Zophobas morio* (larvae), *Alphitobius diaperinus* (larvae), *Acheta domesticus* (adult), and *Blaptica dubia* (adult). It was found that the investigated insect proteins had the ability to form gels depending on their concentration and on pH and could potentially be used as gelling agents or texturizers in food. Omotoso [153] studied the functional properties of *Cirina forda* (Lepidoptera: Saturniidae) – one of the most widely eaten insects in Southern Nigeria. The water holding capacity

of dried ground insect was 300%, whereas the water holding capacity values for silkworm (*Bombyx mori*) larvae and pupae were 175% and 115%, respectively. Acid-extracted protein fractions from five different insect species, including cricket (*Acheta domesticus*) protein or mealworm (*Tenebrio molitor*) protein, were shown to have poor or no foam capacity, over a range of pH [3]. In turn, crickets (*G. sigillatus*) heated at 50 °C for 30 min were found to have a FC of 100% with a FS of 90% after 1 h [152].

Hall et al. [152] demonstrated that controlled enzymatic hydrolysis of whole crickets successfully yielded protein hydrolyzates with improved protein functionality. Improved solubility of hydrolyzates makes them suitable for acidic food systems, such as nutritional beverages and sports drinks. The authors also observed better emulsifying and foaming properties for cricket protein hydrolyzates than the unhydrolyzed cricket protein.

These are only a few examples of the functional properties of insects. Due to the biodiversity of insects, these properties can vary considerably; therefore, it is important to investigate the properties of insect proteins before using them in food products.

6 Why Should We Look for New Sources of Nutrients?

It is estimated that around 7.6 billion people live in the world, and the urban population has been constantly increasing by approximately 1.84% per year between 2015 and 2020. To maintain proper health and functioning of the organism, it is necessary to have access to safe food rich in nutrients [161]. It is estimated that the human population in 2050 will amount to nine billion, and the demand for meat will increase by 76%. Therefore, the issues of food quantity and safety as well as the quality of food, feed, and fuel and environmental protection have become a priority for policy makers [162–164]. In order to achieve sustainable development and stability of food markets, the impact of all human activities on the environment should be reduced. Therefore, it is necessary to change and improve the technology of food production and the approach of consumers and food producers in a stepwise manner. The International Human Dimensions Programme identified food, water, and energy as the most important targets of quality change [165]. It should be noted that these main activities are mutually independent, since food production is dependent on freshwater resources and energy production [166]. Given the impact of animal production on the environment, e.g., soil erosion, deforestation, greenhouse gas emission, and water pollution, increasing production does not seem to be a good solution for the protein amount requirements in the future. Moreover, the prices of soybean and fishmeal that are used in feeding due to the demand are still increasing [17]. Therefore, we are looking for alternative sources of protein and nutrients. As edible insects are a diverse food and feed market, they can become an alternative source of protein, and the main reasons why the insects can be an alternative for lamb, beef, poultry, and pork are the economic, environmental,

and nutritional aspects. Nevertheless, the European Novel Food Regulation prohibits the production and processing of edible insects on a commercial scale for humans [164].

7 Environmental Impact of Entomophagy

Conversion of plant protein to animal protein is naturally inefficient (6 kg of vegetable protein is needed to obtain 1 kg of meat protein) and responsible for the negative influence on the environmental condition [167]. Furthermore, only 15% of protein and energy are applied as human food, and 85% are wasted. In 2000, 942 and 617 million tons of grains were used for food and feed, respectively [168]. It is worth noting that this is more than 500 tons of wasted food production and turned into polluting emissions by animal metabolism. The actual conversion efficiency of protein depends on the animal type and breed and the conditions of farming, such as climate and feed. Poultry and pigs are more productive species of animals than cows if they are grass-fed. Moreover, their compound stomachs are not adapted to feeding with maize. Furthermore, the use of water, amount of feeding stuff, and influence on the environment (water pollution or gas emission) depend on the type of animal protein production. For example, to produce 1 kg of beef, pork, and chicken meat, 15,400 l, 6000 l, and 3400 l of water, respectively, need to be used [169]. It should be noted that generally 1 kg of animal protein requires about 100 times more water than 1 kg of grain protein [167]. It should be noted that generally 1 kg of animal protein requires about 100 times more water than 1 kg of grain protein [167]. Since water is the main part of feed and occupies a particular place in food production, the low energy conversion efficiency, especially in the case of cattle, is obvious. In general, insects are characterized by a lower feed conversion rate (FCR), which is defined as the amount of feed required to grow 1 kg of conventional livestock animals, which corresponds to high feed efficiency. To produce 1 kg of beef, lamb, pork, and chicken meat, 7.7, 6.3, 3.6, and 2.2 kg of feed are required [170]. In comparison, 1.7 kg of feed is needed to obtain 1 kg of cricket meat [171]. Further, 2.2 kg of feed are used production for 1 kg of mealworm [172], 2.7 kg of feed for the Argentinean cockroach, 1.8 kg of feed for the black soldier fly, and 2.3 kg of feed for the house cricket [173]. This factor depends on the mode of feeding.

It should be noted that production of edible insects has a lower negative influence on the environment than breeding conventional livestock animals. Production of greenhouse gases (GHS), i.e., carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O), is said to be an important cause of climate change. The latter two gases are considered as the key global warming factors [16]. According to the life cycle analysis (LCA) which takes into account all animal production, the contribution of the animal sector to global greenhouse gas emissions is 9% for CO_2 (on-farm energy, animal product processing expenditures, feed and animal transport, fertilizer production for feed crops, and land-use changes), 35–40% for CH_4 (enteric fermentation in ruminants and farm animal manure), and 65% for N_2O (farm manure and

urine) [174]. A relevant indicator of the environmental impact is emission of ammonia (NH_3) by animal livestock related to manure and urine production, which causes nitrification and acidification of soil [175]. The GHS production by five species of insects, the first three of which are considered edible: *Tenebrio molitor*, *Acheta domesticus*, *Locusta migratoria*, *Pachnoda marginata*, and *Blaptica dubia*, and comparison with the GSH production by livestock animals were the objects of an experimental study [16]. The comparison with GHS production by animal livestock is not easy since the differences in the size of the animals determine differences in the metabolic rate and, hence, CO_2 production. However, the CO_2 eq. (g/kg mass gain) production in the case of the aforementioned insect species was estimated at 7.58, 1.57, 17.72, 121.86, and 37.54, respectively. This factor is in the range of 79.59–1130 for pigs and 2850 CO_2 eq. (g/kg mass gain) for beef cattle [16]. Moreover, in the case of *Anabrus simplex* (Orthoptera, Tettigoniidae), a production rate of 37 g CO_2/kg BM/day was reported, while 40 g CO_2/kg BM/day were noted for the locust *Schistocerca americana* (Orthoptera, Acrididae) [176] and 94 g of CO_2/kg BM/day for adult *Tribolium castaneum* (Coleoptera, Tenebrionidae) [177]. It should be noted that CO_2 production is influenced by the species, temperature, feeding status, stage of development, and activity level [16, 178, 179]. As far as the CH_4 production is concerned, *Acheta domesticus* and *Locusta migratoria* did not produce this compound, and 4.96 CH_4 (g/kg mass gain) were produced by *Pachnoda marginata*, 0.16 CH_4 (g/kg mass gain) by *Tenebrio molitor*, and 1.46 CH_4 (g/kg mass gain) by *Blaptica dubia*. In comparison to pigs, which produced 1.92 CH_4 (g/kg mass gain) and beef cattle, 114 CH_4 (g/kg mass gain) [16], these are low values, and this suggests that edible insects have a lower negative influence on the environment than livestock animals. Similarly, lower values of NH_3 emission were recorded in the case of edible insects. There are many reports about NH_3 emission by livestock animals. For example, pigs emit 4.8–75 mg/kg BM/day [180–182], cattle 14–170 mg/kg BM/day [180, 183], and poultry 72–436 mg/kg BM/day [180, 184]. The emission of NH_3 in the case of insects was different, i.e., from 1.57 to 4.29 mg/kg BM/day for B. *dubia* and from 2.46 to 8.01 mg/kg BM/day for *A. domesticus* [16]. Furthermore, edible insects need less space than livestock animals; they are able to live in high densities (kg biomass per m^2) and exhibit low vulnerability to disease (high resistance). Besides, crickets can eat a wide range of organic and waste biological material, and the farm takes up little space (2000 insects/m^2) [185]. It has been reported that around three quarters of the world's agricultural crop is used for livestock production either directly or indirectly [186].

A high impact of entomophagy on the environment is exerted by the potential decrease in application of pesticides, as collecting edible insects from crops or wild plants can prevent pests and thus decrease the demand for insecticides. Insects can also be used to compost manure that is produced in huge amounts by animal livestock, especially by poultry, pigs, and beef cattle. This can be a way to prevent soil acidification [187]. Moreover, organic material is the diet of edible insects, and thus waste of food can be reduced [8]. The production of edible insects has great potential not only in terms of supply of protein and nutrient for humans but also as an economic aspect in the food sector.

8 Safety Aspect of Edible Insects as Food

One of the aspects of the lack of acceptance of edible insects by Western consumers is the safety of insect consumption. Although insects are a good source of protein, nutrients, and minerals, it should be kept in mind that not all insect are safe to eat.

Like other food ingredients derived from plants or animals, insects can cause allergies (Table 4). Three allergens, arginine kinase (AK), hemocyanin (HC), and glyceraldehyde 3-phosphate dehydrogenase (GAPDH), have been identified in the muscle of *Macrobrachium rosenbergii*. Moreover, a novel specific allergen

Table 4 Main allergens identified in animals

Allergen substance	Origin
Arginine kinase (AK)	Black tiger prawn (*Penaeus monodon*) [191]
	Pacific white shrimp (*Litopenaeus vannamei*) [192]
	Giant freshwater prawn (*Macrobrachium rosenbergii*) [193]
	Banana shrimp (*Penaeus merguiensis*) [194]
	Moth (*Plodia interpunctella*) [195]
	American cockroach (*Periplaneta americana*) [196]
	German cockroach (*Blattella germanica*) [197]
	Silkworm (*Bombyx mori*) [190]
	Locust (*Locusta migratoria manilensis*) [198]
	Myxobacteria (*Myxococcus xanthus*) [199]
Tropomyosin (TM)	Indian white prawn (*Penaeus indicus*) [200]
	Spiny lobster (*Panulirus stimpsoni*) [201]
	Brown shrimp (*Penaeus aztecus*) [202]
	Pacific white shrimp (*Litopenaeus vannamei*) [203]
	Black tiger prawn (*Penaeus monodon*) [204]
	Carpet clam (*Paphia textile*) [205]
	Lobster (*Panulirus stimpsoni*) [201]
	German cockroach (*Blattella germanica*) [206]
	American cockroach (*Periplaneta Americana*) [207]
	Silverfish (*Lepisma saccharina*) [208]
Glyceraldehyde 3-phosphate dehydrogenase	Banana shrimp (*Penaeus merguiensis*) [194]
	Giant freshwater prawn (*Macrobrachium rosenbergii*) [188]
	Sardine (*Sardinops sagax*) [209]
	Cricket (*Gryllus bimaculatus*) [188]
Hemocyanin	Giant freshwater prawn (*Macrobrachium rosenbergii*) [188, 210] Lanchester's freshwater prawn (*Macrobrachium lanchesteri*) [188]
	Cricket (*Gryllus bimaculatus*) [188]
Hexamerin1B	Cricket (*Gryllus bimaculatus*) [188]
	Firebrat (*Thermobia domestica*) [211]

hexamerin1B (HEX1B) was detected in *Gryllus bimaculatus* [188]. Allergenicity may depend on the stage of development. Pupae of the African silkworm (*Anaphe venata*) have thiaminase in their composition, which can cause thiamine deficiency [189], and arginine kinase has been identified in *B. mori* (silkworm) larvae [190]. Certain insects can produce toxins as a defense mechanism. Inset specimens collected in the wild may contain pesticides or other chemicals from the environment.

Insects also can directly or indirectly cause diseases. Food poisoning due to the content of aflatoxins and cases of botulism and parasitic diseases were noted after consumption of edible insects [212]. Edible insects can also be a source of zoonotic agents such as bacteria, fungi, and parasites, or vectors [213]. *Escherichia coli*, *Klebsiella aerogenes*, and *Staphylococcus* were identified in freshly collected palm grubs (*Rhynchophorus phoenicis*) from Nigeria [214]. Following the recent scientific findings, the European Food Safety Authority (EFSA) indicates that the possible microbiologic threat from insects accepted for consumption is comparable to other threats associated with animal protein. The biological and chemical hazard of insect-based food and feed products mainly depends on insects' diet as well as production and processing methods. Moreover, experts have demonstrated that the insect species used as a food ingredient is not the main risk, but the diet, handling, and storage of farmed insects can pose some threat. Insects cannot be considered as possible biological vectors or amplifiers of mammalian prions because they cannot replicate in the insect body, provided that no ruminant or human substrates are used as feed. Moreover, there are no data about accumulation of heavy metals by edible insects; therefore, this aspect is largely unknown. Utilization of postconsumer food wastes and organic sidestreams to feed insects, which is nowadays not allowed in the European Union, should be extensively studied in the future [60, 215].

The risk for health and safety of insects as food can be prevented by consuming insects from farms where insects are fed without pollution. It should be noted that storage conditions, preparation methods, and proper heat treatment decrease the risk for human health and the harmful dose-dependent effects of the compounds. Scientific findings about the benefits and risk factors related to consumption of edible insects are a valuable source of information for the EU Commission to consider the use of insects as feed and food in a uniform fashion within the EU and beyond.

9 European Union Policy on Insects as Food

It is known that insects are not traditional food in Europe. The law governing insects as food and feed is the European Novel Food Regulation (ENFR), which was first established in 1997 (EC 258/97), revised in 2011 (EC 1169/2011), and repealed and replaced in 2015 (EC 2015/2283). Within the European Union, insects have a status of "novel foods," which means "any food that was not used for human consumption to a significant degree within the Union before 15 May 1997 irrespective of the dates of accession of Member States to the Union" and which requires that a risk assessment be performed prior to marketing according to Regulation (EU) 2015/2283 of the European Parliament and of the Council of 25 November 2015 on novel

foods [216]. It shall apply from 1 January 2018. In this regulation, we can find short information about insects: "The scope of this Regulation should, in principle, remain the same as the scope of Regulation (EC) No 258/97. However, on the basis of scientific and technological developments that have occurred since 1997, it is appropriate to review, clarify and update the categories of food which constitute novel foods. Those categories should cover whole insects and their parts."

According to Regulation (EC) No 258/97, it was not totally clear that insects were novel food. Some national food agencies (Belgium, the Netherlands, and the UK) did not recognize that the original Novel Food Act from 1997 clearly specified this issue. Therefore, they accepted companies dealing with insects as food. In Belgium, FASFC (Federal Agency for the Safety of the Food Chain) has established a list of insects that are accepted as food if they are produced in the EU, if the whole insects are used, and if requirements for food safety have been respected [217].

Considering the standards of insect production for food, the European Council requested the European Food Safety Authority (EFSA) for a scientific opinion to assess the microbiological, chemical, and environmental risks arising from the production and consumption of insects as food and feed. In October 2015, EFSA issued a scientific opinion "Risk profile related to production and consumption of insects as food and feed" [60]. A list of 12 insect species that were reported to have the biggest potential to be used as food and feed in the EU was established, thereby indicating that the list should serve as guidance in the overall assessment and should not be considered definitive or exhaustive. In conclusion, EFSA recommended to initiate research on the few issues mentioned such as bacteria, viruses, allergens, prions, chemicals, processing, and environment [60].

10 Insect Business

The increase in the interest in edible insects can be seen on the basis of the number of emerging companies in Europe and the USA. These companies deal with the mass breeding of insects, optimization of this production, processing of insects, and production of feed and food products, most often snacks containing insects. These changes may revolutionize the food market but for some still remain incomprehensible and surprising. In choosing food as in many other areas of life, we often follow stereotypes. The reluctance to consume insects is most often attributed to negative associations, i.e., the mental barrier. Improving the rank of insects can help the catering industry, for example, by placing them in recipes and introducing them to restaurant menus. Emerging start-ups and blogs devoted to insect consumption are an important part of the process of overcoming barriers and stereotypes.

10.1 Insect Farming

Insect farming has the same characteristics as other animal production systems: insects need access to water and feed (substrate) to supply energy and nutrients for

growth and excrete intestinal content (frass). Little information is available about mass production of insects for feed and food. In European insect farms, insects are kept in a closed environment, in boxes/cages, where the atmosphere, substrate, water, etc., can be controlled. For assurance of economically profitable and sustainable insect production, an appropriate level of mechanization, cheap insect feed production, building design, and temperature-controlled rooms have to be adapted.

One of the main elements of insect production is feeding. Most insect species farmed for food or feed around the world are omnivores, but the productivity of farmed insects can be improved by providing a correctly balanced diet [90]. An integrated rearing system with mechanization, information, and automation can be applied competitively and effectively for large-scale insect farming. Smaller farms are not mechanized at all or only to a small extent. Climatic conditions such as temperature or humidity and rearing area are dependent on the species of insects. The advantage of insect farming is the use of a small area. To minimize the space needed to farm a maximum quantity of insects, rearing boxes can be held in multilevel shelves, which are filled with as many rearing boxes as possible to minimize the space usage per kilogram of insect produced [218].

Conventional mealworm production is based on trays to hold larvae during their development and adults, and the most common tray size used is a standard 65 L × 50 W × 15 H cm. Such a tray has sufficient depth to prevent larvae or adults from escaping. Crickets are grown in large 36–60 cm deep boxes filled with different materials, most commonly cardboard, such as egg cartons or packing dividers for shipping to increase surface space. Rearing boxes can be made of different materials, but smooth surfaces are preferred because these make it difficult for crickets to climb the walls [218].

Moreover, traceability of edible insects, as with all agricultural products, from farm to table is essential to maintain safety and trace any hazards or disease outbreaks to their source. Each new production batch of insects harvested must be properly catalogued in a way that can be traced to the raw material used to feed and water that batch [218].

In Europe there are several professional insect farms intended for consumption by animals and humans. “Micronutris” from France produces cricket *G. sigillatus* and mealworm *T. molitor*, of which they produce appetizers, pralines, biscuits, and pastas [219]. In turn, “Proti-Farm” (Netherlands) delivers high-quality insect ingredients of the buffalo (*Alphitobius diaperinus*) for the food and personal care and pharmaceutical industries under the EntoPure brand. Proti-Farm products are HACCP certified, and the factories are certified with FSCC22000, ISO14000, and ISO26000 [220]. Insects farmed for human consumption in the Netherlands (Bugs Organic Food) can be obtained from Ruig and sons at Bugs Originals [221]. A very popular insect in the USA is the house cricket *A. domesticus* produced by “Cowboy Cricket Farms.” They sell three cricket products: chocolate chirp cookie, cricket powder, and cricket flour [222]. “AgriProtein,” operating worldwide, produces two products (a natural protein meal and oil) which can be used as a growth facilitator in agricultural feed preparations. Some of the by-products of their larvae can also be used and sold as a soil. And they also sell the dried larvae directly as by the pet food industry. Protix has

developed a broad range of insect-derived products such as insect protein meal, purified insect oils and lipids, chitin and chitin derivatives, and insect fertilizer pellets [223]. In turn, "Open Bug Farm," a project created in the USA, establishes a new branch of agriculture involved in insect breeding. This is an innovation platform to stimulate interaction between farmers, researchers, and hobbyists who want to change the world with edible insects [224].

10.2 Insect-Based Companies

It is said that the consumption of insects in Europe is new; however, analysis of the number of entrepreneurs dealing with this topic reveals that the issue is highly absorbing. The best example is the list of entrepreneurs around the world that was created for the first edition of World Edible Insect Day (the 23rd of October 2015) by Bugburger. It includes companies, organizations, and individuals who are working on an edible-insect product, planning to deliver one, or just advocating the benefits of eating insects [225]. At present, this list contains 180 items from Europe and the USA, but it is probably incomplete. The list comprises such categories as insect products, insect restaurants, insects as animal feed, online stores, professional insect farmers, and research projects.

Sweets are a very popular category of insect products. The species mostly used are crickets and mealworms. Examples of popular bars are "Kriket" from Belgium, "SWARM Protein" from Germany, "Jimini's" from France, "Crickstart" from the USA, "Jungle Bar" from Iceland, and "Yumpa Bar" and "Sens" from the UK. Attempts are made to create protein shakes and nutrition supplements from insects. In turn, Hotlix, who started their business in 1970, are the pioneers of "insect candy." They sell classic lollipops with worms, dried grasshoppers, etc. They have relied on the scary/yuck effect of insects. Newly established companies have a very serious approach to insect snacks [225]. The assortment is enhanced with pralines, muesli, cookies, and crispy insects [226]. However, insect flour is the most popular product because it is relatively easy to produce, and it may be the basis for many products such as cookies ("Crickelle" the cricket crackers) [227], bread, and pasta ("Aldento") [228]. Some European shops offer burgers and meatballs made from mealworms, for example, supermarket chain "Coop" in Switzerland [229]. Most of the products are sold online in shops such as "Delibugs" (Netherlands) [230], "Insectes Comestibles" (France) [231], and "Minifood" (Belgium) [232].

Insect products are not only designed for humans but also for animals. "Wilder Harrier" offers dog food with added cricket protein [233]; "Conscientious Cat" proposed insect-based cat food [234]. Several companies see the potential in feeding livestock, fish, pigs, and poultry with insects instead of other protein sources: "Protix" (Netherlands), "Ynsect" (France), "Entomo Farm" (France), "Diptera" (Italy), or "HiProMine" (Poland). It is not possible to mention all the companies involved in this business due to their large number, but research projects should be highlighted as well. The main research center in Europe that conducts extensive

research on insects is the Wageningen University [235]. On their web page, there is a list of all edible insects in the world [58].

European and global industry organizations have also been organized. The International Platform of Insects for Food and Feed (IPIFF) "is the voice of the insect sector towards the European Union. IPIFF is an EU non-profit organization which represents the interests of the insect production sector towards EU policy makers, European stakeholders, and citizens." They promote insects as a source of animal proteins for both human consumption and animal feed. Members include Ynsect (France), Protix (Netherlands), Hermetia (Germany), Koppert (Netherlands), Proti-Farm (Netherlands), HiProMine (Poland), Micronutris (France), Jimini's (France), Entomo Farm (France), nextProtein, Andromeda, MealFood Europe, and NextAlim with 26 associated members [236]. In turn, "the ASEAN Food and Feed Insects Association – AFFIA – is a voluntary group of companies, institutions, and natural persons which promotes and supports activities that relate to the use of insects as food and as feed" [237]. Moreover, a journal devoted to edible insects was established in 2015. "Journal of Insects as Food and Feed" is an online journal issued four times a year by Wageningen Academic Publishers. The journal aims to cover the whole chain of insect collecting or rearing to marketing edible insect products [238].

11 Insects as a Source of Nutrients for Animals

The increased production of livestock, poultry, and fish is forced by the continuously growing human population and the decrease in areas available for agricultural production [17]. The increasing intensity of farming animals requires higher amounts of feed with high-value nutrients to cover their nutritional requirements [31, 63, 85, 239]. The nutritive needs of monogastric species include a high quality and quantity of protein in the diet, provided proteins should have an adequate amino acid profile, high digestibility, good palatability, and no anti-nutritional factors [240]. Nowadays, the most useful protein sources in livestock feeding are fishmeal and soy meal [241]. The European Union currently imports 40 million tons of crop proteins each year (mainly soya). The profitability of the EU livestock and aquaculture sectors is at risk, taking into account the fluctuations in soybean meal prices as well as the prices of fishmeal, which have risen fourfold over the last decade [242, 243]. These economic issues underscore the strategic importance of developing an alternative protein source involving new protein sources in animal feed [244]. Insects might be a sustainable solution answering the urgent need for an alternative source of feed compounds: fishmeal, fish oils, and soymeal [185, 245].

The farming of insect intended for animal feed has been the subject of studies for years [246–248]; however, insects have not yet become a replacement for traditional forage based on plant material [168] Both scientists and feed industrial sectors have begun to reconsider the use of insects as feedstuff for farming animals [249] given the economic, environmental, and nutritional aspects of entomophagy [17, 66, 85, 250–252]. Moreover, insects can be reared on organic waste, and they exhibit

favorable feed conversion efficiency [85, 253]. Therefore, it seems justified to consider inclusion of insect proteins in commercial feed manufacturing. It is important to elaborate intensive farming systems with selected insect species that have a short life cycle, can be easily reared, are highly nutritious, and provide high concentrations of proteins [239]. The use of insects as a diet compound is justified by the fact that in nature, most insectivores (e.g., fish and birds) prey on a variety of arthropod species [85]. The natural behavior of chicks is to pick up and eat insects from the ground, which indicates that poultry are evolutionarily adapted to be insectivores [254].

Among the millions of insect species living on earth, over 2000 are considered as edible for humans, and only several species have the potential to be a new source of nutrients for farmed animals [58, 255]. Currently, only few species of insects are massively reared for food and feed, i.e., yellow mealworm (*T. molitor*), domestic cricket (*A. domestica*), black soldier fly (*H. illucens*), the domestic house fly (*M. domestica*), locusts (*L. migratoria*, *S. gregaria*, *Oxya* sp.), and silkworms (*B. mori*) [185, 253, 256]. However, as suggested by van Huis et al. [256], when insects are considered as feed for poultry, aquaculture, and pigs, they have to be reared on a mass scale with stable quality. This can be achieved only by automated rearing facilities with complete optimization and synchronization of the production processes adjusted to the insect species that will be reared.

Regulation of European Commission EC 999/2001 and consecutive EU regulations on processed animal protein (PAP) led to categorization of insects as ingredients that cannot be present in the food chain or in animal feed [257]. Afterward, Regulation EC 56/2013 opened a discussion on the use of PAP obtained from non-ruminants in feed for nonruminants, which might be considered under strict conditions. In turn, as specified by Regulation EC 1069/2009, invertebrates are classified as "fit but not intended for human food chains" (category 3 materials). The use of processed animal proteins (including insects) was reauthorized for the aquaculture sector in June 2013 and is expected to be included in poultry and pig feeding in the near future [258]. Several feed companies have committed themselves to include insects and insect compounds in the forage for livestock as soon as the EU legislation allows doing so [259]. Moreover, a study conducted by Verbeke et al. [45] shows that farmers, agriculture sector stakeholders, and citizens express a favorable attitude toward the use of insects in animal feed, especially for fish and poultry. In contrast to Europe, poultry in West Africa is already fed with termites collected in the wild [260].

12 Promising Opportunities of the Use of Insects

As mentioned above, the list of positive results of the consumption of insects is long. Nevertheless, besides being food and feed, insects have other uses. Firstly, they can be used in food-waste recycling – insects have favorable feed conversion efficiency; waste sidestreams or other ingredients that cannot be used for feeding traditional livestock species can be utilized as a source of feed [173, 257, 261–264]. The most promising in this respect is the black soldier fly (*Hermetia illucens*). The use of

Hermetia for waste reduction has been extensively studied since the 1970s [265]. The life cycle of this species is linked with organic waste matter. Its larval stage can be reared on a wide range of decaying materials such as rotting fruits and vegetables, distiller grains, coffee bean pulp, fish offal, and especially on animal manure and human excreta [17, 67, 266, 267]. This species has a capability of rapid food processing – it is estimated that its food intake ranges from 25 to 500 mg of fresh matter per larva per day [67]. Moreover, the study carried out by Barroso et al. [268] showed that *Hermetia* meal (to be used as a livestock forage compound) could be easily modified by dietary manipulation of larval feed.

Secondly, insects may be used for producing oils. Oil extracted from black soldier fly larvae is a by-product of insect meal production, which makes them more useful than the source of proteins. *Hermetia*-derived oil has a good fatty acid profile, which can be optimal for feed purposes and for producing high-quality biodiesel [269]. Moreover, Zeng et al. [269] claims that the oil extracted from black soldier fly larvae meets most of the requirements set by the international standard (EN 14214) for biodiesel.

Thirdly, every biomaterial left with waste from insect farming can be used as a fertilizer. Such a biofertilizer contains insect frass with addition of any matter that falls on the floor of the rearing cage, e.g., wings, body parts, leftovers, dust, or shredded egg carton. The use of cricket fertilizer was assumed to substitute the application of mineral fertilizers on key crops in Thailand (e.g., rice paddies) [270].

Fourthly, insects have a mechanism of induced detoxification of plant material with toxic compounds. This allows herbivorous insects to catabolize secondary plant compounds before they are absorbed [271, 272]. However, a study by van Broekhoven et al. [90] showed that longtime exposure of *Z. atratus* to diet with high content of potato steam peelings caused high mortality of larvae. It should be taken into account that chronic toxicity may result in reduced growth and lower feed conversion efficiency [273, 274].

Finally, insects are able to process polystyrene. A study conducted by Yang et al. [275] confirmed that mealworms (*T. molitor*) are the very first species of insects that is capable to degrade and mineralize petroleum-based plastic polystyrene. Moreover, Yang et al. [276] reported that the gut of the mealworm should be considered as an efficient bioreactor, where the gut microbiota (especially *Exiguobacterium* sp. strain YT2) plays the key role in Styrofoam degradation.

13 Conclusions

Insects are a good source of many nutrients, although the contents of most nutrients vary widely depending on a few factors such as the insect species [10], gender [277], stage of development [68], or diet [127]. In general, most species appear to be good sources of proteins with essential amino acids, fatty acids (omega-3), most minerals, and most vitamins B [10, 14, 113]. Moreover, insects are a source of biologically active substances such as antimicrobial and antifungal peptides [75, 77, 116] and angiotensin-converting enzyme (ACE) inhibitory peptides [73], and antioxidant peptides [12, 13]. In

addition to the high nutritional value and bioactive ingredients, insects are environmentally friendly. Low greenhouse gas emissions and low drinking water and biomass consumption are just some of the factors in favor of the insect breeding [16, 172]. Furthermore, insects can be helpful in the management of by-products of the food industry [173, 187], and their feces can be used as a fertilizer [270].

Despite the many positive sides of introducing insects to our diet, there are a number of issues that must be met to make this happen. First of all, consumers need to be convinced to eat insects. They should want to do it voluntarily, being certain of their own beliefs. It is important to raise awareness about the dangers associated with the constantly growing population which is related to, among other things, food security and environmental pollution. The food industry can help by proposing products containing insects in the form acceptable to consumers. Dishes with invisible insects, e.g., only protein isolates, are a good way to expand our menu. Research on the functional properties of the insects or components isolated from their organisms [3, 152, 153] is a good start to gain detailed knowledge of insects as food ingredients. There is a need for further analysis, given the multitude of edible insect species. A better understanding of each aspect of insect consumption brings us closer to accepting them on a par with other sources of protein. At the same time, mass insect breeding systems should be developed by automating the production and optimizing the breeding parameters. In addition, veterinary control should be applied. Currently, insects cost more than they should because in Europe they are still sold as novelties. The way insects are bred certainly has an impact on their high price. Improving the farming system will probably be a factor in lowering production costs. The combination of all the above factors will help the edible insects to gain a better reputation among unconvinced consumers. However, in order to exploit the potential of insects fully, they should become an increasing proportion of our diet partially replacing other sources of protein such as pork, beef, and poultry.

For many years, the agricultural sector has been moving in the same direction – maximization of plant and animal production. The use of insects as food and feed will undoubtedly be a revolution in this sector and will change the direction of further development of agriculture.

Entomophagy becomes an object of interest of an increasing number of researchers, and its promotion through the media is still increasing. Although EU legislation is cautious about the consumption of insects, the number of companies dealing with edible insects has exponentially grown over the past few years. Start-ups are successful on the food market and their popularity exceeds expectations. This proves that perhaps insects will soon be acceptable and produced as feed and food on a large scale.

Plant Proteases in Food Processing

16

Manzoor Ahmad Shah and Shabir Ahmad Mir

Contents

Abstract

Proteases are enzymes that hydrolyze protein molecules into peptides and amino acids. Proteases are the most commercially important enzymes because of their multiple applications in food and other industries. In recent decades, interest in plant proteases has been increased rapidly. The number of industrially employed enzymes of plant origin is still small but growing fast. Plants are an important source of proteases as plants require proteases throughout their life cycle. These are present in all kinds of plant tissues and, thus, can be extracted from their natural sources or can be prepared using in vitro techniques. Plant proteases can

1 Introduction

Proteases are enzymes that hydrolyze protein molecules into peptides and amino acids. These form a very diverse and complex group of enzymes. The specificity of these enzymes is governed by the type of the amino acid and other functional groups close to the bond being hydrolyzed [1]. Proteases can be classified into many ways. Based on the site of action, they can be grouped into exoproteases and endoproteases. Exoproteases can cleave N- or C-terminal peptide bonds, while endopeptidases cleave internal peptide bonds [2]. Exoproteases can be further divided into aminopeptidases and carboxypeptidases based on the ability to cleave the N-terminal and the C-terminal peptide bond. Endoproteases are classified on the basis of their catalytic mechanism, i.e., enzyme active site. The MEROPS database classifies them into seven families: aspartic, cysteine, glutamic, metallo, asparagine, serine, and threonine. But only five types of endoproteases have been reported in plants [3].

Proteases are the most commercially important enzymes because of their multiple applications in various industries and particularly in food, pharmaceutical, detergent, and leather industries. In recent decades, interest in plant natural products has grown rapidly. The number of industrially employed enzymes of plant origin is still small but growing fast [4]. Plants are an important source of proteases as plants require proteases throughout their life cycle [5]. The most widely used plant proteases are papain, bromelain, ficin, actinidin, zingibain, and cardosins. Plant proteases are being used in dairy processing, meat tenderization, bioactive peptide production, and baking industry.

2 Sources

Plants are an important source of proteases as plant physiology and development require a diverse number of proteases [6]. Proteases are required by plants throughout their life cycle [5]. Proteases obtained from plant sources are very attractive because they can be used over a broad temperature and pH range [7]. Proteases have been isolated and purified from various plant sources (Table 1).

Cardosins and cyprosins are obtained from *Cynara cardunculus* flowers [8–24], cynarase is from *Cynara scolymus* flowers [25–30], and cardosin like protease is prepared from *Cynara humilis* [10].

Actinidin, bromelain, caprifig coagulant, cucumisin, dubiumin, ficin, hieronymain, lettucine, onopordosin, oryzasin, papain, pomiferin, procirsin, salpichroin, streblin and zingibain are obtained from *Actinidia spp.*, *Ananas comosus*, *Ficus carica sylvestris*, *Cucumis melo*, *Solanum dubium*, *Ficus spp.*, *Bromelia hieronymi*, *Lactuca sativa*, *Onopordum acanthium*, *Oryza sativa*, *Carica papaya*, *Maclura pomifera*, *Cirsium vulgare*, *Salpichroa origanifolia*, *Streblus asper*, and *Zingiber officinale*, respectively. Neriifolin and neriifolin S are obtained from *Euphorbia neriifolia* [43, 44]; religiosin, religiosin B [47, 48], and religiosin C from *Ficus religiosa* [49]; and caricain from *Carica papaya* [117].

Protease extracts were obtained from *Albizia lebbeck* [61], *Balanites aegyptiaca* [65], *Centaurea calcitrapa* [53–55], *Foeniculum vulgare* [66], *Helianthus annuus* [61], *Jacaratia corumbensis* [62], *Moringa oleifera* [63], *Onopordum turcicum* [60], *Silybum marianum* [58, 59], *Solanum elaeagnifolium* [64], and *Withania coagulans* [56, 57]. Sun et al. [118] isolated three serine proteases from tomato (*Lycopersicum esculentum* Mill.) fruit and Li et al. [119] prepared tamarillin from tamarillo fruit (*Cyphomandra betacea*).

Many of the plant proteases are obtained from plants that grow in tropical or subtropical, geographically remote areas. These plants are subjected to various internal and external stresses, which affect the quality and quantity of proteases. Additionally, the selection of high-yielding varieties is difficult due the long cultivation periods between planting and harvesting, leading to the expensive products. Thus, the development of alternative and complimentary techniques to the extraction of proteases from whole plant sources is quite important from socioeconomic point of view [120]. An alternative to this is the plant cell culture using in vitro technologies. These techniques can be used to produce large quantities of proteases which are homogenous in nature and thus can be easily commercialized [4].

3 Production

Proteases are required by plants for various physiological and developmental processes from the beginning up to death of a plant. They are present in all kinds of plant tissues and, thus, can be extracted from their natural sources or can be prepared using in vitro techniques [4].

Table 1 Plant proteases in food industry

Protease	Source	Function/ application	Reference
Cardosins and cyprosins	*Cynara cardunculus*	Milk clotting activity	[8–24]
Cynarase	*Cynara scolymus*	Milk clotting activity	[25–30]
Cardosin	*Cynara humilis*	Milk clotting activity	[10]
Onopordosin	*Onopordum acanthium*	Milk clotting activity	[31]
Oryzasin	*Oryza sativa*	Milk clotting activity	[32]
Procirsin	*Cirsium vulgare*	Milk clotting activity	[33]
Ficin	*Ficus racemosa*	Milk clotting activity	[34]
Caprifig coagulant	*Ficus carica sylvestris*	Milk clotting activity	[35]
Ginger protease, zingibain	*Zingiber officinale*	Milk clotting activity	[36, 37]
Actinidin	*Actinidia chinensis,*	Milk clotting activity	[38–41]
	Actinidia deliciosa		
Cucumisin	*Cucumis melo*	Milk clotting activity	[42]
Neriifolin	*Euphorbia neriifolia*	Milk clotting activity	[43]
Neriifolin S	*Euphorbia neriifolia*	Milk clotting activity	[44]
Dubiumin	*Solanum dubium*	Milk clotting activity	[45, 46]
Religiosin	*Ficus religiosa*	Milk clotting activity	[47]
Religiosin B	*Ficus religiosa*	Milk clotting activity	[48]
Religiosin C	*Ficus religiosa*	Milk clotting activity	[49]
Streblin	*Streblus asper*	Milk clotting activity	[50]
Lettucine	*Lactuca sativa*	Milk clotting activity	[51]
Hieronymain	*Bromelia hieronymi*	Milk clotting activity	[52]
Protein extract	*Centaurea calcitrapa*	Milk clotting activity	[53–55]
Protein extract	*Withania coagulans*	Milk clotting activity	[56, 57]

Papain	*Carica papaya*	Flour/dough modification	[113–116]
Caricain	*Carica papaya*	Dough modification	[117]

3.1 Production from Natural Sources

Plant proteases can be extracted from natural sources by aqueous maceration of various plant organs such as flowers, seeds, roots, and leaves [121]. The crude extract thus obtained may be further purified to obtain partially purified enzyme or pure enzyme depending upon the degree of purification. Precipitation with ammonium sulfate is an effective way to produce substantial amounts of active proteases [8].

A protease tamarillin was extracted from tamarillo fruit (*Cyphomandra betacea* Cav.) and purified by ammonium sulfate precipitation and diethylaminoethyl-Sepharose chromatography. Sodium dodecyl sulfate polyacrylamide gel electrophoresis analysis showed that the peak with the highest protease activity consisted of one protein of molecular mass ca. 70 kDa. The protease showed optimal activity at pH 11 and 60 °C [119]. Beka et al. [65] isolated protease extract from *Balanites aegyptiaca* fruit pulp. These fruits were disinfected, husked, and soaked in different buffers and saline solutions. The extracts obtained were diafiltered, concentrated, and decolored with active charcoal.

Gagaoua et al. [37] isolated zingibain from *Zingiber officinale* rhizomes. Chopped ginger rhizomes were homogenized with 50 mM sodium phosphate buffer (pH 7.0) containing 10 mM L-cysteine. The homogenate thus obtained was stirred continuously for 45 min at 4 °C and then filtered. The filtrate was centrifuged and concentrated using ammonium sulfate up to 80% saturation. After an overnight dialysis of the precipitate, the dialyzed extract was subjected to three-phase

partitioning purification system. The enzyme was found to be exclusively partitioned in the aqueous phase. The enzyme exhibited maximal proteolytic activity at a temperature of 60 °C and pH 7.0.

3.2 In Vitro Production

The plant cells are totipotent and thus are able to produce the same chemical compounds in vitro and in vivo. The yield of enzymes differs between the two processes [122]. Generally, the yield of plant proteases obtained in vitro is lower than in vivo conditions [4]. Different plant organs produce proteases with different activities [123].

Different in vitro techniques such as callus and cell suspension cultures have been used to produce proteases from various plant tissues by several authors. Proteases were produced from *Mirabilis jalapa* culture [124], cell suspension culture of *Centaurea calcitrapa* [54, 125], and callus culture of *Silybum marianum* [126] and *Cynara cardunculus* [127]. Proteases from *Hohenbergia penduliflora* were produced using micropropagation technique by Perez et al. [123]. The molecular cloning, expression, and characterization of procirsin from the flowers of *Cirsium vulgare* were studied by Lufrano et al. [33]. Feijoo-Siota et al. [128] produced recombinant progaline B, an aspartic protease from *Galium verum* and expressed in the yeast *Pichia pastoris.*

Callus tissue cultures were obtained from cotyledons of *Cynara cardunculus*. Calli were subcultured every month using Gamborg's B5 medium supplemented with dichloro-phenoxyacetic acid (1 mg/l), benzyladenine (0.1 mg/l), ascorbic acid (5 mg/l), and citric acid (5 mg/l). The cultures were maintained at 24 °C and in the dark [127]. Cell suspension of *Centaurea calcitrapa* were homogenized in 50 mM Tris–HCl, pH 8.1, 1 mM EDTA, and 3 mM mercaptoethanol (buffer A), at 4 °C, and sonicated. The homogenate was centrifuged at 4 °C, to produce the crude extract [125].

In vitro techniques offer many advantages. Production of plant proteases by in vitro techniques leads to higher enzyme yields and minimizes the extraction procedures used in extraction from natural sources. Furthermore, these techniques reduce the effects of climate and seasonal changes and also the heterogeneity of enzymes produced from different parts of plant [4].

4 Applications

4.1 Cheese Production

Plant proteases have the ability to coagulate milk proteins and thus have been utilized as milk clotting enzymes in cheesemaking for centuries. These proteases are used as crude or in purified form; they are a substitute to the calf rennet. Plant proteases are a better alternative to calf rennet because of the limited availability and

high price of calf rennet, religious factors, diet, or ban on recombinant calf rennet in some countries. Most of the proteases used as milk clotting enzymes are aspartic proteases, but proteases belonging to cysteine and serine groups have also been reported to have milk clotting activity under certain conditions [121].

Plant proteases are used for making different varieties of cheese in Mediterranean, West African, and southern European countries. Spain and Portugal are the largest producers of cheeses using plant proteases from *Cynara* spp. [129]. Portuguese Serra and Serpa cheese and Spanish Los Pedroches cheese, La Serena cheese, Torta del Casar cheese, Los Ibores cheese, and Flor de Guía cheese are prepared with proteases from *Cynara* spp. [121]. The traditional cheeses in West African countries are prepared using proteases from *Calotropis procera* [129].

A large number of plant proteases have been isolated from various plant sources and studied for milk clotting activity (Table 1). The proteases from *Cynara cardunculus* were reported to have milk clotting activity. Sanjuan et al. [11] investigated the effect of animal and plant protease (*Cynara cardunculus*) on the physicochemical properties of Los Pedroches cheese prepared from ewes' milk and reported that moisture, protein, and water activity were higher, while fat and soluble nitrogen were lower in the cheeses prepared with animal rennet compared with cheeses prepared with plant protease. Silva et al. [12] studied the milk clotting activity of proteases (cardosins A and B), prepared from *Cynara cardunculus* flowers, and chymosin and reported that the highest specific milk clotting activity was shown by chymosin followed by cardosin B.

Tejada et al. [15] studied the effect of animal rennet and plant coagulant obtained from *Cynara cardunculus* on the sensory properties of Murcia al Vino cheese prepared from goat milk and reported that the cheeses prepared with rennet showed less odor and taste intensities, exhibited a bit clearer color, and were harder and grainier but less creamy than the cheeses made with plant coagulant. In another study, Tejad et al. [16] reported that the proteolysis was more intense, and after 60 days of ripening, it was higher in cheeses prepared with plant coagulant than with animal rennet. The use of plant coagulant for goat cheese manufacture might accelerate ripening, and, thus, a cheese with different sensory characteristics may be prepared [16].

Galan et al. [17] studied the effect of two different concentrations of plant coagulant from *Cynara cardunculus* in comparison with calf rennet on cheese prepared from sheep milk and reported that higher concentration of plant coagulant resulted in higher casein hydrolysis in cheese compared with lower concentration after 2 days of ripening. The plant coagulant improved the sensory properties of cheese than calf rennet. Pino et al. [19] studied the effect of plant coagulant extracted from *Cynara cardunculus* and calf rennet on cheese prepared from goat milk cheese during ripening and reported that no significant differences were found between the compositions of cheeses made with these two types of coagulants. But the plant coagulant resulted in higher amounts of pH 4.6-soluble nitrogen, greater breakdown of α_s-casein and formation of hydrophobic peptides, and higher ratio of hydrophobic/hydrophilic peptides throughout the ripening than calf rennet.

Ben Amira et al. [21] prepared a protease extract from *Cynara cardunculus*, at different pH, and reported that the best milk clotting properties and highest enzyme content were shown by the extract extracted at pH 3. In another study, Ben Amira et al. [23] studied the effect of the ripening stage and the lyophilization of *Cynara cardunculus* flowers on their chemical composition, enzymatic activities of extracts, and technological properties of cheese curds and reported that flowers harvested at the middle of ripening stage and lyophilized produce plant coagulant with better clotting properties, resulting in higher yield, moisture, and texture parameters of curd.

Liburdi et al. [24] developed a technically friendly enzyme bioreactor by optimizing the immobilization procedure of calf rennet and plant coagulant from *Cynara cardunculus* on CLEA® magnetic supports. The developed technique may be used to produce soft cheeses by a continuous milk coagulation process. In another study, Esposito et al. [30] isolated aspartic proteases from alpine thistle flowers and immobilized it on polyacrylic support. The enzyme showed an optimal pH of 5.0, a value very similar to the one generally used for milk clotting during cheesemaking, and exhibited a satisfactory stability over time.

Llorente et al. [26] studied the protease activity in crude extracts from different parts of the globe artichoke (*Cynara scolymus*) and reported that mature flowers are the main source of proteolytic and milk clotting enzymes. According to Chazarra et al. [29], the rennet strength of *Cynara scolymus* flower extract increased hyperbolically with increase in concentration of calcium, and the concentration was saturated at 50 Mm. Llorente et al. [27] used *Cynara scolymus* flower extract and animal rennet for the production of Gouda-type cheeses from bovine milk and reported that the cheese yield was equal to that produced with animal rennet. Also, chemical and sensory properties of the cheeses prepared with plant and animal coagulants were similar. Overproteolysis and background flavor development can be prevented by extending the brining process (40 h) of the cheeses prepared with plant coagulant.

Salvador et al. [55] isolated and purified aspartic proteases from *Centaurea calcitrapa* seeds during germination and reported that the purified enzyme has an optimum pH range of 3.5–4.5, using FTC-hemoglobin as a substrate and an optimum temperature at 52 °C. The clotting time of seed extracts was similar to that of flower extracts. The extract may be used for the production of special cheeses requiring weak coagulants. Egito et al. [61] studied the milk clotting activity of seed extracts from albizia (*Albizia lebbeck*) and sunflower (*Helianthus annuus*) and reported that albizia seed extract showed higher specific clotting activity than sunflower seed extract. The albizia and sunflower extract hydrolyzed κ-casein at the Lys116-Thr117 bond and at the Phe105-Met106 bond, respectively. Ahmed et al. [45, 46] prepared and purified a protease dubiumin from *Solanum dubium* seeds. The protease showed high milk clotting activity and coagulated skimmed milk to form a white and firm curd. The ratio of milk clotting activity to the proteolytic activity of dubiumin was comparable to those of calf and microbial rennet.

Vairo-Cavalli et al. [59] studied the effect of proteases isolated from flowers of *Silybum marianum* (L.) on degradation of caprine and ovine caseins. The proteases degraded the caprine α_{s1} to a lower percentage than ovine α_s but the caprine

β-caseins to higher percentage than ovine β-caseins. The major cleavage site in ovine α_{s1}-casein was Leu99-Arg100.

Duarte et al. [62] extracted and purified a protease from the root latex of *Jacaratia corumbensis* O. kuntze and reported that the purified protease showed the highest milk clotting activity and higher optimal pH in comparison to the crude extract. Both the crude and purified proteases showed the maximum clotting at 55 °C. Faccia et al. [35] studied the effect of plant coagulant extracted from caprifig latex on artisanal-type Cacioricotta cheese (traditional Italian cheese) in comparison with the industrial type prepared with calf rennet. Higher concentrations of nitrogen fractions and peptides were observed in artisanal-type cheese prepared with the plant coagulant than in the industrial type.

Bruno et al. [52] isolated a protease named as hieronymain from unripe fruits of *Bromelia hieronymi* and reported that caseinolytic activity and milk clotting activity was 3.3 Ucas/ml and 40 ± 0.2 IMCU/ml, respectively, at 30 °C and pH 6.5. Whey proteins, bovine serum albumin, and α-lactalbumin were quickly degraded after 30 min, while β-lactoglobulin was considerably degraded only after 60 min at 50 °C. Cheeses prepared with hieronymain and chymosin showed similar sensory attributes as analyzed by a taste panel. Nestor et al. [64] prepared protease extracts from ripe *Solanum elaeagnifolium* berries and reported that these extracts showed lower milk clotting activities than rennin or chymosin but produced firm gels under acidic conditions. The cheeses prepared with these extracts were softer than cheeses manufactured with rennin or chymosin. Thus, these extracts can be suitable for the preparation of filata-type cheeses as well as cream cheeses.

Withania coagulans fruit has traditionally been used as milk clotting agent in cheesemaking. Protease extracts were prepared from *Withania coagulans* fruits [56, 57]. Pezeshki et al. [56] reported that severe proteolysis occurred in cheeses prepared with protease from *Withania coagulans* in comparison to cheeses prepared with animal and fungi coagulants. The α_{s1}-caseins and β-caseins were absent in cheeses prepared with *Withania coagulans* protease extract. The plant protease led to an increase in soluble nitrogen in 12% trichloroacetic acid (SNTCA) during ripening of cheeses. This may be due to higher proteolytic activity of *Withania coagulans* protease extracts as compared to other coagulants. Salehi et al. [57] reported that the protease prepared from *Withania coagulans* fruits showed optimal activity at temperature 65 °C and pH 5.5. The activity of the plant protease was reduced by NaCl and $CaCl_2$ and thus may be suitable for producing low salt content cheeses.

A milk coagulating protease was isolated and purified from ginger rhizomes [36, 37]. The purified enzyme showed maximum activity at pH 5.5 and at a temperature of about 60 °C. This enzyme showed higher specificity toward α_s -casein followed by β- and κ-casein, and thus the purified protease may be used as a rennet substitute in the dairy industry [36].

Brutti et al. [31] isolated a protease onopordosin from fresh *Onopordum acanthium* flowers and used it to prepare semihard-type cheese from bovine milk. It was reported that the sensory quality of cheese prepared with onopordosin was similar to that of commercial cheeses. Pontual et al. [63] reported caseinolytic and milk clotting activities from *Moringa oleifera* flowers and reported that the

precipitated protein fraction promoted extensive cleavage of κ-casein and low level of α_s- and β-casein hydrolysis.

Grozdanovic et al. [39] reported that three kiwifruit extracts prepared from a single fruit pulp showed significantly different levels of active actinidin, depending on the extraction buffer used. The extract prepared at pH 5.0 showed the best milk clotting properties, with a higher ratio of clotting activity to proteolytic activity than purified actinidin. This extract produced a casein coagulum clearly separated from the whey proteins and was shown to be stable at room temperature for up to 2 months. In another study Puglisi et al. [40] used aqueous solution of kiwi juice for manufacture of mozzarella cheese and reported that the aqueous solution exhibited high levels of milk clotting activity and a cheese yield of 10.6% was obtained. No bitterness was found in the prepared cheeses. Zhang et al. [41] studied the milk clotting activity and protease activity of actinidin from seven Chinese kiwifruit cultivars and reported that the highest milk clotting activity and protease activity were shown by actinidin from Xuxiang cultivar.

Beka et al. [65] prepared an extract from *Balanites aegyptiaca* fruit pulp and reported that this extract contains two types of proteases, an aspartic protease and a serine protease, with an optimum activity at pH 5.0 and pH 8.0, respectively, and an optimal temperature at 50 °C. The aspartic protease from the *B. aegyptiaca* extract mainly involved in milk clotting conditions, like other plant proteases, is more thermostable than bovine chymosin.

Bey et al. [66] prepared protease extracts from fennel stems and leaves and reported that milk clotting activity of the extracts depends on coagulation temperature, pH, and calcium concentration in milk. The proteases remain active and stable in the pH ranging from 6 to 7.5 and temperatures ranging from 40 to 60 °C.

Most of the plant coagulants cause excessive proteolysis and thus result in lower cheese yield and defects in flavor and texture [51]. Therefore, new plant coagulants are being continuously investigated so that the increasing global demand for diversified and high-quality cheese production may be fulfilled [36, 121].

4.2 Meat Tenderization

Tenderness is an important attribute of meat that affects its acceptability. There are many methods used for tenderizing meat and may be either chemical or physical methods. Meat tenderization by protease treatment is one of the popular methods used in meat industry. Proteases extracted from different plant sources have been widely used in meat tenderization [41, 68, 69, 71, 75–78, 80].

Naveena et al. [77] studied the effect of proteases from *Cucumis trigonus* and *Zingiber officinale* rhizome on buffalo meat tenderness in comparison with papain. The meat pieces from *Biceps femoris* muscles were marinated with these proteases leading to an increase in protein solubility and reduction in shear force values compared to control. Extensive proteolysis and reduction in the number of protein bands were observed in enzyme-treated samples. The sensory values were higher for enzyme-treated samples in comparison to control.

Liu et al. [68] injected kiwifruit juice in freeze–thaw abused porcine meat and reported that shear force values increased two times after one freeze–thaw cycle but reduced after additional freeze–thaw treatments. The kiwifruit juice injection decreased the pH of meat from 5.6 to 5.2 and enhanced the cooking loss from 21% to 30%. The decrease in the shear force values improved tenderness of meat more than two times after kiwifruit juice treatment. Myosin degradation was observed in kiwifruit juice-treated meat samples.

Ha et al. [69] investigated the effect of different plant proteases (papain, bromelain, actinidin, and zingibain) on beef proteins and reported significant differences in protease activity. Myofibril proteins were most effectively hydrolyzed by the actinidin while connective tissue proteins by the zingibain. Thus, these enzymes have the potential for specific tenderizing applications. In another study, Ha et al. [70] reported that the protease activity of kiwifruit protease extract was more effective at hydrolyzing beef (myofibrillar and collagen) proteins than the asparagus protease extract. The two protease extracts hydrolyze myofibrillar and collagen proteins differently. Thus, these proteases can be used to improve the tenderness of specific cuts of meat, based on their intrinsic protein composition.

Enzyme extract prepared from *Calotropis procera* latex was applied to different meat samples (pork, beef and chicken), and it was observed that moisture content decreased in all the enzyme-treated samples. Firmness and toughness values of the meat samples decreased significantly with the increased concentration of enzyme extract. The enzyme extract had no significant effect on water holding capacity and cooking yield of the treated samples. Protein solubility and TCA-soluble peptides content increased in all the treated samples. The enzyme extract resulted in extensive proteolysis in the treated samples [78].

Abdel-Naeem and Mohamed [75] investigated the effect of ginger extract, papain, and their mixture on camel meat burger patties and reported that the ginger, papain, and their mixture increased the collagen solubility and sensory scores and decreased the shear force values, significantly. Ginger extract led to extensive fragmentation of myofibrils, while papain extract resulted in the degradation of connective tissue. Also, these extracts improved the lipid stability of treated burger patties during storage.

Choe et al. [79] prepared a crude extract from Asian pear and reported its meat tenderization activity. In another study, Nam et al. [71] investigated the effect of purified pear protease on beef myofibrillar proteins, individually and in combination with fig and kiwifruit proteases, and reported that pear protease has a good proteolytic activity on beef myofibrillar proteins, especially in combination with purified kiwifruit protease.

Wang et al. [80] investigated the effect of *Actinidia arguta* fruit protease on meat tenderness and reported that the protease was effective in tenderizing beef and decomposing actomyosin. Zhang et al. [41] studied the effect of actinidin from seven Chinese kiwifruit cultivars on pork and rabbit meat and reported that actinidin treatment improved the tenderness in pork and rabbit meat. The shear force was decreased by more than half in pork and rabbit meat using the purified actinidin at a dosage of 0.5 mg/100 g muscle.

Plant proteases in combination with other techniques can have promising effects on meat tenderness. Barekat and Soltanizadeh [76] studied the effect of papain enzyme alone or in combination with ultrasonication and reported that the application of enzyme, either alone or in combination with ultrasound, significantly reduced the filtering residue, Warner–Bratzler shear force, and textural parameters. The highest proteolytic activity and tenderness were observed using the combined treatment at ultrasonic power of 100 W for 20 min.

4.3 Bioactive Peptide Production

Bioactive peptides are specific protein fragments that have a positive effect on body functions and may influence health [130]. These are short sequences of amino acids (~2–30) with a low molecular weight that may be generated from both animal [94, 104, 131] and plant sources [88, 86, 103, 132]. These peptides are inactive within the sequence of the parent protein but become active and exert a positive impact on body functions once released. The amino acid composition and sequence of a bioactive peptide determines its activity [133].

Bioactive peptides have high potential to be used as nutraceuticals and functional foods to improve health and decrease the chances of disease occurrence. These peptides have positive effect on the immune, cardiovascular, nervous, and intestinal systems [134]. These peptides act as antimicrobials and antioxidants [135–137]. They have cholesterol-lowering effect and antihypertensive, antithrombotic, immunomodulatory [138, 139], and anticariogenic properties [140].

Bioactive peptides are produced during food processing or from food by-products by microbial fermentation or by chemical/enzymatic hydrolysis using proteolytic enzymes derived from animals, microorganisms, or plants [141, 142]. Enzymatic hydrolysis is the most common process used for bioactive peptide production. Plant proteases have been used for bioactive peptide production from both the plant and animal sources. The plant proteases such as papain, bromelain, ficin, actinidin, zingibain, salpichroin, pomiferin, cyprosin, cardosins, cynarases, and onopordosin have been used to produce bioactive peptides.

Bah et al. [94] reported that plant proteases (papain and bromelain) generated hydrolysates of plasma of various animals (deer, sheep, and pig) with a lower yield of soluble peptides compared with fungal proteases. The hydrolysates produced with plant proteases showed lower DPPH radical scavenging, oxygen radical scavenging capacity, and ferric reducing antioxidant power in comparison with those produced with fungal proteases. In another study, Bah et al. [95] prepared protein hydrolysates from red blood cell fractions separated from the blood of various animals (deer, sheep, pig, and cattle) using plant and fungal proteases and reported that papain-generated hydrolysates from red blood cell fractions exhibited higher ferric reducing antioxidant power and oxygen radical absorbance capacity compared to those generated with bromelain and fungal proteases. Bah et al. [96] reported that the hydrolysates of cattle plasma generated with fungal protease had higher antioxidant activities than hydrolysates generated with papain and bromelain.

Rocha et al. [104] used a protease from *Salpichroa origanifolia* fruits to hydrolyze whey protein concentrates and reported that this protease hydrolyzed α-lactalbumin protein with a higher affinity than β-lactoglobulin. The fraction containing peptides with a molecular mass below 3 kDa demonstrated a strong DPPH (2,2-diphenyl-1-picrylhydrazyl) radical scavenging effect.

4.4 Flour/Dough Modification

Enzymatic modification of food components is an effective means to improve their techno-functional properties. Proteases are used in the baking industries to hydrolyze gluten for making gluten-free products or improve various other functional properties of the flour such as modifications of dough handling properties, gluten elasticity, and texture accompanying shorter mixing time and larger loaf volume [143]. Some of the plant proteases such as papain, bromelain, and caricain have been used in flour/dough modification in baking industry.

Tanabe et al. [112] used bromelain to hydrolyze wheat glutenin IgE epitope and produce hypoallergenic wheat flour. The bread prepared from hypoallergenic wheat flour showed higher sensory scores than the control bread made from soft flour.

Chen et al. [113] studied the effects of the papain hydrolysis on wheat flour pasting properties and reported that papain hydrolysis significantly affected the pasting properties of flour by changing the structural characteristics, amylase activity, and exothermic transition, especially during the early stage of hydrolysis. The pasting parameters (peak and setback) significantly decreased with the increase in papain concentration. Pasting temperature and pasting time increased significantly with the increase in papain concentration. In another study, Yang et al. [114] studied the effect of papain on fresh whole wheat dough browning index and rheology and reported that papain had no effect on carotenoid content of dough. The higher papain concentration (0.010%, w/w) decreased the polyphenol oxidase activity, which may be due to either binding or hydrolysis of the specific amino acid sites of polyphenol oxidase. Papain reduced the browning rate of whole wheat dough as compared to the control dough. Rheological investigations revealed that papain led to decreases of elastic (G') and viscous modulus (G'') of doughs and this may be due to the degradation of flour protein and liberation of amylolytic enzymes by papain.

Hatta et al. [115] reported that papain increased the specific volume of gluten-free rice breads and decreased crumb hardness compared with control breads. Scanning electron microscopy revealed many fine bubble cells in the crumb of the papain-treated rice breads. Sodium dodecyl sulfate polyacrylamide gel electrophoresis of protein in the rice batter revealed that the concentration of low molecular weight proteins (less than 10 kDa) increased with the use of papain compared to control rice batter. The small protein aggregates were formed through disulfide bonds, and this network helped to retain CO_2 gas during the fermentation process. This resulted in an increase in the specific volume and a decrease in the crumb hardness of gluten-free rice bread. Li et al. [116] optimized and evaluated the effect of different enzymes on wheat flour and reported that alcalase and papain had greater ability to reduce

gliadin content of wheat flour than flavourzyme, pepsin, trypsin, or α-chymotrypsin. The sequential treatment of wheat flour by alcalase–papain was more effective in decreasing gliadin content than single enzyme treatment. The optimized conditions of sequential enzymatic treatment resulted in complete removal of gliadin in the flour extract, showing lowest IgE binding, and thus may be used for preparing low allergenic wheat products.

Buddrick et al. [117] investigated the effect of enzyme caricain to reduce gliadin content in whole wheat flour and prepare gluten-free bread. The authors reported that the caricain was more effective in reducing the gliadin content in treated breads compared to control breads.

5 Conclusion

Proteases hydrolyze protein molecules into peptides and amino acids. In recent decades, interest in plant proteases has grown rapidly. Plants provide an attractive source of plant proteases. They are present in all kinds of plant tissues and, thus, can be extracted from their natural sources or can be prepared using various cell culture techniques. The most widely used plant proteases are papain, bromelain, ficin, actinidin, zingibain, and cardosins. Plant proteases are being used in dairy processing, meat tenderization, bioactive peptide production, and baking industry.

Abstract

Historically, lipids have been considered just as a source of energy for our bodies and as the basic unit of membranes. The discovery of the platelet-activating factor in 1979 as one of the first biologically active phospholipids was a relevant landmark in this field. Since then, some unique biological activities have been assigned to every single lipid class. For example, lipids, as small hydrophobic molecules, are extraordinary as chemical messengers to send information between organelles and to other cells. Additionally, polar lipids that contain hydrophobic and hydrophilic regions can interact distinctly with membrane proteins modulating their activities, while glycosphingolipids including their structure complex carbohydrates can play important roles in the immune system. Therefore, in this chapter, many relevant biological functions of some lipid classes from dietary sources will be extensively reviewed.

Keywords

Free fatty acids · Glyceryl ethers · Phospholipids · Isoprenoids · Phenolic lipids · Lipid delivery systems

1 Introduction

For many years, fats have been associated with dangerous substances to our health and consequently should be minimized or avoided in our diet. Fortunately, more and more people recognize that fats are essential ingredients for food palatability. More interestingly, some lipids such as cholesterol have been recognized as essential for the production of hormones, vitamin D, and bile salts, among other physiological functions. Additionally numerous health benefits have been attributed to unsaturated fats from seafood. However, the essential role that lipids play in life similar to proteins and genes is not broadly understood. Very few people are aware that fat is the most relevant part of our brain and plays an extremely important role in all other soft tissues. Lipids are studied by nutritionists who try to find out the relationship between fats in our diet and the composition of different organs and tissues. Biochemists investigate synthesis and breakdown of lipids to produce energy and building material for cells. However, lipids have not been extensively recognized as essential molecules in cell membranes. Lipids form fascinating and intriguing structures as a consequence of basic physical principles of self-organization that governs interaction among many molecules. In this scenario, water plays a key role functioning as the definite biological solvent. The unique properties of water oblige lipid molecules to self-assemble and to produce subtle structures. Consequently, lipids, in aqueous medium, form lipid bilayers and membranes. Lipid membranes can be considered as extended thin layers with the thickness of only two molecules. These structures constitute the backbone of all biological membranes which are omnipresent in all living cells [1].

Dietary bioactive lipids, from a food science point of view, can be generically defined as lipids with specific roles on health. Their function can be related to

physical or chemical properties of these molecules. Numerous evidences point out that lipid classes provide health benefits based on mainly two mechanisms: (1) changing the fatty acid composition of different tissues or (2) promoting cell signaling pathways [2]. Some health benefits can be attributed to short- to medium-chain fatty acids, although most evidences suggest that the most important bioactive lipids are polyunsaturated fatty acids (PUFAs). PUFAs are precursors in the biosynthesis of cellular hormones (eicosanoids) and various signaling compounds with relevant roles in human health [3].

Recently, more and more interest for natural substances with beneficial activity to humans has been observed. Among these substances, those with strong antioxidant activity have brought a lot of attention because oxidative stress induced by multiple factors is the main cause of many pathological conditions. However, many phenolic compounds are mainly hydrophilic which decreases their application in oil-based formulations and emulsions. For that reason, sources, production, and formulation of more lipophilic derivatives of these phenolic compounds will be also discussed in this chapter [4].

2 Neutral Lipids: Fatty Acids

The term "fatty acid" refers to any aliphatic monocarboxylic acids able to be liberated by hydrolysis from naturally existing fats and oils. "Neutral fats" are mono-, di-, or tri-esters of glycerol containing one, two, or three fatty acids and are termed monoacylglycerides, diacylglycerides, and triacylglycerides, respectively [5]. Fats and oils consisting of triglycerides are one of the main components of every living organism, and they are also important constituents of the human diet. Bioactivity and nutritional value of these fats depend on the length and number of unsaturated bonds of the fatty acid chains that they contain. Depending on the length, fatty acids are classified into long-chain fatty acids (LCFAs) with >12 carbons, medium-chain fatty acids (MCFAs) with 6–12 carbons, and short-chain fatty acids (SCFAs) which contain <6 carbon atoms [6]. Their absorption into the human digestive system will depend to a large extent on the stereospecific distribution of the fatty acids in the triglyceride molecule. Long-chain saturated fatty acids located at the outer positions sn-1 and sn-3 have limited absorption, and this may influence lipemia and serum cholesterol levels [7].

2.1 Essential Fatty Acids and Ratio Omega-6/Omega-3

Polyunsaturated fatty acids (PUFAs) have aroused great interest based on their beneficial properties, so there is a trend toward obtaining foods rich in this type of fatty acids. These fatty acids are generally classified into omega-3 fatty acids and omega-6 fatty acids, depending on the position of the first double bond counting from the methylene extreme of the hydrocarbon chain. A number of information sources suggest that humans evolved on a diet whose ratio of omega-6 to omega-3

essential fatty acids was close to 1 [8]. Due to the modern western diets, food processing, and agribusiness, the intake of omega-6 PUFAs has increased, and the omega-3 PUFAs have decreased, leading to a ratio around 20:1 [9]. Although the percentage of total calories ingested from fat is decreasing, nowadays the prevalence of overweight and obesity has increased which represent a major public health problem. The excessive intake of omega-6 PUFAs and very high omega-6/omega-3 ratio contribute to the development of several diseases, including obesity; cardiovascular, autoimmune, and inflammatory diseases; and cancer, whereas increased levels of omega-3 show suppressive effects. High amounts of omega-6 fatty acids, linoleic acid (LA) and arachidonic acid (AA), compete with omega-3 PUFA absorption [10]. There is also a competition for desaturation and elongation enzymes between LA and α-linolenic acid (ALA) [11]. Moreover, anti-inflammatory mediators are cleaved from omega-3 fatty acids, while omega-6 fatty acids provide precursors for pro-inflammatory metabolites [457]. Most of the health benefits associated with omega-3 fatty acids are attributable to the long-chain polyunsaturated fatty acids (LC PUFAs), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) [12].

It has been established that consumption of omega-3 PUFAs ameliorates the risk of cardiovascular disease [13], produces a decrease in blood pressure, and shows a positive association with serum high-density lipoprotein (HDL) and inverse association with very-low-density lipoprotein (VLDL) and triglyceride [14]. Besides, it is associated with lower risk of glucose tolerance and non-insulin-dependent diabetes mellitus [15].

On the other hand, EPA, DHA, and lately docosapentaenoic acid (DPA, 22:5n-3) have shown beneficial effects in a variety of neurodegenerative and neurological conditions [16, 17]. They exert positive effects on neuronal membrane properties (such as membrane fluidity and permeability) and increase brain phospholipid levels, phosphatidylserine, phosphatidylethanolamine (PE), and phosphatidylinositol [18]. They are also promoters of differentiation of neural stem cells via metabolic oxidation [19, 20].

A variety of studies have investigated the relationship of neuroprotection and risk of cognitive decline with the fatty acid composition in the blood (EPA, DPA, and DHA). Specifically, EPA has been associated with slower cognitive decline [21], depressive symptom risk, and dementia risk in the elderly [22]. Inflammation has an important effect in learning and memory parameters. In this line, DHA have shown to reduce inflammatory cytokine release, and EPA change the pro-inflammatory profile of Alzheimer patient's cells to a healthy cell profile, reducing the IL-6/IL-10 ratio [23, 24].

The most widely used natural source of EPA and DHA is fish oil. This has led to overexploitation of the seas by the fishing industry, which has seriously affected a large number of marine species. Algae aquaculture could also provide a new important source for omega-3 PUFAs [25]. Alternatively, stearidonic acid (SDA, 18:4 omega-3) is of great interest, since its endogenous conversion to EPA and DHA has been shown to be very efficient [26, 27]. Natural sources of SDA are the seed oils of corn gromwell, hemp, blackcurrant, and cyanobacterium *Spirulina*.

Furthermore, there is a variety of plants high in SDA, including some of the families Grossulariaceae, Caryophyllaceae, Primulaceae, and Boraginaceae (such as echium), that could serve for oil extraction to human consumption and to supplementation of livestock feeds, in order to increase the omega-3 PUFA content in dairy products and meat [28]. Recently, refined oils extracted from *Echium L.* species have been positively evaluated as a novel food ingredient by the EFSA (European Food Safety Authority) because of their high concentrations of SDA and other PUFAs such as alpha-linolenic acid (ALA, 18:3 omega-3) and gamma-linolenic acid (GLA, 18:3 omega-6) [29]. GLA is a metabolic precursor of AA, which exerts pro-inflammatory activities; however this conversion in humans is slow and gives rise to the production of anti-inflammatory eicosanoids [30]. In addition, the combination of GLA and EPA appears to enhance the anti-inflammatory activity, for competition with the AA cascade, and it could also be useful in prostate and breast cancer prevention or cancer-cachexia [31–33].

2.2 Monounsaturated Fatty Acids

Other fatty acids that have recently shown interesting health effects are omega-7 fatty acids such as palmitoleic acid (C16:1 n-7). Doses of 300 mg/kg in the form of free fatty acid have shown to reduce body weight, improved hyperglycemia, hypertriglyceridemia, and insulin sensitivity in mice fed during 4 weeks, when compared with the same doses of palmitic acid (16:0 n-9). Furthermore, palmitoleic acid administration suppressed pro-inflammatory gene expressions and lipogenic genes in the liver [34]. We can find it in animal fats, marine oils, and vegetable oils (such as macadamia nut oil and hawthorn oil).

Moreover, extensive epidemiological studies have shown that the omega-9 fatty acid such as oleic acid (C18:1 n-9) decreased incidence of coronary heart diseases, metabolic syndrome, and cancer [35] and regulates many biological processes. Oleic acid is a monounsaturated fatty acid present mostly in olive oil and other vegetable oils such as pecan oil, macadamia oil, peanut oil, canola oil, and sunflower oil and seed oils such as sesame oil, poppy-seed oil, and avocado oil. It is also present in animal fats of turkey or chicken and other animals fed on grass. Oleic acid is not an essential fatty acid; it can be formed by de novo synthesis in humans [36] and from other fatty acids such as stearic (C18:0).

2.3 Saturated Fatty Acids

Consumption of saturated fats in Western countries is high, and their intake, especially of palmitic acid (C16:0) and myristic acid (C14:0), is related to a higher incidence of cardiovascular diseases. After palmitic acid, stearic acid is the most consumed saturated fatty acid in Western countries with a total of 26% of consumption. Stearic acid is ingested through the consumption of animal fat derived from pork or beef, as well as vegetable fat such as coconut or soybean oil [37]. Compared

with other saturated fatty acids, stearic acid lowers LDL cholesterol, has no effect on HDL levels, and lowers total cholesterol [38, 39]. According to [40], this beneficial effect of stearic on cholesterol is based on its malabsorption in the body and its reduced solubility after being released from the triglyceride by pancreatic lipase [41]. In addition, this fatty acid is rapidly transformed to oleic acid in the liver during its metabolism. Unlike stearic acid, palmitic acid raises total cholesterol mainly by increasing LDL levels, which is attributed to its ability to suppress the expression of LDL receptors. This increase in total cholesterol by palmitic acid is also attributed to its slower passage to oleic acid, since it must be first elongated to stearic acid [40]. On the contrary, stearic acid is used to synthesize hypocaloric fats considering its low digestibility and high excretion. An example of hypocaloric fats recognized as novel food is Salatrim®, which is composed of triglycerides with random positional distribution of fatty acids; it contains LCFAs (mainly stearic) and SCFAs, such as propionic or butyric acid [42].

On the other hand, capric acid (10:0) and lauric acid (12:0) have been shown to possess antimicrobial and anti-inflammatory properties [43, 44]. In addition, lauric acid has been also associated with positive effects on cardiovascular system related to the increase of HDL levels [45] and decrease of blood pressure in rats [46]. Moreover, lauric acid has shown to prevent the prostatic hyperplasia and exert inhibitory effects in colon cancer, endometrial cancer, and breast cancer cells [47], and consumption of virgin coconut oil as a natural source of these two fatty acids has shown to improve quality of life in patients during chemotherapy [48]. Lauric acid is also present in other plant oils, seeds, and fruits and in breast milk [49, 50].

Recent studies on myristic acid have shown contradictory effects on its impact on health. Although it has always been considered detrimental to health [51–53], a group of authors has shown that myristic acid increases diacylglycerol kinase levels and improves glucose uptake into cells [54]. This raises the question regarding the potential role of myristic acid on the prevention of type 2 diabetes. These fatty acids are presented in high concentration in high-fat dairy products which could explain the diabetes-protective properties associated with their intake [55].

2.4 Medium- and Short-Chain Fatty Acids

Medium-chain fatty acids (MCFAs) are minor dietary components. However, their intake provides a quick source of energy because they are easily digested and absorbed. Triacylglycerides with three molecules of MCFAs are quickly absorbed and transported to the mitochondria where they serve as combustible; therefore they do not accumulate as body fat. MCFAs do not pass through the enterocyte and do not require the formation of chylomicrons; they are directly transported by the portal system [56].

Several studies have confirmed the potential of MCFA to reduce body fat; they suppress fat deposition improving thermogenesis and fat oxidation in both humans and animals [57–59]. Triglycerides enriched in MCFA are attractive for use in

low-calorie products [60]. In addition, it has been reported that MCFAs preserve insulin sensitivity in patients with type 2 diabetes [59].

Triacylglycerides with MCFAs are used as part of liquid diet formulas suitable for patients with digestive problems or conditions that demand fluid restriction, such as burn injury, postoperative cancer, AIDS, respiratory distress, cystic fibrosis, and hepatic or renal disease [61]. A relevant example of this type of fatty acid is the case of lauric acid (C12:0). As previously mentioned, this compound as well as its monoester monolaurin possesses numerous antibacterial and antiviral activities [62]. It is reported to be effective against *Staphylococcus aureus*, *Enterococcus faecalis*, *Mycobacterium terrae*, *Streptococcus agalactiae*, and *Listeria monocytogenes* [63] and against viruses such as herpes simplex-1, HIV, cytomegalovirus, vesicular stomatitis, measles, and visna virus [64]. Myristic acid (C14:0), capric acid (C10:0), and caprylic acid (C8:0) can also be virucidal and bactericidal [62].

SCFAs, mainly acetate, propionate, and butyrate, are microbial end products generated by fermentation of fiber from the intestinal microbiota. Their presences inside the intestine have shown a positive influence on intestinal barrier function. Disruption of intestinal barrier function can lead to the development of many diseases such as inflammatory bowel disease, obesity, and HIV infection. Thus SCFAs play an important role in human physiology affecting neuroimmune function, nutrition, and protection from pathogen colonization [65–67]. SCFAs also modulate the secretion of hormones including peptide YY and leptin and cell differentiation and proliferation [68, 69].

The association of the plasma and colonic SCFAs with metabolic syndrome has been extensively documented. Recently, the relation between SCFAs and regulation of energy homeostasis have been studied [70, 71]. Many of the SCFAs produced in the gut are used as host energy source, and this could represent 10% of our caloric requirements per day [72]. Acetate and butyrate are involved in the synthesis of cholesterol and palmitate in the liver and propionate in the gluconeogenesis [73]. It is estimated that 90% of SCFAs produced in the colon are rapidly and efficiently absorbed [74]. Furthermore, acetate and propionate are energy substrate for peripheral tissues and butyrate for the colonic epithelium [75].

Focusing on SCFA pathway and signaling, it has been reported that the free fatty acid receptors, GPR43 and GPR41, can regulate host energy homeostasis in the gut and adipose tissues [76, 77]. Mice deficient in GPR43 are obese following a normal diet, while mice overexpressing GPR43 remain lean even with a high-fat diet [78]. Thus gut microbiota and SCFAs could affect the development of obesity, diabetes, and insulin resistance. These disorders are characterized by the low presence of specific microbial groups (*Akkermansia muciniphila* among them) and SCFAs, leading to alteration on glucose, lipid, and energy homeostasis, gut barrier dysfunction, and low-grade inflammation [79]. Therefore SCFAs are playing significant roles in several inflammatory mechanisms including atherosclerosis [80] and also in cancer [81]. The anti-inflammatory effect of butyrate in the colon, which is produced by some microbial groups such as *Faecalibacterium prausnitzii* [82] or *Ruminococcus* [83] and other butyrate-producing bacteria, has been extensively reported. SCFAs are involved in the pathophysiology of neuroimmune and

immune-inflammatory disease having effect on T cell differentiation, cytokine expression, epithelial barrier function, and the recruitment of leucocytes to areas of inflammatory activity [84]. Chronic intestinal inflammation increases the development of colon cancer. SCFAs confer protection in carcinogenesis. Propionate and butyrate were observed to induce apoptosis and inhibit proliferation on cancer cells [85]. SCFAs have also reduced colitis and allergic asthma in animal models [86–88]. Indeed treatments with SCFAs in ulcerative colitis patients have shown to ameliorate colitis [89].

In order to drive the metabolic activity of microbiota toward fermentation of carbohydrates, the intake of dietary fibers and prebiotics (nondigestible carbohydrates) is essential [90]. These nondigestible carbohydrates, such as xylans, cellulose, inulin, fructooligosaccharides, or resistant starch, are fermented by the anaerobic colonic bacteria to generate energy for microbial growth, moderate concentrations of SCFAs in the colon, as well as peripheral circulation [66, 91, 92]. There are other strategies such as supplementation with specific probiotic strains (live microbiota) to promote production of butyrate, other SCFAs, or lactate that is also implicated in the cross-feeding mechanism between colonic bacteria [93, 94]. However, when SCFAs are produced fast and in large amounts or under special unhealthy conditions, they could disrupt barrier function and instead exert beneficial effects [95, 96]. Hence, it is necessary to study the appropriate concentrations of these SCFAs to provide health benefits in each situation.

2.5 Trans-Fatty Acids and Conjugated Fatty Acids

It has been established that consumption of trans-fatty acids (TFAs) increased the risk of heart disease [97]. But there are TFAs originated from different sources which produce diverse effects in human health. Nonnatural or industrial TFAs (iTFAs) are mainly formed by hydrogenation in order to achieve the conversion of liquid oils into semisolid or plastic fats. These newly formed fats have interesting technological characteristics but include different proportions of TFAs [98]. iTFAs are rich in elaidic acid (*trans*-9-18:1) and *trans*-10-18:1, and their intake has shown to stimulate atherosclerosis in humans [99]. However, some natural TFAs (nTFAs), such as vaccenic acid (*trans*-11-18:1), have shown to protect against atherosclerosis [99]. Vaccenic acid is produced inside the digestive tract of ruminant animals becoming the main trans-isomer of oleic acid (18:1) in the fat of dairy and beef products [100]. Nevertheless ruminant TFAs (rTFAs) are in low proportion in food (4–8% of total fatty acids) [101], whereas iTFAs are present in shortenings and pastries and can reach up to 61% of total fatty acids [102]. Several studies focus on the role of different trans-isomers on lipid metabolism. Comparison of the effects of trans-isomers of 18:1 in vitro has shown that *trans*-9 isomer upregulated the lipogenic genes and enhanced total cell fatty acids, whereas isomers *trans*-11 and *trans*-13 did not have this effect [103]. The same authors have observed that C18:1 *trans*-9 and *trans*-10 increased cholesteryl ester content and triglyceride in cultured liver cells compared to trans-isomers 11, 14, and 15 [104]. Moreover, trans-isomers 6, 9,

and 10 upregulated genes related to cholesterol and fatty acid synthesis. A meta-analysis of studies on iTFA and nTFA did not show association between coronary heart disease (CHD) and nTFA intake (0.5–1.9 g/day), whereas intake of iTFA (1.3–5 g/day) showed to increase the risk of CHD [105]. In the same line, another meta-analysis of observational studies has reported an increase in CHD (30%) and in the risk of CHD mortality (28%), but not in type 2 diabetes, associated with 1.8% of total energy intake of iTFA. However, rTFA intake had no effect on CHD, and ruminant C16:1 *trans*-9 showed inversely association with type 2 diabetes [106]. Another review of 29 and 6 treatments with intake of equivalent range of iTFA and rTFA did not find significant difference between the TFA from either source and the effects on LDL/HDL ratio [107]. Further studies are needed in order to clarify these contradictions, but it seems clear that rTFA intake does not increase the risk of CVD and may exert certain beneficial effects on health.

The fatty acid composition of milk and dairy products is very important for its effect on human health and depends on the cow diet, the metabolism inside the digestive tract of ruminant animals, and the mammary metabolism [100]. Briefly, after lipolysis of dietary lipids, bacteria inside the rumen produce, via biohydrogenation of unsaturated fatty acids, different isomers (*cis* and *trans*) of 18:1, non-conjugated 18:2, conjugated linoleic acids (CLA), and conjugated linolenic acids (CLnA) [108]. The two isomers of CLA (*cis*-9, *trans*-11 and *trans*-10, *cis*-12) and their mixture have demonstrated a variety of biological activities, among them reduction of body fat, prevention of atherosclerosis, modulation of immune and inflammatory responses, and anticancer effects [109–111].

Conjugated fatty acids also have diverse origin. Rumenic acid (*cis*-9, *trans*-11 18:2) is the predominant CLA isomer in ruminant milk fat (75–90%) [112], followed by *trans*-10, *cis*-12 and *trans*-7, *cis*9. Rumenic acid is basically a product of the endogenous synthesis by the action of the enzyme γ-desaturase on the mammary gland, which is used as a substrate vaccenic acid (*trans*-11 C18:1). Other preparations of CLA are produced by chemical synthesis via alkaline isomerization of sunflower or safflower oils (rich in 18:2n-6) containing equally proportions of c18:2 *trans*-10, *cis*-12 and c18:2 *cis*-9, *trans*-11. Human studies have demonstrated that C18:2 *trans*-10, *cis*-12 is implicated in lipolysis and fat oxidation (catabolic effect) and C18:2 *cis*-9, *trans*-11 isomer has anti-inflammatory and anabolic effects [113]. Supplementation with 6 g/day of CLA for 12 weeks improved symptoms of inflammatory bowel disease in humans [114]. However, more studies to compare the form of administration of CLA as triacylglycerols (TAG) or free fatty acids (FFA) are necessary [115]. Studies in animal models have shown an increase of lean body mass and reduction of fat deposition associated with the isomer *trans*-10, *cis*-12 rather than *cis*-9, *trans*-11 [116]. However, the effects of individual isomers on body weight have not been shown in human, although modulation of insulin resistance [117, 118] was observed. On the other hand, effects of CLA mixture intake during 6 months (3.2–3.4 g/day) have been reported to slightly decrease body fat mass in humans [119]. Regarding regulation of blood pressure, the finding of a meta-analysis of eight human studies did not report favorable effect of CLA [120]. In addition, several studies have reported inhibitory effects of CLA on cell proliferation

of cancer and induction of apoptosis and antimutagenesis in rats and cell lines [121–123]. However, a systemic review in humans has shown a weak inverse relation between CLA dietary intake and breast cancer risk [124].

Conjugated linolenic acid (CLnA) is the term for the isomers of octadecatrienoic acid (18:3) with three conjugated double bonds. CLnA are present in milk fat and mainly in seed oils [125] such as pomegranate, which contains *cis*-9, *trans*-11, *cis*-13 C18:3 (punicic acid), bitter melon with *cis*-9, *trans*-11, *trans*-13 C18:3 (α-eleostearic acid), or pot marigold containing *trans*-8, *trans*-10, *cis*-12 C18:3 (calendic acid) [126]. Studies in rat and mouse models and in human cells have indicated that isomers of conjugated eicosapentaenoic acid, conjugated non-adecadienoic acid, and CLnA (mostly *cis*9, *trans*11, *cis*15 isomer) possess anti-adipogenic, anti-inflammatory, anticarcinogenic, and immune-modulating properties. Several recent studies have also reported the health benefits of pomegranate seed oil (PSO) consumption, rich in punicic acid. After 2 weeks of feeding obese mice with PSO (2 ml/kg/day), a reduction of pro-inflammatory cytokines (interleukin-6) and tumor necrosis factor-α in plasma was observed. The treatment showed anti-inflammatory properties and also improved insulin sensitivity [127]. Punicic acid from PSO has also shown in vivo anti-inflammatory effects by limiting neutrophil activation and decreasing lipid peroxidation [128]. Schubert et al. [129] have reported that polyphenols and pomegranate seed oil, in a fermented juice, retard prostaglandin synthesis and oxidation, promote apoptosis of breast cancer cells, and inhibit breast cancer cell invasion and proliferation. Diet supplemented with PSO has inhibited colonic adenocarcinomas in rats. The inhibition of colonic tumors was related to an increase in the content of CLA in liver and colonic mucosa lipid fraction. In the nontumor mucosa, an increase of peroxisome proliferator-activated receptors after administration of PSO was observed [130]. Toi et al. [131] have also reported significant potential of PSO and other pomegranate fractions for down-regulation of angiogenesis in vitro and in vivo. Białek et al. [126] have reported that pomegranate seed oil intake leads to an increment in the content of *cis*-9, *trans*-11 CLA in the liver of rats and decreases the activity of the enzymes Δ5- and Δ6-desaturase more than other CLA supplements. However, other studies of lipid profile and insulin resistance associated with exercise in healthy humans did not show significant effect on insulin resistance and lipid profiles, except for HDL [132]. Further investigations are needed in order to demonstrate all these positive effects in humans.

2.6 Branched-Chain Fatty Acids

Branched-chain fatty acids (BCFAs) are mostly saturated fatty acids with one or more methyl branches on the carbon chain. Most of them are at terminal (iso) or next to the terminal (anteiso) methyl group [133, 134]. Overall, BCFAs are found in ruminant milk and adipose tissue of animals such as cows, sheep, and goats. They are presumably produced and utilized as membrane lipids by microorganisms of the rumen. The composition of BCFAs varies depending on the animal and its diet

[133, 135, 136]. Those with chains of 14–18 carbons are typically found in the fat of beef and dairy products [137]. A study of the US retail cow milk supply has shown that BCFA constitutes 2% w/w of the milk fat [138]. Amounts of BCFA in lanolin, wool wax, exceed 40% [139]. Although less studied than PUFA omega-3s, BCFAs are also present in fish. Wang et al. [140] have reported that mean BCFA content in edible muscle across 27 freshwater fish species analyzed was 1.0 ± 0.5% of total fatty acids, being 1.8 ± 0.7% in fish skin. Most of the BCFAs found were anteiso-15:0, iso-15:0, iso-16:0, anteiso-17:0, and iso-17:0.

BCFAs are also synthesized by the skin in humans, and they constitute almost one third of the fatty acids in the vernix (fatty film covering the fetus in utero). The fetuses swallow the vernix suspended in the amniotic fluid, exposing their gut to BCFA. They are also natural components of colostrum and breast milk (>1.5%w/w) [141–143]. Moreover, BCFAs are important components of the membranes of *Lactobacillus* and *Bifidobacterium*, bacterial genera present in the gastrointestinal tract of newborns [144–146].

Ongoing research revel that BCFAs are bioactive compounds with positive impact in the development of the intestinal microbiota, and anticancer effects have been also attributed to them [147–149]. A recent study with neonatal rat pup model has shown that BCFAs reduce necrotizing enterocolitis incidence by more than 50%, influence microbiota composition, and are selectively incorporated into the membrane lipids of the intestine [138].

2.7 Edible Cold-Pressed Oils

In recent years, a variety of edible cold-pressed oils obtained from fruits and seeds of different plants in the market are increasing. These oils have advantages compared to those obtained by other technologies of extraction or refining, since their characteristics and flavor are not altered by the increase of temperature or the use of solvents [150]. Thus, they present a large number of intact bioactive components including polyunsaturated fatty acids, free and esterified sterols, tocopherols and tocotrienols, squalene, carotenoids and chlorophylls, and various phenols and triterpene alcohols. These compounds are characterized by possessing anti-inflammatory properties, reducing oxidative stress, and positively modulating the immune system, as well as chemopreventive and neuroprotective activities [150]. In this chapter, many of the bioactive qualities of several of these compounds have been reviewed, but further research is needed in both nutrition and pharmacology areas to better document their functionality and contribution to health [151]. In addition, legislative aspects regarding their identity, denomination, and certification must be defined, as well as clarifying issues related to authenticity, safety, presence of contaminants, rancidity, susceptibility to light and heat (for proper storage and use in cooking), and naturally health claims [152].

Some examples of the best known bioactive-rich cold-pressed oils are virgin olive oil, an important ingredient of the Mediterranean diet, whose health benefits are linked to the presence of monounsaturated oleic acid, squalene, triterpenes, and

bioactive phenolic compounds. Among the bioactive phenolic compounds, those that are raising greater attention interest are tyrosol, hydroxytyrosol, ligstroside and oleuropein, and dialdehydic forms of elenolic acid. It is recognized for their antioxidant, cardiovascular, anti-inflammatory, neuroprotective, and chemotherapeutic effects and the disease-related gene modulation; cold-pressed sesame oil, typical of Asian cuisine, is rich in polyunsaturated fatty acids, vitamin E, and phenolic compounds (such as gamma-tocopherol, sesamin, and sesamolin). Among their biological activities, we find reduction of oxidative stress, liver oxidative damage protection, and decreased cholesterol level in the blood; flaxseed oil is not classified under the category of "cooking oils" whereby it has to be added just before serving. This oil contains α-linolenic acid, sterols, carotenoids, and a tocochromanol plastochromanol-8. When it is enriched with particulates, it contains lignans which are recognized for its protective effect against colon, skin, and prostate cancer; *Camelina* seed oil is suitable for cooking due to its resistance to heat. It is rich in gamma-tocopherol, alpha-linolenic acid, and polar phenolic and possesses antioxidant, anti-inflammatory, and immune system stimulation properties. Virgin argan oil is rich in monounsaturated fatty acids and linoleic and oleic acids and also contains squalene, tocopherols, spinasterol, and schottenol (a bioactive sterol). It is suitable for cooking and frying and in salad dressings; it is very useful in Moroccan cooking; cold-pressed coconut oil contains antioxidants such as phenolic compounds and alpha-tocopherol. It is not resistant to heat due to its high content of medium-chain triacylglycerols; walnut oil is used as uncooked condiment; it is rich in omega-6 and omega-3 fatty acids. Rapeseed oil contains brassicasterol and plastochromanol-8. Pumpkin seed oil is rich in linoleic and oleic acids, phenolic compounds, and low amounts of gallic acid; *Echium*, black currant, and hempseed oils contain high amounts of stearidonic acid, whose health benefits have been previously described; evening primrose seed and borage oils are rich in gamma-tocopherol and gamma-linolenic acid; macadamia seed oil is rich in alpha-tocopherol and monounsaturated fatty acids. It is very resistant to heat and shelf-stable; avocado oil can be used for frying and cooking. It is rich in monounsaturated fatty acids, chlorophylls, tocopherols, and carotenoids [152–154].

At present, they are also being investigated for their anti-inflammatory activity and high content in tocopherols, carotenoids, alpha-linolenic acid, squalene, and phenolic antioxidants and oils from other seeds such as blackberry, amaranth, black caraway apple, black currant, boysenberry, cardamom, cranberry, blueberry, raspberry, strawberry grape, marionberry, sea buckthorn, poppy, cumin, hemp, *Pistacia atlantica*, coriander, parsley, and carrot [155, 156].

3 Polar Lipids

The biological activity of phospholipids is mainly based on their amphiphilic properties that self-assemble the polar heads and the hydrophobic hydrocarbon chains to create bilayers which are the keystones to build cells' and organelles' membranes [157]. Phosphatidylcholine is the main phospholipid in the external layer

of cellular membranes, basic to warrant their function and integrity. Besides its role in membranes, phosphatidylcholine is also implicated in the hepatic secretion of VLDL, with an important function in cholesterol and lipid distribution to organs and tissues. Another role of phosphatidylcholine is the formation of digestive micelles in the intestinal lumen, as a part of the biliary secretions, promoting the absorption of lipids. Phosphatidylethanolamine is more abundant in the internal membrane leaflet and in mitochondria, with a relevant role in growth and stability. Phosphatidylethanolamine is also a precursor of glycosylphosphatidylinositol and helps protein binding to the membrane. This last activity can be explained by the small size of PE, which confers stability to the membrane [158].

After hydrolysis of phospholipids, the formed lysophospholipids participate in diverse biological activities related to their molecular structures. Multiple activities have been attributed to lysophosphatidylethanolamine [159]. Lysophosphatidylinositol has been used as a cancer biomarker [160]. Lysophosphatidylserine [161] participates in signal transduction related to activation of neutrophil, and it could also have anti-inflammatory properties. Finally, lysophosphatidylcholine [162] could be used in rheumatoid arthritis treatments and is also involved in DNA methylation preferentially in the central nervous system [163].

Plasmalogen activities have not been fully described, but its deficiencies have been correlated with peroxisomal disorders associated with mental retardation, deafness, or adrenal dysfunction [164]. Moreover, plasmalogens have also potential as biomarker in different diseases related to aging, such as Alzheimer, oxidative stress, and inflammation [165, 166].

The role of some phospholipids in some organelles should be also considered. In this sense, the main phospholipids in mitochondrial membrane are phosphatidylethanolamine and phosphatidylcholine. One unique property of these membranes is the presence of cardiolipin, a tetraacyl phospholipid. One of the most important activities of cardiolipin in mitochondria is the promotion and organization of the respiratory chain. Besides, its role is also relevant in keeping fluidity and osmosis [167]. Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are the main responsible of oxidative stress. This situation occurs when these species are produced in excess and the cell is unable to destroy them with the help of natural antioxidants [168–171]. In addition, ROS can also oxidize cardiolipin. This newly restructured cardiolipin is related to mitochondria dysfunction associated with multiple pathologies such as diabetes, obesity, heart failure, hyperthyroidism, neurodegeneration, and aging. All of these diseases are highly related to oxidative stress, low levels of cardiolipin, and also anomalous high content of DHA in cardiolipin [172]. Another important activity induced by fatty acid oxidation products is apoptosis with the participation of the mitochondrial permeability transition pores (MPTP) [173, 174].

It is well known that many cell and membrane protein functions are related to membrane lipids [175]. This protein function regulation by membrane lipids involves mechanisms ranging from specific and non-specific interactions between proteins and membrane lipids [176]. In general terms, membrane lipids can be categorized in two broad groups [2]:

1. Lipids that bind to points of recognition of specific proteins, acting as ligands, such as platelet-activating factor that can be grouped to the G protein-coupled receptor family [177]. This category is based on a well-known protein-small molecule interaction without any role on the collective membrane properties. Such specific interaction is the case of polyphosphoinositide interactions with specific proteins [178–181]. Another example of specific regulation takes place with membrane lipids that are cell signaling precursors – such as arachidonic acid in prostaglandin biosynthesis [182].
2. Lipids that, by altering their biophysical properties, have an impact on membrane and membrane protein functions and organization [183, 184].

Membranes behave as macrostructures with a collective physical property such as thickness, curvature, or elasticity [185–188]. An example of non-specific regulation of membrane protein function by the membrane lipids occurs by hydrophobic coupling between both molecules. Protein activity is modulated by the hydrophobic thickness and intrinsic curvature of the lipids at the bilayer [188], indicating that changes in bilayer physical properties can modify membrane protein conformation and function [189].

Sphingolipids (SLs) are ubiquitous constituents of cell membranes in many pro- and eukaryotic organisms. In vertebrates, they are also found in lipoproteins (especially LDL) and other lipid-rich structures, such as epidermis. For a long time, SLs were considered to play primarily structural roles in the membrane formation and fluidity regulation. Likewise, SLs have long been recognized as important structural components of the epidermis, securing the epidermal permeability barrier [190]. However, over the last decades, intensive research on SL metabolism and function has recently evidenced that SLs function as effector molecules in several cell processes and have key roles in stimulus−/agonist-mediated signaling pathways involved in cell response modulation. Hence, sphingomyelin participates in regulatory functions by interaction with specific proteins and serves as a receptor for the intake of transferrin, promoting the incorporation of iron to the cells. On the other hand, the most important property of sphingomyelin is its implications in rafts together with cholesterol, in both cell membranes and lipoproteins. It has been recently proposed that metabolism of sphingomyelin and cholesterol is closely related. Sphingomyelin could be responsible for cholesterol distribution in cells [191, 192]. Sphingomyelin has been extensively used as a chemopreventive agent, taking into account its activities as messenger in development, growth, differentiation, and apoptosis of human cells.

SLs exert their effects through two general mechanisms:

1. Biophysical mechanism (based on lipid-lipid interactions), whereby SLs, mainly sphingomyelin and glycosphingolipids, and cholesterol spontaneously self-associate and fuse into SL-enriched platforms (also referred to as microdomains or rafts). The formation of these microdomains has consequences to cell signaling by altering membrane structure and, subsequently, the interaction of protein membrane receptors with the cell membrane bilayer [193–198].

2. Biochemical mechanism (based on lipid-protein interactions), whereby SLs act as first and second messengers by interacting with several target proteins or receptors in a number of cell signaling pathways [199, 200].

In addition, a comprehensive understanding of bioactive SL function requires further knowledge of the metabolic organization of enzymes of SL metabolism and their interrelationships, as well as the compartmentalization of SL-mediated signaling pathways, the metabolic transformation of bioactive SLs, and the integration or coordination of overall responses. A number of studies have shown that many pathways of SL metabolism constitute an interconnected network of specialized and compartmentalized enzymes that not only regulates the levels of individual biologically active molecules but also their interconversion and, ultimately, the balance among them.

Ceramides (Cer), which are composed of sphingosine (Sph) (core of all SLs) esterified to a fatty acyl chain via an amide linkage [201, 202], are the center of SL biosynthesis and catabolism and precursors of complex SLs (Fig. 1a). Briefly, Cer can be produced through the de novo pathway (from serine and palmitate by the action of the serine palmitoyl transferase (SPT), ceramide synthases 1–6 (CerS1–6), and desaturase (DES)) and the hydrolysis of complex SLs, especially sphingomyelin (SM), by several sphingomyelinases (SMases). In SL biosynthetic reactions, Cer is primarily used for the synthesis of more complex SLs, including ceramide-1-phosphate (C1P), through phosphorylation by ceramide kinase (CK) [203]; sphingomyelin (SM), by transferring a phosphocholine head group from phosphatidylcholine, through the action of SM synthases (SMS) [204]; or glycosphingolipids (GSLs), through glycosylation (mainly with glucose and galactose) by glucosyl- and galactosyl-Cer synthases (GCS) [205]. In the catabolic pathway, glycosphingolipids are cleaved to glucosylceramide (GlcCer) and galactosylceramide (GalCer), which are subsequently hydrolyzed by specific β-glucosidases and galactosidases to release Cer [206]. Cer can also be metabolized by ceramidases (CDases) [207–209] to yield sphingosine (Sph), which in turn is phosphorylated by sphingosine kinases (SKs) to generate sphingosine-1-phosphate (S1P). S1P can be cleared by the action of specific phosphatases that regenerate Sph or by the action of a lyase that cleaves S1P into ethanolamine-1-phosphate and a C_{16}-fatty-aldehyde [201]. The many pathways of sphingolipid metabolism constitute an interconnected network that not only regulates the levels of individual biologically active molecules but also their interconversion and, ultimately, the balance among them.

Most enzymes of sphingolipid metabolism show specific subcellular localization(s) (Fig. 1b). This could dictate distinct functional responses, since, coupled with the poor solubility of SLs in cells, it imposes clear restrictions on the subcellular localization of bioactive lipids. Thus, in the absence of specific mechanisms of SL transport, the site of generation of a bioactive SL is likely to dictate its site of action. Among all of these SLs, the most extensively studied so far have been sphingosine (Sph), ceramides (Cer), and sphingosine-1-phosphate (S1P). Cer and Sph are reported to act as tumor-suppressor lipids involved in both intracellular and extracellular processes. The long-chain amino alcohol sphingosine (Sph) was the first

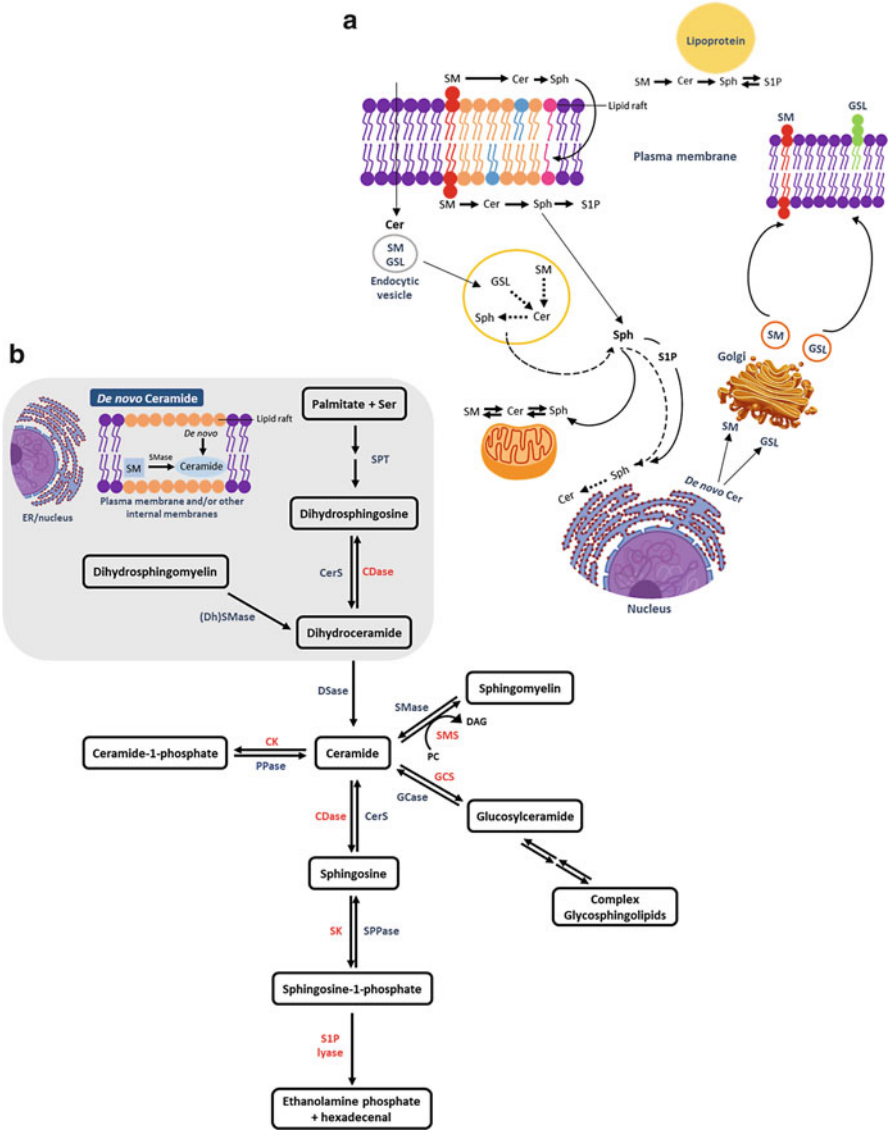

Fig. 1 Sphingolipid metabolism. (**a**) Sphingolipid biosynthesis. (**b**) Sphingolipid localization

SL metabolite to be identified. Sph has been connected with cellular processes such as inducing cell cycle arrest and apoptosis by modulation of protein kinases and other signaling pathways. It has roles in regulating the actin cytoskeleton and endocytosis and has been shown to inhibit protein kinase C (PKC) [210]. Kinase targets for sphingoid bases including pkh1p and pkh2p have been found in yeast, indicating functions in regulating endocytosis, cell cycle arrest, and protein

synthesis [211]. Sphingosine is, along with other sphingoid bases (sphinganine or dihydrosphingosine), the core of all sphingolipids. The simplest SLs, ceramides (Cer), are composed of a sphingoid base esterified to a fatty acyl chain via an amide linkage [201, 202]. The length of the fatty acyl chain (from C14 to C28) conjugated to the sphingoid backbone characterizes the different species of ceramide, which have shown diverse biological functions.

Many different ceramide species have been observed in different human tissues (including brain, skeletal muscle, skin, testicular, leukocyte, cardiomyocyte, and hepatocyte tissues), differing in relative abundance, fatty acid composition, and, hence, biological function [212, 213]. Ceramides often exert their effect via biophysical mechanism by forming ceramide-rich platforms that modify both receptor- and stress-mediated cell signaling and, hence, may influence various disease states and neurotransmission [214–217]. Thus, for example, Kolesnick and Gulbins have recently proposed a mechanism by which FasL/Fas interaction leads to caspase-8-dependent activation of acid sphingomyelinase, with the resultant ceramide formation capable of orchestrating raft reorganization into large cell-surface microdomains where the proteins of the death-inducing signaling complex of Fas can oligomerize thereby amplifying or modifying cell signaling [218]. Moreover, it is believed that ceramide-rich platforms serve to cluster the receptors for the pathogen, and the negative membrane curvature induced by ceramide facilitates cellular invasion of pathogens, including several microbes, parasites, and viruses [219–223]. Often the end result of ceramide-mediated cellular entry of pathogens is containment and/or inactivation of the pathogen. Moreover, ceramides may also influence membrane permeability via interactions with ion channels [224].

In addition, Cer may act as second messengers in a number of stress stimulus-mediated signaling pathways by regulating specific protein targets, mainly phosphatases (as PP1A and PP2A) [225] and kinases (as protein kinase C (PKC) z [226], raf-1 [227], and the kinase suppressor of Ras [228]). In this way, ceramides play a role in multiple vital cell processes such as cancer cell growth, differentiation, senescence (by telomerase inhibition and suppression of key mitogenic pathways [229]), and apoptosis [200, 230]. Many cytokines, chemotherapeutic agents, and other stress-causing agonists (such as heat stress, ultraviolet (UV), ionizing radiation, DNA damage, and ligation of death receptors) result in an increase of endogenous ceramide levels through de novo synthesis and/or the hydrolysis of sphingomyelin [231, 232] (Fig. 1a). Reciprocally, decreased levels of endogenous ceramide caused by increased expression of glucosylceramide synthase (GCS), which clears ceramide levels by incorporating it into glucosylceramide, result in the development of a multidrug resistance phenotype in many cancer cells [233]. In contrast to the actions of ceramide, S1P is emerging as a key regulator of proliferation, inflammation, vasculogenesis, and resistance to apoptotic cell death [234]. Many growth factors, such as epidermal growth factor and platelet-derived growth factor, as well as the cytokines TNF-α and IL-1, activate SK1 acutely, resulting in transient elevations in the levels of S1P. S1P is then secreted from the cell and acts either in a paracrine or autocrine manner to engage specific transmembrane hepta-helical G-protein-coupled receptors (GRCR). In mammals,

S1P receptors are widely expressed and are thought to regulate important physiological actions, such as immune cell trafficking, vascular development, vascular tone control, cardiac function, and vascular permeability, among others. In addition, S1P may participate in various pathological conditions. For example, S1P has been implicated as an important mediator in autoimmunity, transplant rejection, cancer, angiogenesis, vascular permeability, female infertility, and myocardial infarction [235].

Sphingolipids other than ceramide and S1P are emerging as candidate bioeffector molecules. These include C1P, which has roles in activation of phospholipase A2 [236, 237], release of arachidonic acid in response to interleukin-β (41), regulation of vesicular trafficking, phagocytosis [238], macrophage degranulation [239], and mitogenesis [240]. Dihydroceramide, which had been shown to be inactive in apoptosis, has been implicated in mediating the growth inhibitory actions of fenretinide (a retinoid analogue used in the treatment of neuroblastoma), which has been shown to inhibit the activity of the desaturase [241, 242]. Lysosphingomyelin as been shown to induce multiple cellular effects, possibly mediated by binding to specific GPCRs [243]. Finally, glucosylceramide (GluCer) has been implicated in resistance to chemotherapeutic agents [244] and may serve as the endogenous cargo for the P-glycoprotein transporter MDR1 [245]. Another property of GSLs, such as monoglycerides and gangliosides, with application in health sciences is their protective effect against certain pathogens. As commented above, several microorganisms, microbial toxins, and viruses link themselves to the cells using SL-enriched platforms. Therefore, when such compounds are present in the diet, they compete for the active union sites and help in the elimination of pathogens from the intestine [246]. Since microbial adherence is the first step in infection [247], site competition may have a protective effect against pathogens from food sources.

In addition to GSLs, other complex lipids that have attracted a lot of attention because of their significant biological and technological functions are glycoglycerolipids [248]. They are distinguished from GSLs by their lipid moieties, having glycans linked to the C-3 hydroxyl of diacylglycerol, and are very minor constituents of most animal tissues, other than the testes. Several biological activities, such as anti-algal, antiviral, antitumor, and anti-inflammatory, have been attributed to galactolipids [248]. Monogalactosyl diacylglycerols and digalactosyl diacylglycerols have shown inhibitory activity of DNA polymerase, antitumor promotion, inhibition of cancer cell proliferation, and antiangiogenesis properties [249–251]. In addition, hydrolyzed glycolipids have higher anticancer activity than the non-hydrolyzed form [249]. The anti-inflammatory activity of monogalactosyl diacylglycerols and digalactosyl diacylglycerols is lower as the fatty acid saturation degree is increased [251]. Apart from that, digalactosyl diacylglycerols have also been proposed for controlling the appetite [252].

GSLs are widely distributed in microbes and plants. Due to their amphipathic properties, they are collectively known as biosurfactants (BS) [253]. BS offer several advantages as compared to their surfactant homologues derived from petroleum, due to their low toxicity, high biodegradability, environmentally friendly, high foaming capacity, and high selectivity and specificity at extreme temperatures, pH, and saline

conditions. They are also synthesized from renewable sources and have a low critical micellar concentration and high surface activity and biological activity, which is important in the therapeutic and biomedical (antimicrobial) fields. Therefore the interest in BS has increased considerably in recent years, as well as their potential application in different industries as there is a higher concern for the protection of the environment and sustainability [254, 255].

The oral application of dietary glycerophospholipids with a specific fatty acid composition has the potential to cause defined alterations of the fatty acid composition of membrane phospholipids within a certain cell type. As a consequence, cellular functions, including signaling and transport, as well as the activity of membrane-bound enzymes, could be modulated by dietary phospholipids and hence contribute to their health benefits [256]. Recently, lipid replacement therapy has surged as a natural medicine approach to restore function in cell membranes and organelles by replacing damaged membrane lipids [257]. Besides, the importance of polar head groups from membrane lipids in protein-lipid interactions is also relevant to the coupling of hydrophobic complementary structures, such as diacylglycerol chains from phospholipids and proteins [258]. This coupling can be perturbed by oxidation of the acyl chains from diacylglycerols. This oxidation and subsequent disorder can promote enzyme activation [184, 259]. The proposed mechanism is the change produced in the hydrocarbon chain packing and interruption of hydrophobic bounding. This hydrophobic match can be facilitated by the conformational state of the lipids or by selecting the optimum lipid species for that particular hydrophobic coupling [260–262]. In order to reduce phospholipid oxidation and degradation that take place along ingestion, digestion, and adsorption, phospholipids utilized in oral lipid replacement therapy should be protected from acid pH of the stomach, alterations by bile salts, and breakage by pancreatic enzymes and microflora. This task can be achieved by complexation of phospholipids with certain fructooligosaccharides, which insert in the phospholipid micelles and prevent interactions with other molecules [263, 264]. Another important feature of phospholipids is that enrichment of plasma membranes of the colonic mucosa with these molecules protects from different pathogenic conditions such as ulcerative colitis and other chronic inflammatory. The proposed mechanism for that is the hydrophobic barrier they provide, which regulates signaling pathway involved in different conditions such as inflammation [265]. Lipid replacement therapy has applicability in fatigue associated with cancer and cancer therapies [266, 267]. In this sense, a nutritional supplement called NTFactor [268] has been successfully utilized in cancer-associated fatigue that was reduced by 30% in an 8-week treatment. The combination of lifestyle and lipid replacement therapy could be a very efficient treatment to improve mitochondrial fusion and decrease inflammation and oxidative stress, becoming a powerful remedy in noncommunicable prevalent diseases. As an example, a pilot trial utilizing lipid replacement therapy has shown metabolism changes in the direction of reducing body mass and moderating appetite [269]. In this sense, alterations in fatty acid metabolism and glucose have an influence in insulin resistance and metabolic syndrome [270]. Considering that metabolic syndrome has been associated with the excessive presence of reactive oxygen species (ROS) and

reactive nitrogen species (RNS) in membranes, lipid replacement therapy could restore big oxidized membrane fragments in blood lipoproteins. New dietetic patterns in conjunction with the administration of membrane phospholipids can remove oxidized cholesterol and phospholipids from HDL and LDL [271].

4 Glyceryl Ethers

Glycerol-based ether lipids (Fig. 2) are normally minor constituents of cell membranes of mammals, and its presence is major in the liver of some fish of the Chondrichthyes class [272]. Different bioactive properties have been attributed to 1-*O*-alkyl-sn-glycerols (AKGs). The oral administration of AKG reduced the tumor growth and the number of pulmonary metastases of mice inoculated with 3LL cells [273]. AKG with hydrocarbon chains of 18:1, 14:0, and 16:1 showed the most active antiproliferative effect, compared to 16:0 and 12:0, inducing a reduction of the tumor blood vessel endothelial marker, suggesting an antiangiogenic effect. AKGs reduced also the major angiogenesis stimulator, basic fibroblast growth factor (bFGF), on endothelial cell proliferation [274] and influenced endothelial cell growth, without showing cytotoxic effects, decreasing the cell proliferation [275].

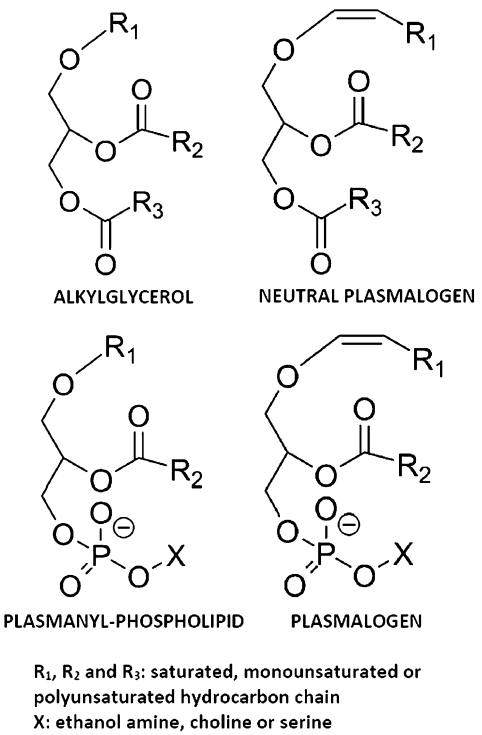

Fig. 2 Main glyceryl ether chemical structures

The antiproliferative effect of AKG was also tested in human mammary carcinoma (MCF7), ovarian carcinoma (OVP10), and prostate cancer (DU45, LnCap) cell lines, showing an increased percentage of apoptotic cells of ovarian and prostate carcinoma and a significant reduction in the number of prostatic cells [276, 277]. A methoxy-substituted alkylglycerol inhibited the growth of three human colon cancer cell lines (Moser, HT29, and HCT116) [278]. AKG supplementation was able to reduce Walker 256 tumor cell growth proportionately to the increase of lipid peroxidation, apoptosis, and reduction of cancer cell proliferative capacity. Additionally, the cachexia state, associated to patients of cancer and other progressive illnesses, was reversed with the intake of AKG [279, 280]. The prophylactic administration of AKG on patients affected by cancer can reduce the side effects and complex injuries derived from the radiation treatments, in particular leucopenia, thrombocytopenia [281], and fistulas [282].

Cytotoxic macrophages are activated by AKG, enhancing Fc-receptor-mediated phagocytosis, increasing humoral immune response, and delaying hypersensitivity reactions [283]. Regardless the carbon chain length, AKG stimulates the production of IL-12, a cytokine involved in the activation of Th1 responses [284], and IL-2 [285], enhancing the proliferation and activation of lymphocyte B, whereas levels of IL-4 and IL-10, involved in the activation of Th2 responses, are decreased [286]. Levels of C1q are also raised with the administration of AKG [287]. The intake of AKG to very old people before surgical treatment induces a significant increase of WBC, lymphocytes, IgM, and IgA in the postoperative period [288]. The administration of AKG to gestating and lactating mammals induces a positive effect on the immune system of the litter, with higher concentrations of IgG, erythrocytes, and hemoglobin in their blood and a modification on the lipid profile and immune properties of the mother's milk [289, 290].

Short-chain AKGs have the ability to increase blood-brain barrier permeability, allowing therapeutic molecules to cross it [291–293]. Even the penetration of high-molecular-weight materials, such as albumin and antibodies, into the brain could be significantly increased [292, 294]. The opening of the blood-brain barrier by the action of AKG is short and reversible and does not affect tight junction [295].

A recent experimental study has shown that unsaturated AKGs can promote a decrease in the high-fat-induced obesity and improve the insulin resistance in rats [296]. Likewise, the administration of AKG in obese patients can reduce the total cholesterol levels as well as complements 3 and 4, associated with higher risk of metabolic syndrome [297].

The in vitro treatment of spermatozoa improves their motility and fertility, related to PAF metabolism, resulting in a better fertilization performances when used for artificial inseminations [298]. In vivo studies have shown similar effects in motility and velocity of sperm after the oral intake of AKG [299].

AKG have been reported to exhibit antibacterial activity against several strains by releasing or activating proteases, such as the enzyme autolysin [300], increasing their activity with 1-O-chains from C8:0 to C12:0 and decreasing with longer 1-O-chains [301].

5 Isoprenoids

Isoprenoids are considered one of the most diverse families of compounds produced by biological systems; approximately 40,000–70,000 isoprenoid molecules are known, including sterols, carotenoids, and quinines [302–305]. Among their biological activities are maintenance of membrane fluidity, electron transport, protein prenylation, and cellular development. They are also utilized as fragrances and essential oils, antibacterial and antifungal agents, and highly valuable pharmaceuticals and fuel alternatives [304, 305].

According to the number of isoprene (C5) units that they contain, terpenes are classified in hemiterpenoids (C5), such as isopentenols; monoterpenes (C10), such as menthol and camphor; and sesquiterpenes (C15), such as zingiberene (ginger). These are the major constituents of herbs and spices. Other sesquiterpenes and diterpenes (C20) are pheromones, defenses, and signal transduction substances [306–308]. The roles of isoprenoids with higher molecular weight are membrane stabilization (such as cholesterol and other C30 compounds) and photoreception (such as carotenoids and other C40 compounds).

Many terpenoids have been found to exhibit potent biological activity, with several of them in development or in use therapeutically. Taxol, a diterpene extracted from the Pacific yew, is extremely effective in the treatment of certain cancers (ovarian, breast, lung and neck, bladder and cervix, melanoma, and Kaposi's sarcoma) [305, 309, 310]. A range of medicinal diterpenoid compounds (i.e., phorbol esters and the related casbanes, lathyranes, jatrophanes, and ingenanes) are solely produced in *Euphorbiaceae* and *Thymelaeaceae* species [311] from casbene and neocembrene diterpene backbones [312]. These diterpenoids have gained interest due to unique anticancer, anti-HIV, vascular relaxing, neuroprotective, anti-inflammatory, or immunomodulatory activities [311, 313–316]. The monoterpene limonene and related derivatives are believed to inhibit farnesylation of the growth-promoting protein RAS, inhibiting malignant cell proliferation [317–319]. The ability to produce terpenoid drugs in microbes could significantly reduce their production costs, reduce pressure on unsustainable plant-derived sources, and increase their chances of reaching clinical trials and the market.

Tocopherols and tocotrienols also known as tocochromanols are a group of compounds with vitamin E activity with numerous biological activities essential for human nutrition. They are comprised of different molecules: α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol [320]. Vitamin E is incorporated in plasma through chylomicrons. The transformation of chylomicrons to remnant particles is the mechanism to distribute the absorbed vitamin E to circulating lipoproteins and tissues [321]. On the other side, newly absorbed dietary lipids are incorporated into nascent very-low-density lipoproteins in the liver. This organ controls the release of α-tocopherol into blood plasma. This release is mediated by α-tocopherol transport protein (TTP). When TTP is absent, tocopherol is not secreted back into the plasma, and excess vitamin E is metabolized and excreted by the bile.

TTP is responsible of α-tocopherol transport to vital organs but is poorly effective on tocotrienols [322]. Surprisingly, in some tissues, the level of tocotrienol is higher

than that of tocopherols pointing out the presence of an alternative tocotrienol transport system in vivo [323].

Emulsification is a technique broadly utilized to improve absorption of hydrophobic drugs. One of the most well-known formulations are SEDDS (self-emulsifying drug delivery systems) [324–326]. In addition, soft gelatin capsules (Tocovid Suprabio™, Carotech Inc., NJ) of tocotrienol have been also developed. A study utilizing Tocovid Suprabio™ has studied the postabsorptive fate of the different tocotrienol isomers associated with lipoprotein subfractions in humans [327]. α-Tocotrienol concentrations in supplemented individuals are distributed among 3 μM in blood plasma, 1.7 μM in LDL, 0.9 μM in triglyceride-rich lipoprotein, and 0.5 μM in HDL. The plasma concentration of α-tocotrienol observed in SEDDS is two to three times higher than that previously reported in using generic supplements [328, 329].

Considering structural similarities in all eight tocols, it is logical to think they should have comparable antioxidant efficacy. However, current studies indicate that some members of the vitamin E family possess unique biological functions not shared by other family members. For example, α-tocopherol may inhibit platelet adhesion apart from its antioxidant properties. In addition, α-tocopherol has shown anti-inflammatory, antineoplastic, and natriuretic functions related to specific binding interactions [330]. Tocotrienols' main peculiarity is the presence of three trans-double bonds in the hydrocarbon tail. These unsaturations in the isoprenoid side chain provide a unique conformation [331]. For this reason, α-tocotrienol is much more flexible producing greater curvature stress on phospholipid membranes. It has been described that α-tocotrienol possesses numerous functions that are not shared by α-tocopherol [332]. Hence, tocotrienol inhibits the activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, key enzyme in cholesterol biosynthesis [333, 334]. This activity is not shared by tocopherols [335]. In addition, tocotrienol, but not tocopherol, reduces oxidative damage in proteins [336].

It is well known that pure and mixed isoprenoids possess anticancer activity [337]. In strict sense, it should be indicated that tocotrienols, but no tocopherols, are isoprenoids. Regarding the neuroprotection activity, α-tocotrienol seems to be the most potent isoform [332, 338–340], and γ- and δ-tocotrienols have been considered as the most potent anticancer isoform of all tocotrienols.

One special group of isoprenoid derivatives are sterols with relevant functions in eukaryotes, including higher plants [341]. Two predominant types of sterols, cholesterol and ergosterol, are found in animal and fungal cells, respectively [342]. One of the principal functions of sterols is the structure ordering of the biological membranes [343]. Different biophysical studies of the structure and physicochemical properties of membrane sterols have indicated that cholesterol shields negative charges reducing the net membrane surface charge [344]. It also contributes to closer packing of hydrocarbon chains in the gel phase and increasing membrane microviscosity and decreasing its permeability. Membrane permeability is affected by free sterols at different extents. The highest permeability reduction is attained with cholesterol followed by campesterol, β-sitosterol, and stigmasterol [345]. Some studies have attributed to β-sitosterol and campesterol, a role in ordering fatty acid

chains at the membrane, which have an influence on water and ion permeability and also on the activity of some membrane proteins [346].

Sterols also act as important regulatory molecules. They are hormone precursors, regulating plant growth and development [342, 347, 348]. Moreover, sterols are implicated in the formation of specific lipid membrane microdomains called "lipid rafts," with an important role in cells as transmembrane signal transduction and enzyme anchoring [349, 350].

Sterols in plants are present in three different chemical forms: free sterols, esterified with fatty acids (sterol esters), steryl glycosides, and acylated steryl glycosides, also known as the carbohydrate derivatives of sterols. Much higher proportion of free sterols is found in plants compared to sterol esters. It has been established that the main role of sterol esterification is to maintain the physiological level of sterols in cell membranes [351].

β-Sitosterol has been extensively utilized in drugs and dietary supplements for restoring lipid and cholesterol level in humans. Plant sterols and saponins combined have shown hypolipidemic and angioprotective activities [352]. Another biological activity attributed to β-sitosterol is inhibition of cancer cell proliferation besides other pharmacological properties such as anti-hypercholesterolemic [353], anti-inflammatory, and antiangiogenic [354–356]. A proposed mechanism of β-sitosterol is the activation of the sphingomyelin cycle which increases the ceramide production associated with apoptosis in various cancer cells, such as human colon cancer cells [357], human prostate cancer cells [358], human leukemic cells [359], human stomach cancer cells [360], and human breast cancer cells [361]. It has been recently published that stigmasterol, sitosterol, campesterol, and brassicasterol may be involved in the regulation of lipid metabolism and the pathogenesis of dementia [362, 363].

The chemical form of phytosterols plays an essential role on their activity, since it is well known that crystalline phytosterols are not soluble in the bile and, therefore, are unable to reduce cholesterol absorption [364]. On the contrary, development of formulations of free phytosterols with several emulsifiers has produced significant reduction in cholesterol absorption and LDL cholesterol [64]. Esterification of phytosterols with fatty acids increases their solubilization in the oily phase and consequently their activity [365]. Differently, phytosterol glycosides have amphipathic structure, which give rise to questions about their solubilization in bile and mechanism of action. Glycosylation is very common in many cell compounds [366], and for these compounds, bioavailability is the main concern. For example, more than 80% of phytosterols in potatoes are found as glycosides [367]. In a study based on a single dose, it was observed that the measured reduction of cholesterol absorption was similar to phytosterol glycosides and phytosterol esters [368].

A recent meta-analysis trying to elucidate if plant sterols reduce plasma concentrations of fat-soluble vitamins and carotenoids indicates that both plant sterols and stanols reduce hydrocarbon carotenoid concentrations (β-carotene, α-carotene, and lycopene), differently affect oxygenated carotenoid concentrations (not reduction in zeaxanthin and β-cryptoxanthin but not in lutein), and have no influence on tocopherol, retinol, and vitamin D plasmatic concentrations [369].

Finally, a recent study concerning to phytosterol oxidation products points out the relevance of the assessment of their potential adverse effects [370].

6 Phenolipids

Phenolic lipids are a class of natural products composed of a phenolic head group and an aliphatic side chain. These compounds are secondary metabolites that are not essential for cell growth but can assist against possible stress conditions of the producing organisms, such as infection, wounds, and UV radiation. Phenolic lipids mainly occur in plants but also in fungi and bacteria. Originally, its production was attributed to plant families of Anacardiaceae, Ginkgoaceae, Myristicaceae, and Orchidaceae, but later studies showed that these compounds can be produced by bacteria and mycobacteria pathogens. Besides, the synthesis of phenolic lipids by several other plant families was also reported [371].

Chemically, phenolic lipids can be considered as derivatives of mono- and dihydroxy phenols that generally contain a catechol, a resorcinol, or a hydroquinone nucleus alkylated by a carbon chain, mostly C11–C17 (see Fig. 3) [372].

Although phenolic lipids can be toxic, causing different allergic issues, they have been the subject of much attention due to other physiological properties. Phenolic lipids show amphiphilic properties, caused by the simultaneous presence of a hydrophilic phenol and a lipophilic alkyl chain in the same molecule. In aqueous media, they can be organized in micellar structures [373]. They can also incorporate into phospholipid membranes forming hydrogen bonds with these compounds. As consequence, phenolic lipids have the potential to affect biophysical properties of cell membranes, including many cellular metabolic processes, fluidity, charge and mobility of phospholipids, and the activity of membrane-bound enzymes [372]. Stasiuk and Kozubek extensively reviewed the various biological activities of phenolic lipids [373]. In addition, the possible participation of these compounds as antimutagens was suggested, since they can exert protection of cells against carcinogenesis and serve as cytotoxic and antitumor agents by causing apoptosis [374–376]. Moreover, due to their interaction with proteins and/or on their membrane-disturbing properties, the ability of these compounds to inhibit bacterial, fungal, protozoan, and parasite development besides the activity of several enzymes has been reported [377–380].

Among short-chain alkylphenols, the phenylpropanoids are present in essential oils and include isochavicol and derivatives, which displayed an interesting antiplasmodial activity [381].

The group of catechol lipids includes urushiol, which is found in plants of the family Anacardiaceae, especially *Toxicodendron* spp., and it is well known by its allergic properties. The likelihood and severity of allergic reaction to urushiol are dependent on the degree of unsaturation of the alkyl chain [382]. Similar compounds with a catechol nucleus esterified with a fatty acid (palmitic, stearic, and oleic acids) have been synthesized for their lipophilic antioxidant properties. All derivatives showed better radical-scavenging capacities than α-tocopherol and ascorbyl

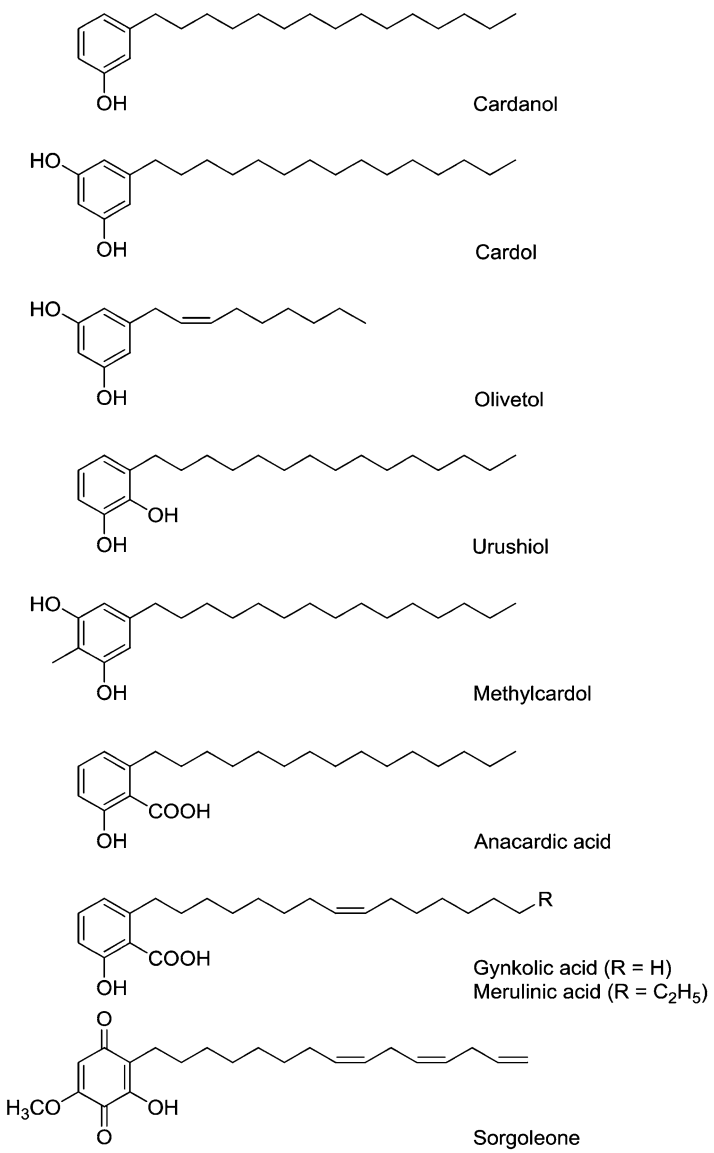

Fig. 3 Structural diversity of phenolic lipids [372]

palmitate [383]. Bonediol, an alkyl catechol from the Mayan medicinal plant *Bonellia macrocarpa*, showed to have antiproliferative and antiestrogenic activities. Additionally, bonediol could induce oxidative stress and activation of detoxification enzymes. For these reasons, it may serve as a potential chemopreventive treatment with therapeutic potential against prostate cancer [384].

The acid form of urushiol leads to the group of anacardic acids, which also cause an allergic skin rash on contact. These molecules consisted of a salicylic acid substituted with an alkyl chain (saturated or unsaturated) that has 15 or 17 carbon atoms. Moreover, anacardic acids from cashew nut shell liquid, a Brazilian natural substance, have antimicrobial and antioxidant activities and modulate immune responses and angiogenesis. The 15 carbon unsaturated side chain compound found in the cashew plant is lethal to Gram-positive bacteria [385]. In a study in mice, all doses of anacardic acids improved the antioxidant enzyme activities and decreased vascular adhesion molecule in vessels. With doses of 50 mg/kg of anacardic acids, animals showed decreased levels of neutrophils and tumor necrosis factor in the lungs and bronchoalveolar lavage fluid. Thus, it was demonstrated that this supplementation has a potential protective role on oxidative and inflammatory mechanisms in the lungs [386]. In this field, Hamad and Mubofu extensively reviewed the potential biological applications of bio-based anacardic acids and their derivatives [387].

Alkylresorcinols, also known as resorcinolic lipids, are phenolic lipids composed of long aliphatic chains and resorcinol-type phenolic rings [388]. Alkylresorcinols are relatively rare in nature, with the main known sources being wheat, rye, barley, triticale (cereal grasses), *Ginkgo biloba*, several other Anacardiaceae (*Anacardium occidentale*), mango latex and peel, and some species of bacteria. In these plants, resorcinol lipids were also related to strong allergic responses. Alkylresorcinols can also be used for specific applications, for example, 4-hexylresorcinol is a food additive (E-586) used as an antioxidant and color-stabilizing agent [389]. Bioactive properties of alkylresorcinols usually based their ability to integrate into membranes and inhibit enzymes. A wide number of in vitro studies have been carried out with alkylresorcinols, ranging from induction of apoptosis, inhibition of lipoxygenases, and cleavage of DNA to triglyceride reduction in adipocytes [390]. Alkylresorcinols were shown to have anticancer activities. Hence, in vitro studies presented inhibition of human colon, breast, lung, central nervous system, adenocarcinoma, hepatocarcinoma, cervix squamous carcinoma, and ovarian cancer cell lines, at micromolar alkylresorcinol concentration. Model studies suggest a high cytotoxicity of alkylresorcinols toward cancer cells; however, intervention studies to confirm their preventive action are needed [391].

Hydroquinone lipids are phenolic lipids with an aromatic ring belonging to the hydroquinone group linked to a straight carbon chain. Embelin and sorgoleone and their derivatives are included in this group of natural compounds reporting bioactive properties. Embelin was used in traditional Asian medicine as anti-vomiting and antidiarrhea agent [392], whereas sorgoleone can act as inhibitor of mitochondrial respiration and photosynthesis, and it has been used as natural herbicide [393].

In addition to the aforementioned compounds, other types of phenolic esters can also be found in nature. Phenolic compounds constitute a heterogeneous group that consist of simple phenols and polyphenols as well as their derivatives including phenolic acids, stilbenes, lignans, and flavonoids, by far the largest group of phenolics. Hence, for example, alkyl esters of ferulic and/or p-coumaric acids are present in soybean, cereals, propolis, periderm of potato, latex of sweet potato, parts

of *Artemisia assoana*, and leaves of *Larix kaempferi*. In addition, pods of *Piliostigma thonningii*, roots of *Tanacetum longifolium*, and wax of gala apples contain phenolic fatty acid esters of p-coumaryl alcohol, and docosyl caffeate can be found in the halophytic plant *Halocnemum strobilaceum* [394].

In this regard, acylated flavonoids were reported to protect glycosides from enzymatic degradation, to enhance pigment solubility in water, and to increase affinity to cell membranes (resulting in better penetration), antioxidant activity, enzyme inhibitory, and antiproliferative, cytogenetic, and antimicrobial properties. The enhanced hydrophobicity of these molecules results in a higher degree of penetration through the cell membrane, which permits them to interact with multiple cellular or molecular targets leading to their various biological activities [395].

It should to be noted that apart from natural sources, phenolic lipids can also be obtained from their corresponding phenolic compounds by modification techniques. Hence, different strategies were intended to produce these new molecules with potential use in technological applications or with targeted physiological properties.

One of the main purposes of these modifications is to improve the antioxidant activity of phenolic compounds in a variety of media. Redox properties of phenolic compounds promote their antioxidant activity, since they can act quenching singlet and triplet oxygen, neutralizing free radicals, or decomposing peroxides [396]. The polarity of the environment, in particular, strongly affects the antioxidant activity of phenolic antioxidants [397]. According to the antioxidant polar paradox, hydrophilic antioxidants tend to be more active in bulk oils or nonpolar media, whereas lipophilic antioxidants would inhibit lipid oxidation more efficiently in emulsions since they have more affinity for the oil-water interfaces [398]. Because phenolic antioxidants are highly polar, its lipophilization becomes a crucial step in the design of new antioxidant additives and drugs. Basically, lipophilization consists of the esterification of a lipophilic moiety (fatty acid or fatty alcohol) to a given substrate resulting in new more surface-active molecules [399]. Until now, numerous lipophilized antioxidants have been synthesized. Modification of a wide range of phenolic acids, flavonoids, tocopherols, triacylglycerols, or phospholipids has been performed to obtain lipophilized phenolics, also known as *phenolipids* [400]. As with ones found in nature, these structured lipids possess a saturated and/or polyunsaturated hydrocarbon chain and an aromatic ring bearing one or more hydroxyl or methoxyl substitutes, attached via an ester bond [401].

These molecules, with an appropriate lipophilicity, have shown improved bioavailability in vivo over their polar analogues. As reported with natural phenolic lipids, they enhance miscibility and incorporation into lipid phases and lipocarriers and can also be used in micellar, emulsified, and liposomal systems, so they open potential new applications for drug delivery systems and food, nutraceutical, pharmaceutical, and cosmetic industries [389].

It should be noted that the selection of the critical chain length of the alkyl moiety is crucial in the design and use of lipophilic antioxidants. Although the polar paradox states that apolar antioxidants are more active in oil-in-water emulsions than their polar analogues, the antioxidant activity regarding alkyl chain length is actually defined by a nonlinear trend [398]. Hence, the efficiency of hydrophobic antioxidants

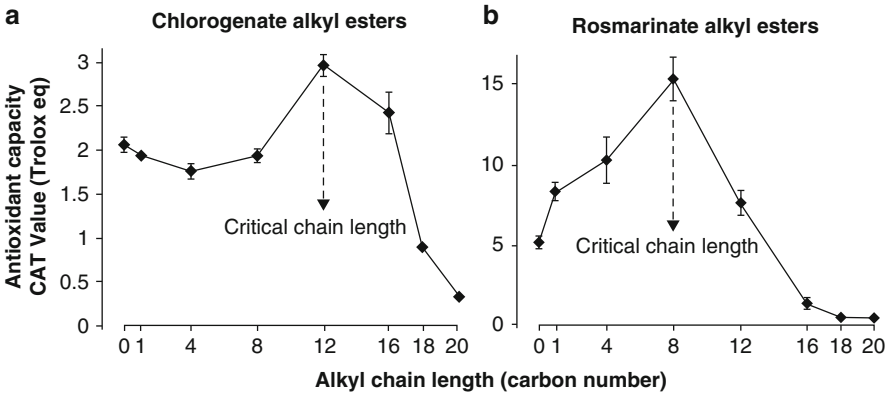

Fig. 4 Influence of the alkyl chain length of chlorogenate (**a**) and rosmarinate (**b**) alkyl esters on antioxidant activity in stripped tung oil-in-water emulsion [400]

increased with the alkyl chain length in emulsions and other more complex systems as liposomes, until a maximum is reached, but from that point, the antioxidant activity remarkably decreases, leading to a "cutoff" phenomenon [402]. Different studies established that esters of medium-chain length (C8–C12 alkyl chains) provided the highest activity [398]. Figure 4 shows two examples of different critical chain length providing the best antioxidant activity for chlorogenate and rosmarinate alkyl esters.

This nonlinear behavior can be explained because antioxidants with medium alkyl chain length tend to locate more at the oil-in-water interface, where antioxidants can provide greater protection against oxidation. Increasing the hydrocarbon chain could drive the antioxidant away from the interface into the emulsion droplet core, where the phenolics would be less efficient, which may explain the cutoff effect [403].

Apart from their wide use as food additives due to their antioxidant properties, it has been reported that, for example, propyl (E-310), octyl (E-311), and dodecyl (E-312) gallates also possess antifungal and antibacterial activities, essentially on Gram-positive bacteria [404]. Likewise, sapienic acid esters comprising hydroxybenzyl alcohol, tyrosol, and coniferyl alcohol exhibited some cytotoxicity toward different tested cell lines [389]. The effect of phenolipids on LDL oxidation has been of interest recently. Katsoura et al. reported that methyl, ethyl, and octyl ferulate had significantly higher antioxidant capacity toward LDL, HDL, and total serum oxidation. In this study, the protection effectiveness increased with the increasing length of the alkyl chain [405]. In this field, Shahidi's group lipase-catalyzed the synthesis of phenolipids to test the potential inhibitory effect of these compounds on LDL oxidation as well as radical-induced DNA cleavage [389, 401]. Moreover, Danihelová et al. reviewed the biological properties of lipophilic flavonoid derivatives (see Table 1) [406].

These functionalized antioxidants resulting from the grafting of lipid on a phenolic moiety can be prepared by a wide range of lipophilization strategies such as esterification, transesterification, amidation, and etherification. Normally, lipophilization of phenolic acids can be achieved by chemical, enzymatic, or chemo-

Table 1 Biological properties of lipophilic flavonoid derivatives [406]

Flavonoid	Substituent	Biological effect
Naringin, hesperidin, neohesperidin, hesperetin glucoside	Butyrate, decanoate, laurate	↑Antifungal
Rutin	Laurate, palmitate	↑↓Antioxidant
Chrysoeriol-7-*O*-β-D-(3″-E-pcoumaroyl)-glucopyranoside, chrysoeriol-7-[6″-*O*-acetyl-β-D-allosyl-(1→2)-β-D-glucopyranoside]	Vinyl laurate	↑Antioxidant, ↑antibacterial
Flavone, isoflavone	Prenyl, geranyl, dimethylallyl, methyl, methoxy	Antiproliferative
Flavone	Geranyl	Antiproliferative
Isorhamnetin-3-*O*-glucoside	Ethyl laurate, ethyl butyrate	↑Anticancer, ↓antioxidant
Quercetin	Tert-butylhydroxy	↑↓Antioxidant
Isoquercitrin	Butyrate, caproate, caprylate, decanoate, laurate, palmitate, stearate, oleate	↑↓Antioxidant, ↑anticancer
Flavane, thiaflavane	Methoxy	↑↓Antifungal
Rutin, phloridzin, esculin	Butyrate, caproate, caprylate, decanoate, laurate, myristate, palmitate, stearate, oleate, linoleate, linolenate, arachidonate, erucate	↑↓Antiprotease
Flavone	Methylethylamine, diethylamine, piperidine, pyrrolidine	Neuroprotective
Flavone	Alkyl	↑Anti-inflammatory
Rutin, naringin	Oleate, linolenate, linoleate	↑Anticancer
Quercetin	Alkyl	↑Antioxidant
Rutin	Butyrate, caproate, caprylate, decanoate, laurate, palmitate, stearate, oleate, linoleate, linolenate	↑Antioxidant
Biochanin A	Alkyl	↓Anti-inflammatory
Flavone	Methyl, naftyl, nitro, halogen	↑Anticancer
Chrysin	Methoxy, dodecoxy, diacetyl, methoxycinnamate	↑Anti-inflammatory
Flavone, isoflavone	Trifluoromethyl	↓Anticancer
Flavanone	Methoxy, benzyl	↑Anticancer
Flavone	Aliphatic and heterocyclic with N	↑↓Anticancer

enzymatic esterification of (a) the carboxylic acid group (−COOH) of phenolic acid with fatty alcohols or (b) the phenolic hydroxyl group (−OH) with fatty acids [403].

Although chemical esterifications are quite quick, cheap, and simple, they usually involve drastic conditions of temperature and pH, so they can promote deoxidation of phenolic compounds. In addition, as another drawbacks, chemical processes are

generally not selective and require many steps to remove residues and by-products [399]. On the other hand, enzymatic syntheses offer some advantages since they provide high selectivity, occur at mild conditions, are environmentally friendly, and require fewer purification steps. However, it should be taken into account that enzymatic processes may imply high costs, possible deactivation of the catalysts, and longer reaction times. Phenolic acids have been efficiently esterified with enzymes of the carboxylic ester hydrolase family, such as lipases, tannin acyl hydrolases, feruloyl esterases, and cutinases, by using different organic solvents or in a solvent-free media [407].

As aforementioned, synthetic lipophilization of phenolic acids with fatty alcohols can be used as a tool to produce these new amphiphile antioxidants. Figueroa-Espinoza et al. report some examples to obtain phenolipids from phenolic acids via chemical or enzymatic esterification at different conditions [407]. More particularly, Figueroa-Espinoza and Villeneuve extensively reviewed the background of the enzymatic esterification of phenolic acids as caffeic, cinnamic, ferulic, chlorogenic, gallic, etc. with fatty alcohols with different chain length [394].

The acylation of flavonoids, a class of phenolic compounds with a wide range of bioactive properties, has been the subject of much investigations, since it also permits to enhance their solubility in various media, stability, and antioxidant activity, among other physiological properties [408]. As with phenolic acids, acylation of flavonoids can be performed by using chemical catalysts [409]. However, apart from other advantages of enzymatic technology aforementioned, the regioselectivity of enzymes plays a crucial role in these processes, since it remarkably affects the functionalization of phenolic hydroxyl groups, which is responsible for the antioxidant activity of flavonoids. Chebil et al. extensively reviewed a multitude of investigations dealing with the regioselectivity and performance of the enzymatic acylation of flavonoids [410]. Several factors should be taken into account in order to enhance the performance of acylation, e.g., type, regioselectivity, and load of enzyme, nature of the flavonoid, acyl donor, operating conditions, etc. The reaction can be carried out using different organic solvents or almost solvent-free systems [411]. In this regard, both ionic liquids [412] and eutectic mixtures [413, 414] have also provided good properties as solvents, becoming an alternative solution for these enzymatic transformations.

Lipophilization with different acyl donors has also been applied to other polar antioxidants to increase its solubility and activity in nonpolar matrices. For example, ascorbic acid (vitamin C) has traditionally been hydrophobized by esterification or transesterification reactions with different aliphatic chains [415], mainly palmitic acid [416], or even with polyunsaturated fatty acids [417].

Last decades, there is a growing interest in the development of *structured lipids* with enhanced functional properties and health benefits. Structured lipids are originally triacylglycerols in which the composition and the distribution of fatty acids at the glycerol backbone are modified. The use of structured triacylglycerols seemed to be the most efficient way of delivering bioactive fatty acids, increasing their bioavailability, and thus enhancing their physiological effects [418]. Improvements in the solubility and miscibility of phenolic compounds in nonpolar systems can be attained upon their incorporation into triacylglycerols [419]. Hence, the structuring

of triacylglycerols with phenolic acids could potentially result in novel structured phenolic lipids becoming an interesting strategy for medical, nutraceutical, and food applications [420]. These novel structured molecules may provide a great number of beneficial properties by the combination of bioactive fatty acids (e.g., PUFA) and phenolic compounds in the same molecule [421]. Phenolic structured lipids were generally obtained via transesterification by acidolysis using enzyme catalysts. Acidolysis can be used to replace the existing fatty acids in the triacylglycerol molecule by other desired fatty acids, phenolic acids, or other organic acids [422].

It should be noted that Novozym 435 (*Candida antarctica* lipase) was the most widely used and showed the best catalysis performance [423]. As examples, this lipase was employed to effectively incorporate dihydrocaffeic acid in flaxseed oil [424], *p*-coumaric acid in seal blubber oil and menhaden oil [401], dihydrocaffeic acid and ferulic acid in trilinolein and trilinolenin [425], and cinnamic acid in triolein [426]. The same methodology was also used for acidolysis between flaxseed oil and selected phenolic acids (ferulic, *p*-coumaric, sinapic, etc.), including hydroxylated and/or methoxylated derivatives of cinnamic, phenyl acetic, and benzoic acids [419]. Besides, synthesis of phenolic lipids by transesterification of ethyl ferulate with castor oil [423], dihydroxyphenylacetic acid and dihydrocaffeic acid with krill oil [427], 3,4-dihydroxyphenyl acetic acid [421], and other selected phenolic acids [428] with flaxseed oil was affected in solvent-free media, using Novozym 435 from *Candida antarctica* as the biocatalyst. Supercritical carbon dioxide is a *green* solvent that was also used as solvent in the reaction medium for the acidolysis between flaxseed oil and ferulic acid [429].

The synthesis of structured phenolic lipids has great potential in the production of lipids with health benefits. On the one hand, it permits the combination of the antioxidant capacity of the phenolic compounds with the bioactive properties of specific fatty acids in the triglyceride molecule. On the other hand, the lipophilization of phenolic compounds occurs, improving the solubility, stability, and activity of these compounds in nonaqueous systems. For these reasons, structured phenolic lipids have potential applications in functional foods, nutraceuticals, pharmaceuticals, or cosmetics for health promotion and disease risk reduction.

7 Lipid Delivery Systems

As described above, a number of lipid-based compounds have shown in vitro and in vivo health benefits besides their normal nutritional role [430], so that their consumption is thought to promote human wellness and to reduce the risk of certain chronic diseases. Moreover, some of them also provide specific functional attributes to the product, as desirable color, flavor, or texture, and longer shelf life. Consequently, the interest of food and beverage industries in the incorporation of these compounds (called from now “lipophilic actives”) into commercial products is growing [431–433]. Moreover, many of the lipophilic actives covered in this book chapter are also applicable as nutraceuticals (therapeutic/preventive agents) and cosmetics.

However, application of lipophilic actives is often challenging due to their physicochemical properties, such as low chemical stability, poor water solubility, low oil solubility, high oil-water partition coefficient, high melting point, and crystalline state at room temperature [431, 434, 435]. Such characteristics make them incompatible with the aqueous matrix of food and beverage products and prone to physical, chemical, and biological degradation, either during product storage or during gastrointestinal (GI) digestion and systemic circulation (extensive metabolism and quick clearance). This may result in the generation of off-flavors or, even, potentially toxic reaction products, a poor and variable bioavailability, and the loss of in vivo bioactivity. All this limits industrial applicability of this kind of compounds, thereby highlighting the need of appropriately formulating them before their final application to improve these aspects.

Formulation strategies usually used by food, pharmaceutical, and cosmetic industries to overcome limitations of lipophilic actives include:

1. To mix them with other oil phase components (usually edible neutral oils) prior to preparing the product (conventional emulsion-based products) [436]. Neutral oils used for this purpose are usually TAG or terpene oils, which, moreover, make the product more palatable or desirable to consumers.
2. To modify their chemical structure, mainly by esterification [437].
3. To incorporate them into a suitable nanoparticle-based and microparticle-based delivery system before their final application [431, 432, 438].

The latter is the most commonly used strategy to efficiently incorporate lipophilic actives into commercial products and increase their in vivo efficacy after product ingestion or nutraceutical administration (usually by oral route). Preferably used delivery systems are those manufactured from food-grade ingredients (such as proteins, carbohydrates, lipids, and surfactants) and specifically designed for oral administration applications.

Among them, polymer-based delivery systems (PBDS) (as polymeric micelles, polymeric nanoparticles (PNPs), polymer-bioactive conjugates (PBCs), dendrimers, and biopolymer-based nanocarriers) have been popularly adopted. To a lesser extent, inclusion complexes with cyclodextrins and its derivatives as well as inorganic, hybrid, and other novel nanocarriers (as liquid crystals and lipid nanocapsules) are being currently used [439]. However, in recent years, an increased interest has been focused on the incorporation of lipophilic compounds into lipid-based delivery systems (LBDS), which has been shown to be one of the most powerful strategies for the formulation of these kinds of compounds [440, 441]. LBDS used for oral administration include vesicle systems (liposome and phospholipid complexes), lipid particulate systems (solid lipid particles (SLPs) and nanostructured lipid complexes (NLCs)), and emulsion-based systems (microemulsions (MEs), nanoemulsions (NEs), and self-emulsifying delivery systems (SEDSs)) [439].

No single delivery system is suitable for every lipophilic active. Due to their unique physicochemical characteristics, delivery systems must be carefully designed taking into account specific physicochemical properties of the lipophilic active to be

incorporated up (including physical state, solubility, partitioning, diffusion, interactions, optical characteristics, rheological properties, and stability) to overcome its specific challenges and, thus, reach the following goals [436]:

Before ingestion:

1. To readily disperse active compound in the aqueous matrix of food and beverage products.
2. To incorporate the active compound into food matrices without adversely affecting quality attributes of the product, such as appearance, texture, flavor, or stability.
3. To mask possible off-flavors of the lipophilic active (such as bitterness or astringency).
4. To efficiently protect the active ingredient against chemical, physical, or biological degradation, either during product storage, to avoid the generation of off-flavors and the loss of bioactivity. Knowledge of the degradation mechanism and the major factors that affect it (e.g., oxygen, light, pH, heat, enzyme activity, etc.) will facilitate the design of a more effective delivery system.
5. To improve the product storage and handling and extend product shelf life, which is directly related to goal 4.
6. To release the active ingredient (e.g., antimicrobial or antioxidant) at a particular site of action during food storage. For example, the physical location of an antioxidant within the food matrix is particularly important for determining its effectiveness, as it should be present as the site where lipid oxidation primarily occurs (within the oil, water, or interfacial regions). Appropriately designed delivery systems can be used to improve the efficacy of antioxidants in food and beverage products by delivering them to the appropriate site of action.

After ingestion of the fortified product or nutraceutical:

1. To enhance (or at least not adversely affect) the active compound bioavailability and reduce its inter- and intra-subject variability, leading to higher in vivo efficacy and more reproducible results in clinical assays. The Food and Drug Administration defines bioavailability as "the rate and extent to which the active ingredient or active moiety is absorbed from a drug product, reach plasma and body tissues and becomes available at the site-of-action in an unchanged form." The impact of bioavailability is especially pronounced when the bioactive compound is intended for oral use, whereby gastrointestinal absorption constitutes the primary barrier between the active ingredient and systemic circulation. Delivery systems have shown to enhance oral bioavailability of lipophilic actives by improving their dispersion in GI tract (GIT) environment (which avoids their precipitation), protecting them against chemical (low pH in the stomach) and biological degradation (microbiota metabolism and enzymatic degradation) in the GIT, favoring their transportation until absorption area during GI digestion, and increasing GI wall permeability, which significantly enhances the intestinal absorption [439].

2. To enhance permeability of other mucosal membranes besides of GI membrane (such as the cornea, the nasal mucosa, the respiratory mucosa, and the stratum corneum of the epidermis) and the blood-brain barrier and increase the lipophilic active penetration into tumoral matrices [442, 443].
3. To increase the pharmaceutical stability of the active compound, thereby lengthening its systemic circulation time [444].
4. To release the active ingredient at a particular site of action (e.g., released in the mouth, stomach, small intestine, colon, or targeted organ/cells), at a controlled rate (sustained release), or in response to a specific environmental trigger (e.g., pH, ionic strength, temperature, or enzyme activity), which leads to targeted effects and increased in vivo efficacy.
5. To overcome multidrug resistance [445].
6. To enhance efficiency of co-delivery of lipophilic actives and therapeutic agents [446].
7. To reduce the effect of co-ingested food ingredients on pharmacokinetics of the active molecule [447].

As commented above, oral route is the most commonly used for the delivery of drugs and nutraceuticals (including lipophilic actives and other dietary bioactives). This is generally considered as the easiest and most convenient method since it is noninvasive, cost-effective, and less prone to side effects, such as injection-site reactions [448]. However, to overcome limitations in the oral administration of poor water-soluble compounds, parental (intravenous and intraperitoneal) and topical (transdermal, nasal, and ocular) administration routes can be used to increase dose precision and clinical efficacy. In recent years, topical delivery of bioactive compounds has also drawn great attention owing to its advantages over other administration routes and outstanding contribution in improving local action [151] or systemic absorption, which can minimize the first-pass hepatic metabolism [152]. Moreover, we should not forget that this administration route is the one used by cosmetic industry. These applications, however, also show several barriers that limit their use (including low skin permeation, injection-site reactions, short biological half-life, presystemic metabolism, or systemic toxicity [449]), and the use of nanocarriers has demonstrated to be also an efficient formulation strategy. In case of the parenteral route, most of the investigations have focused on utilizing nanocarriers (as liposomes, SLNs, NCLs, PNPs, and PBCs) to enhance bioactive efficiency through targeting of effects [450, 451], controlling drug release at site of action to minimize side effects [452, 453], or overcoming multidrug resistance [454]. For topical application, the incorporation of active compounds into nanocarriers (as MEs, liposomes, ethosomes, NLCs, PNPs, and PBCs) aims to enhance skin permeation and stability, lengthen systemic circulating time, and minimize metabolic degradation and systemic toxicity [439].

Table 2 summarizes the major types of lipophilic actives that need to be formulated, the specific challenges associated with their application, and the formulation strategies commonly used to overcome such challenges and increase their industrial applicability degree as therapeutics or in food fortification.

Table 2 Types of lipophilic actives commonly formulated

Lipophilic active	Challenge	Formulation strategy	Advantage of formulation
Neutral lipids			
• ω-3 PUFA (mainly ALA, EPA, and DHA) • CLA	• Low water solubility (aqueous matrix incompatibility) • Susceptible to lipid oxidation (problematic long-term storage, rancid off-flavors, and potentially toxic reaction products)	Use of LBDS (liposomes, spray-dried emulsions, multilayer emulsions, multiple emulsions) and filled hydrogel particles (complex coacervation)	• Easier incorporation into aqueous medium • Easier handling and storage • Prevention of lipid oxidation
Polar lipids			
Sphingolipids (ceramides)	• Low water solubility and in vivo bioavailability	• Use of LBDS (cationic pegylated liposomes) • Alteration of ceramide structure (e.g., cationic pyridinium, C_{16}-serinol, 4,6-diene-ceramide)	• More effective at crossing the cell membrane • Increased bioavailability/bioactivity • Targeting of antitumor effects • No side effects or lower toxicity to normal cells
Unsaponifiable lipids			
• Terpenes			
Essential oils	• Low water solubility • Some water solubility (instability by Ostwald ripening) • Low and variable bioavailability	• Use of LBDS (O/W emulsions, MEs, NEs, multilayer emulsions, multiple emulsions, and SLNs) • Esterification (e.g., citral acetate)	
	• Poor chemical stability (loss of bioactivity, off-flavors during storage) • Low molecular weight and high volatility (ease to loss of desirable flavors)		• Mask undesirable off-flavors • Easier incorporation into aqueous medium and handling • Easier handling and storage • Prevention of chemical degradation • Increased efficacy
Carotenoids	• Crystalline state at room temperature • Low oil solubility	• LBDS (O/W emulsions, surfactant micelles, MEs, NEs, NLCs), PBDS (PNPs and biopolymer-based nanocarriers), and CD inclusion complexes (vitamin A)	
Vitamin A (retinoid)	• Low water solubility • High melting point • Poor chemical stability • Low and variable bioavailability		
Vitamin E (tocopherols)		• Esterification (α-tocopherol acetate)	

• Sterols			
Vitamin D	• Low water solubility • Poor chemical stability • Low and variable bioavailability	• Use of LBDS (liposomes, O/W emulsions, surfactant micelles, NEs) and PBDS (PNPs and PBCs)	• Easier incorporation into aqueous medium and handling • Easier handling and storage • Prevention of chemical degradation • Increased efficacy
Phytosterols and phytostanols (stigmasterol, β-sitosterol, and campesterol)	• Low water solubility • Low oil solubility • High melting point • Poor chemical stability	• Esterification with PUFAs	
• Polyphenols			
Puerarin		LBDS (MEs, SMEDS, SLNs) and PBDS (dendrimers)	
Genistein		LBDS (MEs) and PBDS (dendrimers).	
Luteolin		LBDS (SMEDS, SNEDS)	
Silymarin		LBDS (SMEDS, NLCs), PBDS (PNPs), inorganic nanocarriers, and crystalline liquid nanocarriers	
EGCG	• Low water solubility • Extensive metabolism and quick clearance	LBDS (liposomes, PL-complexes, SMEDS, SNEDS)	• Increased bioavailability/bioactivity • Targeting of antitumor effects
Curcumin	• Low and variable bioavailability	LBDS (liposomes, S(N)EDS, NLCs) and PBDS (PNPs, PBCs, dendrimers)	• No side effects or lower toxicity to normal cells
Kaempferol		LBDS (PL-complexes)	
Quercetin		LBDS (MEs, PL-complexes[a]) and folate-modified lipid NCs	
Tyrosol		LBDS (phenolipid tyrosol-enriched lecithin)	
Resveratrol		LBDS (MEs, SLNs) and hybrid nanocarriers	

EGCG (−)-epigallocatechin-3-gallate, *LBDS* lipid-based delivery system, *PBDS* polymer-based delivery system, *SLN* solid lipid nanoparticle, *NLCs* nanostructured lipid complexes, *ME* microemulsion, *NE* nanoemulsion, *SMEDS* self-microemulsifying delivery systems, *SNEDS* self-nanoemulsifying delivery systems, *PNP* polymeric nanoparticle, *PBC* polymer-bioactive conjugate, *CD* cyclodextrin

[a]Phospholipid (PL)-complexes include phytosomes and phenolipids (quercetin-enriched lecithin)

It is worth mentioning that some of the bioactive lipids that have been discussed in the present book chapter can act, in turn, as efficient lipid-based delivery systems. This is the case, for example, of alkylglycerols (AKGs). AKGs, previously isolated from shark liver oil, have been used as efficient delivery systems of bioactive substances such as butyric acid [454] and hydroxytyrosol esters [455]. Likewise, ratfish liver oil, with an exceptionally high content in AKG, has been recently used to obtain a bioactive lipid-based delivery system with potential self-emulsifying properties by enzymatic glycerolysis [456]. In addition to all the advantages that the formulation of bioactive molecules with delivery systems offer, the use of bioactive AKG to design lipid-based delivery systems provides additional benefits, since its bioactivity could have an addition or even synergistic effect with the loaded bioactive compound, giving rise to highly bioefficient formulations.

Acknowledgments This study has been funded by the Comunidad Autónoma de Madrid (ALIBIRD, project number S2013/ABI-2728) and by Ministerio de Economia y Competitividad (project number AGL2016-76736-C3-1-R). Abstract

Edible plant oils play a vital role in daily diets of people worldwide. Stability against oxidation is the major factor limiting the application of most edible plant oils for cooking and processing. Most native plant oils vary greatly in their stability to oxidation depending on their composition. Oxidative stability of edible plant oils has been extensively studied to find out the ways of improving their stability against oxidation to widen their application. Synthetic antioxidants are effective to improve the oxidative stability of these oils, however, recently, following the evidences on possible toxicities of synthetic antioxidants, the use of natural plant sources as antioxidant is gaining interest. In addition, modification of composition of the oils through genetic modification is another successful means to improve the oxidative stability of these oils. This chapter focuses on the mechanism and factors of oxidation and ways of improving oxidative stability of oils.

Antioxidants · Autoxidation · Hydroperoxides · Photooxidation · Radicals · Refining

1 Introduction

Edible oils from various sources are important components of the daily diet of people from around the world. Plant oils account for more than 75% of edible oil consumption worldwide [1]. According to the US Department of Agriculture, 189.11 million metric tons of vegetable oils have been produced globally during the season 2016/2017. Further, the world vegetable oil production is increasing continuously, especially the production of palm, soybean and sunflower oil. Palm oil found to be the major plant oil ranked highest (more than 60%) in the world production followed by soybean oil [2]. In the recent past, the use of blended oils is becoming popular in several countries such as Europe, China, Thailand, and Japan. Two or more vegetable oils are mixed at different proportion to get blended oils for different nutritional and processing purpose [3]. Vegetable oils are the healthier choice relative to animal fats in view of their fatty acid contents and cholesterol-free nature [4].

Studies on edible oils remain one of the prime areas of research, and nowadays people are much health-conscious. Diet-related noncommunicable diseases,

especially coronary heart diseases, are the major cause of death in developed as well as developing countries. In this context, edible oils play a crucial role in maintaining human well-being. Edible oils differ in their characteristics based on their composition. Oils are used as cooking oils and ingredients in variety of foods. Thus, the oils undergo various processing, mainly, heat treatment. Therefore, the stability of these oils for processing as well as storage conditions is the major property of oils. Major deteriorative reaction occurring in most of the edible oils is the oxidation. Lipid oxidation primarily depends on the fatty acid composition and the presence of minor components. Lipid oxidation leads to the production of primary and secondary oxidative compounds which are harmful to health. This chapter emphasizes the mechanism and factors of oxidation of oils, effect of processing conditions and antioxidants in oxidation, oxidative stability of some major edible oils, and measurement methods.

2 Mechanism of Lipid Oxidation

Lipid oxidation is the major cause of deterioration of the quality of edible oils. Oxidative stability of oils is defined as the resistance to oxidation during processing and storage [5]. Lipid oxidation breaks down the fatty acids, thus, causes the loss of nutritional quality, and produces undesirable color, flavor, and toxic components making the food unacceptable or less acceptable by consumers; thus it is an indicator to determine the quality and shelf life [6]. Different mechanisms have been proposed as responsible for the oxidation of edible oils during processing and storage such as autoxidation and photosensitized oxidation. The kind of mechanism depends on the kind of oxygen available. Triplet oxygen ($^3O_2$) and singlet oxygen ($^1O_2$) can react with oxygen to cause autoxidation and photosensitized oxidation, respectively [7].

2.1 Lipid Autoxidation

Unsaturated fatty acids are prone to autoxidation which proceeds via free-radical chain mechanism. Rate of oxidation depends on the degree of unsaturation and increases with increase in the number of double bond [8]. Free-radical mechanism of lipid autoxidation involves the attack of oxygen at the allylic position leading to the formation of hydroperoxides. These primary oxidation products further decompose into secondary oxidation products [9].

Lipid autoxidation involves three steps: initiation phase (induction period), propagation phase (exponential phase), and termination stage [10]. In the initiation step, when lipid (LH) is exposed to an initiator (heat, light or metal ions), hydrogen atom of double bond is abstracted, and alkyl radical (L•) is formed [11]. This free radical abstracts hydrogen from other lipid molecules and reacts with the hydrogen to form hydroperoxide (LOOH) (primary oxidation product) and another alkyl radical. Alkyl radical also reacts with molecular oxygen ($^3O_2$) to form peroxy radical (LOO•), which abstracts hydrogen from other lipid molecules and reacts with hydrogen to

form hydroperoxide and another alkyl radical. These radicals catalyze the oxidation reaction, and autoxidation is called the free-radical chain reaction [7]. The rate of formation of peroxy radical and hydroperoxide depends only on oxygen availability and temperature [12]. Radicals react with each other to form non-radical species, and the reaction is terminated [7]. The most labile hydrogen atom in monounsaturated acids is on the carbon atoms adjacent to the double bond, whereas, in polyunsaturated acids, the most labile hydrogens are on methylene groups between two double bonds. The abstraction of hydrogen is followed by electron rearrangement to form conjugated dienes since the radicals formed are unstable [13].

Hydroperoxides are nonvolatile, odorless, and very unstable and further break down via several steps into secondary oxidation products called carbonyl compounds such as aldehyde, ketones, acids, alcohols, acids, esters, and short-chain hydrocarbons via monomolecular and bimolecular reactions [7, 13–15]. Hydroperoxides begin to decompose as soon as they are formed. During the first stages of autoxidation, their rate of formation exceeds their rate of decomposition, and the reverse is true at later stages of autoxidation [16]. Most of the secondary oxidative products are responsible for the off-flavor in the oxidized edible oil. Aliphatic carbonyl compounds (alkanals, 2-alkenals, and *trans*, *trans*-2,4-alkadienals) have more influence on the oxidized oil flavor because of their low threshold values [7]. Breakdown of hydroperoxides also produces nonvolatile monomeric compounds, including di- and tri-oxygenated esters derived from the corresponding keto-, hydroxy-, hydroperoxy-, and epoxide esters. During induction period, only very little changes occur in lipids, followed by fast deterioration of lipids, and off-flavors become noticeable and the lipid is no longer edible [13].

Autoxidation of oleate (C18:1, n−9) produces four allylic hydroperoxides containing OOH groups on carbon 8,11 (*cis*-8-OOH, *cis*-11-OOH) and 9,10, (*trans*-9-OOH, *trans*10-OOH). Autoxidation of linoleate (C18:2, n−6) produces a mixture of *cis*, *trans* and *trans*, *trans* (9-OOH and 13-OOH) conjugated diene hydroperoxides. Autoxidation of linolenate (C18:3, n−3) produces a mixture of *cis*, *trans*, *trans*, *trans*, and *cis* (9-OOH, 12-OOH, 13-OOH and 16-OOH) conjugated diene hydroperoxides [13, 16].

Initiation:

$$LH \rightarrow L\cdot + H\cdot$$

Propagation:

$$L\cdot + O2 \rightarrow LOO\cdot$$

$$LOO\cdot + LH \rightarrow LOOH + L\cdot$$

Termination:

$$LOO\cdot + LOO\cdot \rightarrow \text{non-radical product}$$

$$LOO\cdot + L\cdot \rightarrow \text{non-radical product}$$

$$L\cdot + L\cdot \rightarrow \text{non-radical product}$$

Hydroperoxides initiate new chain reaction after reacting with free radicals [17].

2.2 Photooxidation

Oxidation of edible oils is accelerated by light, especially in the presence of sensitizers [7]. In the presence of light, photosensitizers such as chlorophyll and porphyrin convert triplet oxygen into singlet oxygen, which is a highly reactive non-radical molecule [15]. If wavelength of solar light is less than 220 nm, unsaturated fatty acids cannot absorb light; however photosensitizers absorb light energy and convert triplet state sensitizer to singlet-state sensitizer. Ground-state singlet sensitizers absorb light energy very rapidly and become excited singlet sensitizer which can return to their ground state via emission of light, internal conversion, or intersystem crossing. Fluorescence, heat, and excited triplet state of sensitizers are produced by emission of light, internal conversion, and intersystem crossing, respectively [7]. Photooxidation can proceed via two types of mechanism. An electron or a hydrogen atom transfers between an excited triplet sensitizer and a substrate, producing free radicals or radical ions (Type I). Excited triplet sensitizers react with triplet oxygen to produce superoxide anion by electron transfer. Superoxide anion produces hydrogen peroxide which reacts with superoxides and forms singlet oxygen in the presence of transition metals (iron or copper). Excitation energy of triplet sensitizers can be transferred to triplet oxygen by triplet–triplet annihilation to produce singlet oxygen, which reacts with the double bond of unsaturated fatty acids, producing an allylic hydroperoxide (Type II). The rate of type I and type II process may differ depending on the kinds of sensitizers, substrates, and concentrations of substrates and oxygen [7, 13, 15, 18–20]. Hydroperoxides formed by photooxidation are decomposed by the same mechanisms for the hydroperoxides formed by autoxidation. The mechanism of photooxidation is explained in detail by Choe and Min [7].

2.3 Lipoxygenase Catalyzed Oxidation

Lipoxygenase is an enzyme found in plants. It is another reason for the deterioration of edible plant oils, especially during oil extraction. Lipoxygenase reacts with oils containing1,4-*cis*, *cis*-pentadiene system producing corresponding hydroperoxy derivatives and *cis-trans* conjugated hydroperoxide [21]. Reaction of this enzyme produces hydroperoxides, which decompose to form secondary oxidation products with strong undesirable flavors. Lipoxygenase produces similar volatile compounds to those produced by autoxidation [22]. Lipoxygenase contains a ferrous atom as inactive Fe (II) and is oxidized to active Fe (III) by fatty acid hydroperoxides or hydrogen peroxide. The active enzyme abstracts a hydrogen atom from the methylene group of a polyunsaturated fatty acid with the iron being reduced to Fe (II) producing conjugated dienes followed by reaction with oxygen generating peroxyl radical and hydroperoxide [13, 20]. Rice bran and soybean are the two major plant sources containing lipoxygenase; thus the oils extracted from these sources can easily undergo lipoxygenase-catalyzed oxidation during processing.

3 Harmful Effects of Oxidation of Edible Oils

Lipid oxidation reduces the shelf life and nutritive value of food by limiting the content of essential polyunsaturated fatty acids [23]. Lipid oxidation products are considered to be harmful for health as they consist of compounds with mutagenic, carcinogenic, and cytotoxic properties [24]. These compounds cause health problems such as growth of tumor cells through lipid peroxidation as hydroxides of fatty acids are cytotoxic. Oxidation of long chain fatty acids causes neuromyopathic disease both in infant and adults [15, 25].

Consumption of lipids containing excessive free radicals may cause alterations in the redox state of human body, leading to lipid peroxidation [4]. Unstable free radicals tend to stabilize themselves by abstracting electrons from membrane lipids to start a self-propagating chain reaction causing structural rearrangement of the lipids. The rate of bond cleavage increases until the molecule gets stabilized. Oxidative damage to lipid structures eventually leads to disorganization and dysfunction of, as well as damage to membranes, enzymes and proteins [4, 26].

4 Factors Affecting the Oxidative Stability of Edible Plant Oils

The oxidative stability of oil is influenced by the fatty acid composition of the oil; processing, heat or light; the concentration and type of oxygen; free fatty acids, mono-, and diacylglycerol concentration; transition metals; peroxides; thermally oxidized compounds; pigments; and antioxidants. These factors interactively affect the oxidation of oil, and it is not easy to differentiate the individual effect of the factors [7].

4.1 Fatty Acid Composition

The natural fatty acid composition of oil and the positions of the fatty acids in the glycerol backbone determine the susceptibility and resistance to oxidation [27]. Oils containing more unsaturated fatty acids are oxidized more quickly than the oils containing less unsaturated fatty acids [28]. As the degree of unsaturation increases, the rate of oxidation increases [7] producing more complex mixtures of hydroperoxides. In addition, as the degree of unsaturation of fatty acids increases, the rate of formation and the amount of primary oxidation products are accumulated [29]. The relative rate of autoxidation of oleate/linoleate/linolenate was reported to be in the order of 1:40–50:100 on the basis of the oxygen uptake and 1:12:25 on the basis of peroxide development [13]. Soybean, sunflower, corn and rapeseed oils are often considered unsuitable for continuous frying due to their high content of polyunsaturated fatty acids [30]. Xu and others [31] studied the stability of camellia oil after frying potatoes by comparing with palm oil and peanut oil and reported that camellia oil possesses highest oxidative stabilities followed by palm oil, while peanut oil

showed the least stability. They have concluded that the fatty acid composition and tocopherol contents of oils are the important factors of oxidative stability of the oils. Camellia oil contains higher proportions of monounsaturated fatty acid compared to saturated and polyunsaturated fatty acid than other two oils, and the peanut oil contains higher proportion of polyunsaturated fatty acid. The monounsaturated fatty acid is relatively stable toward oxidation, while polyunsaturated fatty acids are highly susceptible to oxidation [32]. Even though the fatty acid composition of the oils is the major factor determining the oxidative stability of the oil, oxidative stability of oils is a function of several other factors [30].

4.2 Oil Processing

The oil processing affects the oxidative stability of an oil. All crude oils after extraction from their sources contain nontriglyceride components such as free fatty acids, partial acylglycerols, sterols, tocopherols, hydrocarbons, pigments (gossypol, chlorophyll), vitamins, phosphatides, protein fragments, trace metals, and resinous and mucilaginous materials. The objectionable nontriglycerides cause unwanted effects during processing such as darkening and formation of foam, smoke, and precipitate and develop off-flavors. Thus, crude oils are refined to remove the objectionable constituents [33]. Typical refining process consists of neutralization, bleaching, winterization, and deodorization steps. Even though the objective of the refining is to remove impurities with minimum damage to the oil, unfortunately, these processing steps may result in losses in naturally occurring bioactives such as tocopherols, tocotrienols, sterols, and phenols, and the extent of loss depends on the processing parameters and nature of the oil [33, 34]. Thus, the refined oils may have less oxidative stability than their unrefined counterparts [30].

4.3 Temperature and Light

Autoxidation of oils and the decomposition of hydroperoxides increase as the temperature increases. As temperature increases, the solubility of oxygen decreases drastically although all the oxidation reactions are accelerated [35]. At temperatures above 150 °C, hydroperoxides are reduced to very low level or become absent, and the formation of new compounds is very rapid, indicating that the rate of peroxide decomposition is higher than that of their formation [36].

The formation of autoxidation products during the induction period of autoxidation is slow at low temperature, and the content of polymerized compounds increases significantly at the end of the induction period. Light of shorter wavelengths has more detrimental effects on the oils than longer wavelengths, and the effect of light on oil oxidation becomes less as temperature increases [7, 12]. However, as temperature increases, the influence of light on oxidation becomes less important [35]. The effect of temperature on photooxidation is less prominent than on autoxidation. Light has more influence than temperature in photooxidation [7].

The packaging of oils is very important to minimize the photooxidation. Transparent plastic bottles can increase oil oxidation. The incorporation of UV absorbers such as Tinuvin 234 (2-(2-hydroxy-3,5-di (1,1-dimethylbenzyl)phenyl) benzotriazole) or Tinuvin 326 (2-(3′-*tert*-butyl-2′-hydroxy-5′-methylphenyl)-5-chlorobenzo-triazole) into the transparent plastic bottles can be effective to improve the oxidative and sensory stability of edible plant oils stored under light [7, 37, 38].

4.3.1 Frying

Frying is one of the commonly used culinary methods. In recent years, frying oils became an important component of daily diet due to rising demand for deep-fried products. However, much concern has been raised on the biological effects of consumption of fried foods containing oxidized lipids. During the frying process, oil is exposed to an extremely high temperature in the presence of air and moisture. It may result in a high rate of production and decomposition of peroxides. Deep-fat frying decreases the unsaturated fatty acids and increases polar material [39]. Thus, the quality of the frying oil is of paramount importance.

The chemistry of oxidation during frying is very complex since both thermal and oxidative reactions take place during frying at high temperatures. Reaction mechanism of thermal oxidation is principally the same as the autoxidation mechanism; however, the thermal oxidation takes place at faster rate than the rate of autoxidation [39–41]. These oxidative reactions are mainly influenced by the phenolic compounds, tocopherols, and fatty acid composition of the oil and frying temperature [4, 16, 42, 43]. Repeated frying accelerates the oxidation of oil leading to formation of primary and secondary oxidative products which are absorbed by the fried food and eventually get into the gastrointestinal tract and the circulation system after ingestion leading to health problems such as high blood pressure [4].

Juárez and others [44] investigated the discontinuous deep frying of churros in soybean oil, sunflower oil, and partially hydrogenated fats and found that, after 80.5 h of deep frying, all the oils exceeded 25% of total polar compounds except partially hydrogenated fat and losses of tocopherols during frying reached 76.0%. Marinova and others [39] investigated the oxidative stabilities of refined sunflower, grape seed, soybean, corn, and olive oils at frying temperature. Their results demonstrated that olive oil possesses better stability against thermal oxidation when compared to polyunsaturated oils. Further, it is shown that corn and soybean oils are most resistant to oxidation at frying temperature among unsaturated oils.

4.4 Oxygen Concentration

The oxidation of oil takes place when oxygen and catalysts are in contact with the oil. Both concentration and type of oxygen affect oxidation of oils. The oxygen concentration in the oil depends on the oxygen partial pressure in the headspace of the oil [45]. If the partial pressure of oxygen in the headspace is high, invariably high amount of oxygen becomes dissolved in the oil. The amount of dissolved oxygen is positively associated with enhanced oxidation of the oil. Prooxidants such as

transition metals and light accelerate the effect of oxygen concentration on the oxidation of oil [7, 45]. For example, addition of 70 ppm copper to rapeseed oil exposed to air for 35 days resulted in 70 times higher hexanal concentration compared to the sample devoid of copper [45]. If the oxygen concentration is sufficiently high, the rate of oxidation of oil is independent on oxygen concentrations and vice versa. Ratio of surface to volume of the oil also has influence on the oxidative stability. When the surface to volume ratio is increasing, oil can react more efficiently with oxygen; thus, the relative rate of oxidation is less oxygen-dependent with a low oxygen content [7, 45, 46].

4.5 Prooxidants

Crude oils contain nontriglycerides which can act as prooxidants such as free fatty acids, mono- and diacylglycerols, metals, phospholipids, peroxides, and chlorophylls. Trace amounts of metals such as copper, iron, manganese, and nickel can be absorbed by plants during the growth and during fat and oil processing. These metals substantially reduce the oxidative stability of oils [47]. Transition metal ions are involved in redox reaction, which leads to hydroperoxide decomposition [13]. These metals' effects can be diminished by the use of chelating agents such as citric and phosphoric acids [47].

Free radicals produced during hydroperoxide decomposition act as initiators of autoxidation. Radicals generated from food contaminants may also participate in oxidation process acting as catalysts. Some molecules absorb UV light energy and are converted into an excited singlet state. Pigments such as riboflavin and porphyrins (chlorophyll, hemoglobin, myoglobin) and some synthetic dyes can act as initiators of lipid oxidation [13].

4.6 Antioxidants

Antioxidants are the compounds which inhibit the oxidation of fats and oils. They extend the induction period or slow down the rate of oxidation [7]. The presence of antioxidants (naturally present or intentionally added) is one of the most important factors determining the stability of oils against oxidation.

Tocopherols, tocotrienols, carotenoids, phenolic compounds, and sterols are the naturally occurring antioxidants in plant oils. Among these, tocopherols are the most important antioxidants, especially in soybean, canola, sesame, sunflower, and corn oils. Palm oil contains a high amount of tocotrienols. β-Carotene is one of the important natural antioxidants present in unrefined plant oils. β-Carotene acts as antioxidant by light filtering, singlet oxygen quenching, sensitizer inactivation, and free-radical scavenging [7]. In addition to tocopherols, lignans are important antioxidants in sesame oils, which is well known to possess high stability against oxidation, even though it contains high level of unsaturation [46].

Non-refined oils have a better stability at elevated temperature than refined oils [30] as the refining can lead to reduction in the natural antioxidants. Szydłowska-Czerniak and Łaszewska [48] reported that the refining process of rapeseed oils decreased the antioxidant capacity by about 60% and total phenolic content by above 80%.

5 Oxidative Stability of Important Edible Plant Oils

Edible plant oils can be categorized into three groups based on their fatty acid composition such as oils containing high levels of saturated fatty acids (lauric acid, myristic acid, palmitic acid, and stearic acid), oils with high levels of monounsaturated fatty acids (oleic acid), and oils containing high amount of polyunsaturated fatty acids (linoleic and linolenic acid). Examples for first category include coconut oil and palm kernel oil. Examples for oils with high levels of monounsaturated fatty acid include olive, canola, rapeseed, peanut, hazelnut, avocado, and sesame oils. Corn, soybean, sunflower, cottonseed, grape seed, and safflower are examples for the third category [49]. Table 1 shows the range of fatty acid found in important plant oils.

5.1 Coconut Oil

Coconut (*Cocos nucifera*) oil remains an important edible oil for the food industry for many years. It contains more than 90% of saturated fatty acids [51]. Coconut oil being a highly saturated oil is extremely stable against oxidation, therefore suitable for frying [52]. Lauric acid is the major saturate fatty acid present in coconut oil. The generation of *trans*-fatty acids is also very minimal during frying operations.

5.2 Palm Oil and Palm Kernel Oil

Palm oil and palm kernel oil are obtained from oil palm (*Elaeis guineensis*). In addition to palm oil and palm kernel oil, their fractions are also produced globally to be used for edible purposes. Palm oil is edible oil derived from the fleshy mesocarp of the oil palm fruit, and palm kernel oil is derived from the kernel of the fruit of the oil palm. Palm oil contains almost equal portions of saturated and unsaturated fatty acids, mainly as palmitic acid (42–47%) and oleic acid (37–41%). Palm oil is highly stable against oxidation [33, 53]. Palm kernel oil contains high amount of lauric acid (45–55%), thus known as lauric oil. Fractionation of palm oil into palm stearin and palm olein and palm kernel oil into palm kernel stearin and palm kernel olein further enhances their applications in foods with different stabilities [54].

5.3 Olive Oil

Olive (*Olea europaea*) oil is best suited for food applications involving high temperatures such as frying. Fatty acid composition of the oils determines the suitability of oils for various applications. In this context, the fatty acid composition of the olive oil complies with the criteria of the stable healthy frying oils, that is, olive oil contains high ratio of monounsaturated-to-polyunsaturated fatty acid, low in saturated and polyunsaturated fatty acids, and most importantly very low in linolenic acid [35, 55].

Further, olive oil is considered to be a good-quality frying oil owing to its relatively low melting point; thus, the oil can drain easily from the fried food resulting in low content of trapped oil in the fried food [56].

Virgin olive oil has a higher resistance to oxidative deterioration compared to refined oils because of the presence of phenolic antioxidants such as polyphenols and tocopherols and low polyunsaturation. Polyphenols are eliminated or reduced drastically during the refining process [35].

5.4 Canola (Rapeseed) Oil

The edible canola/rapeseed oil is obtained from low erucic and low glucosinolate species such as *Brassica campestris*, *Brassica napus*, and *Brassica juncea*. Canola oil carries excellent nutritional value because of its unique fatty acid composition with a high amount of oleic acid (50–66%) and also contains linoleic acid (18–30%) and linolenic acid (8–12%) [33, 57]. However, canola oil has less oxidative stability because of the high amount of polyunsaturated fatty acids. Thus, canola oil is subjected to various modifications to improve their oxidative stability such as hydrogenation, fractionation, interesterification, and physical blending [57].

5.5 Soybean Oil

Soybean (*Glycine max* L.) oil is an important plant oil in terms of nutritional quality attributed to its high content of polyunsaturated fatty acids (n−6 and n−3) and tocopherols; however, it is highly susceptible to oxidation [58]. Soybean oil is mainly composed of polyunsaturated fatty acids such as linoleic acid (n−6) (56%) and α-linolenic acid (n−3) (8%) which are considered essential fatty acids as they are necessary for growth and development of the human body. They act as precursors of prostaglandins and hormones which play an important role in the regulation of some physiological and biochemical functions of the human body [58]. However the high amount of linolenic acid reduces oxidative stability of the oil, leading to decreased shelf life [59].

Soybean oil contains relatively high amount of tocopherol compared to other major polyunsaturated oils such as rapeseed, corn, and sunflower [60]. Research

studies have shown that refined soybean oil is highly susceptible to oxidation because of its high content of unsaturated fatty acids and the absence or less amount of natural minor compounds with antioxidant effect [58].

5.6 Sesame Oil

Sesame (*Sesamum indicum*) oil contains mainly monounsaturated fatty acids (45–49%) and polyunsaturated fatty acid (37–41%). It contains thermally stable natural antioxidants as lignans; however, its high content of polyunsaturated fatty acids makes sesame oil highly prone to autoxidation [51].

5.7 Sunflower Oil

Sunflower (*Helianthus annuus* L.) oil contains linoleic (48–74%) and oleic acid (14–39%) as the major fatty acids [33]. High content of unsaturation makes the sunflower oil highly susceptible for autoxidation and less suitable for deep frying. As explained later in this chapter, new phenotypes with modified fatty acid composition, mainly with increased oleic acid content, have been developed through genetic and breeding techniques in order to make the sunflower oil suitable for thermal applications such as deep frying.

6 Improving Oxidative Stability of Oils

6.1 The Use of Antioxidants

Antioxidants are substances that when introduced into substrate at low concentration compared to that of an oxidizable substrate significantly inhibit oxidation of that substrate by inhibiting formation of free radicals or by interrupting propagation of the free radical [61, 62]. Addition of antioxidant during oil processing is one of the most effective means to retard fat oxidation. Antioxidants are of two types based on mechanism of action: primary antioxidants and secondary antioxidants. This can be further classified into natural and synthetic.

6.1.1 Primary Antioxidants

Primary antioxidants are chain-breaking antioxidants, that is, they are capable of neutralizing lipid free radicals by stopping their radical state by donating hydrogen. Butylated hydroxy anisole (BHA), butylated hydroxyl toluene (BHT), tertiary butylhydroquinone (TBHQ), tocopherols, and flavonoids are examples for primary antioxidants [62, 63].

The reaction mechanism can be explained schematically as follows (antioxidant molecule is denoted by AH).

$ROO\bullet + AH \rightarrow ROOH + A\bullet$
$R\bullet + AH \rightarrow RH + A\bullet$
$RO\bullet + AH \rightarrow ROH + A\bullet$
$ROO\bullet + A\bullet \rightarrow ROOA$
$RO\bullet + A\bullet \rightarrow ROA$
$A\bullet + A\bullet \rightarrow A - A$

Some primary antioxidants such as propyl gallate, proanthocyanidins, and ascorbic acid act as antioxidants via more than one mechanisms such as free-radical scavenging, oxygen sequestering, metal chelation, and light energy absorption [64].

6.1.2 Secondary Antioxidants

The secondary antioxidants (preventive antioxidant) retard the rate of oxidation through the removal of the substrate or singlet oxygen quenching mechanism [65–67]. Mechanisms of secondary antioxidants include metal chelating, singlet oxygen quenching and inactivation of photosensitizers and lipoxygenase [7]. Metals act as prooxidants by reducing the activation energy of the oxidation, especially in the initiation step, to accelerate oil oxidation. Metal chelators form insoluble metal complexes or provide steric hindrance between metals and food components. Examples include citric acid, EDTA, polyphenols, lignans, and ascorbic acid [7, 45, 64].

The mechanism of action of singlet oxygen quenchers involves deactivation of singlet oxygen to the ground-state triplet oxygen or getting oxidized themselves by singlet oxygen [7, 68]. Tocopherols, carotenoids, phenolics, and ascorbic acid retard oxidation of lipids through quenching singlet oxygen [69]. Photosensitized compounds such as chlorophyll and riboflavin transfer the energy to triplet oxygen to form singlet oxygen, or transfer an electron to the triplet oxygen to form a superoxide anion radical, which react with lipid to produce free radicals [7]. Energy of the photosensitizers is transferred to the singlet state of antioxidant to become a triplet state of antioxidant, which is changed to singlet state by transferring the energy to the surrounding or emitting phosphorescence. Carotenoids retard lipid oxidation through inactivating photosensitizers [70].

Synergism

Addition of combinations of primary and secondary antioxidants is often reported to have synergistic effect, that is, combined action is more effective to retard lipid oxidation than the sum of their single effect and increases the length of induction period [71, 72].

6.1.3 Natural and Synthetic Antioxidants

Natural antioxidants are found in several plant sources such as grain, seeds, cereals, nuts, fruits, vegetables, and spices [73]. Plant extracts contain various antioxidants such as flavonoids (quercetin, kaempferol, myricetin), catechins or phenols (carnosol, rosmanol, rosamaridiphenol), and phenolic acids (carnosic acid, rosmarinic acid) [74–76]. Tocols are the natural antioxidants found in plant-based oils, which include four tocopherol and four tocotrienol isomers, each designated as

alpha, beta, gamma, and delta on the basis of the chromanol ring. The α-tocopherol has been reported to be the most active isomer biologically, whereas the γ-tocopherol is perceived as the best antioxidant [47]. The vitamin E, most importantly α-tocopherol, is the well-known antioxidant found in vegetable oil. They are known to give protection against peroxidation of polyunsaturated fatty acids [77]. Among all types of tocopherols, α-tocopherol is the most unstable, thus easily destroyed at high temperatures [31]. Juárez and others [44] reported that there were significant losses of α-tocopherol during frying because α-tocopherol degrades more quickly at high temperatures than at room temperature [78].

Vegetable oils containing high amounts of unsaturated fatty acids such as soybean, sunflower, sesame, corn, and peanut oils are very unstable for continuous frying due to their content of polyunsaturated fatty acids. However, the presence of natural substances such as tocopherols, oryzanol, sterol fraction, squalene, among others enhances their stability at higher temperatures [30].

Several studies attempted to study the effect of addition of synthetic antioxidants to the edible plant oils. Azeez and others [67] investigated the effect of direct incorporation of TBHQ, BHT, and mixed (TBHQ and BHT) on the oxidative stability of palm olein, soybean oil, and linseed oil at room temperature and 70 °C for 168 h and reported that TBHQ had significant effect on the oxidative stability of palm olein at 70 °C, while TBHQ and BHT had synergetic effect on stability of soybean oil at room temperature and Linseed oil at 70 °C.

Gertz and others [30] investigated the efficacy of some antioxidants on stability of refined sunflower and rapeseed oils and reported that α-tocopherol, tocopherol esters, and BHA exhibit low antioxidant effects at frying temperature, while ascorbic acid 6-palmitate and some phytosterol fractions were found to possess the greatest antioxidant activity.

Synthetic antioxidants, such as BHT, BHA, and TBHQ, are very effective in edible plant oils to protect against oxidation and, thus, widely used in many oils. However, recently, their use has been discouraged following findings related to possible toxicity and carcinogenicity of these synthetic antioxidants as evidenced by animal studies [79]. For example, BHA and BHT have been shown to possess carcinogenic activity in rodents [80–82]. This has drawn considerable attention to the use of natural antioxidants from plant sources as replacement for synthetic antioxidants for improving the oxidative stability of oils [58, 74].

During the past two decades, research studies have been focused extensively toward the use of natural plant extracts as sources of antioxidants to replace the synthetic antioxidants [79]. In recent years, tendency toward the use of agro-industrial by-products as sources of antioxidant is increasing [73, 74, 83, 84]. Compared to synthetic antioxidants, natural plant extracts have been shown to exhibit higher antioxidant activity and thermal stability which are the most important criteria for an antioxidant to be used for fats and oils [62, 79]. Some examples for such sources include α-tocopherol, pomegranate peel [85, 86], green tea [87], olive waste [88], sesame cake [74], sesame seed [89], rosemary (*Rosmarinus officinalis* L.) [85, 90], *Eucalyptus citriodora* leaf [91], celery [92], oregano (*Origanum vulgare*) [85], cinnamon, and other spices and herbs [62]. In recent years, ascorbyl palmitate is

gaining popularity to be used in edible oils. Ascorbyl palmitate is "generally recognized as safe" (GRAS) according to the Food Drug Administration without limitation on levels to be used in food [70].

Antioxidative effect of α-tocopherol (vitamin E), fat-soluble carotenoid, has been extensively studied [62]. Hraš et al. [93] studied the antioxidative activities of four natural antioxidants such as rosemary extract, α-tocopherol, ascorbyl palmitate, and citric acid in sunflower oil stored at 60 °C. Among them, rosemary extract had the best antioxidative activity. Rosemary extract exhibited additive antioxidative effect when combined with citric acid and ascorbyl palmitate. Further they have reported that α-tocopherol exhibited prooxidative effect. Choe and Min [7] explained that at high concentration, tocopherol radical may abstract hydrogen from lipids with very low concentration of peroxy radical and produces tocopherol and lipid radical, which may increase the lipid oxidation; thus, tocopherol act as prooxidant instead of antioxidant. Thus, the natural antioxidants may not be always preventive against oxidation [94].

Abdelazim and others [74] found that sesame cake extract possesses stronger antioxidant activity than BHT and BHA, however less than that of TBHQ. Hassanien and Abdel-Razek [95] have found that addition of roasted sesame seed as a source of natural antioxidant can improve the stability of edible oils. Sesame seeds contain a myriad of natural antioxidant components including lignans such as sesamin, sesamolin, and sesaminol. In addition to enhancing the stability of oils against oxidation, these compounds play a vital role in maintaining good health. Green tea extracts at higher concentrations than 200 ppm showed excellent antioxidant activity in both oils, and its efficacy was higher than that of BHA, BHT, and α-tocopherol but less than that of TBHQ. Sayyad et al. [90] studied the effect of rosemary extract on thermoxidative stability of soybean oil and reported the higher stability of the soybean oil added with rosemary extract (3000 ppm) than the oil added with TBHQ (50 ppm).

Gertz et al. [30] reported that natural substances such as squalene, sterol fraction, quercetin, oryzanol, and ferulic acid are more efficient than synthetic antioxidants to enhance the stability of vegetable oils at higher temperatures. Further, ascorbyl palmitate is more efficient than BHA or α-tocopherols to increase the stability of vegetable oils during frying at high temperature [30]. Alavi and Golmakani [66] reported that spirulina can improve the oxidative stability of olive oil.

Recently, a study has been reported on the antioxidant activity of encapsulated olive leaf extract in soybean oil. And their results indicated that nano-encapsulation of olive leaf could be a suitable novel technique to improve the antioxidant activity of natural sources [96].

6.2 Modification of the Fatty Acid Composition

Modification of fatty acid composition through natural plant breeding or genetic modification is another way of improving the oxidative stability of vegetable oils [49]. Refined edible oils such as soybean, rapeseed, sunflower, or peanut oils have

high contents of polyunsaturated fatty acids, linoleic, and linolenic acids; thus, they are not suitable for repeated deep fat frying. Even though palm kernel and coconut oils are more stable, their high content of saturated fatty acid limits their applications [97]. Genetic and breeding techniques are employed mainly to alter the composition of saturates, oleic acid, and linolenic acid. High and mid-oleic acid content can increase the oxidative stability at high cooking temperatures [98], especially during deep frying. In recent years, high and mid-oleic acid oil crops developed through breeding techniques by private companies are commercially available [49, 99]. Some examples are Nexera™ (Omega-9 canola and Omega-9 sunflower oils), Plenish™ high-oleic soybeans by E. I. du Pont de Nemours (Wilmington, DE, USA), and Vistive-Gold™ low-saturated high-oleic soybeans by Monsanto Co. (St. Louis, MO, USA) [49, 100, 101]. Some examples for oil crops developed by genetic means to contain higher oleic acid levels than normal include soybean (from 24% to 84%), palm (from 36% to 59%), canola (from 57% to 89%), sunflower (from 29% to 84%), peanut (from 55% to 76%), cottonseed (from 13% to 78%), and safflower (from 10% to 81%) [49]. Soybean phenotypes with linolenic acid less than 4% (low linolenic) and less than 2% (ultralow linolenic acid) have been developed through mutation [59].

High content of linolenic acid is the important factor responsible for the poor oxidative stability of some oils such as soybean oil. Partial hydrogenation of highly unsaturated oils can increase the oxidative stability significantly. However, the use of partially hydrogenated oils is discouraged because partial hydrogenation leads to formation of *trans* fats. Therefore, modification of fatty acid composition by breeding and genetic methods is effective [49]. New phenotypes of soybean, sunflower, corn, safflower, and rapeseed have been produced to have improved oxidative stability as well as nutritional value. High-oleic peanut oil developed through breeding has much greater autoxidation stability as compared to normal oleic peanut oil [102].

6.3 Blending

Blended oils are prepared by blending of different oils together. Blending is a way of modifying the fatty acid composition, physicochemical properties, and functional properties of edible oils without changing their chemical composition [89].

Okogeri [103] studied the frying stability of peanut oil blended with palm kernel oil at different ratios (90:10, 80:20, 70:30 and 60:40) and reported that all blends after used for frying contained less polar compounds than control.

6.4 Modifications in Oil Processing

The heat applied during the conventional oil processing technique accounts for the major loss of natural antioxidants present in edible oils. Cold-pressing oils may help retain higher levels of natural antioxidants to have acceptable shelf life

without added synthetic antioxidants [95]. Oils obtained by cold pressing are known as virgin oils, which are very popular due to their typical color, taste, and flavor. Since there is no heat treatment, most of the natural components are present in the oil [104]. It is reported that cold-pressed olive oil has a stronger antioxidant activity attributed to the presence of natural phenolic compounds [89]. Wroniak et al. [105] have reported that oil flushing with nitrogen was a very effective way to reduce the changes caused by oxidation in cold-pressed rapeseed and sunflower oil.

7 Conclusion

Autoxidation and photosensitized oxidation are the main deteriorative processes that occur in edible plant oils during processing and storage. The oxidation of edible oil leads to the production of off-flavor and toxic compounds and diminishes the oil quality and shelf life. Oxidative stability of edible plant oils is thus the determining factor of the selection of suitable oil for different processing and storage methods. Oxidative stability of oils differs depending on fatty acid composition, the presence of minor components (antioxidants or prooxidants), and the processing or storage conditions, mainly, temperature, light, and oxygen. Oxidative stability of the oils can be improved by modifying the processing conditions such as the use of low temperature, exclusion of light and oxygen, removal of prooxidants, and the use of antioxidants.

Abstract

Cardiovascular diseases (CVD) are the leading cause of death globally. Inflammation is central to the pathology of CVD and is present throughout the atherosclerotic process. Unresolved inflammation can lead to atherosclerosis and the subsequent development of CVD that can cause a major cardiovascular event. Lifestyle and nutrition are modifiable risk factors for the prevention of CVD.

Research shows that some dietary patterns, such as the Mediterranean diet, are associated with a decreased risk of CVD. Polar lipids, which are found in abundance in foods of the Mediterranean diet, are lipids that possess potent anti-inflammatory and antithrombotic effects against the actions of platelet-activating factor (PAF). PAF is potent phospholipid mediator of inflammation that plays a significant role in all stages of atherosclerosis. Bioactive lipids present in various foods can inhibit the pro-inflammatory activities of PAF via their effects on the PAF/PAF receptor (PAF-R) signaling but also via modulating PAF metabolism toward homeostasis. This chapter reviews the relevant research pertaining to the anti-inflammatory and cardioprotective properties of polar lipids in various foods.

Keywords
Polar lipids · Inflammation · Platelet-activating factor · Cardiovascular disease · Mediterranean diet

Abbreviations

CHD	Coronary heart disease
CRP	C-Reactive protein
CVD	Cardiovascular disease
FA	Fatty acids
HDL-C	High-density lipoprotein cholesterol
IHD	Ischemic heart disease
IL-6	Interleukin-6
LDL-C	Low-density lipoprotein cholesterol
Lyso-PAF AT	Lyso-PAF acetyltransferases
MFGM	Milk fat globule membrane
MI	Myocardial infarction
PAF	Platelet-activating factor
PAF-AH	PAF acetylhydrolase
PAF-CPT	PAF-cholinephosphotransferase
PAF-R	Platelet-activating factor receptor
PC	Phosphatidylcholine
PE	Phosphatidylethanolamine
PI	Phosphatidylinositol
PS	Phosphatidylserine
ROS	Reactive oxygen species
SFA	Saturated fatty acids
SM	Sphingomyelin

1 Introduction

Cardiovascular diseases (CVD) are the leading cause of death in Europe accounting for 45% of all deaths; however, with increased success in lifestyle alteration, developing new treatments, and advancements in medicine, CVD mortality is modestly

falling in most European countries. CVD is a collective term used to describe diseases affecting the heart and/or blood vessels and includes coronary heart disease (CHD) also referred to as ischemic heart disease (IHD), cerebrovascular disease, peripheral artery disease, congenital heart disease, hypertension, heart failure, and stroke [1].

However, CHD is still the leading single cause of mortality accounting for 19% of all deaths among men and 20% of all deaths among women each year. Stroke is the second most common single cause of death in Europe, accounting for 9% in men and 13% of all deaths in women each year [2]. Atherosclerosis is a slow progressive vascular disease, which underpins CVD. Atherosclerotic lesions or plaques develop in large- and medium-sized arteries, through the formation of foam cells that leads to a plaque covering a necrotic core in the vessel wall that can fissure, erode, and rupture, resulting in a major cardiovascular event such as a myocardial infarction (MI) [3, 4]. Systemic and unresolved inflammation not only participates in all stages of atherosclerosis but is also proposed as one of the major causes for the development of this disorder and its subsequent CVD manifestations [5].

Increasing evidence suggests that lifestyle and nutrition play a pivotal role, either in the development or in the prevention of chronic diseases such as CVD [6, 7]. It is well-established that several risk factors for CVD are modifiable through dietary and lifestyle changes. Thus, healthy nutrition plays a key role in the primary prevention of CVD, particularly in relation to the attenuation and prevention of systemic inflammation [8]. Over the last 70 years, evidence suggests that the Mediterranean diet may be a particularly healthy dietary pattern, which if adopted can reduce cardiovascular disease risk.

In the last decade, there has been a surge of reviews and meta-analyses referring to the beneficial outcome of the adoption of Mediterranean diet in a plethora of chronic diseases that are either directly or indirectly related to inflammation and chronic diseases such as heart failure and CVD [5, 9–14]. It is thought that this dietary pattern is full of bioactive nutrients that work synergistically to reduce the inflammatory milieu and prevent the onset of chronic disease.

In particular, platelet-activating factor (PAF) seems to play a key role in inflammatory signaling and manifestations associated with all stages of atherosclerosis development and its subsequent cardiovascular disorders. However, specific micronutrients of the Mediterranean diet, belonging to the food-derived polar lipids family, beneficially affect the activities of this potent inflammatory mediator [5]. This chapter reviews the recent literature surrounding the relationship between PAF, inflammation, atherosclerosis, CVD, and the anti-inflammatory properties of food-derived polar lipids.

2 Inflammation and Platelet-Activating Factor

2.1 Inflammation and Cardiovascular Diseases

The human body encounters a large number of stimuli, many of which lead to injury or infections, damaging cells and tissues. Inflammation is a necessary and protective physiological response of the innate immune system designed to overcome such

damage. Upon an inflammatory response, activated immune cells, such as blood leukocytes, produce various agents including reactive oxygen species (ROS), elastases, cathepsins, proteinases, eicosanoids, and other lipid mediators such as PAF that either promote or suppress inflammation. If the injury or infection is unresolved, the inflammatory response becomes chronic, leading to oxidative damage of plasma lipoproteins that results in the inappropriate recruitment of immune cells to the site of the inflammatory response, thus further exacerbating the inflammatory response [15].

Previously, atherosclerosis and CVD were referred to as simply lipid-related disorders due to dyslipidemia (hypercholesterolemia or hyperlipidemia) in humans and various evidence from animal studies. It has long been believed that atherosclerosis is merely involved in the passive accumulation of cholesterol into the arterial walls as part of the formation of foam cells, which was recognized as the hallmark of atherosclerotic lesions and subsequent CVD. However, recent systematic reviews and meta-analyses have begun to question the validity of the lipid hypothesis since they have revealed that there is lack of an association or an inverse association between low-density lipoprotein cholesterol (LDL-C) and both all-cause and CVD mortality in the elderly [16]. As such, these studies underpin the rationale for more research in relation to the cause (and not only the risk factors) of chronic diseases such as atherosclerosis and CVD, but also it may be time to re-evaluate the guidelines for cardiovascular prevention [5].

Even though atherosclerosis and CVD were previously viewed as lipid storage disorders, thanks to recent research advancements, we now recognize that inflammation plays a key role in the initiation and progression of atherosclerosis [5, 17]; chronic and unresolved inflammatory manifestations seem to be the key causative underlying mechanistic players at the molecular and cellular level that are responsible for the onset and development of subsequent inflammation-related chronic disorders such as atherosclerosis and CVD. In particular, endothelial dysfunction plays a significant role [5].

Evidence from epidemiological studies also supports the hypothesis that inflammation is the underlying cause of atherosclerosis and the development of CVD [18, 19]. For instance, it has been demonstrated that elevated levels of C-reactive protein (CRP) and inflammatory markers in the blood are associated with an increased risk of future CVD events, even when classical risk factors have been taken into account [18–22]. Furthermore, several systematic reviews and randomized trials targeting a number of cytokines suggest that low-grade or systemic inflammation precedes incident cardiovascular events, and as such that also implies that inflammation might cause vascular diseases that lead to major CVD events [19].

Inflammation plays a key role in all stages of the formation of vascular lesions maintained and exacerbated by several risk factors such as an unhealthy diet and lifestyle, smoking, hyperlipidemia/hypercholesterolemia, hypertension, autoimmune diseases, etc. [5]. The consequence of chronic inflammation is endothelial dysfunction. Endothelial dysfunction is usually characterized by an inflammatory milieu acting on leukocytes and endothelial cells, through an interplay with other immune cells such as T lymphocytes, neutrophils, mast cells, dendritic cells, and

platelets, which is orchestrated by the overexpression and increased production of pro-inflammatory cytokines, such as interleukin-6 (IL-6), tumor necrosis factor (TNF) and its receptor, CRP, type I interferons (IFN-α, IFN-β), adhesion molecules, chemokines, lipid inflammatory mediators such as PAF and eicosanoids, increased generation of ROS, increased oxidation of LDL-cholesterol, and a reduction of the bioavailability and levels of protective nitric oxide [5]. Inflammation is governed by the crosstalk between all of these molecules and their cellular interactions [5].

Therefore, deciphering the mechanistic pathways implicated in the inflammatory crosstalk in the onset, development, and progression of atherosclerosis is of great importance, in order to unravel possible preventive and therapeutic approaches to CVD, with less side effects [5]. Common junctions in the mechanistic crosstalk of inflammatory mediators, signaling pathways, and cellular interactions that occur during chronic and unresolved inflammation seem to be a promising therapeutic target for the prevention and treatment of inflammation-related chronic diseases. Drug-based therapeutic interventions targeting inflammatory mediators such as cytokines (i.e., by using specific antibodies against pro-inflammatory cytokines and their receptors) and eicosanoids (i.e., by using specific inhibitors of COX-1 and COX-2) have also been proposed, and relevant trials such as CANTOS and CIRT are still in progress. However, such approaches can sometimes lead to undesirable effects and may leave the individual immunocompromised and at greater risk of infections, since disruption of the physiological balance of the immune system seems to be a risky strategy [23, 24]. These observations are clearly due to the multifaceted effects of such mediators in normal physiology.

On the other hand, it is also important to elucidate the mechanistic pathways of inflammation in order to timely and beneficially resolve inflammatory process. Several lipid mediators play specific roles in resolving systemic inflammation [25]. Characteristic examples of such lipid mediators are metabolites derived from omega-3 (ω3) or omega-6 (ω6) polyunsaturated fatty acids (PUFA), including linoleic acid (18:2 ω6), arachidonic acid (20:4 ω6), eicosapentaenoic acid (EPA, 20:5 ω3), and docosahexaenoic acid (DHA, 22:6 ω3). Generally, ω6 PUFA are described as pro-inflammatory, whereas ω3 are described as anti-inflammatory, while the ratio of ω6/ω3 also gives an insight into the correlation between the inflammatory status related to these lipid mediators and several pathologies [26]. Furthermore, Serhan et al. have proposed that the resolution of inflammation is an active process orchestrated by distinct cellular events and endogenous lipid mediators, including lipoxins, resolvins, protectins, and maresins [27–29]. These novel lipid mediators are derived from ω3 and ω6 fatty acids, which may explain some of the mechanistic beneficial effects of dietary PUFA; thus research in this field is ongoing. For instance, ω6 PUFA supplementation from fish oil has been associated with anti-inflammatory and cardioprotective properties, due to their interactions with the eicosanoid pathways [30]. However, recent reviews suggest that the protective properties of ω3 and ω6 may be exaggerated somewhat and have come under scrutiny in recent years. In particular, administration of fish oil supplements high in ω3 may not have any significant beneficial effect against CVD [31]. This will be discussed further in Sect. 3.1.

Since PAF-related inflammatory cascades belong to the most vital joint mechanistic pathways of inflammation-related chronic disorders, these inflammatory pathways have been identified as promising targets for the attenuation of the inflammatory response, with respect to dietary interventions studies, especially to those with foods containing bioactive polar lipids [5, 32]. The inverse effects of the Mediterranean diet on chronic diseases are mostly related to the pleiotropic effects of its food constituents on several of the inflammation-related pathways. For example, following a Mediterranean dietary pattern leads to the reduction of several inflammatory mediators and biomarkers related to the endothelial functionality, such as decreases in plasma CRP, IL-6, and intracellular adhesion molecule-1 (ICAM-1) [33]. Moreover, the Mediterranean diet beneficially affects the PAF pathway and metabolism toward homeostasis. These beneficial effects may be due to the presence of polar lipids with anti-inflammatory potential [5].

2.2 The Role of Platelet-Activating Factor in Inflammation and Atherosclerosis

PAF, 1-*O*-alkyl-2-*sn*-acetyl-glycero-3-phosphocholine [34], is a potent phospholipid mediator, which is characterized by an alkyl ether linkage at the *sn*-1 position, an acetyl group at the *sn*-2 position, and a phosphocholine group at the *sn*-3 position (Fig. 1). These are important structurally distinguishing features that are critical to the biological activity of PAF, which is mediated by stereospecific binding to its specific receptor (PAF-R) [35, 36]. PAF plays a role in several chronic diseases, in particular CVD [5, 37]. The structure of PAF is distinctive due to the position of an ether linkage at the *sn*-1 position; as such moieties are not common in animals. Similarly it is unusual for an acetic acid to be esterified directly to the *sn*-2 position of glycerol. PAF was the first phospholipid known to possess messenger functions by binding to its specific receptor on the cell membrane, rather than by physicochemical effects on the plasma membrane of the target cell [38]. Interestingly, there are several proposed phospholipid structures that are considered part of the "PAF family," a newly coined term to describe these PAF-like molecules that not only share similar

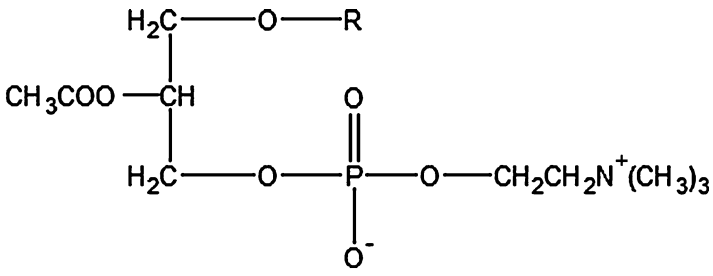

Fig. 1 The structure of the classic platelet-activating factor molecule [34]

structures but can also exhibit similar bioactivities [37]. However, these molecules do not seem to possess the same level of activity as the classical PAF structure, as increasing the chain length beyond three carbons at the *sn*-2 position decreases its biological potency. For instance, there are several compounds synthesized by numerous cells that are similar to PAF but bear a fatty acid instead of a fatty alcohol at *sn*-1 position. These moieties have less than 1% of the potency of PAF. Similarly, modifying the polar group at the *sn*-3 position decreases the potency of the PAF-like molecules [39, 40].

PAF and PAF-like molecules act through their binding to a unique G-protein-coupled seven-transmembrane receptor (PAF-R), which triggers multiple intracellular signaling pathways depending on the target cell and the levels of PAF in the tissue or blood [41]. As a result, PAF is involved in several physiological processes including the modulation of the normal inflammatory response, regulation of blood pressure and the coagulation response, fetal implantation, lung maturation, initiation of parturition, and exocrine gland functions [32]. PAF is most known for its role in anaphylaxis [42] and atherosclerosis [5, 43].

PAF is produced and released in large amounts by inflammatory cells in response to certain stimuli including upstream regulators like IL-1, IL-6, endothelin, TNF-α, and PAF itself [37, 44, 45]. Increased PAF levels at the site of inflammation can activate several cells that can lead to a broad spectrum of effects as a result of PAF production, depending on the type of cell or tissue. This occurs due to the effects of various downstream mediators enhancing production and release of PAF and several other inflammatory mediators, including eicosanoids, TNF-α, IL-1α, IL-6, IL-8, growth factor, and ROS, and the expression of integrins and selectins in the membranes of activated cells [32, 43, 44]. The crosstalk between PAF and various upstream and downstream mediators that affect PAF production seems to be interconnected during inflammatory manifestations [5, 32]. In particular, PAF can induce leukocyte adhesion, leukocyte degranulation, chemotaxis, respiratory burst, and increased vascular permeability [46, 47]. Recently it has been demonstrated that the activation of mast cell PAF-R promotes the immunosuppressive effects of PAF in part through histamine and prostaglandin E_2-dependent mechanisms [48].

The PAF pathways serve as one of the main junctions between many inflammatory cascades that can lead to inflammatory-related disorders such as CVD and cancer [5]. As a result the PAF pathways have been identified as a possible therapeutic target for a number of inflammation-related diseases. Research in this field initially were focused on inhibiting the PAF/PAF-R interactions, thus preventing the initiation of the complex PAF inflammatory pathways [32, 37, 49–52]. Several molecules of synthetic and natural origin [3, 53] have been have been identified, which have the capacity to competitively or noncompetitively displace PAF from its binding sites [54]. Although specific PAF antagonists have exhibited promising results in various studies, the most beneficial effects have been identified in polar lipid extracts of several foods [5]. These food extracts exhibit antithrombotic, antioxidant, and anti-inflammatory activities through inhibiting PAF activities and beneficially modulating PAF levels by altering its metabolism [32]. These molecules are discussed further in Sect. 3.

2.3 PAF Metabolic Enzymes

PAF is biosynthesized at sub-picomolar concentrations [55] and is strictly controlled by two enzymatic pathways known as the remodeling pathway and the de novo pathway [56]. The de novo pathway is catalyzed by a specific dithiothreitol-insensitive CDP-choline, 1-alkyl-2-acetyl-*sn*-glycerol cholinephosphotransferase (PAF-cholinephosphotransferase [PAF-CPT], EC 2.7.8.2) [57], which converts 1-*O*-alkyl-2-acetyl-glycerol to PAF. The remodeling pathway is catalyzed by lyso-PAF acetyltransferases (lyso-PAF ATs, EC 2.3.1.67) [57], which acetylates lyso-PAF. The de novo pathway is known as the minor endogenous PAF synthesis pathway [58], which maintains hemostatic levels of PAF during normal cellular functions [59]. The remodeling pathway is considered the primary enzymatic pathway for PAF synthesis in various inflammatory and allergic disorders [60].

Interestingly, apart from the remodeling pathway which is always activated in both acute and chronic inflammation, the key enzyme of the de novo pathway, PAF-CPT, seems to be more active during chronic inflammatory manifestations, thus contributing to an increase of basal levels of PAF that seem to be related to the continuous activation of inflammatory cascades during the development of inflammation-related chronic disorders [5, 44, 61, 62]. Thus, the regulation of the biosynthetic pathways of PAF seems to be more complicated than was initially thought. In addition, both PAF biosynthetic routes correlate with well-established inflammatory and immunological biomarkers (i.e., several cytokines, viral load, CD40L, etc.) in several chronic diseases [5, 38, 44, 61–66].

Apart from its enzymatic biosynthetic pathways, PAF and PAF-like lipids can also be produced through nonenzymatic synthesis by oxidative transformation of other lipids during oxidative stress or inflammation [55, 67]. When lipids on lipoproteins such as LDL are oxidized, Ox-LDL is produced where bonded PAF-like molecules can mimic the actions of PAF affecting PAF-related inflammation [5]. These pathways are not regulated enzymatically. Vice versa, PAF and PAF-like lipids can also stimulate the production of ROS and nitrogenous species such as reactive nitrogen species (RNS) during oxidative and nitrosative stress in inflammation-induced endothelial dysfunction and atherosclerosis [37].

PAF is catabolized to its biologically inactive form, lyso-PAF, by a specific PAF-acetylhydrolase (PAF-AH, EC 3.1.1.47). The plasma isoform of PAF-AH is known as lipoprotein-associated phospholipase A_2 (Lp-PLA_2) [68], since it circulates in blood in association with plasma lipoprotein particles such as LDL-C and high-density lipoprotein cholesterol (HDL-C), or PLA_2 group 7 [68–71]. PAH-AH also has the capacity to cleave short-chain acyl chains at the *sn*-2 position of oxidized phospholipids, PAF-like phospholipids, and PAF [43].

The amount of PAF present in biological tissue is controlled by the balance of the anabolic and catabolic PAF pathways [72]. Enzymatic biosynthesis of PAF contributes to basal PAF levels and a periodic increase of PAF levels during normal inflammatory responses, while during unresolved and chronic inflammatory manifestations, the enzymatic biosynthesis of PAF is responsible for pathologically increased PAF levels through a continuous induction of the PAF cycle [5]. Oxidative

stress and inflammatory conditions also favor nonenzymatic synthesis of both PAF and PAF-like molecules, such as oxidized phospholipids and oxidized lipids bonded to Ox-LDL. These molecules can amplify the PAF cycle-related inflammatory cascades [5]. On the other hand, PAF catabolism is activated during both acute and chronic inflammatory manifestations and inactivates both PAF and PAF-like molecules, as a homeostatic response against PAF-related inflammatory manifestations. Thus, the PAF metabolic enzymes are implicated in a number of inflammatory manifestations, including heart failure [73, 74], inflammatory bowel disease [72], HIV [62], cancer [44], and atherosclerosis [5].

2.4 Polar Lipids, Inflammation, and Cardioprotection

Polar lipids, such as phospholipids, glycolipids, sphingolipids, etc., are a lipid class that structurally contain hydrophobic hydrocarbon residues and a hydrophilic group such as a carbohydrate group, or a phosphate head group. Phospholipids consist of a glycerol, usually esterified to a saturated long-chain fatty acid at *sn*-1 position, to an unsaturated long-chain fatty acid at *sn*-2 position, and to a phosphorylated head group at *sn*-3 position [8]. Phospholipid head groups are generally cytidine monophosphate, hydroxyl, choline, ethanolamine, serine, or inositols [75]. The general structure of phospholipids is outlined in Fig. 2.

Even though the main function of phospholipids is to support the formation, integrity, and functionality of cell membranes, there are various phospholipid species that possess a plethora of additional functions, in cell signaling, inflammation, and digestion [32]. For example, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) are concentrated in the plasma membrane of macrophages [76] and are major phospholipids in human plasma, where 76% and 17% of the total glycerophospholipids present are PC and PE, respectively [77]. PC and PE are also the most abundant phospholipids in erythrocytes [78]. Dietary phospholipids are usually digested in the lumen, while almost 20% of intestinal phospholipids are absorbed passively and without hydrolyzation and preferentially incorporated directly into plasma lipoproteins. These phospholipids travel through the blood stream and may be incorporated into several cell membranes [32]. The same processes occur for phospholipids baring PUFA within their structures, which are mainly of marine origin. Thus, PC and PE are the largest phospholipid reservoirs of dietary ω3 and ω6 PUFA in the cells and biological fluids involved in inflammatory processes [15]. Other less abundant phospholipids can affect inflammatory responses independent of the production of lipid mediators; cardiolipin, which contains two phosphatidic acids esterified to glycerol, is the most abundant phospholipid in the inner membrane of mitochondria [79]; it can mediate apoptosis [80] and compromise cellular respiration [81] under conditions of oxidative stress. Other phospholipids also seem to contribute directly and/or indirectly to several inflammatory cascades and thus are involved in the onset, progression, and often remediation of inflammatory diseases. These phospholipids include plasmalogens, PAF, oxidized phospholipids, and phospholipids that are carriers of fatty acids precursors of eicosanoids [32].

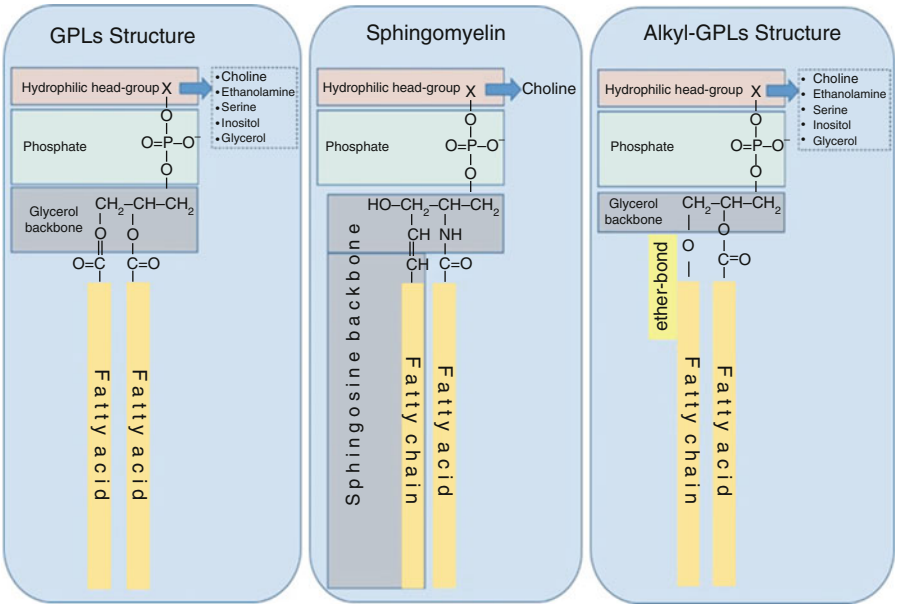

Fig. 2 Phospholipids are generally composed of glycerol, two fatty acids esterified to glycerol at the *sn*-1 and *sn*-2 positions, and a phosphorylated head group esterified at the *sn*-3. The most common structures of various phospholipids are presented. Phospholipids possess a glycerol backbone (GPLs). Sphingomyelin is characterized by a sphingosine backbone (SPLs). Alkyl-phospholipids (Alkyl-GPLs) have a fatty chain linked with an ether bond at the *sn*-1 position of the glycerol backbone. (Reproduced with permission from Lordan et al. [32])

On the other hand, several foods contain bioactive polar lipid compounds that have well-established modes of anti-inflammatory action, whose pleiotropic therapeutic effectiveness and lack of toxicity ensure clinical safety [5, 32]. Dietary polar lipids have been found to exert anti-inflammatory actions in various models of inflammation [3]. Research has shown that there are specific structures of polar lipids that possess antithrombotic and anti-inflammatory effects against PAF [5, 82]. For example, specific PC and PE lipid species of marine origin as well as specific glycolipids in wine and olive oil have exhibited potent bioactivity against PAF-induced inflammation, with beneficial effects against atherosclerosis and CVD [5]. Some of these bioactive structures are presented in Fig. 3. These structures will be further discussed in Sect. 3.

2.5 Diet and Inflammation

Research has established that there is a clear link between an individual's diet and systemic inflammation [84–86]. A maladaptive diet and lifestyle are the dominant underlying causes of low-grade inflammation [87, 88]. Processed and energy-rich

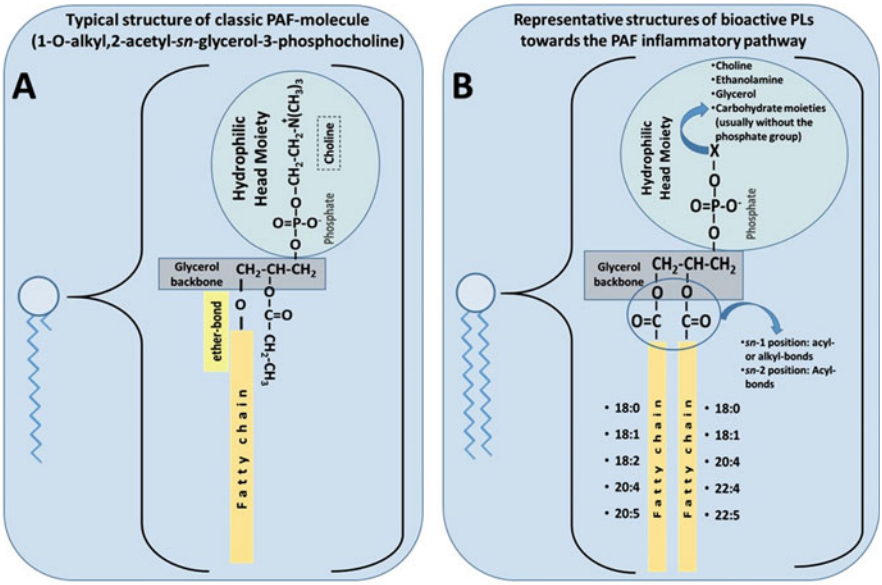

Fig. 3 (**a**) The typical structure of PAF. (**b**) A representative diagram of the bioactive marine phospholipids as elucidated previously by Sioriki et al. and Nasopoulou et al. [82, 83]. Generally, PC and PE derivatives exhibit the greatest biological activity in marine sources. (Reproduced with permission from Tsoupras et al. [5]). *PAF* platelet-activating factor, *PLs* polar lipids

foods and beverages lead to exaggerated postprandial elevations in plasma glucose and triglycerides. As a consequence of our increased intake of these foods in Western societies, postprandial hyperglycemia and hyperlipemia are common [3, 87]. Furthermore, postprandial lipemia is now considered an independent risk factor for CVD, obesity, type 2 diabetes mellitus, and metabolic syndrome [3]. Spikes in glucose and triglycerides can lead to the production of excess plasma ROS that can initiate pro-inflammatory reactions [87–89]. Furthermore, it has been demonstrated that excessive intake of macronutrients such as glucose and saturated fat promotes various inflammatory responses, including an increase in cytokine activity and inflammatory transcription factors [87, 90, 91]. Activated immune cells can either promote or suppress inflammatory processes. It is postulated that prolonged exposure to such inflammatory responses on a daily basis can contribute to the pathogenesis of chronic diseases by establishing a perpetual low-grade inflammatory state [92]; therefore, reducing inflammation to homeostatic levels is essential to avoid long-lasting damage to host tissue [93].

Various dietary patterns can resolve the inflammatory process due to the presence of various bioactive molecules in foods, such as bioactive lipids [3] and peptides [94]. The Mediterranean and Nordic dietary patterns seem to be two such diets that evidence suggests may affect health due to anti-inflammatory properties [95]. Recently, a significant number of studies refer to the beneficial outcomes observed due to the adoption of a Mediterranean dietary pattern in a plethora of several chronic

diseases that are either directly or indirectly related to inflammation [5]. In addition, the Mediterranean diet has also been associated with beneficial outcomes in secondary CVD prevention [12]. When patients suffering from CVD or diabetes adhere to the Mediterranean dietary pattern, the incidence of recurrent myocardial infarction and cerebrovascular events is reduced. The protective effect of the Mediterranean dietary pattern can be maintained for up to 4 years after the first myocardial infarction (Lyon Diet Heart Study) [96]. Moreover, in contrast to the contradictions of lipid hypothesis and mortality in elderly people [16], the HALE project has also shown that individuals aged 70–90 years adhering to the Mediterranean diet and a healthy lifestyle have a 50% lower rate of all-cause and cause-specific mortality [97]. Followers of the Mediterranean diet are also less likely to suffer sudden cardiac death and age-related cognitive decline [14].

The inverse association between Mediterranean diet and all-cause mortality and cardiovascular mortality has been attributed to several of its pleiotropic protective effects. The Mediterranean diet can beneficially influence several risk factors including lowering BMI, blood pressure, and lipid levels (i.e., the ratio of LDL-C/HDL-C), reducing insulin resistance, and improving HDL-C functionality. However, the main beneficial impact of Mediterranean diet seems to be associated with the improvement of endothelial function and a decrease of the inflammatory milieu. It seems that the reduction of inflammation-related mediators and biomarkers such as PAF and several cytokines and of oxidative stress (with lower concentrations of oxidized LDL and improved apolipoprotein profiles) and platelet aggregation and blood coagulation are responsible for the observed beneficial effects of the Mediterranean diet [5, 8, 32].

Even though the beneficial outcomes of healthy dietary patterns such as the Mediterranean diet are profound and well documented, in Westernized and developing countries, there is an increase in the consumption of ultra-processed foods, which is associated with systemic inflammation [87, 98] and may contribute to the rise in noncommunicable diseases. It is suggested that reducing the dietary share of ultra-processed foods by increasing the consumption of unprocessed or minimally processed foods and freshly prepared meals made from these foods can be an effective way to substantially improve the substantial and nutritional quality of Westernized societies. However, given the ubiquity of ultra-processed foods in general, radical whole population strategies are needed to achieve the necessary reductions in ultra-processed food consumption [99].

3 Food Polar Lipids with Anti-inflammatory and Cardioprotective Properties

Polar lipids from various foods, particularly from foods of the Mediterranean diet, seem to exhibit biological activities against the PAF pathway [5]. Some polar lipids act as PAF antagonists that block the binding of PAF with its receptor, and others act as PAF-R agonists but, as aforementioned, possess far less potency than PAF itself. Polar lipids are also thought to directly or indirectly interrupt the binding of PAF to

its receptor by altering the lipid raft microenvironment of the PAF-R in cell membranes and thus its subsequent intercellular pathways [32]. In addition, polar lipids can modulate the activities of the regulatory metabolic enzymes of PAF. Several studies show that these lipid constituents can downregulate the metabolic enzymes that control PAF biosynthesis and upregulate the enzymes responsible for PAF degradation [61, 100]. Thus, dietary patterns based on foods rich in such bioactive polar lipids seem to possess beneficial effects through the modulation of PAF metabolism toward homeostatic PAF levels and activities [5]. Bioactive polar lipids are present in various foods of the Mediterranean diet and seem to exhibit specific structures (Fig. 3). These foods include fish, dairy, wine, olive oil, and various other foods. Interestingly, the anti-inflammatory properties of various types of polar lipids seem to be as a result of a synergistic effect between the different polar lipids [5]. The various sources of polar lipids and their bioactivities are discussed.

3.1 Fish Polar Lipids

Epidemiological studies and clinical trials have demonstrated the protective role of fish and fish oil consumption against CVD [101], while their nutritional benefits have mainly been associated with their omega-3 PUFA content [102, 103]. However, several recent reviews and meta-analyses have concluded that insufficient evidence exists to suggest a beneficial effect of ω3 PUFA supplementation in adults with chronic diseases such as atherosclerosis and CVD [31, 32]. It is now well-established that more complex mechanisms underlie the beneficial effects of fish and fish oil consumption and administration of marine products that go far beyond the ω3 PUFA-/eicosanoid-related mechanisms [32]. Other lipid constituents are also present in fish and fish oils that have different metabolic effects after absorption with distinct biological activities not only limited to their superior incorporation to plasma lipoproteins and cell membranes and bioavailability of their omega fatty acids but also to their reported anti-inflammatory activities through also other mechanisms than the ARA/eicosanoid pathway, such as the inhibition of the PAF pathway and the modulation of PAF metabolism [32].

Fish contains between 1% and 1.5% phospholipid by weight, where PC derivatives are generally the predominant phospholipids followed by PE, phosphatidylinositol (PI), phosphatidylserine (PS), lyso-PC, and sphingomyelin (SM) [32]. Polar lipids of fish exhibit both in vitro antithrombotic [82, 83, 104–109] and in vivo antiatherogenic properties [110]. In 1996, Rementzis et al. [104] reported the presence of polar lipids in *Scomber scombrus* (mackerel) that exhibited inhibitory activity against PAF and thrombin-induced platelet aggregation. This leads to a series of other studies that identified polar lipids in various fish species that exhibited effects against PAF in vitro and in vivo [32].

Notably, Nasopoulou et al. have explored the anti-PAF and antiatherogenic properties of marine polar lipids in a series of studies that examined the polar lipid extracts from wild and cultured sea bass (*Dicentrarchus labrax*) and sea bream (*Sparus aurata*). These polar lipids seem to exhibit strong agonistic and antagonistic

effects against PAF-induced platelet aggregation [106, 110, 111], and they seem to inhibit the activities of the basic biosynthetic enzymes of PAF [61]. Furthermore, an in vivo study separated 12 healthy male New Zealand rabbits of specific weight and age into 2 even groups: A and B [110]. Group A was given an atherogenic diet for 45 days as was group B; however, the group B diet was also supplemented with marine polar lipid extracts from *Sparus aurata.* After 45 days the HDL-C levels were significantly increased in the rabbits that were supplemented with marine polar lipids in comparison with the control group. In addition, PAF catabolic enzyme activity (plasma PAF-AH) was significantly increased, and platelet aggregation efficiency was reduced in the rabbits fed marine PL in comparison with the control group. Of greater significance was the fact that hypercholesterolemic rabbits supplemented with polar lipids developed early atherosclerotic lesions that were of a statistically significant lower degree ($p < 0.017$) than that of the control group as demonstrated in Fig. 4. It seems the overall anti-PAF effects exhibited by the marine polar lipids led to a reduction in the formation of foam cells indicating that these lipids possess antiatherogenic properties and thus may explain some of the beneficial effects observed due to fish consumption.

A follow-up study was published that utilized plasma from the same rabbits fed the same fish polar lipids, which investigated the effects of the polar lipids on PAF biosynthesis and PAF catabolism [64]. The specific activity of PAF-AH was decreased in rabbits' platelets of both groups A and B and in rabbits' leukocytes of group A ($p < 0.05$). On the other hand, the specific activity of Lp-PLA_2 was increased in both groups A and B in both leukocytes and platelets ($p < 0.05$). PAF-CPT demonstrated an increased specific activity only in rabbits' leukocytes of group A ($p < 0.05$). Neither of the two groups showed any change in lyso-PAF-AT-specific activity ($p > 0.05$). Free and bound PAF levels increased in group A while decreased in group B ($p < 0.05$). These results indicate the fish polar lipids modulate PAF metabolism upon atherosclerotic conditions in rabbits leading to lower PAF levels and PAF activity in the blood of rabbits with reduced early atherosclerotic

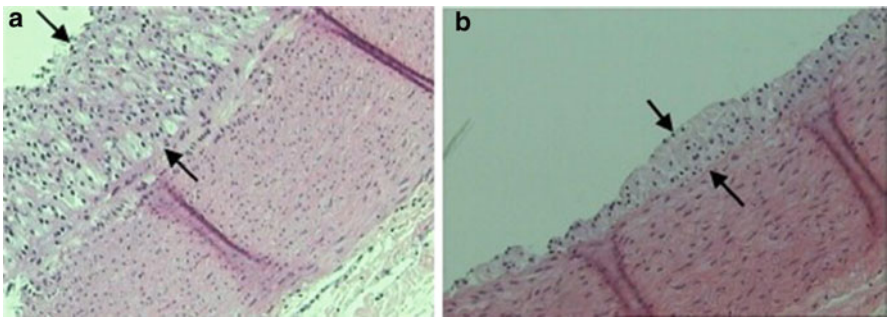

Fig. 4 Representative optic micrographs x100 of aortic wall sections stained with hematoxylin and eosin from the two experimental groups, where atherosclerotic lesions appear as foam cells between the arrows. (**a**) Group A (atherogenic diet); (**b**) group B (atherogenic diet enriched with marine polar lipids)

lesions compared to the control group. Therefore, it can be said that the joint inhibitory effects of these lipids against PAF/PAF-R interactions and the ability to modulate the catabolic and biosynthetic enzymes of PAF are due to the intake of the polar lipids in this investigation. Further studies are required to see if these effects are demonstrated in other animal models and in human studies.

Notably, recent studies have revealed the existence of bioactive polar lipids in several oily fish species, such as sardines. Polar lipids were also present in cod liver oil, which is the main source of marine-derived health [112]. Sardine polar lipid extracts possessed a higher content of bioactive polar lipids that also demonstrated higher antithrombotic activities against platelet aggregation when compared to that of fish oil derived from cod liver oil [112]. Similar studies in Irish organic farmed salmon (*Salmo salar*), another oily fish species, revealed that Atlantic salmon is also a rich source of bioactive polar lipids with potent antithrombotic activities against platelet aggregation [113]. Moreover, it was revealed that the antithrombotic effects of salmon polar lipids were attributed to their anti-PAF effects, since they exhibited potent inhibitory effects against PAF-induced human platelet aggregation and much less potent effect toward thrombin-induced platelet aggregation. It was thus proposed that these bioactive polar lipids seem to act synergistically against platelet aggregation either by inhibiting PAF-induced activities or by very low agonistic effects to its receptor [113]. Structural elucidation of these salmon-derived polar lipids revealed that they also belong to the alkyl-acyl PC and alkyl-acyl PE derivatives that bare ω3 PUFA such as the EPA and DHA at the *sn*-2 position of their glycerol backbone [113]. These results suggest that salmon is a source of bioactive polar lipids rich in ω3 PUFA and that the physiological and pleiotropic beneficial effects of marine polar lipids can be attributed to the coexistence of both important structural elements such as their polar head groups and the constituting PUFA within their structures.

3.2 Dairy Polar Lipids

The negative perception of dairy fats stems from the effort to reduce dietary saturated fatty acid (SFA) intake due to their association with increased cholesterol levels upon consumption and thus an increased risk of CVD development [3, 114]. However, recent research and meta-analyses have demonstrated the benefits of full-fat dairy consumption, based on greater bioavailability of high-value nutrients (such as vitamin D) and anti-inflammatory properties [114]. Dairy products contain a complex lipid profile and are distinguished by the fact that they are the most natural source of short-chain fatty acids (C4–C8, 4–13 wt% total FA), which are generally esterified on the *sn*-3 position of the triglyceride [115]. The nonpolar lipids or neutral lipids (triglycerides or TG; 96–97% of milk lipids), the polar lipids (glycerophospholipids, sphingolipids, glycosphingolipids, glycolipids; 0.2–2% of milk lipids), and cholesterol create an oil in water emulsion to form milk. These lipids form spherical milk fat globules that contain triacylglycerides (0.1–15 μm) that are surrounded in a complex trilaminar membrane (4–12 nm) composed of proteins,

phospholipids, and sphingolipids, suspended in an aqueous liquid phase, which is derived from mammary endothelial cells [116]. This unique structure is the milk fat globule membrane (MFGM), which mainly consists of lipids (40%), proteins (60%), and cholesterol [117]. The membrane of the outer leaflet consists of phospholipids and cholesterol, which stabilizes the triglyceride-rich milk fat globule against coalescence and protects the core from lipolytic degradation and oxidation [32]. The MFGM structure is depicted in Fig. 5.

Other sources of phospholipids in dairy products include MFGM fragments and lipoprotein particles, which are believed to be remnants of the mammary secretory cell membranes. Similar to the MFGM, phospholipids originate from the apical plasma membrane of the mammary gland secretory cell [116–122]. The phospholipids present

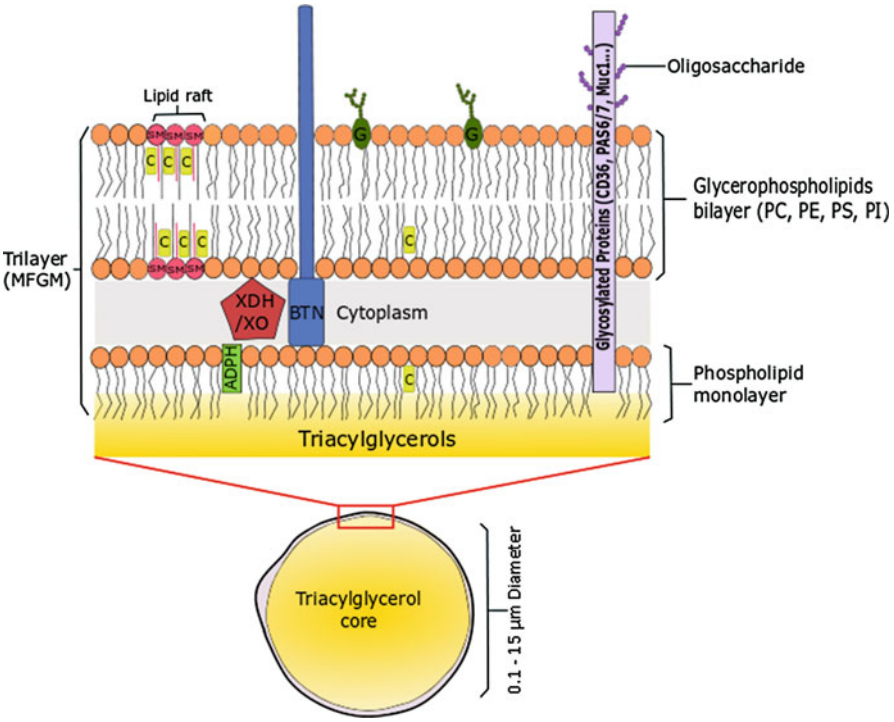

Fig. 5 Illustration of the milk fat globule membrane (MFGM). The sizes in this schematic are not in proportion. A phospholipid monolayer surrounds the triacylglycerol core, followed by a proteinaceous coat connecting the monolayer to the outer phospholipid bilayer. Adipophilin (ADPH) is located in the inner layer polar lipid layer, while xanthine dehydrogenase/oxidase (XDH/XO) is located between both layers. PE, PS, and PI are generally concentrated on the inner surface of the membrane, whereas PC, SM, glycolipids (G), cerebrosides, and gangliosides are mainly located in the external membrane. SM and cholesterol (C) can form rigid domains in the cellular membrane known as lipid rafts. Glycoproteins are distributed over the external membrane surface; these include butyrophilin (BTN), mucin 1 (MUC1), PAS 6/7, and CD36. (Reproduced with permission from Lordan et al. [32])

Table 1 Typical phospholipid composition of bovine, caprine, and ovine milk

Dairy polar lipids	TPL[a]	PC[b]	PE[b]	PI[b]	PS[b]	SM[b]
Bovine milk [118, 130–132]	0.3–1.1	20–40	20–42	0.6–12	2–11	18–35
Ovine milk [133]	0.2–1.0	26–28	26–40	4–7	4–11	22–30
Caprine milk [133]	0.2–1.0	27–32	20–42	4–10	3–14	16–30

in bovine, caprine, and ovine milks are quantitatively minor lipid constituents of milk; however they possess several beneficial techno-functional properties and are involved in various physiological processes making them nutritionally valuable [32].

Research by our group has demonstrated that bovine, ovine, and caprine dairy products possess polar lipids with potent anti-inflammatory activities against PAF as demonstrated in a series of in vitro experiments on washed rabbit platelets [123–125]. Research has shown that as milk is fermented to yoghurt and then to cheese, the bioactivity of the PAF inhibitors seems to increase [3]. This indicates that the processes of fermentation and lipolysis are crucial to altering the bioactivity of the polar lipid fractions of milk, and this bioactivity increases the further fermentation proceeds [3, 114]. It is thought that the fermentation process alters the fatty acid composition of the polar lipids, thus leading to variation in the biological activity, depending on the microorganisms used. Therefore, yoghurt and cheese seem to exert greater biological activity against PAF than just milk polar lipids. In particular, these effects have been attributed to microorganisms such as *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Streptococcus thermophilus*, which are commonly used in yoghurt production [3, 126]. However, further research is required to identify whether these microorganism may also play a role in the biosynthesis of these bioactive lipids or if they interact with the MFGM. It is also imperative to identify other fermented foods that may contain bioactive polar lipids such as wine, beer, and *kefir* in order to elucidate and establish how fermentation impacts the health effects of various foods.

Research also indicates that polar lipids of caprine and ovine milk and dairy products possess greater bioactivity against PAF than those of bovine milk and dairy products [125, 127]. This may be due to their varied phospholipid content (Table 1). Therefore, further research is required to confirm these observations. Furthermore, polar lipids seem to be bioavailable in in vivo and clinical studies and seem to be able to exert their biological activities [110, 128, 129]; thus whether dairy lipids share the same bioavailability remains to be seen.

3.3 Wine Lipid Microconstituents

Associations between wine consumption and the "French paradox" motivated intensive research into the health benefits of moderate wine consumption. The nutritional

superiority of wine over other alcoholic beverages is thought to be attributed to microconstituents within wine that contain bioactive compounds whose mechanistic pathways are currently under investigation [134]. Alcohol consumption has a complex relationship with human health, and the harmful effects of alcohol are well-known and in contrast to the beneficial effects [135]. Various studies have linked excessive alcohol consumption to various chronic diseases and conditions including cancers and liver cirrhosis [136]. Despite these negative associations, moderate alcohol consumption is associated with a number of health benefits [135]. Research indicates that moderate alcohol consumption (1–2 drinks/day) is associated with positive effects against a number of cardiovascular risk factors [134, 137, 138]. In addition, large epidemiological studies have demonstrated that moderate alcohol consumption significantly reduces cardiovascular risk factors, morbidity, and mortality through a dose-effect relationship that is characterized by a J-shaped curve [138].

Generally, wine contains between 12% and 15% (v/v) ethanol. The ethanol content of wine is associated with a number of beneficial effects including alterations of plasma lipoproteins and modifications of blood platelet function and coagulation [139]. However the benefits of moderate ethanol intake due to alcoholic beverage consumption can only partly explain the protective effects of wine [140]. Mechanistically, lipid and phenolic microconstituents in wine may play a role in attenuating inflammatory processes associated with CVD. Phenolic compounds include phenolic acids (p-coumaric, cinnamic, caffeic, gentisic, ferulic, and vanillic acids), trihydroxy stilbenes (polydatin and resveratrol), and flavonoids (catechin, epicatechin, and quercetin), while their polymerization gives rise to the viniferins and procyanidins. The phenolic content of white wines is considerably lower than red wines due to their manufacturing process. Red wines are usually produced with the grape skins, whereas white wine is generally produced from free-running juices that do not have contact with the skin of the grapes [140, 141]. Initially, the biological activity of wine was attributed to their antioxidant properties; however, currently it is well-established that wine consumption is associated with anti-inflammatory activities [142], and these cardioprotective effects are induced irrespective of their antioxidant properties.

In fact, these anti-inflammatory effects may be attributed to the anti-PAF effects of various lipid and phenolic microconstituents within the wine [140]. Studies show that polar lipids in wine can inhibit the biological actions of PAF [143–146] and modulate enzymes involved in PAF metabolism in vitro [147]. Interestingly, within these studies it was also unexpectedly revealed that white wines, musts, and the specific grapes that produced the white wines possessed polar lipids with potent anti-PAF activities, while structural elucidation of these lipids revealed that they were mostly glycoglycerolipids or glycol-glycerophospholipids and not phenolic compounds [143, 144, 146], supporting the notion that their beneficial effects can be attributed to their anti-PAF effects and not to any putative antioxidant effects.

Clinical studies have also been conducted, which demonstrate that the beneficial effects of wine consumption may be due to bioactive components in wine that affect platelet function. Most notably, in the pursuit for answers to the observed French

paradox, researchers saw a reduction of platelet aggregation due to moderate alcohol consumption [148, 149].

Clinical studies have been conducted that demonstrate that wine consumption may exert its anti-inflammatory effects through the modulation of PAF interaction with the PAF-R and PAF metabolism. A recent study took ten healthy men who participated in four daily trials on separate days. They consumed a standardized meal along with white wine, red wine, an ethanol solution, or water. Blood samples were collected before and after meal consumption and at several time points over a 6-h period, and various hemorheological values were determined. It was found that wine consumption improved platelet sensitivity independently of the alcohol, triglyceride levels were lowered during postprandial elevations, and plasminogen activator inhibitor-1 levels were not impacted negatively by the alcohol consumption. These effects are attributed to the presence of PAF inhibitors in wine [129]. A similar clinical study by the same group also examined the postprandial effects of wine consumption on the PAF metabolic enzymes. The same trial methodology, standardized meal, wines, and controls were used. It was found that consumption of wine, but not alcohol alone, reduced the activity of specific PAF biosynthetic enzymes (PAF-CPT and lyso-PAF AT) during postprandial elevation, thus attenuating postprandial inflammation [150]. Again these effects have been attributed to microconstituents within wine that exhibit potent anti-PAF effects. It seems that the attenuation of the inflammatory may be as a consequence of the attenuation of PAF levels by lipid microconstituents and/or polar lipids that act as PAF inhibitors. Further research is required to further our understanding of this phenomenon and to discern whether these effects are seen in other fermented alcoholic beverages such as beer or spirits.

3.4 Polar Lipids of Olive Oil and By-Products

Virgin olive oil is the main source of dietary lipid in the Mediterranean diet, and it has been linked to numerous health benefits including reduced systolic blood pressure, an enhancing effect of T-cell-mediated function, and an increase in HDL-C [151, 152]. The beneficial effects of olive oil consumption have been attributed to its high concentration of monounsaturated fatty acids (MUFA), namely, oleic acid [153, 154]. However, other seed oils have similar levels of MUFA but do not seem to possess the same biological activity. Therefore, research has turned its attention to other compounds such as polar lipids or phenolic compounds [155]. Polar lipids of virgin olive have demonstrated antagonistic effects against PAF, and following various chromatographic separations, the most active fraction was identified as a glycerol ether glycolipid [156].

A subsequent in vivo study aimed to investigate the effects of virgin olive oil consumption in 40 male hypercholesterolemic white New Zealand rabbits [128]. The rabbits were randomly distributed into four groups. Group A were fed an atherogenic diet containing cholesterol; group B were fed the same atherogenic diet supplemented with 15% (w/w) virgin olive oil; group C were fed atherogenic

diet supplemented with olive oil polar lipids isolated from the same volume of olive oil supplemented in group B; finally, group D were fed the atherogenic diet supplemented with olive oil neutral lipids isolated from the same volume of olive oil supplemented in group B. Baseline measurements were taken for a number of parameters, and the rabbits were fed their respective diets for 45 days before testing and prior to being euthanized. Rabbits that received the polar lipid extract had a significant reduction of early atherosclerotic lesions compared to group A that received only an atherogenic diet, and they also retained the elasticity of the aortic wall. Rabbits that received neutral lipids of olive oil did not exhibit a reduction in early atherosclerotic lesions compared to the control group. PAF levels in the blood were higher for group A and decreased in group D by day 45. In group A, along with increased PAF levels, PAF-AH was also increased, atherosclerotic lesions formed, and vessel wall elasticity was decreased. In groups B and C, blood PAF-AH increased, platelet aggregation was attenuated, less oxidation occurred in the plasma, lesion thickness was reduced, and vessel wall elasticity was retained. However, most of these effects were not observed in animals fed neutral lipids (group D), although blood PAF and plasma oxidation were lower [128]. This study demonstrated for the first time that it was the polar lipid composition of the virgin olive oil that was responsible for the antiatherogenic activities observed [155].

Interestingly, studies have also shown that polar lipids present in the by-products of the olive oil industry possess potent antithrombotic, anti-inflammatory, and anti-PAF activity in vitro and in vivo [157–159]. It has also been shown that these lipids may also beneficially modulate PAF metabolism toward the reduction of PAF levels to homeostatic levels, thus explaining the rationale for their observed in vivo effects on reducing PAF levels [100].

Olive pomace is one of two major by-products of the olive oil industry, the other being olive mill wastewater. Unfortunately, for every 100 kg of olive oil produced, there is 35 kg of olive pomace produced that is generally an underutilized waste product, which has been proposed as a viable alternative to fish oil in the aquaculture industry [160]. In a study by Nasopoulou et al. [107], cultured fish (*Dicentrarchus labrax* and *Sparus aurata*) were fed olive pomace as a substitute for fish oil in fish feed. These fish demonstrated satisfactory growth performance and statistically decreased levels of fatty acids while also possessing potent inhibition of PAF-induced platelet aggregation. A follow-up study demonstrated that the most active polar lipid fractions were specific PC and PE derivatives [83]. Overall, studies carrying out structural elucidation of fish polar lipids from fish fed a diet enriched with olive pomace indicate that the most biologically active lipid fractions contain various diacyl-glycerophospholipid species that seemed to mainly consist of 18:0 or 18:1 fatty acid in the *sn*-1 position and either 22:6 or 20:2 fatty acids in the *sn*-2 position [82, 83]. The proposed structures of these novel bioactive phospholipid species are demonstrated in Fig. 3. Therefore, replacing fish oil in the diet of sea bream and sea bass may improve their cardioprotective effects upon consumption by humans while also tackling the problems associated with by-products of the olive oil industry.

3.5 Various Foods of the Mediterranean Diet

It is well-accepted that lifestyle plays a crucial role in the prevention of CVD [161]. Evidence suggests the most important behavioral risk factors of CVD are an unhealthy diet, physical activity, and harmful use of alcohol and tobacco [162]. Previous research has focused on targeting specific nutrients, particularly the reduction of SFA in an individual's diet; however, recent research indicates that this approach was short-sighted and ineffective and that nutritional interventions in CVD have proved to be an effective strategy with tangible evidence, indicating that the synergistic effects of food combined into a dietary pattern provide the maximum benefit obtainable from nutrition [5, 9, 114, 163]. It seems that most are in agreement that the optimal dietary pattern to reduce CVD includes high consumption of fruits, vegetables, legumes, whole grains, nuts, fish, and poultry, moderate dairy and heart-healthy vegetable oil intake, low red meat intake, and minimal consumption of refined grain products, added sugars, industrial *trans* fats, sugar-sweetened beverages, and processed meat [163, 164]. The Dietary Approaches to Stop Hypertension (DASH) diet and Mediterranean diet reflect these dietary patterns and are palatable, relatively easy to adhere to, and continually recommended for good cardiovascular health [5, 9, 163, 165, 166]. Certainly, while nutritional research should move away from simply focusing on single nutrients as a panacea to prevent CVD, it is important to recognize that it is most likely these nutrients working synergistically together in the diet that leads to the beneficial effects observed against CVD.

There have been several studies published that have identified various food sources containing anti-inflammatory polar lipids. Many of these foods are found in the Mediterranean diet. The traditional Mediterranean diet originates in the olive-growing regions of the Mediterranean and has strong cultural associations with these areas [95]. Various definitions of the Mediterranean diet have been proposed, and the diet has been adopted beyond the Mediterranean region and becomes increasingly medicalized as both a treatment and prevention intervention [167]. Despite these variations, the Mediterranean diet remains based on fresh, seasonal, and local food [166]. The Mediterranean diet is generally characterized by the high consumption of fruit, vegetables, legumes, cereal foods (preferably whole grains), breads, tree nuts, and olive oil, including moderate servings of milk, dairy products, eggs, fish, shellfish, and white meat, and low consumption of processed foods or red meats. Wine is consumed in moderation in non-Islamic countries, and coffee is considered the hot beverage of choice, which nowadays is consumed with sugar [168–170]. In addition, the Mediterranean diet has qualitative cultural and lifestyle elements, such as conviviality, culinary activities, adequate rest, and physical activity [171], which seem to be key for good health and longevity as witnessed in the Blue Zones [5]. However, whether these cultural aspects are vital to the success of the Mediterranean diet or they simply improve the health effects observed through a healthier habitual lifestyle approach requires further in-depth research.

The Mediterranean diet is rich in beneficial fatty acids with a characteristically high content of MUFA and a higher MUFA/SFA ratio than other diets [172, 173]. Due

to the low glycemic index and glycemic loads [174], high dietary fiber [175], and anti-inflammatory effects [176], the Mediterranean diet is synonymous with favorable effects on health status. Evidence suggests that Mediterranean diet is associated with a number of beneficial health effects, including lower incidences of several chronic diseases such as CVD [9, 14], cancer [177, 178], diabetes [179], and neurodegenerative diseases [180, 181]. It has been proposed that these associations are mainly due to the anti-inflammatory nature of the Mediterranean diet [5, 182].

In particular, evidence suggests that these effects may in part be due to the presence of bioactive polar lipids in foods of the Mediterranean diet, which possess inhibitory properties against PAF activities [5, 183]. The polar lipids found in foods of the Mediterranean diet exhibit in vitro and in vivo anti-inflammatory activities through either directly or indirectly inhibiting the PAF/PAF-R pathways and thus PAF activities but also by downregulating its levels through modulating the activities of key metabolic enzymes of PAF by either upregulation of the PAF catabolic enzymes or the downregulation of the basic PAF biosynthetic enzymes [44, 61, 64, 100, 147, 150]. These polar lipid microconstituents in association with various other beneficial components of the Mediterranean diet may be responsible for the observed preventative effects of the Mediterranean diet against the development of CVD. Several of the foods that have demonstrated anti-PAF effects are presented in Table 2 along with other foods and components of the Mediterranean diet that exhibit inhibition of PAF-related inflammatory pathways and manifestations.

Notably, the uptake of dietary polar lipids seems to beneficially affect the functionality of HDL lipoproteins especially in atherosclerotic conditions [5]. HDL-C is generally described as the "good" cholesterol, since it removes excess cholesterol from the blood stream and from atherosclerotic plaques, and it has exhibited anti-inflammatory and antioxidative properties through a plethora of cardioprotective enzymes bonded to HDL, including the aforementioned PAF-AH enzyme activity, which is the main catabolic enzyme of PAF [71]. These HDL-associated activities contribute to the maintenance of endothelial cell homeostasis, which protects the cardiovascular system [191]. Plasma PAF-AH is also found in atherosclerotic lesions, since it comigrates there along with the lipoproteins (i.e., LDL-C), where it is incorporated. Plasma PAF-AH (Lp-PLA_2) mainly plays an anti-inflammatory role in leukocyte/platelet/endothelium activation and seems to suppress atherogenic changes in plasma lipoproteins (such as LDL-C) by promoting the catabolism of PAF and by removing oxidized phospholipids present in Ox-LDL. These oxidized phospholipids mimic the actions of PAF and are generated by oxidative modifications of lipoproteins such as LDL during pro-atherogenic and atherosclerotic events [5, 68, 70, 71]. Thus, during inflammatory cascades that increase PAF levels, this isoform of PAF-AH ($LpPLA_2$) seems to be activated as a homeostatic mechanism to down-regulate these events, by downregulating the levels of PAF and oxidized phospholipids, as a terminator signal [192].

Thus, HDL and its enzymes, including PAF-AH, seem to protect against these manifestations. Dietary intake of bioactive polar lipids, particularly those baring ω3 PUFA, increases HDL-C levels and the incorporation of such anti-inflammatory and antioxidant dietary polar lipids to HDL, thus providing an additional protective

Table 2 Studies on the beneficial impact of microconstituents from foods of the Mediterranean diet, such as polar lipids and vitamins, toward inflammation-related disorders, through their effects on the PAF pathways and metabolism. (Modified with permission from Tsoupras et al. [5])

Studied food and components	Type of study	Results
PL of goat and sheep meat	Ex vivo studies in hPRP	Inhibition of PAF-induced platelet aggregation [193]
PL of red and white wine, musts, grape skins, and yeast	In vitro studies in WRP and in U937 macrophages In vivo postprandial dietary interventions studies in humans	Inhibition of PAF-induced platelet aggregation and modulation of PAF metabolism toward reduced PAF levels [129, 134, 143, 144, 146, 147, 150]
PL of fish (sea bass, sea bream, salmon, etc.)	In vitro studies in WRP, hPRP, and HMC Ex vivo studies in hPRP In vivo studies in hyperlipidemic rabbits	Inhibition of PAF-induced platelet aggregation, modulation of PAF metabolism toward reduced PAF levels, and reduction of the thickness of atherosclerotic lesions in hypercholesterolemic rabbits [61, 64, 82, 83, 104–107, 109–111, 113, 184]
PL of olive oil and olive pomace	In vitro studies in WRP and in HMC In vivo study in hyperlipidemic rabbits	Inhibition of PAF-induced platelet aggregation, modulation of PAF metabolism toward reduced PAF levels, reduction of the thickness of atherosclerotic lesions in hypercholesterolemic rabbits, and regression of the already formed atherosclerotic lesions [100, 128, 156, 157]
PL of seed oils (soybean, corn, sunflower, and sesame oil)	In vitro studies in WRP	Inhibition of PAF-induced platelet aggregation [156]
PL of hen egg	In vitro studies in WRP	Inhibition of PAF-induced platelet aggregation [185]
PL of dairy products (milk, yoghurt, cheese, etc.)	In vitro studies in WRP and ex vivo studies in hPRP	Inhibition of PAF-induced platelet aggregation [114, 123–125]
Lipid extracts from garlic	Ex vivo studies in hPRP	Inhibition of PAF-induced platelet aggregation and de-aggregation of aggregated platelets [186]
Vitamin D and its analogues	In vitro studies in WRP and human leukocytes, ex vivo studies in hPRP, and in vivo studies in hemodialysis patients	Inhibition of PAF-induced platelet aggregation and modulation of PAF metabolism toward reduced PAF levels and reduced levels of several cytokines [38]
Vitamin E	Ex vivo studies in hPRP and whole blood	Inhibition of PAF-induced platelet aggregation [187, 188]

(*continued*)

Table 2 (continued)

Studied food and components	Type of study	Results
Mediterranean-based meals and diets, rich in PL with anti-PAF effects	In vivo studies in humans	Reduction of PAF-induced platelet activity in patients with type 2 diabetes mellitus and metabolic syndrome and healthy subjects
Eugenol in cinnamon and basil	In vivo studies in male Wister rats	Reduction of PAF-induced gastric ulcers [189]
Dietary gangliosides	In vivo studies in male Sprague-Dawley rats	Reduced PAF synthesis and PAF levels [190]
Curcumin	In vitro studies in hPRP	Inhibition of PAF-induced platelet aggregation

Abbreviations: *HMC* human mesangial cells, *hPRP* human platelet-rich plasma, *PAF* platelet-activating factor, *PL* polar lipids, *WRP* washed rabbit platelets

mechanism by increasing plasma PAF-AH activity and by protecting the HDL enzymes (such as PAF-AH) from oxidation-related inactivation. This is in agreement with the beneficial in vitro and in vivo effects of several dietary polar lipids, especially on PAF metabolism and HDL biofunctionality [32].

Overall, the protective outcomes of the adoption of Mediterranean diet toward chronic diseases seem to be associated with the pleiotropic beneficial effects of its bioactive microconstituents that are not only limited to increasing plasma HDL-C levels and functionality and providing better stability against oxidation but mainly on their effects on the levels, activities, and metabolism of key inflammatory mediators such as PAF [5, 32, 44]. However, more in vivo results are required in several chronic disorders and their inflammation-related manifestations in order to further support these findings. In particular, clinical trials implementing dietary patterns such as the Mediterranean diet that are rich in bioactive polar lipids interacting with the PAF/PAF-R pathways and metabolism are required to gain further insight into the role of PAF in chronic diseases.

4 Future Research and Applications of Food Polar Lipids

Systemic inflammation leads to chronic diseases such as CVD; therefore it is imperative to research and understand the mechanisms that govern inflammation. Inflammation is a multifactorial process that leads to occurrence of complex conditions and diseases. Due to the complex etiology of CVD, there is not one single solution or 'panacea' to prevent its occurrence; hence the array of pharmaceutical treatments such as statins and antihypertensives that are available to patients to tackle the various risk factors associated with CVD. Successful dietary and lifestyle interventions are credible alternatives to pharmaceutical treatments that have the potential to tackle multiple risk factors at a time [103], albeit difficult for the

individual that undertakes these changes. Adherence to a healthy dietary pattern such as the Mediterranean diet has demonstrated favorable effects for the primary prevention of CVD. Bioactive components of the foods of the Mediterranean diet play a role in the attenuation of systemic inflammation [5]. PAF plays a critical role in the inflammatory process that seems to be underappreciated. Polar lipids have the ability to disrupt the binding of PAF to its receptor and modulate the PAF metabolic enzymes; therefore these lipids may prove important in the modulation of the inflammatory response. Polar lipids are found in abundance in the Mediterranean diet; thus further studies are required in order to discern their mechanisms and potential in the prevention of CVD and other chronic disease. As CVD is still the leading cause of death worldwide, scientific research on healthy dietary patterns such as the Mediterranean diet and the DASH diet are imperative. Furthermore, the development of novel nutraceutical and pharmaceutical products targeting inflammatory pathways such as the PAF pathway or targeting numerous inflammatory pathways at once will play an integral role in the primary prevention and treatment of CVD in the future.

Furthermore, polar lipids such as phosphatidylcholine (lecithin) are functional food ingredients and are currently used as food additives in a broad range of products including dairy products, instant drinks, baked goods, chocolate, and food supplements. Polar lipids are widely utilized as emulsification agents in the food manufacturing and pharmaceutical industry. The increased accessibility of high-quality polar lipids derived from animal and marine products or by-products will open the field of polar lipid research to new opportunities in food, both for their future use as a superior nutritional source of bioactive molecules with beneficial effects and for use in the food, pharmaceutical, nutraceutical, and cosmetic industries. Further research and development in these areas have the potential to induce significant social, commercial, health, and environmental benefits [32].

Acknowledgments The authors would like to thank the Department of Biological Sciences, University of Limerick, Limerick, Ireland, for their continued support.

Neuroprotective and Antiaging Essential Oils and Lipids in Plants

20

Mamali Das and Kasi Pandima Devi

Contents

Abstract

Age-related neurological disorders, such as Alzheimer's and Parkinson's disease, have a huge medical and economical impact in both the industrialized and nonindustrialized countries. Neurodegenerative diseases alone affect 74 million people worldwide and among them, 6.8 million die every year. Essential oils (EOs) and plant lipids (PLs) are used since long time in traditional medicine for their ability to manage a wide range of diseases. There are numerous reports on the neuroprotective and antiaging potentials and mechanism of PLs and EOs.

J.-M. Mérillon, K. G. Ramawat (eds.), *Bioactive Molecules in Food*, Reference Series in Phytochemistry, https://doi.org/10.1007/978-3-319-78030-6_89

Several clinically important EOs and their components from *Mentha piperita, Eucalyptus globulus, Nigella sativa, Jasminum sambac, Rosmarinus officinalis*, and plant-derived lipids like stearidonic acid (SDA) from Echium oil, stigmasterol, β-sitosterol, from *Datura innoxa*, palmitic acid, linoleic acid from *Celastrus paniculatus*, and many more plants are reported for their neuroprotective and antiaging effects. This chapter aims to emphasize on the current finding on EOs and PLs tested against aging-associated neurodegenerative disorders like Alzheimer disease (AD) and possible molecular mechanism of their neuroprotective effects.

Essential oils · Plant lipids · Alzheimer's disease · Cholinesterase inhibitors · Antioxidants · Amyloid-β · NFTs · Dementia · BACE1

1 Introduction

Aging is a time-dependent natural process that affects almost all living organisms. The oldest definition by Harman defines aging as the progressive accumulation of changes with time that are associated with the ever-increasing susceptibility to disease and death [1]. Though aging is one of the most popular topics among mankind from the historical time period, inauguration of aging research could be addressed back to only 30 years with the discovery of first long-lived strains in *Caenorhabditis elegans* (*C. elegans*) [2]. Currently, age is regarded as the main risk factor for prevalent diseases, including cardiovascular diseases, neurodegenerative disorders, and cancer [3]. Aging leads to accumulation of genetic damage which promotes aging-associated diseases [4, 5]. The epigenetic changes like alteration in DNA methylation, posttranslational histone modification, and chromatin remodeling also augment aging process [6]. Additionally, chronic expression of unfolded or misfolded proteins contributes to the development of some specific and fatal age-related neurodegenerative disorders, such as Alzheimer's disease, Parkinson's disease, and cataracts (Fig. 1) [7]. Aging also reduces efficacy of the respiratory chain by dysfunctioning mitochondrial membrane potential thus increasing electron leakage and reducing ATP generation mediated by activation of inflammasomes [8], therefore mitochondrial dysfunction and aging process has been suspected to be linked.

Essential oils (EOs) represent a mixture of highly complex, naturally occurring plant secondary metabolites abundantly present in flowers, leaves, seeds, rhizomes, and barks and are usually isolated via hydrodistillation and cold pressing methods [9]. They are used as spiritual, mental, and physical healing agents from very ancient time period [10] and nowadays are used as traditional medicines, aromatherapy, massage therapies, as well as in cosmetics, perfumes, and food industries [11, 12]. In Egypt, Greece, and Rome, EOs extracted from aromatic plants were employed for the prevention and treatment of various diseases [13]. EOs act as natural safeguards in plants with antimicrobial, herbivores repellent, and insect attractants and thus are

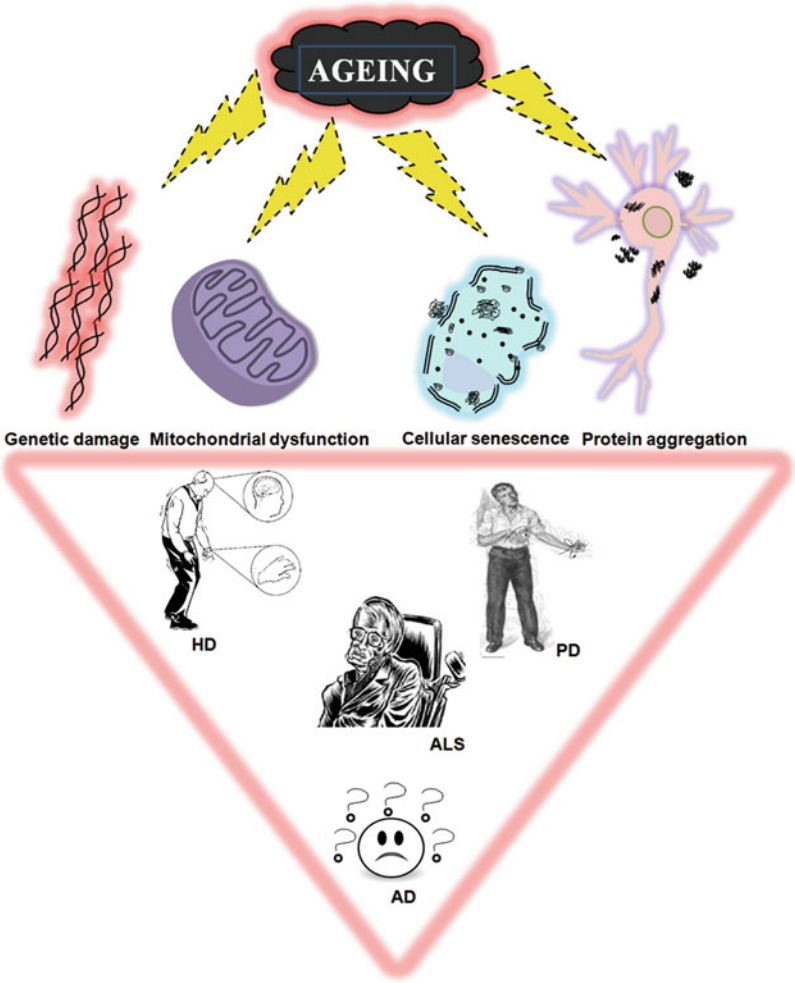

Fig. 1 Aging as a cause of neurodegenerative diseases like AD: Alzheimer's disease, HD: Huntington's disease, PD: Parkinson's disease, and ALS: amyotrophic lateral sclerosis

hugely used as antibacterial, insecticidal, and antifungal agents. Recently, the use of EOs has dragged much scientific attention for the management of several neurological diseases due to improved knowledge on their structure and other biological activities.

Lipids which are basically fatty acids (straight carbon chain, with hydrogen atoms at one end and a carboxyl group (–COOH) at the other end) are important component of fat-soluble part of plants, animals, and microorganisms. Some naturally synthesized fatty acids like omega-9 (ω-9), which need not to be obtained through diets, are termed as nonessential fatty acids [14], while some fatty acids like omega-3 (ω-3) and omega-6 (ω-6) fatty acids (Fig. 2) which form a major part of neuronal tissue

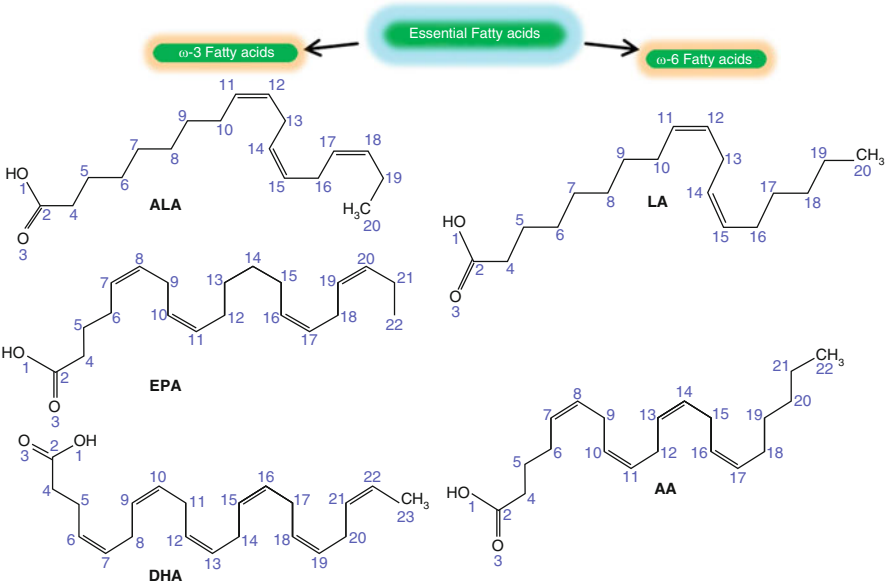

Fig. 2 Major essential fatty acids. ALA: alpha linoleic acid, EPA: eicosapentanoic acid, DHA: docosahexanoic acid, LA: linoleic acid, and AA: arachidonic acid

cannot be synthesized by the body itself and need to be obtained through plant and marine fish oil are considered as essential. In recent years, these ω-3 fatty acids have been found to be critical for the development of human nervous system particularly during neonatal phase [15]. At the same time, its deficiency in adults lead to severe abnormalities in learning, neural, and visual systems and also may cause obesity, cardiovascular disease, inflammation, and cancer. Therefore, investigation of health benefits of dietary supplementation of ω-3 fatty acids has become a promising area for drug developing bodies.

2 Chemistry of Essential Oils

Essential oils are concentrated hydrophobic liquids with several volatile aromatic compounds and have many synonyms like volatile oils, ethereal oils, or aetherolea. Usually, they consist of low molecular weight compounds with terpenes and aliphatic compounds in variable concentrations [16]. Some EOs have usually higher concentrations (20–95%) of two or three components, whereas, other components are present in minor amounts. For instance, linalool constitutes 68% of the *Coriandrum sativum* EO, whereas, α/β thuyone and camphor constitute 57% and 24% of *Artemisia Herbaalba* EO, respectively. Similarly, D-limonene constitutes >80% of citrus peel oils, α-phellandrene and limonene make 36% and 31% of *Anethum graveolens* leaf EO, respectively. The chemical composition of EOs vary

both numerically and stereochemically depending on several factors like extraction techniques, climate, plant origin, soil composition, vegetative cycle stage, and age [17]; therefore, they are needed to be extracted from the same plant part and harvested under the same growing conditions and in most efficient season. Essential oils combat wide range of health issues that are listed in Table 1.

3 Chemistry of Plant Lipids

Lipids including fatty acids, fats, oils, steroids (sterols), waxes, cutin, suberin, glycerophospholipids (phospholipids), glyceroglycolipids (glycosylglycerides), terpenes, and tochopherols are ubiquitous compounds in plants. Several groups of lipids have been shown to provide health benefits either through modification of tissue fatty acid composition or induction of cell signaling pathways. While some health benefits are derived from consumption of short- to medium-chain fatty acids, evidence suggests that the polyunsaturated fatty acids (PUFAs) are the most important bioactive lipids. Among the essential PUFAs, the most important are ω-3 and ω-36 fatty acids. PUFAs are found mostly in plant seed oils and are important substrates for the biosynthesis of cellular hormones (eicosanoids) and other signaling compounds that modulate human health. They are essential for storing metabolic energy, provide protection against pathogens and dehydration, they carry electrons, and absorb light. Gas-liquid chromatography (GLC) and normal-phase high-performance liquid chromatography (HPLC) analysis of fatty acids and fat-soluble

Table 1 Common essential oils and their health benefits

Name of essential oil	Effective for
Lemon	Toning, circulation, and respiration
Lavender	Acne and relaxation
Orange	Respiration and skin moisturizer
Pine	Anxiety, dump skin, and muscle ache
Rose	Obstruct menses and dry skin
Rosemary	Dandruff, digestion, and pain relief
Sandalwood	Insomnia and respiratory infection
Sage	Joint pain, fever, and appetite loss
Tea tree	Fungal infection in skin
Patchouli	Sexuality problem and damaged skin
Peppermint	Poor digestion and sore feet
Cinnamon	Poor digestion and nausea
Ginger	Stomach upset and muscle ache
Clove	Respiratory and skin infections
Fennel	Menstrual dysfunction and constipation
Jasmine	Depression
Grapefruit	Depression
Cedarwood	Eczema and acne

bioactives from Datura and Hyoscyamus seeds showed major fatty acid as linoleic acid followed by oleic, palmitic, and stearic acids. Also, the crude seed extract was rich in phytosterols, like stigmasterol, β-sitosterol, lanosterol, D5-avenasterol, and sitostanol. Datura seed extracts showed stronger radical scavenging activity than Hyoscyamus species [18]. Similarly, studies on the lipid profile of Indian *Celastrus paniculatus* seed oil revealed oleic, palmitic, and linoleic as the major fatty acids followed by glycolipids and phospholipids in its oil. Phytosterol like β-sitosterol were also found in high amount with campesterol and stigmasterol in low amount. *Celastrus paniculatus* oil exhibited stronger radical scavenging activity [19]. Plants especially leafy vegetables and nuts are rich in ω-3 PUFAs, and these are currently the main source to obtain α-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) [20]. ALA is commonly present in plant sources walnuts, flax seeds, butternuts, red and black currant seeds, pumpkin seeds, wheat germ, soy and canola oil, and leafy green plants like Purslane in high concentrations. *Perilla frutescens* seed oil is also a rich source of ω-3 linolenic acid [21]. Among the plant sources, flax seeds have the highest concentration of ALA.

4 Are Aging and Neurodegenerative Diseases Related?

As we age, along with some visible changes like hair and skin, our brain and central nervous system also undergo the aging process. This is one of the facts that people are more likely to suffer from many neurological problems after the age of 65. Aging makes the patients more vulnerable to irreversible diseases like Alzheimer's disease, Parkinson's disease, and stroke and thus has been considered as a major risk factor of the above said diseases. With advances in molecular biology, many age-related signaling pathways like rapamycin (TOR) [22], and insulin/IGF-1 signaling, have been found to be connected with neurodegeneration [23]. Most of the age-related neurodegenerative diseases like AD are characterized by accumulation of disease-specific misfolded proteins in the central nervous system which leads to neurodegeneration, synaptic dysfunction, and neuroinflammation in central nervous system, causing several pathological effects [24] (Table 2).

5 Alzheimer's Disease

Alzheimer's disease (AD) is the fifth leading age-related neurological disorders in the world and is characterized by cognitive dysfunction, memory loss, psychological changes, and disability to perform day-to-day activities due to oxidative stress-induced scarcity in cholinergic neurotransmission, accumulation of amyloid plaques (amyloid-β, Aβ), and neurofibrillary tangles (NFTs) in the brain [25, 26]. The risk of AD considerably increases with aging, affecting 7–10% of 65, and 40% of people over 80 years of age. It is a multifactorial dementia; therefore, exploration of pathway-based inhibitors is the most helpful way in the anti-AD drug development. In this context, acetylcholinesterase (AChE) and butyrylcholinesterase (BChE)

Table 2 Some of the common age-related neurological disorders and their pathological effects

S. No.	Age-associated neurodegenerative diseases	Pathological hallmarks	Disease consequences
1	Alzheimer's disease	Aggregated β-amyloid and tau in cerebral cortex and hippocampus, oxidative stress, activated microglia	Mental decline, difficulty in thinking and understanding, delusion, disorientation, forgetfulness, inability to create new memories, depression, and hallucination
2	Parkinson's disease	Aggregated α-synuclein in substantia nigra areas of the midbrain and basal forebrain	Bradykinesia, rigidity and rest tremor, sleep disturbance, executive dysfunction, depression, psychosis, and confusion
3	Amyotrophic lateral sclerosis or Lou Gehrig's disease	Aggregated superoxide dismutase-1 (SOD1) in spinal cord and motor cortex	Cramping, muscle weakness, problems with coordination, fatigue or feeling faint, shortness of breath vocal cord spasm, apathy, difficulty raising the foot, difficulty swallowing, drooling, lack of restraint, severe constipation, and tremor
4	Huntington's disease	Aggregated huntingtin (Htt) protein	Jerky body movements, mood swinging, reduced mental abilities, coordination

inhibitor compounds such as donepezil, galanthamine, rivastigmine, tacrine, etc. represent majority of drugs approved for clinical use in the symptomatic AD relief, while EOs target several pathways and thus provide better healing.

6 Neuroprotective Effects of Essential Oils

6.1 Effect on Cholinesterase Activity

Cholinesterases are one of the potential AD targets and a variety of EOs show promising anticholinesterase activity. EOs from the leaves and flowers of *Polygonum hydropiper* are recently reported to show free radicals scavenging and AChE, BChE inhibitory activity [27]. Extensive GC-MS analysis of the leaf and plant extract showed caryophylene oxide (41.42%) as the major EO in leaf and decahydronaphthalene (38.29%) as major EO of the flower. Also, EO from *Rumex hastatus* has reported anticholinesterase and antiradical potentials with IC50 values of 32.54 and 97.38 mg/ml for AChE and BChE, respectively, and IC50 values of 3.71 and 6.29 mg/ml for antioxidant assays [28]. *Narcissus poeticus* L. flower oil also show *in vitro* AChE, BChE inhibitory activity [29]. EOs like thymol and

p-cymene (19% and 16.1% concentration, respectively) from *Origanum ehrenbergii* showed potential antioxidant and AChE, BChE inhibitory activity [30]. Similarly, the anti-AChE activity of spathulenol from *Marlierea racemosa* Vell. were evaluated by de Souza et al. [31]. Cistaceae family (*Cistus creticus, Cistus monspeliensis, Cistus salvifolius, Cistus villosus*, *and Cistus libanotis*) were investigated for antioxidant and cholinesterase inhibitory potentials [32]. EOs from *C. monspeliensis and C. libanotis* were found to be most potent antioxidants. *C. salvifolius* exhibited AChE inhibitory, while, *C. libanotis, C. creticus*, *and C. salvifolius* showed BChE inhibitory activity.

6.2 Effect on Learning and Memory (Cognition)

Learning is the ability to acquire new and modify existing information, while, memory refers to the storing and retrieving ability of this information, and cognition is the combination of these two vital processes. In AD, deterioration of cholinergic neurons lead to cognitive deficits [33], and therefore, a cholinergic boost may potentially revert the cognitive dysfunction [34]. Based on this idea, several nicotinic and muscarinic agonists were tested, but the process failed due to limited efficacy, toxicity, and bioavailability problems [35]. EOs are reported for their beneficial effects in Alzheimer and dementia by several research groups. Shimizu et al. reported the effect of EOs from *Eucalyptus globulus* Labill. and *Lavandula angustifolia* Mill. on persistent attention [36, 37]. *Rosmarinus officinalis* L. of family Lamiaceae which is frequently used in diet formulations was also found to be a great source of EOs with strong antiradical, antibacterial, antifungal, and anticancer properties [38]. Rosemary EOs are also reported as neurostimulants, moderate AChE inhibitors, locomotor activity enhancers, vigor motivators, and cerebral cortex stimulators [39].

6.3 Effect on Aβ Aggregation

Formation of senile Aβ plaques and NFTs are important hallmarks of AD [40]. Aβ originates from enzymatic hydrolysis of the amyloid precursor protein (APP). The APP is cleaved by α, β, and γ secretase enzymes in a sequential manner, leading to the formation of $A\beta_{17–42}$ by α- and γ-secretases and neurotoxic $A\beta_{1–42}$ by β and γ secretases [41]. An imbalance in the generation and removal of Aβ results in its neuronal accumulation and becomes the starting point for neurodegeneration and neuroinflammation in AD. As a result, inhibition of β-amyloid cleaving enzyme 1 (BACE1) or β-secretase becomes an important target in management of AD. 6-gingerol, a predominant constituent of ginger EO, showed the neuroprotective potential against $A\beta_{25–35}$-mediated oxidative and nitrosative cell death in SH-SY5Y cells via inhibition of DNA fragmentation, interruption in mitochondrial membrane potential (MMP), activation of caspase-3 and increased Bax/Bcl-2 ratio, suppression of reactive oxygen species (ROS) and reactive nitrogen species (RNS) [42].

6-gingerol also upregulate the expression of mRNA and proteins responsible for the synthesis of c-glutamylcysteine ligase, implicated in the biosynthesis of glutathione. Similarly, the EO from SuHeXiang Wan (SHXW), a Chinese traditional medicinal prescription consisting of 15 crude herbs whose essential oil has been shown to have anticonvulsant and antioxidative activity used as traditional medicine to treat seizures, infantile convulsions, AD, and other neurodegenerative disorders [43]. Pre-inhalation of SHXW EO revitalized the memory of AD animal model injected with $A\beta_{1-42}$, suppressed $A\beta_{1-42}$ mediated c-jun N-terminal kinase (JNK), protein kinases (p38), and tau phosphorylation in the hippocampus of animals. Also, SHXW EO decreases Aβ-mediated apoptosis and ROS production by upregulation of HO1 and Nrf2 expression in SH-SY5Y cells. Consecutively, thymol and carvacrol on cognitive function, it was found that both the EOs improved cognitive functions in animal models [44]. Most importantly, both samples were safe at their highest concentrations. Also, EO from *Coriandrum sativum* var. microcarpum (coriander) had antidepressant, anxiolytic, and antioxidant potentials upon inhalation in $A\beta_{1-42}$ rat models of AD [45]. Similarly, EOs of *Zataria multiflora* Boiss. (Lamiaceae) showed profound cognitive and neuroprotective effects in AD animal models by improving their cognitive abilities in a concentration-dependent manner [46].

6.4 Effect on Oxidative Stress

Generation of free radicals during aerobic respiration is an essential part of living beings. These free radicals readily attack DNA, proteins, fatty acids, and other essential molecules and therefore are implicated in a variety of disorders including AD, cancer, aging, and inflammation, and several plant extracts has been found to have potential radical scavenging activities [47–52]. Free radicals are neutralized to nonradical forms by various enzymes including CAT, SOD, and hydroperoxidase. But, when free radical generation is abnormally high, then administration of free radical scavengers from outside becomes necessary. Furthermore, in aging brain and AD patients, mitochondrial dysfunction lead to excessive production of free radicals and subsequently result in pathological abnormalities. Aβ is a potent initiator of ROS and RNS production which rapidly cause oxidative damage of neural, microglial, and cerebrovascular cells and tissues [53]. Investigation of the neuroprotective effects of lavender (*Lavandula angustifolia* ssp. Angustifolia Mill. and *Lavandula hybrida* Rev) revealed that its EO showed antioxidant and antiapoptotic potentials [54]. Lavender EO mediates its protective effects via strong antioxidant activities. In addition, there are numerous examples of EOs from chamomile, clove, thyme, eucalyptus, juniper, basil, cumin, cinnamon, and coriander to possess considerable antioxidative potentials [55–57]. Similarly, dietary intake of oregano oil has been reported to delay lipid oxidation in animal models [58]. EOs from *Achillea millefolium* were reported to scavenge hydroxyl free radicals via inhibition of lipid peroxidation [59]. Studies on EOs from *Salvia multicaulis* and *Salvia cryptantha* showed antioxidant activities higher than the standard drugs [60]. Many aroma components of EO like linalool, α-terpinene, 1,8- cineole, β-terpinolene, β-terpinene,

menthon, thymol, eugenol, and isomenthone have reported antioxidant potentials [61]. Similarly, the EO of *Melissa officinalis* L. rich in menthone, geranial, isomenthone, and citronellal has reported antioxidative properties [62]. A comprehensive account of possible neuroprotective mechanism of EOs is given in Fig. 3.

7 Neuroprotective Effects of Plant Lipids

7.1 Contribution of Long Chain ω-3 PUFAs to Brain Function and Its Molecular Mechanism

Brain is a repository of DHA and AA that are highly susceptible to free radical-induced damage [63]. Oxidative damage of the brain is characterized by increased lipid peroxidation, which deteriorates neuronal functions [64]. Recent studies shows participation of DHA in brain pathological activities and involvement in regulation of many metabolic and inflammatory pathways, and postmortem samples from AD brains show gradual decline of DHA in patient's brain [65]. Also, studies reveal that higher dietary intake of DHA can reduce the risk of cognitive impairment or AD [66–68]. It has also been found that ω-3 PUFAs cannot benefit patients with already diagnosed AD progression but can enhance learning and memory function only in age-related cognitive decline in healthy elderly populations [69]. Recently, through a study carried out in rats, it has been found that DHA deficiency activates caspases in AD models and intensify the age-related decline of glutamatergic transmission in learning and memory functions [70]. On the other hand, DHA supplementation diminish oxidative stress or lipid peroxidation and protect against memory loss in AD rat models [71] by reducing the accumulation of neuronal Aβ and tau protein [72]. This information may help researchers to design application of ω-3 PUFAs for better relief from age-related cognitive consequences.

DHA that is transferred from the maternal circulation to fetal brain plays a crucial role in synaptogenesis. DHA is incorporated into fetal brain through fatty acid transport protein-4 (FATP 4) [73]. However, the amount of maternal DHA in the synapses and neural membranes depends on the dietary intake [74–78]. Studies have shown that DHA acts as an endogenous ligand for retinoic acid receptors (RAR) and retinoid x receptors (RXR) [79] which decrease with age and correlated with age-related memory deficits. Dyall and colleagues suggest that DHA supplementation reverse the decrease of RAR and RXR which alleviate the memory deficits and increase neurogenesis [80]. Patients diagnosed with AD show lower DHA levels in plasma and brain [81, 82] which not only could be due to lower dietary intake of ω-3 fatty acids but also due to increased oxidation of PUFAs [83, 84]. Preclinical evidence suggests that a DHA-enriched diet reduces amyloid formation [85, 86]. Akbar and coworkers provided additional evidence that DHA is highly enriched in neuronal membranes and provides neuroprotection via PI3, Akt pathway which is a critical signaling pathway for neuronal survival [87]. Dietary supplementation of DHA has been shown to increase the levels of hippocampal BDNF (brain-derived

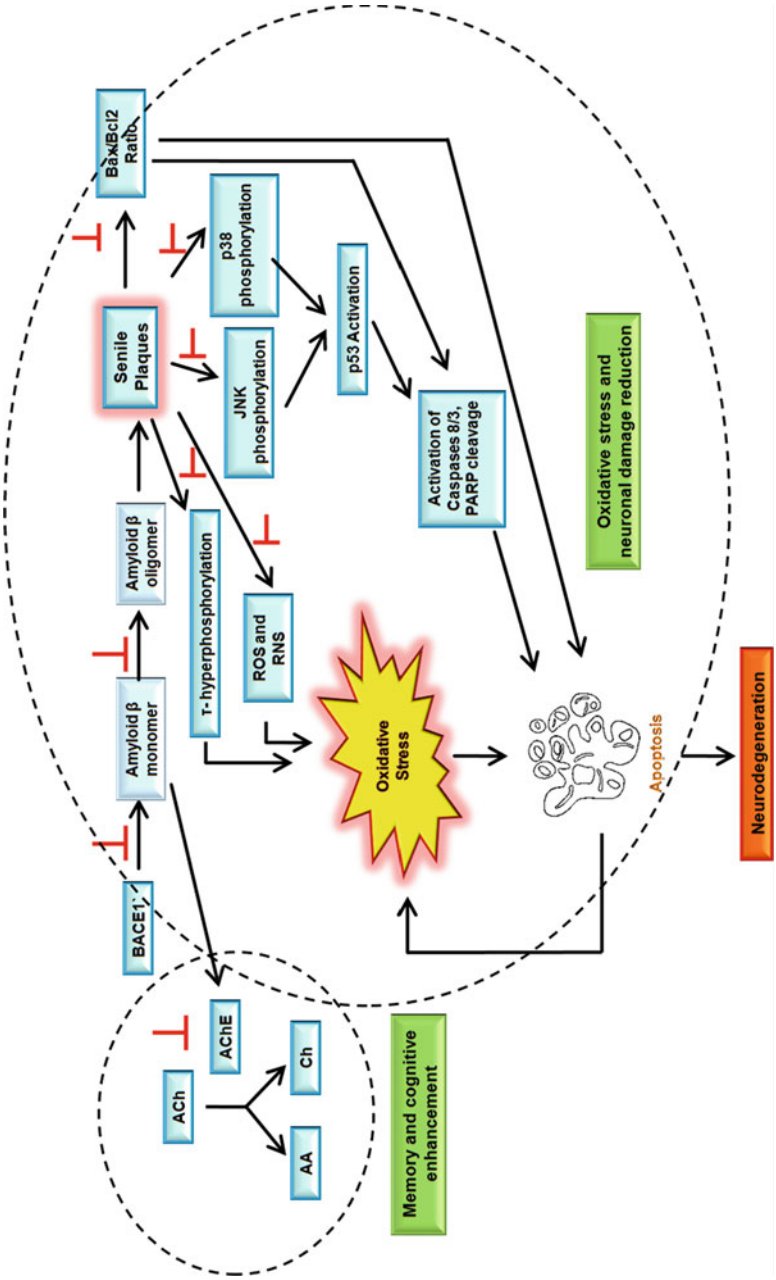

Fig. 3 Overview of possible molecular mechanism of essential oils executing multifactorial neuroprotective effects in Alzheimer's disease condition. EOs mitigate AChE, BACE1 activity; Aβ oligomer formation; τ, JNK, and p38 phosphorylation; Bax/Bcl2 ratio; and ROS and RNS production, thus enhancing memory and cognitive power and simultaneously reducing oxidative stress and neuronal apoptosis

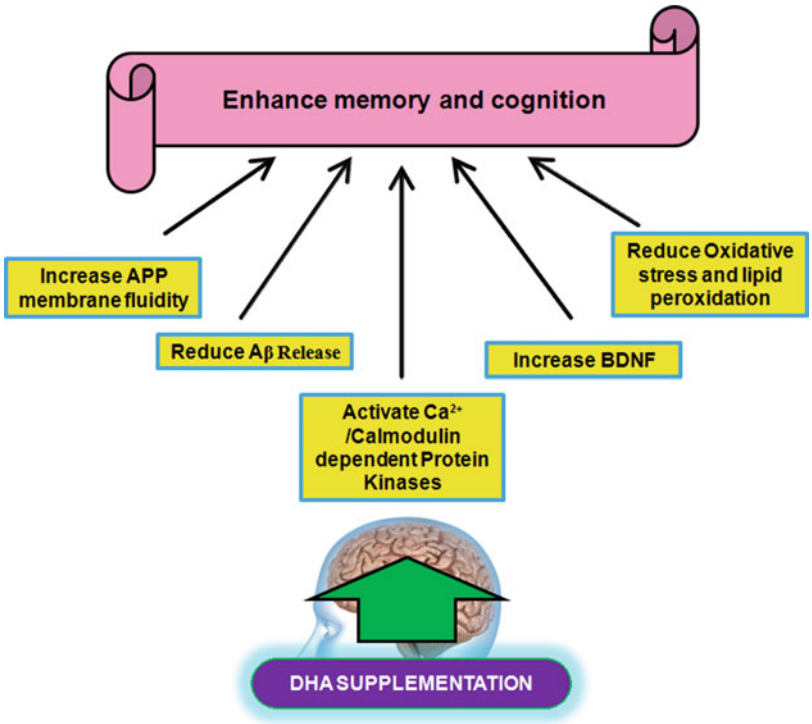

Fig. 4 Outline of possible molecular mechanism of DHA executing multifarious neuroprotective effects in Alzheimer's disease condition. DHA reduce overall Aβ-induced neurodegeneration and apoptosis by increasing APP membrane fluidity, thus reducing Aβ release, activating Ca^{2+}/calmodulin-dependent kinases, and increasing brain-derived neurotrophic factor and reducing oxidative stress and lipid peroxidation

neurotrophic factor which is essential for maintaining synaptic plasticity and cell survival [88], and activation of Akt is known to be linked to increase in BDNF. Also, DHA-rich diet activates Ca^{2+}/calmodulin-dependent protein kinase (CaMKII) which is critical for learning and memory and plays a crucial role in induction and maintenance of long-term potentiation in hippocampus [89, 90]. Literature survey also propose that DHA modulates multiple cellular functions like enhanced membrane fluidity of amyloid precursor protein (APP) and reduced amyloid-β release by shifting the mechanism towards nonamyloidogenic pathway [91]. DHA is also suggested to assist N-methyl-D aspartate (NMDA) responses [92] and block K^+ channels [93], thus directly affecting memory and learning [94]. Most recently, DHA supplementation has also been shown to amend gene expression at the transcriptional level, by activating members of peroxisome proliferator-activated receptor (PPAR) family [95] and stabilizing mRNA of several enzymes associated with glucose and lipid metabolism [96]. Figure 4 gives a broad outline of DHA imparting neuroprotective effect through various mechanisms.

7.2 DHA Depletion and Cognitive Impairment

Studies in AD animal models suggest that DHA deficiency in neural tissue leads to behavioral changes similar to that in patients with AD. Furthermore, experimental evidence suggests that DHA decreases with age, particularly in regions of the hippocampus which are crucial for higher brain functions such as memory formation and cognition [97, 98]. Decreased DHA levels are reported to detrimentally affect the major excitatory neurotransmitter, glutamate, which contributes to the integrity of brain function in learning memory performance [99]. Recently, it has been demonstrated that DHA protects rat cortical neurons from soluble Aβ oligomer-induced neurodegeneration and apoptosis [100, 101].

8 Conclusions

In recent times, plant-based therapies have got considerable attention owing to their comparative safety, potency, and efficacy on multiple targets. Among the natural products, EOs from aromatic and medicinal plants is of great interest because of their antioxidant, cholinesterase inhibitory, anti-amyloid properties, and high availability at the target due to their lipophilic character. Thus, EOs can be very effective alternative for the management of AD in comparison to synthetic drugs which are associated with severe side effects. Also, numerous EOs have been reported to possess strong antioxidant potentials and can be effectively used in free radical-induced disorders including neurological diseases and aging. This chapter also highlighted the potentiality of long chain ω-3 fatty acids to reduce low-grade inflammation in the early stages of age-related neurodegenerative diseases like AD.

Contents

Abstract

Neurodegenerative diseases (ND) are characterized by the death of neurons in different regions of the nervous system, followed by functional deterioration. The most frequent pathologies are the group of dementias such as Parkinson's disease (PD) and Alzheimer's disease (AD), which represent an important impact on society and quality of life of people, mainly in the elderly group. Omega 3 is a polyunsaturated fatty acid, whose anti-inflammatory effect has been related to benefits on the neuroinflammatory processes characteristic of ND. Although the clinical evidence is unclear, epidemiological studies report improvement in cognitive performance and provide evidence on its neuroprotective effect in specific regions of the nervous system. The objective of this review is to determine the neuroprotective effects of omega 3 fatty acids on neurodegenerative disease.

1 Neurodegenerative Disease: Epidemic of the Twenty-First Century

The ND integrate a heterogeneous group of diseases with involvement of the central nervous system (CNS) characterized by a progressive neuronal loss in specific brain areas or anatomic systems. This progressive loss of nerve cells is what causes the neurological and neuropsychological signs and symptoms characteristic of this group of diseases [52]. ND affect several activities of the organism, such as balance, movement, speech, respiration, and functions of the heart. Some ND are Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS), Friedreich's ataxia (AF), Huntington's disease (HD), Parkinson's disease (PD), and spinal muscular atrophy [40].

Currently, intervention in issues related to ND faces a complex context. There are multiple sociological factors such as increase of the life expectancy, increase of the population and aging, greater difficulty of scientific-technical advances, and predictable chronification of the diseases. Likewise, the presence of socioeconomic factors (increased job insecurity, impoverishment of the middle classes, increased healthcare costs, and weakening public social and health investment) has been circumstances that, in their combination, have increased the prevalence of ND [16].

According to the report of the World Health Organization (WHO), the ND affect around the world about one billion people. The report *Neurological Disorders: Public Health Challenges* shows that around a billion people are affected worldwide; 50 million suffer from epilepsy and 24 million suffer from Alzheimer's and other dementias. Neurological disorders affect people from all countries, without distinction of sex, educational level, and economic status. Given the above, the WHO advocates that neurological care be integrated into primary healthcare, in order to prevent ND, through strategies that may also directly affect the aspects of metabolic alteration [59, 60].

As the global aging rate increases, the impact of ND will be felt in both developed and developing countries. According to Rita Levi-Montalcini, Nobel Prize in Medicine, "the burden of neurological disorders is reaching significant proportions in countries where the percentage of people over 65 years of age increases" [59]. Until 2015 and because of its prevalence, the three main ND were Alzheimer's and other dementias, reporting 35 billion global cases, Parkinson's with 23 billon worldwide cases, and multiple sclerosis with 2 billion [61].

2 The Nervous System as an Immuno-Privileged Site

The nervous system (NS) is one of the smallest and at the same time most complex of the organism. It consists of an intricate, specialized, and highly organized network of cells called neurons and glial cells. The NS carries out a complex set of activities that

allow a human being to feel different smells, produce speech, and remember past events. It also provides signals that control body movements and regulate the functioning of tissues and organs [47].

The NS is subdivided into CNS, consisting of encephalon and spinal cord, and the peripheral nervous system (PNS), which includes all nerve tissues located in the periphery. The brain is the main constituent organ of the CNS, whose cognitive function involving networks of cells including neurons, one of the most important cell populations in the NS, is involved. Neurons are the main functional units of the CNS and have the ability to communicate with each other quickly and efficiently through electrical or chemical signals that are translated as action potentials [2]. The CNS is protected from damage and injury, by the blood-brain barrier (BBB), which is a physical barrier located between blood vessels and brain tissue, with a very high selective permeability that limits the access of molecules to protect the brain from any type of pathogen or toxic substance. The foregoing allows this system to be immunologically specialized [10].

The CNS is a specialized and essential system in the survival and defense of injuries to the organism, for which reason it has been classified as immunoprivileged. The anatomical sites that present this condition are able to tolerate the introduction of antigens without initiating an inflammatory immune response [22]. Although there is still debate between the homeostatic maintenance of the CNS and the immune system, it is well known that immune cells (lymphocytes and macrophages) play an important role in neurodegeneration [10]. In the particular case of the CNS, the lymphocytes have the capacity to enter through the cerebrospinal fluid in the choroid plexus or the cerebral parenchyma. Said extravasation of immune cells is mediated by the adhesion molecules ICAM (intercellular adhesion molecules) and VCAM (vascular cell adhesion molecules), which are present in the endothelium of the blood-brain barrier. This allows the CNS to develop a more regulated immune response, compared to other sites in the body [47].

Conversely, not all nerve cells produce action potentials; such is the case of glia. Glial cells differ from neurons, since they do not have synaptic contacts and have the ability to divide throughout life. The main functions of glial cells are to (1) maintain an ionic medium in nerve cells, (2) modulate the speed of propagation of nerve signals, (3) modulate the synaptic action by controlling the uptake of neurotransmitters, (4) provide a foundation for neural development, and (5) contribute (or prevent, in some cases) the survival of a neuronal lesion [35].

Glial cells are classified mainly into two groups: (1) macroglia, which include astrocytes and oligodendrocytes, of ectodermal origin, and (2) microglia, of mesodermal origin, which invade the CNS during embryonic development at the time of vascularization [15]. Microglia constitute part of the macrophages and constitute between 5% and 10% of the neuronal cell population [36].

Under normal conditions, the microglia is at rest, but if there is an injury or infection, mechanisms that promote neurotoxic activities are activated, producing reactive oxygen species (ROS) and reactive nitrogen species (RNS) and secreting prostaglandins, chemokines, and cytokines. They favor an inflammation status. If the activation of the microglia remains until it becomes chronic, it leads to an

imbalance in the inflammatory response, generating a cycle of inflammation and tissue damage [35]. Inflammation is defined as the response of vascularized living tissue to the lesion, and in this sense, it is a complex cascade of physiological responses to harmful stimuli from the environment [12].

Another factor that triggers inflammation is oxidative stress (OXS). Several studies show that a state of chronic-systemic oxidation plays a crucial role in the pathogenesis of ND [9, 44]. OXS is defined as the electrochemical imbalance between prooxidant substances (ROS and ROS) and antioxidant substances, in favor of the former. The body has antioxidant defense mechanisms, both enzymatic (superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx)), and nonenzymatic (glutathione), for protection against prooxidants. However, before the chronic development of the disease, such as obesity and diabetes, there is a depletion of the antioxidant systems, which favors the perpetuation of OXS [33]. Particularly, the brain is susceptible to OXS lesions because it is an organ with high energy use and metabolic demand, so minimal imbalances of the redox state favor tissue damage and activation of neuroinflammatory mechanisms [8].

The inflammation present in ND, both acute and chronic, occurs in response to injury or alteration in the CNS. The chronic and unbalanced inflammatory response is a source of damage to the integrity and function of the CNS cells, since the neural tissues have a restricted cell regeneration and are extremely vulnerable to immune and inflammatory processes [46]. Inflammation determines the progression of neuronal death in ND. In this sense, the excessive and destructive immune response becomes a chronic and persistent process that leads to progressive and irreversible neurodegeneration inducing a vicious circle that causes cognitive deterioration, giving rise to the progression of chronic ND such as AD and PD [12].

3 Neurodegenerative Disease and Neuroinflammation

The term neuroinflammation describes an extensive process of physiopathological mechanisms and phenomena mediated by alterations in the glial cell morphology. Neuroinflammation is a reactive state of the immunological component of the CNS. This concept of neuroinflammation encompasses the response or set of responses that occur in the CNS to any damage occurring in the tissue [6].

As previously described, microglia play an important role in the development of the neuroinflammatory response. This cell has toll-like receptors, involved in the recognition of damage to the CNS by chemical agents, such as ROS and RNS, and production of proinflammatory cytokines. Given the exposure to inflammation molecules, the cells of the microglia are activated, and this results in a series of processes that involve the morphological transformation of an inactive branched state to an active phagocytic ameboid and the proliferation and migration toward sites of injury by chemotaxis [32].

The activation of the microglia causes a release of products that may have neurotoxic effects within which they are the proinflammatory cytokines interleukin 1β (IL-1β), interleukin 6 (IL-6), tumor necrosis factor α (TNF-α), interferon gamma

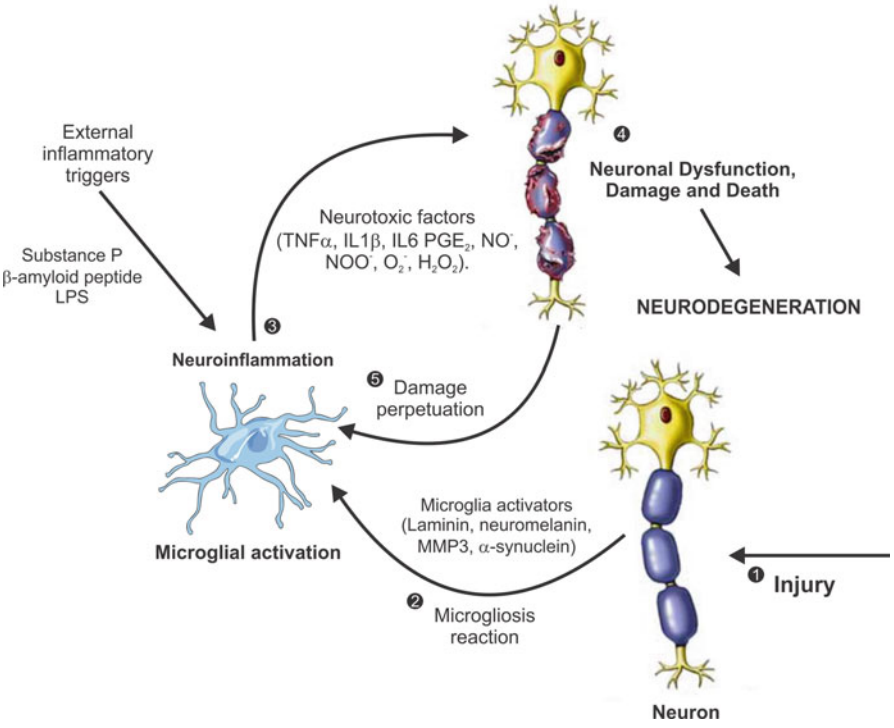

Fig. 1 Microglial activation model conducive to neurodegeneration

(IFN), oxidizing compounds such as ROS and RNs, as well as excitatory amino acids such as glutamate, all act together to modulate the inflammatory processes that affect the permeability of the BBB [12, 30] (Fig. 1).

IL-1β is one of the most important cytokines in the progression of the neuroinflammatory process, playing an important role in the development of acute neuronal injuries. Likewise, it has been demonstrated that the administration of the IL-1 receptor antagonist (IL-1ra) prior to brain injury significantly reduces the death of bark neurons in rats. The use of transgenic animals with specific modifications of the genes that express IL-1β has shown that their deficiency exhibits a reduction of necrosis despite the fact that the animals are subjected to different neuronal aggressions [15].

Also, IL-1β induces the expression of inducible nitric oxide synthase (iNOS), responsible for triggering the release of nitric oxide (NO-) in glial cells and causing nitrosative stress. The RNS are oxidative molecules with special attachment to lipid peroxidation, which favors mainly the rupture of cell membranes in CNS. Lipid peroxidation is the most frequent oxidative damage at the cellular level, produced particularly by the hydroxyl radicals (OH-) and peroxynitrite (ONOO-), on the polyunsaturated fatty acids of cell membranes. Initially, a fatty acid is oxidized by leaving a hydrogen atom of a methylene group to the OH- that acts as an oxidizing

agent, producing peroxyl radical. This, in turn, repeats the chain process until irreversible tissue damage occurs [18].

A second type of glia cell involved in neuroinflammatory processes are the astrocytes that reside in the CNS. Its activation leads to a condition called astrocytosis, where the number and size of the glial fibrillary acidic protein (GFAP), a cytoskeletal protein that contributes to hypertrophy and hyperplasia of astrocytes, increases. This leads to the generation of a glial scar in the area of tissue necrosis, excluding non-neuronal cells, and serves as a complement in spaces of neuronal loss (Zhang et al. 2010a).

For its part, among the main functions of astrocytes is its participation in the CNS immune response. Active astrocytes produce a variety of molecules, which are involved in the initiation, progression, and regulation of the inflammatory response. In addition to the production of pro- and anti-inflammatory cytokines, there is a greater expression of the enzyme genes cyclooxygenase 2 (COX-2) and iNOS as well as higher production of NO-, an important molecule in the development of oxidative stress and neuronal necrosis (Zhang et al. 2010). Table 1 lists the main substances released by glial cells that participate in neuroinflammatory processes.

The constant and prolonged activation of glial cells and astrocytes, as described previously, leads to a chronic state of inflammation, which perpetuates the release of proinflammatory molecules. The above contributes to the development of neurodegenerative processes, for example, AD, Parkinson's, and Huntington's, which are characterized by slow and progressive neuronal loss in certain areas of the brain such as the hippocampus, the striatum, the black substance of compact part (SNpc), and the cerebral cortex [23].

It is important to point out that neuroinflammation is only the mechanism of immunological protection against CNS damage, so its activation is of benefit for the protection of the integrity of the NS. However, chronic inflammation is characterized by the prolonged activation of the microglia and the perpetuation of mediators of inflammation, which increases the cellular oxidative and nitrosative state. In view of the above, a response chain is generated between oxidative stress-inflammation-

Table 1 Molecules released by microglia and astrocytes during the neuroinflammatory process

oxidative stress, which favors necrosis, increasing cognitive decline and the development of NS, as described in Fig. 2 [7].

3.1 Alzheimer's Disease

The greatest evidence of the role of chronic neuroinflammation of the CNS as a trigger for neurodegenerative disease is in studies of AD. Considered as the most common neurodegenerative disease and the main cause of dementia in older adults, approximately 10% of all people over 65 and up to 50% of those over 85 are diagnosed with this disease [50].

AD is an irreversible and progressive disorder characterized by the loss of neurons mainly in the cerebral cortex and hippocampus, which leads to memory loss, cognitive deterioration, and changes in personality. Although its etiology is unclear, it is suggested that the accumulation of β-amyloid proteins in the neuritic plaques and tau protein residues are responsible for the attraction and activation of glial cells, triggering reactive changes in the microglia, and release of pro-inflammatory mediators and ROS that contribute to the necrosis of neuronal cells, leading to chronic and progressive neurodegeneration [49].

It should be noted that genetic susceptibility, trauma, diet rich in fats and simple sugars, alterations in cholesterol homeostasis, deficiency of cyanocobalamin, and iron overload are among the risk factors described. However, although none of the aforementioned appears to be a direct etiological factor, they do act as signaling

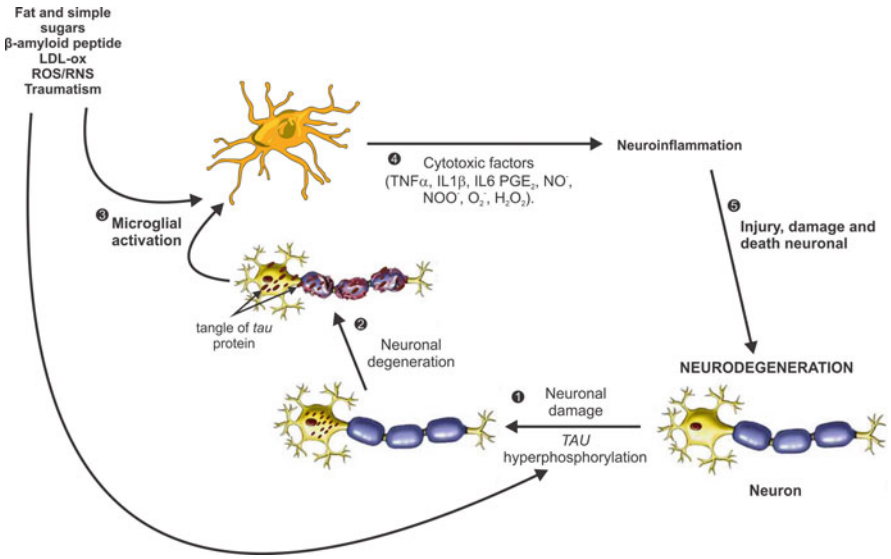

Fig. 3 Microglial activation model responsible for neuroinflammation in AD

devices at the CNS level, triggering alterations in the redox state, activation of glial cells, and protein abnormalities. Therefore, the constant and prolonged exposure of any of these factors could be an important trigger that favors a chronic neuroinflammation response [31].

One of the main approaches about the development of AD is the tau protein, which plays a fundamental role in the maintenance of microtubules of neurons and as a component of axonal transport. Currently, it is known that tau hyperphosphorylation leads to the self-aggregation of this protein, triggering the disarticulation of microtubules, disorders in neuronal activity, and loss in its ability to transmit messages. The above is translated into a cellular lesion that leads to the activation of microglia, release of proinflammatory cytokines, and the development of neuroinflammation (Fig. 3). The persistent alteration of the signaling mechanism produces necrosis of nerve cells and cognitive deterioration, eventually causing the process of neurodegeneration [49, 57].

Currently, evidence of the importance of inflammation in neuronal damage comes from immunohistochemical and molecular biology studies done in the brain tissues of patients with AD, which revealed the distinctive features of inflammation, including the activation of microglia and astrocytes, the expression of cytokines, and the invasion of immune cells. Studies performed in patients with AD reveal high concentrations of proinflammatory cytokines in the blood, mainly IL-6, TNF-α, IL-1β, IL-12, and IL-18. For its part, it has also been shown that the chronic treatment of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin and ibuprofen, significantly reduces the risk of developing AD [50].

3.2 Parkinson's Disease (PD)

PD is the second most common neurodegenerative disorder associated with age and of unknown origin, affecting 4.1 to 4.6 million people over 50 years of age worldwide, and it is predicted that by 2030 this figure will double due to the increase in hope of life [60].

PD is characterized by the presence of disorders in involuntary movements, associated with the selective loss of dopaminergic neurons in the SNpc and by the presence of intraneuronal cytoplasmic protein inclusions (Lewy bodies) in the surviving neurons, as well as in other central regions and peripheral of the CNS. The accumulation of Lewy bodies in neurons is associated with the activation of microglia, the increase of proinflammatory cytokines, and the decrease of some neurotrophic products, which together lead to degenerative changes in the SNpc and locus coeruleus, specifically in dopaminergic neurons. In this process pro-inflammatory, it is believed that the major histocompatibility class II complex (MHC-II), half of the neurodegeneration process, since an increase in its expression due to the proinflammatory activation of the microglia has been related to a greater neuronal death in these regions [25]. Although several causes of PD are described, recent studies show that neuroinflammation and microglial activation play an important role in its pathogenesis, derived from a microenvironment of neurological damage that breaks down the homeostatic mechanisms that promote cell survival [51].

The degeneration of dopaminergic neurons produces a decrease in dopamine levels that causes a loss of synaptic regulation in basal ganglia. The basal ganglia are collections of nerve cell bodies located subcortically near the base of the brain. They include the striatum (caudate and putamen), subthalamic nucleus (NST), pale globe external (Gpe) and internal (Gpi), ventral nucleus of the thalamus, and the SNpc and SN pars reticulata (SNpr). These nuclei are responsible for motor control, since they are interconnected with the cortex and the brain stem and the thalamus [41].

Dopaminergic neurons are very sensitive to any pathological change that occurs in the brain. In response to the damage, the microglia increases the secretion of neurotrophic factors and proinflammatory cytokines and the activation of nitric oxide synthase, NADPH oxidase, and cyclooxygenase, which cause damage to the neuron and the reactivity of astrocytes; therefore a progression of neurodegeneration occurs in a self-powered way [51].

Activated microglia produces large amounts of superoxide radicals and is the main source of oxidative stress responsible for the death of dopaminergic cells in PD (Wang et al. 2015) (Fig. 4). In postmortem brains, high levels of proinflammatory cytokines have been observed and in animal models active microglia from early stages of neuronal degeneration [26, 39].

The in vivo correlation between microglial activation and the corresponding loss of dopaminergic neurons in early PD was studied by Ouchi in 2005. This correlation supports the hypothesis of neuroinflammatory response mediated by microglia that contributes significantly to the degenerative process and suggests the importance of

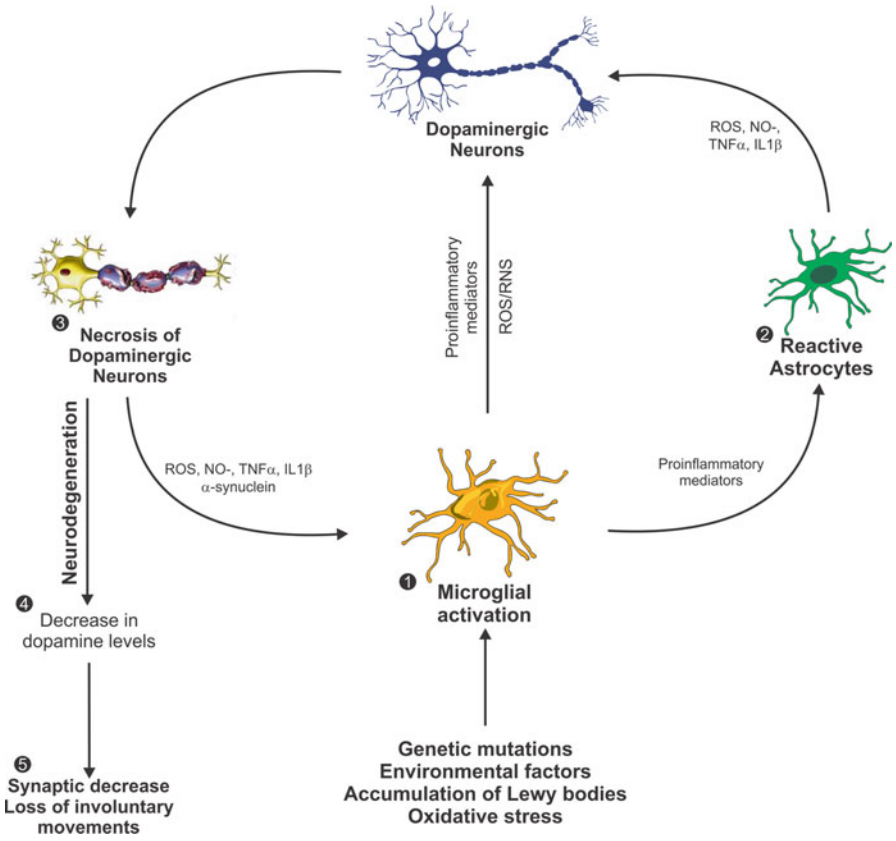

Fig. 4 Representation of the inflammatory mechanisms involved in the development of PD

early therapeutic intervention with neuroprotective drugs [42]. Currently, research is aimed at finding effective and preventive treatments for ND, paying special attention to the search for methods to normalize this phenomenon of excessive reactivity in the cells of the microglia, without inhibiting their elementary functions or causing a reduction in total microglia [58].

4 Advances in the Nutritional Treatment of ND

Scientific and technological advances in nutrition and health make it necessary to have effective interventions in the nutritional management of ND. Functional nutrition is an area of nutriology whose axis is the use of bioactive compounds in food, at specific doses, for the restoration of homeostasis lost in the disease. In the particular case of ND, its mechanisms of biochemical and metabolic alteration are associated

with neuroinflammation process, which is why the use of bioactive compounds with anti-inflammatory effect is a potential neuroprotective agent in ND [34].

The most widely studied anti-inflammatory and used in clinical practice is omega 3. Its anti-inflammatory activity lies in being a substrate of cyclooxygenase (COX) and lipoxygenase (LOX), for the synthesis of prostaglandins, thromboxanes, and leukotrienes of the anti-inflammatory series [34].

4.1 Anti-inflammatory Characteristics of Omega 3

The fatty acids of the omega 3 family are long-chain polyunsaturated fatty acids (PUFA) that present their first unsaturation in the third carbon. Among the main representatives of the family of omega 3 fatty acids is α-linolenic acid, present in foods of plant origin and which is metabolized into eicosapentaenoic acid (EPA) and subsequently into docosahexaenoic acid (DHA) in animal organisms [54].

EPA and DHA are important structural components of the phospholipids of cell membranes. Diets rich in EPA and DHA increase the proportion of these fatty acids in cell membranes, particularly in lymphocytes, which in addition to reducing the content of arachidonic acid (AA) in the membranes of these cells, by a competitive effect, decreases the generation of proinflammatory products derived from ω-6 PUFA. EPA is also a substrate for COX (1 and 2) and lipoxygenase-5, which competes with AA for the generation of eicosanoids, but in the case of EPA, these have anti-inflammatory properties. Due to the above, dietary supplementation with EPA can reduce the formation of prostaglandin E2 (PGE2), thromboxane A2 (TXA2), and leukotriene B4 (LTB4) and maintain the levels of prostaglandin I2, potent vasodilator, thromboxane A3, aggregation inhibitor platelet, and leukotriene B5 anti-inflammatory non-chemotactic that inhibits cell adhesion (Table 2) [55].

While the products of AA metabolism (PGE2, TXA2, and LTB4) have pro-inflammatory properties, the products of EPA conversion have antagonistic properties that decrease inflammation, vasoconstriction, and platelet aggregation and may even antagonize the effects, typically proinflammatory effects of eicosanoids derived from AA [1].

Table 2 Metabolic effects of eicosanoids derived from arachidonic acid (AA) and eicosapentaenoic acid (EPA)

Cyclooxygenase pathway				Lipoxygenase pathway	
Endothelial cells		Platelets		Leukocytes	
AA	EPA	AA	EPA	AA	EPA
Prostacyclin I2 Vasoconstrictor Platelet aggregation	Platelet antiaggregation Vasodilator	Thromboxane A2 Platelet aggregation Vasoconstrictor	Thromboxane A3 Vasodilator	Leukotriene B4 Proinflammatory Chemotactic Cell adhesion	Leukotriene B5 Anti-inflammatory Non-chemotactic Inhibits cell adhesion

The production of proinflammatory cytokines is regulated by the availability of eicosanoids derived from AA, which can be modulated by the intake of ω-3 PUFA, which act at the gene level, since the expression of the genes for cytokines and cell adhesion molecules it is reduced in response to the ω-3 PUFA exposure. In addition, ω-3 PUFA directly affect the intracellular signaling pathways associated with the activation of transcription factors, such as nuclear factor κβ (NF-κβ) and peroxisome proliferator-activated receptors (PPARs) that regulate the expression of a series of genes whose products are proinflammatory [1].

Supplementation with EPA and DHA is also able to reduce the production of proinflammatory cytokines, such as IL-1, IL-6, and TNF-α, which are released when macrophages and monocytes are activated. Although these cytokines are potent activators of immune function, the excess activity of these substances contributes to pathological inflammation, a situation observed in metabolic diseases of inflammatory origin [17].

4.2 Potential Neuroprotective Effect of Omega 3 (ω-3) in ND

Several studies have shown the neuroprotective role of ω-3 fatty acids in various circumstances such as the ND to exhibit benefits in the modulation of neuronal activity, the regulation of immune cell response, and also the production of lipid mediators pro-resolution and more potent anti-inflammatories, such as resolvins [20, 28, 29]. Also, neuroprotective effect is observed in lesions induced by ischemia and by excitotoxicity produced by neurotransmitters (glutamate, mainly) [21].

The neuroprotective effects of ω-3 are due to multiple factors and may be related to a series of molecular effects at the neuronal level, especially in the CNS. Studies in rodents indicate that long-chain ω-3 fatty acids play a role in cognitive and behavioral functions. Although ω-3, due to its chemical structure (with numerous double bonds), are more vulnerable to oxidative stress (characteristic of metabolic and neurodegenerative diseases), in cells in general and especially neurons, they can reduce the damage caused by oxidative stress through neuroprotectins (docosanoids derived from DHA) [5]. In addition, ω-3 regulate the expression of neuroprotective genes, such as the expression of the antiapoptotic Bcl2 gene [4].

According to Chen et al. [13], ω-3 supplementation inhibits microglial activation and the subsequent inflammatory response by regulating the translocation and nuclear secretion of HMGB1 and its activation in the signaling pathway TLR4/NF-κβ, pathways responsible for neuroinflammation after injury neuronal. The above is an important evidence that leads to the neuroprotective effects exhibited by ω-3 fatty acids.

Chronic ω-3 fatty acid deficiency increases anxiety in rodents, particularly in stressful conditions [19]. Also, chronic DHA deficiency is accompanied by anxiety and learning and memory impairments that have been associated with changes in the processes of neurotransmission [11].

Specifically, the diet deficient in alpha-linolenic acid reduces the dopaminergic neurotransmission of the nucleus accumbens of murine models. Through in vivo

microdialysis experiments, elevated basal levels of dopamine and its metabolites (DOPAC and HVA) were observed in rats subjected to a diet deficient in fatty acids, in comparison with controls, indicating alterations in dopaminergic neurotransmission in the nucleus accumbens [67].

Other investigations focused on the neuroprotective effects of ω-3 on AD reveal the presence of low levels of plasma DHA. In an animal model (mouse with Alzheimer's disease), when administering a diet enriched with ω-3 (EPA + DHA), a reduction in the accumulation of β-amyloid peptide (peptide with neurotoxic actions) was observed in more than 70% of the cases [27].

The administration of 15 mg of EPA and DHA per g of intake per day in female rats, treated on the second day of pregnancy up to 14 days after calving, significantly reduced brain damage and improved long-term neurological outcomes up to 5 weeks after a neonatal hypoxic ischemic injury. The ω-3 polyunsaturated fatty acids exerted an anti-inflammatory effect in microglia both in the in vivo model of ischemic-hypoxic and in vitro microglial cultures subjected to inflammatory stimuli by inhibiting the activation of NF-κβ and the subsequent release of inflammatory mediators (Zhang et al. 2010).

In more recent studies, mice induced to neuropathic pain by partial ligation of the sciatic nerve received oral treatment of a fish oil concentrate of 2.3 g/Kg of weight, and reduced levels of TNF-α in the spinal cord, from the myeloperoxidase activity (MPO) sciatica and the expression of activation transcription factor 3 (ATF-3), an important marker of neuronal injury, were observed. Likewise, the diet high in ω-3 improved the sciatic functional index (SCI), as well as the electrophysiological record, which corroborates the increase in the expression of GAP43 and the total number of myelin fibers observed in the sciatic nerve. These results point to the regenerative and possibly protective properties of a combined oral administration of EPA and DHA after a peripheral nerve injury, as well as its anti-neuroinflammatory activity, evidencing the ω-3 fatty acids that promise therapeutic results for the treatment of neurodegeneration [48].

4.2.1 Alzheimer's

The consumption of ω-3 fatty acids is associated with a reduction of neuroinflammation markers in AD [24, 53]. Limited evidence in human models shows that ω-3 improve the metabolic neuroinflammatory alterations present in AD. An intervention study reveals a decrease in the loss of gray matter volume after the combined treatment of DHA/EPA [62]. Yassine et al. [63] showed significant associations between low serum concentrations of DHA with increased cerebral amyloid load, smaller brain volume (SBV), and alteration in nonverbal memory, in volunteers without cognitive or mild impairment.

Correlative epidemiological studies suggest that a high intake of foods rich in ω-3 is associated with greater cognitive performance and possibly less neuronal deterioration and risk of AD [38]. Results recently presented at the Alzheimer's Association International Conference in Toronto indicate that blood DHA levels are significantly associated with superior cognitive ability in two large population-based studies, totaling more than 5000 individuals [56].

It should be noted that although clinical trials of ω-3 supplementation following the diagnosis of AD do not show significant effects, studies have shown its potential preventive effect, associated with its anti-inflammatory effects [43, 45, 64]. Recently published data from the MAPT (Multidomain Alzheimer Preventive Trial) report no significant benefit in elderly participants who received 800 mg/day of DHA supplements for more than 3 years [3].

4.2.2 Parkinson's

Evidence from clinical studies about ω-3 fatty acid supplementation in PD is still very limited. In animal models, it has been observed that DHA induces a recovery of the dopaminergic system after an extensive Parkinson's injury. After the induction of dopaminergic denervation with 6-hydroxydopamine (6-OHDA), a high intake of DHA led to a) increased levels of dopamine in the striatum, b) greater dopaminergic terminals in striated body, and c) increase of the soma area of dopaminergic neurons. Although the cell count remained unchanged, such improvement of key components in the dopaminergic system suggests that DHA activated the compensatory mechanisms that contribute to the functionality and recovery of CNS [14]. Therefore, these data suggest that DHA induced neuroregeneration and could be used after diagnosis of PD.

Recently Mori et al. [37] demonstrated that supplementation of 3 g/Kg of weight (18% EPA and 12% DHA) in Wistar rats mitigates the loss of SNpc neurons and nerve terminals in the striatum, after an induction of damage with 6-OHDA. This protective effect was associated with reductions in iNOS-immunoreactive cell density and reactivity of microglia and astrocytes, thereby reducing dopaminergic damage in PD.

5 Conclusion

The scientific evidence shows the potential neuroprotective effect of omega 3 fatty acids on ND, associated with the reduction of neuroinflammation. Although more clinical studies are necessary to obtain ω-3 dosages in the prevention and treatment of ND, the trials in animal and epidemiological models are an important reference for its recommendation as part of a nutritional treatment.

Abstract

Bioactive compounds effectively contribute to human health, and hence, they have recently attracted great attention in order to fortify food products and develop novel functional foods. However, employment of bioactive compounds in food matrices has some limitations. Most of the bioactive substances are readily decomposed in food as well as within the gastrointestinal tract that cause remarkable losses in their efficiency. Furthermore, they display low water solubility, poor bioavailability, and insufficient dispersibility. Other problems are

related to their interaction with food ingredients and unfavorable effects on sensory attributes of food products. Lipid-formulation nanoencapsulation technologies including nanoliposomes, nanoemulsions, lipid nanoparticles (SLNs, solid lipid nanoparticles, and NLCs, nanostructured lipid carriers), and nano-phytosomes potentially help to solve these issues. These nanodelivery systems provide more stability, solubility in different media, functionality, bioavailability, targeting properties, and the ability of controlled release in food and pharmaceutical practices. This chapter reviews lipid-based nanocarriers in terms of production methods, types, characteristics, and composition for incorporation of different bioactive compounds. Also, food applications of various bioactive compounds incorporated in the commonly used lipid-based nanocarriers are highlighted. In this sense, the relevant recent studies have been discussed.

1 Introduction

Health concerns have recently increased the tendency for development of functional foods and novel food products fortified with bioactive compounds and nutraceuticals especially phytochemicals [14, 205]. However, there are some limitations for direct utilization of bioactive compounds in food matrices. Most of the bioactive substances suffer from low stability and decomposition when exposed to unfavorable conditions during food processing and storage (e.g., light, oxygen, and moisture) as well as within the gastrointestinal tract (GIT) which reduces their efficiency and bioactivity [1, 139]. Moreover, they exhibit low water solubility, poor bioavailability, and insufficient dispersibility in food systems, interact with food ingredients, and negatively influence sensory properties of food systems [39, 46, 51, 66].

Food-grade delivery systems for nanoencapsulation of bioactive compounds represent an efficient way to solve these drawbacks. Among different nanodelivery techniques, lipid-based nanocarriers (Fig. 1) including nanoliposomes, nanoemulsions, lipid nanoparticles (SLNs, solid lipid nanoparticles, and NLCs, nanostructured lipid carriers) and nano-phytosomes have received a great attention owing to their beneficial characteristics [6, 64]. They have great potentials to accommodate and release various bioactive compounds (hydrophilic, lipophilic, and amphiphilic compounds) in a sustained and controlled manner, improve solubility and encapsulation efficiency of hydrophobic bioactive compounds, decrease their volatility, and enhance their target specificity. Lipid-based nanocarriers also promote effectiveness and bioavailability by enhancing stability of entrapped compounds in food mediums and during digestion [43, 79, 192]. Furthermore, these systems are biocompatible and can be fabricated by inexpensive and safe components for large-scale industrial practices via simple and available production technologies without the use of organic solvents [79, 98]. This chapter will review lipid-based nanocarriers in terms of

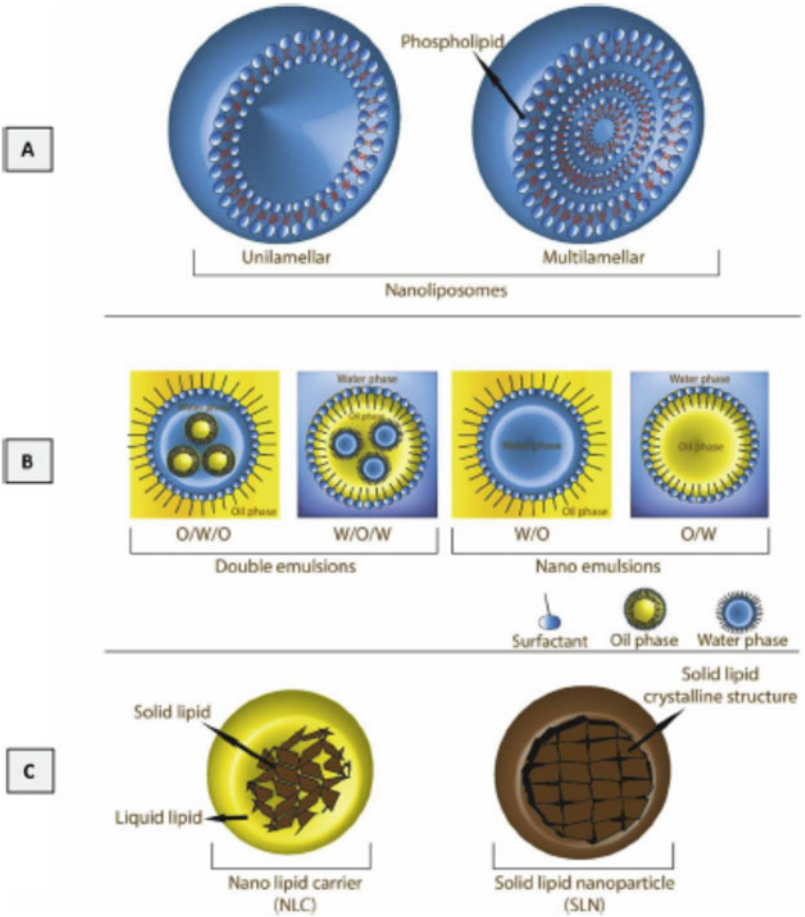

Fig. 1 Schematic illustration of three important nanostructured lipid-based encapsulation formulations: nanoliposomes (**a**), nanoemulsions (**b**) plus NLCs and SLNs (**c**). (Reprinted with permission from Ref. [6])

production methods, types, characteristics, and composition. Also, food applications of different bioactive compounds incorporated in the commonly used lipid-based nanocarriers are highlighted. Future trends will also be discussed in the last section.

2 Nanoencapsulation by Lipid-Based Nanocarriers

Encapsulation is described as an effective and practical technology for incorporating different unstable compounds within carrier materials which can occur in micro- and nanoscale. According to nanotechnology definition, an average size under 1000 nm is referred to as nanoparticle; although for therapeutic and pharmaceutical delivery

systems, it should be lower than 100 nm [54, 194]. Many studies have indicated superiority of nanocarriers to micro ones. Compared to microencapsulation systems, nanosized carriers offer more stability, solubility in different media, functionality, bioavailability, absorption, homogeneity, targeting properties, and the ability of controlled release in food and pharmaceutical practices which are associated with their greater surface area and larger reactivity [48, 52]. Moreover, food formulations containing nanoparticles with sizes smaller than 100 nm have acceptable sensory attributes due to their high optical transparency [114, 115, 160].

There are several methods for preparing nanoencapsulated bioactive compounds which can be categorized into five different classes including lipid-based techniques, specialized-equipment techniques, nature-inspired techniques, biopolymer-based techniques, and disparate techniques [79]. Nanoencapsulation technology should be selected on the basis of various factors such as release pattern, cost, the nature and physicochemical features of the wall and core materials, purpose of encapsulation, etc. [6, 167].

Diverse types of wall materials can be applied to incorporate bioactives including proteins, lipids, and carbohydrates. Carbohydrate- and protein-based nanocapsules cannot be applied in industrial applications because of occurring complex chemical or heat treatments which make it difficult to control processing conditions. In contrast, lipid-based nanocarriers not only have scaling-up potentials and low toxic effects but also offer greater encapsulation potency [54, 199]. The presence of emulsifiers is mostly essential to incorporate hydrophobic bioactive substances (e.g., flavonoids, fatty acids, aromas, phytosterols, lipophilic vitamins, and carotenoids) due to their non-solubility nature. Furthermore, utilization of digestible lipids provides sufficient blended micelles for solubilization and carrying lipophilic compounds which consequently facilitate their intestinal absorption [78, 164]. Accordingly, lipid-formulation nanoencapsulation technologies have received remarkable attention as novel and promising vehicles for bioactive ingredients in food and pharmaceutical industries. Nanoliposomes, nanoemulsions, SLNs, NLCs, and nano-phytosomes are basic kinds of lipid-based nanocarriers which are described in the following sections [50, 64, 79].

2.1 Nanoemulsions

The emulsion is defined as a system composed of two immiscible liquids (mostly water and oil) where one is dispersed as the droplet form (the dispersed or internal phase) in other one (the continuous or external phase). Emulsions can be classified into three main types in terms of particle size of droplets: microemulsion (10–100 nm), macroemulsion (0.5–100 μm), and nanoemulsion (known as miniemulsion, 100–500 nm) [80, 83].

The nanoemulsions are formulated in well-optimized mixtures consisting of at least three components being oil, aqueous phases, and surfactant(s). The oil phase of oil-in-water (O/W) nanoemulsions and water phase of water-in-oil (W/O) nanoemulsions are generally hosting the lipophilic and hydrophilic bioactive ingredients,

respectively [131, 132]. The bioactive compounds are usually solubilized in the related phase prior to the formation of nanoemulsions. The lipophilic phase can be comprised of triacylglycerols (long-chain, medium-chain, and short-chain triglycerides), essential oils, mineral oils, fat substitutes, waxes, or combination of them. In addition to the oil and water phases, the preparation of nanoemulsions requires the use of surfactant(s) which is adsorbed on newly formed droplet surfaces and facilitates droplet disruption and protects droplets toward aggregation [128].

As illustrated in Table 1, nanoemulsions can be generally produced by two different techniques: high-energy (e.g., ultrasonication, electrified coaxial liquid jets, microfluidization, high-pressure homogenization, and high shear mixing) or low-energy emulsification approaches [81, 82]. High-energy techniques need high levels of mechanical energy to provide intense disruptive forces for generating fine droplets. In contrast, low-energy procedures are based on utilizing the internal chemical energy of the oil-water-surfactant mixtures, and emulsification is merely carried out via simple stirring [79]. It is possible to fabricate nanoemulsions by modifying the system conditions. For instance, large amounts of emulsifiers, a high volume fraction of dispersed phase, and changes in the hydrophilic-lipophilic balance of matrix through modifying parameters (e.g., composition or temperature) lead to generation of nanoemulsions by microemulsification, catastrophic inversion, and phase inversion methods (inversion temperature and phase inversion composition), respectively [9, 183]. Low-energy methods are not suitable for scaling up and industrial purposes [11, 12]. High-energy techniques are highly favorable for producing ultra-fine droplets, but they may degrade susceptible compounds [84]. Furthermore, nanoemulsions can be manufactured by cubosomes and colloidosomes as well as microfluidic channels [6].

Nanoemulsions possess distinct features such as a small droplet size, optical transparency, high surface area, and high kinetic stability which make them appropriate candidates for the delivery of bioactive compounds [137, 138]. They display good potentials to improve solubility, absorption, and bioavailability of incorporated bioactive compounds [182, 186]. However, some adverse phenomena may take place in nanoemulsion systems like Ostwald ripening, flocculation, creaming, coalescence, and gelling, which negatively influence their storage stability. On the other hand, they require high levels of emulsifiers and particular devices for nanoencapsulation [6, 127, 172].

2.2 Nanoliposomes

Liposomes are self-assembled spherical vesicles consisting of at least one concentric lipid bilayer that encloses an aqueous phase [145]. Dispersing phospholipids in aqueous solutions results in orientation of hydrophobic groups toward the inside of the sphere with the hydrophilic heads toward outside. Therefore, a spherical bilayer membrane is formed which surrounds the aqueous core [47, 54]. Liposomes are categorized into different classes of large unilamellar vesicles (LUVs), small unilamellar vesicles (SUVs), giant unilamellar vesicles (GUVs), multivesicular

Table 1 Overview of nanoemulsion preparation techniques (Reprinted with permission from Ref. [6])

Technology	Process steps
Hot homogenization technique	1. Melting the lipid and dissolving/dispersing the bioactive compound in the lipid 2. Dispersing the bioactive-loaded lipid in hot aqueous surfactant mixture 3. Premixing using a stirrer to form a coarse pre emulsion 4. High-pressure homogenization at temperatures above lipid melting point 5. Hot O/W nanoemulsion 6. Solidification of the nanoemulsion by cooling down to room temperature
Cold homogenization technique	1. Melting the lipid and dissolving/dispersing the bioactive compound in the lipid 2. Solidification of the bioactive-loaded lipid in liquid nitrogen or dry ice 3. Grinding in a powder mill (50–100 μm) 4. Dispersing the powder in an aqueous surfactant dispersion medium (premix) 5. High-pressure homogenization at room temperature or below
High-pressure homogenization	1. The lipid is pushed with high pressure (100–2000 bars) through a very high shear stress 2. Disruption of particles down to the submicrometer or nanometer range
Solvent emulsification-evaporation method	1. Lipids and bioactive compounds are dissolved in a water-immiscible organic solvent with low boiling point 2. The solution is then emulsified in the aqueous emulsifier solution 3. Evaporate in rotary evaporation at 50–60 °C
Solvent emulsification-diffusion technique	1. Both the solvent and water are mutually saturated in order to ensure the initial thermodynamic equilibrium of both liquids 2. Lipid and bioactive compound are dissolved in water-saturated solvent, and this organic phase is stirred using mechanical stirrer 3. After formulation of O/W emulsion, water in typical ratios from 1:5 to 1:10 is added to the system in order to allow solvent diffusion into the continuous phase, thus leading to the aggregation of the lipid in the nanoparticles
Microemulsion technique	1. Lipids are melted, and bioactive compound is incorporated into molten lipid 2. Mixture of water, co-surfactant, and surfactant is heated to the same temperature as lipids and added under mild stirring to the lipid melt 3. A transparent, thermodynamically stable system is formed when the compounds are mixed in correct ratios for microemulsion formation 4. This microemulsion is then dispersed in a cold aqueous medium under mild mechanical mixing of hot microemulsion with water in a ratio in the range 1:25–1:50
Melting dispersion method	1. Bioactive compound and solid lipid are melted in an organic solvent regarded as oil phase. Simultaneously water phase is also

(*continued*)

Table 1 (continued)

Technology	Process steps
	heated to the same temperature as oil phase 2. The oil phase is added to a small volume of water phase, and the resulting emulsion is stirred at high speed for few hours 3. The emulsion is cooled down to room temperature to yield nanoparticles
Ultrasonication technique	1. The core material is melted 2. Addition of phospholipids along with an aqueous medium 3. Dispersing the melted material at increased temperatures by ultrasonication
Solvent injection	1. Lipids are dissolved in a water-miscible solvent (e.g., acetone, isopropanol, and methanol) or water-miscible solvent mixture 2. Quickly injected into an aqueous solution of surfactants through an injection needle
Double emulsion technique	1. Bioactive compound (mainly hydrophilic ones) is dissolved in aqueous solution emulsified in melted lipid 2. The primary emulsion is stabilized by adding stabilizer that is dispersed in aqueous phase containing hydrophilic emulsifier 3. Emulsion is stirred and filtered

vesicles (MVVs), and multilamellar vesicles (MLVs) regarding their size and lamellarity [68].

A wide variety of methods have been employed for producing nanoliposomes. These techniques are generally divided into mechanical (extrusion, ultrasonication by probe or bath sonicator, microfluidization, and high-pressure homogenization) and nonmechanical methods (reversed-phase evaporation, freeze-drying-rehydration, freeze-thawing, depletion of mixed detergent-lipid micelles, and injection methods) [203]. Mozafari [141] proposed a method for liposome preparation based on heating treatment. Today, novel methods such as dense gas techniques, supercritical fluid technology, dual asymmetric centrifugation, membrane contactor technology, cross-flow filtration technology, and freeze-drying of double emulsions method have been developed for preparing nanoliposomal formulations [76, 121, 207]. Table 2 presents advantages and disadvantages of various preparation methods of nanoliposomes.

Nanoliposomes are mostly used in food, bioprocessing, and pharmaceutical industries for incorporation of bioactive compounds to enhance their solubility, bioavailability, and functionality, provide controlled and sustained release, and protect them against adverse conditions. Also, nanoliposomes can be manufactured from natural and safe components (e.g., soy, egg, or milk) and are biocompatible and targetable. Additionally, liposomal ingredients such as phospholipids and sphingolipids have potential health benefits for humans [51, 171]. Owing to amphiphilic nature, liposomes are capable of encapsulating bioactive compounds with different degrees of solubility. Hydrophobic compounds are distributed within the lipid bilayers, while hydrophilic substances are enclosed inside aqueous space. Compounds with intermediate polarity also can be located between aqueous

Table 2 Overview of conventional and novel methods for nanoliposome production (Reprinted with permission from Ref. [6])

Technology		Advantages	Disadvantages
Conventional methods	Thin-film dispersion (Bangham method)	Rapidly formed; low energy input to form. Highest stability and transition cooperatively	Usually yields large and multilamellar vesicles with low encapsulation efficiencies (EEs)
	Ethanol/ether injection	Organic solvent residue, ready to nozzle blockage in ether system, time-consuming, sterilization issue	Highly heterogeneous dispersion; lower encapsulation efficiency vs. LUVs. Nearly impossible to determine mass
	Ultrasonication: probe	Can be performed directly on hydrated MLVs. Preferred method to form SUVs Excellent for reduction of large MLVs to more homogenous dispersion of SUVs	Probe sonication can degrade sample/localized overheating Requires constant cooling. Liposomes are metastable (low storage stability) Low volume required for effective treatment
	Ultrasonication: bath	Less destructive to liposomes, more homogenous product, and greater reproducibility vs. probe sonicator. Increased sample volume capability. Increased control over sample temperature	Requires extensive sonication to obtain minimum size limit of SUV; not always possible. Nonhomogenous product; requires removal of large vesicles by chromatographic/ centrifugal methods
	Reverse-phase evaporation	Higher entrapment efficiency reported for variety of molecules with MLVs (proteins, nucleic acids, etc.)	Heterogeneous distribution of MLVs and unilamellar vesicles; additional homogenization required. Solvent exposure may inhibit protein activity. Incomplete removal of organic solvent
	Freeze-dried rehydration vesicles	High entrapment efficiency. Improved homogeneity in mixing of lipid species/liposome. Useful for forming antigen-entrapping vesicles	Dehydration best controlled by freeze-drying; long time to process
	Microfluidic channel	Control of particle size, production of vesicles with diameter up to 29 nm	Not suitable for bulk production, organic solvent use, with agitation over treatment, damage of the liposome structure, and the leakage of encapsulated components

(*continued*)

Table 2 (continued)

Technology		Advantages	Disadvantages
	Detergent depletion	No solvent used; protein activity retained. No mechanical energy input. Homogenous distribution of liposomes. Useful for multiple lipids and molecules for encapsulation. Best for entrapping membrane-associated proteins	Limited number of useful detergents. Dialysis is very slow process, and some detergent is likely to remain in the sample. Detergent may negatively interact with molecule of interest
	Membrane extrusion	Homogenization of liposomes improved over other methods; rapid preparation of unilamellar vesicles from MLVs	Liposomes must be held above TM to facilitate extrusion. Manual extruders handle only small volumes (1 ml). Solute leakage can occur during extrusion. High salt concentration
Novel methods	Heating method	Absence of potentially toxic solvents and using very low shear forces; applied to large-scale production	Long time to process
	Freeze-drying of double emulsions	Relatively high encapsulation efficiency and excellent stability during long-term storage	Long time to process
	High-pressure homogenization, microfluidization	Can process high lipid concentration (∼150 mg/ml). Lab data is easily inferred to processing plant. High reproducibility. Most useful for large-scale production of liposomes	Solvent ionic strength must be carefully controlled to control liposome size. Complete homogenization is time-consuming in microfluidizer
	Supercritical fluid injection and decompression	Control of particle size, possible in situ sterilization, low organic solvent consumption	High cost, low yield, high pressure up to 350 bar used
	Dual asymmetric centrifugation	Simple method, homogenous liposome production with 60 nm size, high trapping efficiency	Not suitable for bulk production, high pressure, with agitation
	Dense gas techniques	Possible in situ sterilization, producing stable and homogenous iposome, low organic solvent consumption	Need multiple stages to achieve the final size of liposome, high pressure up to 200–300 bar, readily block nozzles

compartment and the lipid moieties. Furthermore, nanoliposomes provide simultaneous encapsulation, release, and delivery of compounds with different polarities [4]. For instance, this possibility has been revealed for α-tocopherol with ascorbic acid and glutathione [141].

Despite mentioned advantageous properties, some drawbacks restrict potential applications of liposomes. They are unstable systems and easily undergo oxidation, hydrolysis, fusion, and aggregation, decreasing loading capacity of bioactive compounds [37, 203]. Also, liposomes exhibit a short release time and inadequate half-life circulation. Using cholesterol, hydrogenated soy phosphatidylcholine, and neutral long-chain saturated phospholipids (e.g., disteroylphosphatidylcholine) can increase the stability and rigidity of bilayers. Phytosterols have been recently introduced as a suitable substitute of cholesterol in liposomal formulations especially for patients with hypercholesterolemia [47, 121]. Moreover, several techniques such as freezing, lyophilization (freeze-drying), supercritical fluid technology, and spray-drying have been evaluated for extending the shelf life of liposome structures [54]. Overall, lyophilization is considered as the best stabilization method for thermolabile substances loaded within liposomes [28]. Furthermore, polymer coating is a suitable and efficient stabilization method for liposomal systems. Coating with chitosan can improve stability, bioavailability, and sustained release of liposomes containing bioactive compounds [37]. Also, it was demonstrated that polyethylene glycol coating could effectively promote circulation half-life, functionality, and stability of bioactives [125].

2.3 Nano-Phytosomes

The term phytosome comes from two words of “phyto” and “some” which mean plant and cell-like, respectively [19, 184]. Phytosome, also called as herbosome and phytolipid delivery system, is resulted from the complex of plant extracts or phytoactive compounds (i.e., flavonoids and terpenoids) with phospholipids, which are formed via hydrogen bonds between their polar moieties [94, 95].

Basically, main components of phytosome formulations include phytochemicals, phospholipids, and solvents. The ratio of phospholipid to phyto-actives plays an important role in phytosome systems, and 1:1 or 2:1 ratios are often preferred. The common phospholipids for producing phytosomes are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. The former is most widely used for producing phytosomes. Aprotic solvents like acetone, ethyl acetate, dioxane, and methylene chloride can be successfully utilized in phytosome systems, but ethanol as a safe solvent is a good candidate for food purposes [59, 64, 205]. In order to separate organic solvents from obtained phytosomes, various methods can be used including spray-drying, freeze-drying, vacuum evaporation, and precipitation via n-hexane as an aliphatic hydrocarbon. Different techniques have been applied to develop phytosomes such as precipitation, anhydrous cosolvent lyophilization, anti-solvent precipitation, and solvent evaporation [95, 206].

The phytosome and liposomes are similar in the terms of structure. However, phytosomes possess a higher ability to enhance stability, absorption, and bioavailability of incorporated ingredients than liposomes which is associated with presence of H-bonds between phospholipids and the loaded compounds in phytosome structures. In contrast, there is no chemical interaction in liposomes, and the bioactives are merely surrounded by phospholipid bilayer. Intensifying bioavailability and absorption of lipid-soluble compounds by phytosomes as a delivery system is more evident, which reduces required amount to exhibit their advantageous effects and boost functionality [134, 188, 193].

It has been demonstrated that antioxidant activity of phenolic compounds in phytosomal systems is more than their free ones. In addition to food applications, there is a growing trend for usage of phytosomes in cosmetics owing to improving skin penetration of bioactive compounds. They can easily pass through the membrane and release bioactives into the cells, prevent degradation of bioactives by gut bacteria as well as digestive secretions, and provide target specificity [59, 134, 188]. Phytosomal products are commercially available in the market [7].

In spite of the advantages, phytosomes are sensitive to pH variations, and it is better to use them in food products with the neutral pH values such as milk [64].

2.4 Lipid Nanoparticles

2.4.1 Solid Lipid Nanoparticles (SLNs)

SLNs are nanoparticles with an organized crystalline structure and can entrap different bioactive components within their lipid network [212]. SLNs are basically derived from O/W emulsions, but they use solid lipids instead of the liquid one (oil), and therefore, they remain in solid form at ambient as well as human body temperatures [211].

Main ingredients utilized within SLN formulations are solid lipids, surface active materials (emulsifiers), and water. Lipid matrices are fabricated using a wide variety of natural or synthetic digestible lipids. Some of the most common lipids include triglycerides (tripalmitin, tristearin, and trimyristin), glyceryl monostearate (Imwitor), glyceryl palmitostearate (Precirol ATO 5), glyceryl behenate (Compritol 888 ATO), fatty acids (palmitic acid, stearic acid, and decanoic acid), cholesterol, waxes (carnauba wax, cetyl palmitate, and beeswax), and different types of hard fats [49, 63, 214]. Phospholipids as neutral surfactants (lecithin), ionic surfactants (sodium lauryl sulfate, sodium deoxycholate, sodium dodecyl sulfate, sodium cholate, sodium taurodeoxycholate, sodium oleate, trimethylammonium bromide, and stearylamine), nonionic surfactants (Poloxamer, Span, Pluronic, Tween, Solutol, Tego Care, and Brij), polyvinyl alcohol, and polyethylene glycol are the most important emulsifiers or surfactants which improve stability of lipid matrices [49, 110, 190]. Furthermore, mono- and diglycerides as solubilizing agents can enhance solubility and loading efficiency of bioactive compounds [54].

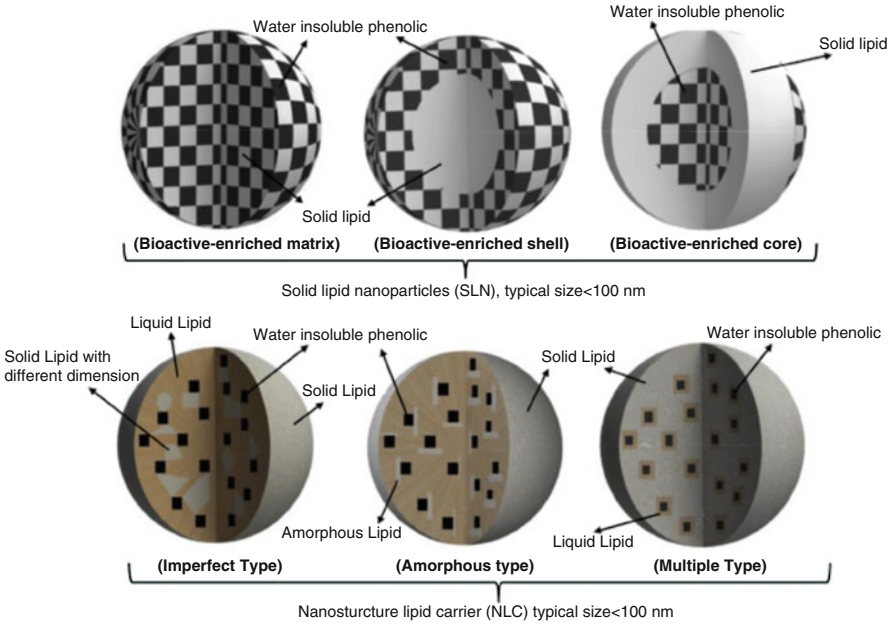

Fig. 2 Classification of SLNs and NLCs. (Reprinted with permission from Ref. [97])

Encapsulation of bioactive compounds within SLNs is usually carried out via three models including homogeneous matrix (solid solution) model, bioactive-enriched shell model, and bioactive-enriched core model (Fig. 2). In homogeneous matrix model, the dispersion of bioactive compounds entirely occurred in the lipid matrix. This type is mainly achieved by cold homogenization technique or when highly lipophilic compounds are entrapped inside SLNs applying hot homogenization. No surfactant is used for fabrication in this model. Bioactive-enriched shell model is formed as high concentration of surfactants is used or when phase separation from the liquid oil droplet takes place during the cooling process. This model has a burst release pattern. When the inverse phenomenon of bioactive-enriched shell model occurs, bioactive-enriched core type can be achieved. In this model, bioactive compounds precipitate first, and subsequently the shell entraps lower amounts of incorporated ingredients. This model results in controlled release of bioactive compounds [60, 97].

SLNs were developed to overcome the defects of other lipid-based nanocarriers such as nanoliposomes and nanoemulsions. They can be prepared without use of organic solvents; provide prolonged release, target specificity, and biocompatibility; protect incorporated compounds against adverse external conditions as well as chemical reactions (e.g., oxidation); improve stability, solubility, dispersibility, and bioavailability; facilitate large-scale production; and be utilized in different food products [148]. However, SLNs have limited space for encapsulating bioactive

compounds. They may also undergo crystallization, gelation, aggregation, and expulsion of core materials during storage period which negatively influences their characteristics and release behavior [40, 60].

2.4.2 Nanostructured Lipid Carriers (NLCs)

To overcome deficiencies of SLNs, NLCs were introduced by [221] as an efficient strategy for nanoencapsulation of bioactive compounds. NLCs are originated from O/W emulsions like SLNs. However, inner core of NLCs is obtained from a mixture of solid lipid (70%) and liquid lipid (30%), while lipid matrix of SLNs entirely consists of solid lipids (100%) [6, 43].

Basically, both saturated oils (e.g., paraffin oil and medium-chain triglycerides) and unsaturated oils (e.g., oleic acid, seed and vegetable oils) are employed for developing NLCs as liquid lipids [49]. Most common type of liquid lipid for producing NLCs is medium-chain triglycerides (MCT) such as Miglyol® 812. However, healthy unsaturated fatty acids (e.g., oleic acid and linoleic acid) can be considered as a substitute for saturated oils [44, 143, 199, 219].

NLCs are structurally divided into three diverse types: imperfect crystal, amorphous, and multiple models by considering type of bioactive compounds, the purpose of nanoencapsulation, preparation techniques, and makeup (Fig. 2). In the first type, NLCs are fabricated by diverse lipids with specific dimensions which increase their capacity for incorporating bioactive compounds. In the second group called amorphous model, noncrystalline structures are produced by a mixture of solid lipids with some other lipids (isopropyl myristate, hydroxyoctacosanyl, hydroxystearate, or MCT). In turn, the mixture can effectively decrease expulsion and release rate by forming an amorphous matrix. This model can prevent degradation of bioactive compounds which are highly soluble within liquid lipids. In the latter group called multiple model, employing certain liquid lipids (e.g., hydroxyl stearate and isopropyl myristate) leads to reduction of crystallization and therefore expulsion. The model is particularly suitable for enclosing and modulated release of bioactive compounds which exhibit great solubility in liquid lipids [60, 97, 143].

Preparation method of NLCs and SLNs are the same. Diverse approaches have been applied to fabricate these nanocarriers as shown in Table 3 which could be categorized into two major groups. The first group includes methods which require large amounts of energy like high-speed homogenization, ultrasound, and high-pressure homogenization, and the second group are methods with low energy consumption like microemulsions, solvent-based methods, and phase inversion temperature [143, 144]. It could be concluded that hot, cold, and the high-pressure homogenization techniques are practically more favorable for making these nanocarriers compared with other methods [6]. NLCs have attracted increasing attention because they possess good capability to optimize penetration, absorption, bioavailability, and release rate of loaded bioactives in food, cosmetic, and pharmaceutical applications [30].

Table 3 Overview of production methods for SLNs and NLCs (Reprinted with permission from Ref. [97])

Technology	Process steps
Hot homogenization technique	1. Melting of the lipid and dissolving/dispersing of the bioactive in the lipid 2. Dispersing of the bioactive-loaded lipid in hot aqueous surfactant mixture 3. Premix using a stirrer to form a coarse pre-emulsion 4. High-pressure homogenization at temperature above lipid melting point 5. Hot O/W nanoemulsion 6. Solidification of the nanoemulsion by cooling down to room temperature
Cold homogenization technique	1. Melting the lipid and dissolving/dispersing of the bioactive in the lipid 2. Solidification of the bioactive-loaded lipid in liquid nitrogen or dry ice 3. Grinding in a powder mill (50e100 mm) 4. Dispersing the powder in an aqueous surfactant dispersion medium (premix) 5. High-pressure homogenization at room temperature or below
High-pressure homogenization	1. The lipid is pushed with high pressure (100e2000 bars) through a very high shear stress 2. Disruption of particles down to the submicrometer or nanometer range
Solvent emulsification-evaporation method	1. Lipids and bioactive compound are dissolved in a water-immiscible organic solvent with low boiling point 2. The solution is then emulsified in the aqueous emulsifier solution 3. Evaporation in a rotary evaporator at 50–60 °C
Solvent emulsification-diffusion technique	1. Both the solvent and water are mutually saturated in order to ensure the initial thermodynamic equilibrium of both liquids 2. Lipid and bioactive are dissolved in water-saturated solvent, and this organic phase is stirred using mechanical stirrer 3. After the formulation of O/W emulsion, water in typical ratio from 1:5 to 1:10 is added to the system in order to allow solvent diffusion into the continuous phase, thus leading to the aggregation of the lipid in the nanoparticles
Microemulsion technique	1. Lipids are melted, and bioactive is incorporated in molten lipid 2. A mixture of water, co-surfactant(s), and the surfactant is heated to the same temperature as the lipids and added under mild stirring to the lipid melt 3. A transparent, thermodynamically stable system is formed when the compounds are mixed in the correct ratios for microemulsion formation. Thus the microemulsion is the basis for the formation of nanoparticles of a requisite size 4. This microemulsion is then dispersed in a cold aqueous medium under mild mechanical mixing of hot microemulsion with water in a ratio in the range 1:25–1:50.

(*continued*)

Table 3 (continued)

Technology	Process steps
Melting dispersion method	1. Bioactive and solid lipid are melted in an organic solvent regarded as oil phase. Simultaneously water phase is also heated to the same temperature as oil phase 2. The oil phase is added to a small volume of water phase, and the resulting emulsion is stirred at high speed for few hours 3. The emulsion is cooled down to room temperature to yield nanoparticles
Ultrasonication technique	1. The core material is melted 2. Addition of phospholipids along with an aqueous medium 3. Dispersing the melted material at increased temperature by ultrasonication
Solvent injection	1. Lipids are dissolved in a water-miscible solvent (e.g., acetone, isopropanol, and methanol) or water-miscible solvent mixture 2. Quickly injected into an aqueous solution of surfactants through an injection needle
Double emulsion technique	1. Bioactive (mainly hydrophilic ones) is dissolved in aqueous solution emulsified in melted lipid 2. The primary emulsion is stabilized by adding stabilizer that is dispersed in aqueous phase containing hydrophilic emulsifier 3. Emulsion is stirred and filtered

3 Nanoencapsulation of Food Bioactive Compounds by Lipid-Based Nanocarriers

3.1 Phenolic Compounds

Phenolic compounds are regarded as a main group of bioactive compounds with many unique features (such as antioxidant, antimicrobial, antiviral, anti-inflammatory, anticancer, antithrombotic, and anti-allergic effects) that make them a qualified choice for food and pharmaceutical sectors [13]. Enrichment/fortification of foods by phenolic compounds not only improves their chemical and microbial stability but also can be effective in prevention and cure of some disease such as cardiovascular and neurodegenerative diseases [145, 148].

In spite of several beneficial properties, employment of phenolic compounds in food matrices has some limitations. Generally, phenolic compounds are readily decomposed in food as well as GIT systems. Nonpolar phenolic compounds are poorly dissolved in aqueous foods due to their lipophilic character. Highly polar ones do not pass through the biological membranes because of low hydrophobicity. Moreover, phenolic compounds with multiple phenolic rings are insufficiently absorbed as a result of forming massive molecular structures [64, 117]. Other problems are related to their bitter and stringent taste, creation of hazy appearance in beverages, and unfavorable effects on sensory attributes. Moreover, phenolic compounds participate in browning reactions as well as oxidation, leading to

produce brown color and undesirable odors along with nutritional losses in fortified foods [145, 148]. Interaction between phenolic compounds and food components not only leads to aggregated and precipitated proteins but also can adversely affect their bioactivity [173].

In contrast to in vitro experiments, phenolic compounds exhibit low bioactivity within body system because they have conditioned solubility, low gastric retention time, and weak penetrability and stability. Thus, higher amounts of these compounds will be required for exerting their biological activities which result in further effects on food products [51].

Lipid-based nanocarriers potentially help to solve these issues. They provide the stability and controlled release for phenolic compounds in food matrices as well as GIT system, consequently causing a longer shelf life and enhancing bioaccessibility. The nanodelivery systems facilitate passage of polar phenolics from aqueous parts toward lipophilic mediums and then bloodstream which enhances their in vivo efficiency and bioavailability [101]. They promote antioxidant and antimicrobial activity of phenolic compounds. Solubility of lipophilic phenolic compounds can be also improved in beverages and aqueous foods without any significant changes in sensorial properties of final products by lipid-based nanocarriers [53].

Many studies have been carried out on incorporation of phenolic compounds into lipid-based nanocarriers as displayed in Table 4. For instance, Ni et al. [147] encapsulated quercetin in nanoemulsions via high-pressure homogenization technology. Quercetin-loaded nanoemulsions displayed good phytochemical properties by considering an average particle size, zeta potential, and encapsulation efficiency. The prepared nanoemulsions exhibited similar antioxidant activity to free quercetin. Furthermore, they found that nanoencapsulation improved release behavior and bioavailability of quercetin in simulated GIT conditions. Also, they added the loaded quercetin into a beverage formulation and observed that it caused no negative effects on texture and appearance of the beverage during storage [147].

Epigallocatechin gallate (EGCG) and catechin loaded in soy lecithin nanoliposomes was prepared by Rashidinejad et al. [174] and then added to ripened low-fat cheese. The results showed that addition of the loaded EGCG and catechin increased antioxidant activity and phenol content of cheese after simulated GIT digestion without any notable effects on pH, chemical composition, and cheese production yield. Moreover, EGCG and catechin completely remained in cheese structure and were not detected in whey [174].

Gaber et al. [58] fabricated SLNs containing myricetin and evaluated effect of some additives, pH variation, and heat treatments on their stability. Based on their results, lipid-soluble antioxidants (vitamin E and BHT) could improve thermal stability of incorporated compounds. Beside antioxidants, presence of Poloxamer 407 and Tween 80 as stabilizer was essential to form stable systems. Loaded myricetin exhibited a lower decomposition rate and longer half-time in buffer solutions compared to its free counterpart. Nanoencapsulation also influenced release pattern of loaded phenolic compounds.

Babazadeh et al. [15] prepared NLCs as carriers of rutin using food-grade components (oleic acid, cacao butter, and Tween) and added nanoencapsulated

Table 4 Some selected studies on incorporation of phenolic compounds into lipid-based nanocarriers

Nanocarrier	Phenolic compound	Results	Reference
Nanoliposomes	Luteolin	Enhancement of bioavailability upon nanoencapsulation	[213]
	Curcumin	- High stability against alkaline pH and metal ions - Good storage stability - Sustained release - Maintenance of cellular antioxidant activity after nanoencapsulation	[31]
	Quercetin and resveratrol	- Higher antioxidant activity than free flavonoids - Suitable stability	[25]
	Curcumin	Nanoliposomes obtained from ethanol injection method were superior to those produced by dry thin-film method regarding encapsulation efficiency and storage stability	[191]
	Quercetin	Better physicochemical and sensory properties along with higher stability of whey drink fortified with whey protein isolate-coated liposomes in comparison with uncoated ones	[57]
	Resveratrol	- Maintenance of antioxidant capability after nanoencapsulation - Effect of preparation method on physiochemical properties of nanoliposomes	[77]
	Resveratrol	Improved stability against UV-B light	[24]
	Catechin and epigallocatechin gallate	- Retention of phenolic compounds in cheese matrix without any significant change in its physiochemical properties - Improved antioxidant activity - Protection against digestion	[174]
	Curcumin	Enhanced bioavailability and plasma antioxidant activity	[198]
	Epigallocatechin gallate	- Increase of stability in simulated intestinal conditions - Retention of antioxidant capacity during in vitro digestion	[220]
	Ellagic acid	Sustained release	[118]
Phytosome	Curcumin	Enhancement of bioavailability and health-promoting properties	([38]; [122])
	Hesperetin	Promoted bioavailability and antioxidant activity	[142]
	Curcumin	Improvement of oral absorption and stability by combining chitosan and phytosome	[217]

(*continued*)

Table 4 (continued)

Nanocarrier	Phenolic compound	Results	Reference
	Rutin	- Maintenance of antioxidant activity upon nanoencapsulation - Good storage stability - Desirable sensory attributes of beverages containing phytosomal formulation	[16]
Nanoemulsion	Curcumin	- Significant effect of emulsifier charge on phytochemical properties, release pattern, and performance of nanoemulsions during digestion	[161]
	Curcumin	- Good stability against ionic strengths, pH, and pasteurization - Gradual release in simulated gastrointestinal condition	[185]
	Quercetin	- Enhanced bioaccessibility - Maintenance of antioxidant activity upon nanoencapsulation - High physical and chemical stability - Good sensorial properties of beverage formulation enriched with nanoencapsulated quercetin	[147]
	Quercetin	Enhanced stability	[92]
	Quercetin	Good physical stability and sustained release	[21]
	Resveratrol	Enhancement of chemical stability against UV light	[42]
	Resveratrol	- Sustained release - Improved stability and bioavailability	[189]
Solid lipid nanoparticles	Resveratrol	Improved oral bioavailability	[153]
	Curcumin	Increase of chemical stability, bioavailability, dispersibility, cellular uptake, and functionality	[197]
	Myricetin	Using stabilizers (tween 80 and Poloxamer 407): prolonged half-life time, decrease of degradation rate of flavonoid and sustained release in buffer solutions	[58]
	Epigallocatechin gallate	Increase of stability and anticancer activity	[170]
	Resveratrol	NLCs had smaller particle size and higher encapsulation efficiency than SLNs	[67]
	Quercetin	NLCs and nanoemulsions had higher bioaccessibility as compared to SLNs and free phenolics	[2]
	Curcumin	Reinforced the permeation under in situ intestinal conditions	[90]

Table 4 (continued)

Nanocarrier	Phenolic compound	Results	Reference
	Curcumin	- Improved oral bioavailability - Increase of permeation after nanoencapsulation	[178]
	Quercetin	Increase of oral absorption	[107]
Nanostructured lipids carriers	Quercetin	Sustained release and improved bioaccessibility	[112]
	Ferulic acid	- Controlled release profile - Increased the pharmacological activities	[73]
	Hesperetin	- Enhanced stability upon coating with different biopolymers - Better release properties - Improvement of solubility and positive effect on sensory attributes of fortified milk regarding color and taste	[55]
	Quercetin	- Promoted solubility - Sustained release - Good storage and oxidative stability	[75]
	Rutin	- Good stability during processing and storage period - Acceptable sensory attributes of fortified beverages	[15]
	Curcumin and genistein	Increment of solubility	[3]
	Curcumin	- Protective role against gastrointestinal digestion - Suitable release behavior in simulated intestinal fluid	([156]; [213])
	Curcumin	Enhancement in intestinal absorption, solubility, and stability	[227]
	Luteolin	Promotion of oral absorption and bioavailability	[112]

rutin into beverages (orange juice, milk, apple juice). The NLCs had good physiochemical and morphological properties. Fortified beverages not only were physically and thermally stable but also presented an acceptable sensorial quality [15]. These researchers in another study applied thin-film hydration method to incorporate rutin into phytosomal systems produced by soybean phosphatidylcholine [16]. Optimized formulations remained highly stable during storage and generated fine particles. Phytosomes preserved antioxidant activity of rutin, while inverse trend was observed for free one. No evident changes were found in sensory attributes and pH values of fortified beverages with loaded phenolic compounds. Furthermore, some studies have demonstrated high potential of phytosomes for improving absorption, bioavailability, and health-promoting properties of curcumin [38, 122, 217].

3.2 Natural Food Colorants

Colorants are extensively applied in the food industry to increase the product attractiveness and consumer satisfaction. Food colorants can be classified into three main groups: natural, synthetic, and inorganic. Consumption of synthetic colorants negatively affects human health and can cause cancer and allergic reactions. Hence, there has been recently growing tendency to natural types [5, 119]. Among natural food colorants, carotenoids and flavonoids are the most common types for food applications. In addition to exhibiting antioxidant activity, some flavonoids like curcumin, quercetin, luteolin, and anthocyanins can be used as coloring agents [79, 124]. Natural colorants are not only a safe alternative to synthetic ones but also can provide numerous health benefits. They seem to be effective in prevention and reducing the risk of many diseases such as cardiovascular diseases, age-associated diseases, cancer, neurodegenerative disorders, and eye diseases [91, 111, 196]. Nonetheless, most of natural colorants display high sensitivity to oxidation and are degraded when exposed to external factors such as light, pH, and heat. On the other hand, food components, enzymes, and other nutrients affect their stability. They also exhibit low bioavailability and limited solubility. Thus, it is necessary to retain structural integrity of natural food colorants in order to exploit them in food products and formulate novel functional foods [111, 120, 176]. In this regard, lipid-based nanocarriers are suitable options, because they have an excellent ability to enhance solubility, absorption, sustained release properties, effectiveness, and stability of natural colorants [70, 200].

Several reports considering the incorporation of different kinds of natural food colorants into lipid-based carriers have been recently published, and some of them have been reviewed in the study published by Akhavan and Jafari [5]. As an example, Tan et al. [202] investigated efficiency of nanoliposomes achieved by thin-film evaporation technique for incorporating diverse carotenoids including β-carotene, canthaxanthin, lycopene, and lutein. They proved that physiochemical properties, release pattern, and bioaccessibility were directly associated with carotenoid type. Indeed, their results indicated a gradual and prolonged release of β-carotene and lutein under GIT tract conditions. By contrast, release of canthaxanthin and lycopene occurred rapidly. Also, bioaccessibility followed the order of lutein> b-carotene> lycopene> canthaxanthin [202]. This group in another study used chitosan to cover liposomal surfaces through layer self-assembly deposition method [201]. Coated nanovesicles could retain lutein and β-carotene better than canthaxanthin and lycopene. Besides, biopolymer coating modified arranged structure of lipid bilayers and increased their rigidity. At the same time, chitosan positively affected release behavior of carotenoids within simulated GIT fluids. Round shape of liposomes was also kept after coating. These authors suggested that coating can be considered as an efficacious way to generate stable nanoliposomal systems.

In a recent work, Rabelo et al. [169] accommodated Açaí berry extract as a rich source of anthocyanins into W/O nanoemulsions via high-pressure homogenizer to boost their stability and functionality. MCT and CR-310 (tetraglycerin monolaurate condensed ricinoleic acid esters) were main components of nanoemulsions and acted

as the oil phase and emulsifying agent, respectively. Formed nanoemulsions demonstrated a good storage stability and no signs of phase separation observed over time. Nanoencapsulation caused a decrease in droplet size. Besides, all formulations were able to preserve phenolic compounds plus antioxidant potency of extracts when stored for up to 1 month at 4 °C [169]. In another research, Li et al. [108] applied high-pressure homogenization approach to formulate astaxanthin-loaded SLNs with three kinds of solid lipids including glycerin monostearate, glycerol distearates, and stearic acid plus Tween 20 as an efficient emulsifier. SLNs were highly stable to degradation at both 4 and 25 °C, and no significant increase was observed in particle size during storage. Indeed, loaded astaxanthin was released slowly over time into simulated intestinal and gastric fluids [108].

Mehrad et al. [130] investigated protective impact of SLNs consisted of corn oil, palmitic acid, and whey protein isolate (as a stabilizer) on β-carotene. They proved a remarkable enhancement in chemical and oxidative stability of this pigment upon nanoencapsulation. However, SLNs were susceptible to increment of ionic strength, elevated temperatures and acidic conditions [130]. Nazemiyeh et al. [222] found that SLNs enabled a prolonged stability for lycopene and there was no evident decrease in encapsulation efficiency after 3 months storage at 4 °C. In another work, Oliveira et al. [150] fabricated NLCs using a mixture of tristearin and high oleic sunflower oil, and their efficiency in incorporation of β-carotene was compared with tristearin SLNs. All samples showed nanometric sizes and a broad particle size distribution (PDI). High oleic sunflower oil created no significant changes in particle size. However, PDI of samples decreased after enclosing β-carotene. NLCs were superior to SLNs in terms of loading efficiency, although both NLCs and SLNs could equally protect β-carotene from deterioration. Better performance of nanodelivery systems was achieved by increasing high oleic sunflower oil levels. Overall, NLCs were more advantageous than SLNs [150].

3.3 Bioactive Oils and Essential Fatty Acids

Main types of omega-3 fatty acids include eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and α-linolenic acid (ALA). Fish oil is regarded as the best source of EPA and DHA [165]. In addition to fish oil, omega-3 fatty acids are found in algae, krill, and land plants [29, 103]. Omega-3 fatty acids possess several health benefits and could effectively prevent and reduce the risk of different diseases such as cardiovascular diseases, inflammation, diabetes, autoimmune disorders, and cancer [27, 61, 146]. Since, the human body does not have the ability to synthesize omega-3 fatty acids; therefore, they are named as essential fatty acids and must be obtained through foods. As most of diets contain insufficient amounts of omega-3 fatty acids, a great interest has been focused on increase of their intake through fortification of different foods. Nonetheless, oxidative, chemical, and thermal instability, poor bioavailability and water solubility, and unfavorable odor and flavor make direct usage of omega-3 fatty acids in food matrices difficult. Lipid-

based nanocarriers allow to take the advantages of omega-3 fatty acids and also offer a wide range of potential applications for these bioactives in food sector [65, 96].

Many nanoemulsion researches have been centered on optimizing preparation methods, composition (regarding oil type, surfactant, and co-surfactant), and different parameters influencing phytochemical characteristics in order to promote stability and bioavailability of fish oil and omega-3 fatty acids. For instance, Gulotta et al. [69] produced fish oil-loaded nanoemulsions by self-emulsification technique and revealed that various parameters including fish oil concentration, oil composition (lemon oil and medium-chain triglycerides), surfactant-to-oil proportion, and cosolvent type (polypropylene glycol and ethanol and glycerol) have a great impact on their characteristics and stability. Moreover, optimized formulations provided stable nanoemulsion systems, and there were no significant changes in the droplet size after storage for 1 month at refrigerated and room temperatures. Nevertheless, particle size increased at higher storage temperatures [69].

Walker et al. [210] indicated that particle size of droplets significantly influences the oxidative stability of fish oil-loaded nanoemulsions, while physical stability of system was dependent on the surfactant-to-oil ratio. On the other hand, microfluidized nanoemulsions contained larger amounts of secondary oxidation products (TBARS) after storage for 2 weeks at 55 °C as compared to those formed with spontaneous emulsification [210]. According to the study of Lane et al. [105], it is better to apply algal oil and mixture of soy lecithin and Tween 40 instead of flaxseed oil and soy lecithin alone for generation of nanoemulsions with fine droplet sizes [105]. Nejadmansouri et al. [146] demonstrated that using whey protein isolate in nanoemulsion formulations leads to a suitable storage stability regarding particle size, but viscosity is slightly increased during storage for 28 days [146]. Polymer coating has a positive effect on the stability of nanoemulsions bearing fish oil. Esquerdo et al. [223] revealed that using chitosan as a coating agent prevents creaming and breaks down of fish oil-loaded nanoemulsions.

Different approaches have been employed for incorporating essential fatty acids and fish oils into nanoliposomes. Hadian et al. [72] produced nanoliposomes entrapping EPA and DHA by sonication (bath and probe types) and extrusion methods. Nanoliposomes produced by sonication contained higher amounts of secondary oxidation products (heptanal propanal, hexanal, and pentanal) than extruded ones. The highest loading capacity was also related to probe sonicated nanoliposomes [72].

Moreover, some food systems have been fortified with incorporated form of these bioactives. In a recent work, Ojagh and Hasani [149] investigated the effect of adding different concentrations of fish oil incorporated in nanoliposomes on the sensory and technological attributes of fortified bread during storage in the refrigerator for 25 days. They confirmed desirable physiochemical properties of nanovesicles regarding particle size, PDI, and encapsulation efficiency. Indeed, addition of the fish oil-loaded nanoliposomes into breads increased nutritional value and loaf volume of the breads without notable adverse effects on their sensory and texture characteristics [149]. Similarly, bread and milk samples enriched with fish oil-loaded nanoliposomes obtained acceptable sensory scores in contrast to free and

microencapsulated ones [175]. In another study, Ghorbanzade et al. [65] used nanoliposome systems to encapsulate fish oil and fortified yogurt with the loaded fish oil. They stated that the fortifying yogurt with the loaded fish oil led to higher EPA and DHA contents as well as a lower peroxide value, acidity, and syneresis than samples treated with its free form during 21 days of storage at 4 °C. Also, they found that the sensory characteristics of the yogurt fortified with nanoencapsulated fish oil was significantly similar to control sample, containing no fish oil [65].

There are few works on fish oil and essential fatty acids loaded within SLNs. Salminen et al. [181] incorporated fish oil into SLNs composed of tristearin (as the carrier) and quillaja extract alone or blended with lecithin (low or high melting point) as a surfactant. They discovered that all formulations showed statistically constant PDI and particle sizes during storage at a dark place for 51 days except for samples containing quillaja/low-melting lecithin. Moreover, the SLNs containing quillaja/high-melting lecithin had a more chemical stability than those containing quillaja alone or quillaja/low-melting lecithin [181].

NLCs have been also successfully used for loading krill oil. Zhu et al. [218] incorporated krill oil into NLCs by hot homogenization technique and used palm stearin and lecithin as oil and emulsifier, respectively. The smallest particle size and the highest homogeneity were obtained from optimized formulation (65% krill oil and 1.1% lecithin). Prepared NLCs showed protective effect against UV light-induced photooxidation. They also had a suitable physical and long-term stability at low temperatures [218]. Salminen et al. [180] utilized NLCs and nanoemulsion systems with similar formulations (except tristearin applied in production of NLCs) for nanoencapsulation of fish oil. Based on their results, NLCs yielded more stable (in the terms of size and aggregation stability) and smaller particles than nanoemulsions. Furthermore, the NLCs showed higher protective effects on fish oil against lipid oxidation compared to the nanoemulsions [180].

3.4 Vitamins

Vitamins are bioactive compounds with outstanding health-promoting properties which effectively contribute to human growth and development. Vitamin deficiencies play a key role in development of some diseases such as cancer and cardiovascular problems [99]. As human body is not able to produce many vitamins, they must be obtained via diet. However, it is not always possible to meet recommended daily intake of vitamins. Thus, fortification of food products with vitamins may be needed to ensure adequate intake of vitamins [20, 157]. Some issues should be considered for successful fortification. Many vitamins are readily degraded under storage and processing conditions. They also exhibit a low stability in GIT system. Depending on type, vitamins show different extents of sensitivity to oxidation, heat treatment, and pH variations. Poor bioavailability is also regarded as an important limitation in direct addition of vitamins into food formulations. Moreover, unit operations of food processing such as blanching cause a considerable decline in the content of water-soluble vitamins [151, 155]. On the other hand, hydrophobic vitamins are not a

suitable choice for fortification of aqueous-based food products due to their low water solubility and insufficient dispersibility [135].

Lipid-based nanocarriers can be applied as a proper alternative in order to protect vitamins against multiple processes and environmental stresses, improve solubility and absorption, and release them in the determined sites [47, 98]. Many researchers have encapsulated different kinds of vitamins into lipid-based nanocarriers as shown in Table 5. For example, Liu et al. [113] evaluated deposition of chitosan and sodium alginate on the surface of nanoliposomes loaded with vitamin C as core material. These nanocarriers showed a slower release and higher rate of oxidation of vitamin C when stored for 90 days at 4 °C than uncoated ones. They concluded that the shell of chitosan and sodium alginate could effectively cover the surface of anionic nanovesicles and enhance their stability toward hydrolysis and oxidation. They also fortified mandarin juice with coated nanoliposomes and observed that microbial stability of the fortified mandarin juice was higher than samples treated with uncoated carriers with a negligible effect on sensory properties of juice [113].

Bochicchio et al. [20] evaluated incorporation of different vitamins (B_{12}, D_2, and E) into nanoliposomes through an ultrasound-assisted method and the thin-film hydration technique. They reported that SUVs and MLVs had a high encapsulation efficiency. Increasing the hydrophobicity of vitamins led to higher encapsulation efficiencies. Moreover, the entrapment of vitamins into lipid nanovesicles protected them against chemical degradation during 10 days of storage at simulated extracellular environment conditions [20]. In another study, Couto et al. [35] loaded vitamin B_2 into the SLN systems through a modified PGSS process using hydrogenated canola oil as lipid phase, polyethylene glycol as stabilizer, and sodium lauryl sulfate as surfactant. They investigated effects of different parameters such as vitamin and stabilizer concentration, pressure, and molecular weight on loading and encapsulation efficiencies and reported that the optimum SLN preparation conditions with respect to loading and encapsulation efficiency were as follow: vitamin concentration of 2%, pressure of 15 MPa, and 5% polyethylene glycol [35].

Walia et al. [209] prepared a fish oil-in-water nanoemulsion via ultrasonication technique to load vitamin D with a high encapsulation efficiency. Their results revealed that nanoencapsulation could preserve antioxidant capacity and antimicrobial activity of vitamin D during storage. Also, the fish oil-based nanoemulsions improved the vitamin D bioavailability in stimulated GIT conditions [209]. Pinto et al. [163] developed different NLCs by using vegetable oils enriched with α-tocopherol and demonstrated that olive, sunflower, coconut, and sweet almond oils could be successfully applied to prepare free and loaded NLCs with negative surface charges and a nanometric size. Also, they found that the formulated NLCs had a high encapsulation efficiency and released α-tocopherol in a controlled manner. However, the DSC analysis has showed that incorporation of α-tocopherol resulted in reduced crystallinity of NLCs but could improve their antioxidant activity. Accordingly, these authors suggested that the formulated NLCs could be successfully used for preparing long-term stable products [163].

Table 5 Incorporation of different vitamins into lipid-based nanocarriers

Nanocarrier	Vitamin type	Results	Reference
Nanoliposomes	Vitamins E and C	- Maintenance of antioxidant activity of vitamins in orange juice before and after pasteurization - Liposomes provided good microbial stability for orange juice during storage without any significant change in sensory properties	[123]
	Vitamin A	- Suitable characteristics - High concentration of cholesterol led to lower encapsulation efficiency	[160]
	Vitamin C	- Higher chemical and microbial stability of mandarin juice and lower release rate after coating of nanoliposomes with chitosan and sodium alginate - Good protection against oxidation without any significant effect of sensory properties of mandarin juice	[113]
	Vitamin C	- Better storage stability and more encapsulation efficiency in nanoliposomes obtained from the double emulsion-dynamic high-pressure microfluidization method	[109]
	Vitamin B_1	High thermal stability during storage	[56]
	Vitamins E, B_{12}, and D_2	Multilamellar large vesicles resulted in the maximum encapsulation efficiency	[20]
	Vitamin C	Enhanced stability during long-term storage	[215]
	Vitamin A	Decreased degradation of vitamin	[102]
Nanoemulsions	Vitamin E	High bioaccessibility in O/W emulsions produced by long-chain triglycerides	[152]
	Vitamin B_2	Improved stability	[22]
	Vitamin E	- Effective protection during storage - Good physical stability	[74]
	Vitamin E	- High thermal stability - The smallest droplets and highest transparency were observed for formulations containing 30% propylene glycol or 20% ethanol	[179]
	Vitamin E	Increase in release rate of vitamin into the buffer solution caused by micellar solubilization	[140]
	Vitamin D	- Increase in thermal stability by using sodium dodecyl sulfate as co-surfactant - Effect of surfactant type, surfactant-	[71]

Table 5 (continued)

Nanocarrier	Vitamin type	Results	Reference
		to-oil proportion, and stirring conditions on characteristics of droplets	
	Vitamin K_1	- Good permeation ability - Good storage stability over time under (at) different temperatures	[26]
	Folic acid (Vitamin B_9)	The optimum conditions for preparing maltodextrin-whey protein double emulsions: 3 mg/ml folic acid in the 12% dispersed phase and water to span 80 ratio of 0.9	(Assadpour et al. 2016)
	Vitamin E	- Enhanced antimicrobial effect, shelf life, and bioavailability of vitamin in fruit juice - High encapsulation efficiency by using mustard oil and tween 80	[41]
	Vitamin E	The optimum condition for incorporating vitamin: 1% vitamin E acetate concentration, 6.18% oil contents, 135 MPa homogenization pressure, and 6.39% surfactant concentration	[129]
	Vitamin D	Enhanced bioavailability acquired by fish oil-based nanoemulsion	[209]
	A type of vitamin B: Thiamine dilauryl sulfate (TDS)	Inhibitory effect on the spore germination of *Fusarium oxypansum* f. sp. as well as mycelial growth	[32]
	Vitamin D_3	Good stability against UV irradiation	[106]
	Vitamin E	Production of nanoemulsions bearing vitamin by natural surfactant (Q-Naturale®) for using in food formulations	[216]
Solid lipid nanoparticles (SLNs)	Vitamin B_2	Encapsulation efficiency and loading capacity influenced by different parameters such as molecular weight and concentration of stabilizer, vitamin concentration, and pressure	[35]
	Vitamin B_{12}	Improved anticarcinogenic activity	[62]
	Vitamin D_2	Protective effect against oxygen and light	[158]
	Vitamin A	- Controlled release during 6 h - Higher release rate compared to nanoemulsions in longer storage times	[89]

(*continued*)

Table 5 (continued)

Nanocarrier	Vitamin type	Results	Reference
Nanostructured lipids carriers (NLCs)	Vitamin A	Good storage stability	[159]
	Vitamin E	The highest stability achieved by adding 5% (w/w) of tween 20 to NLCs formulation	[208]
	Vitamin D_3	- Good physiochemical properties and suitable storage stability - Controlled release	[155]
	Vitamin D_3	Improvement of intestinal absorption Production of stable NLCs by using Precirol as solid lipid and Poloxamer 407 as surfactants	[135]
	Vitamin E	- NLC formulations-based vegetable oils (sunflower, sweet almond, olive, and coconut oils) led to good phytochemical properties and high physical stability - Improved scavenging activity	[163]

3.5 Natural Antimicrobial Agents and Essential Oils

Recently, the tendency for utilizing natural antimicrobial agents has been increased due to hazardous and harmful impacts of synthetic additives on human health and emergence of antibiotic-resistant bacteria [46, 126]. Among natural antimicrobial agents, essential oils and bacteriocins especially nisin have attracted much consideration to inhibit microbial growth in food systems. In addition to antimicrobial effect, essential oils possess numerous beneficial and health-promoting properties such as antioxidant, anti-allergic, anticancer, anti-inflammatory, and antiviral activities. Besides, essential oils and their components act as natural flavoring agents in food, pharmaceutical, and cosmetics industries [45]. In spite of remarkable advantages, there are serious challenges in development of food products containing essential oils. They are extremely reactive, volatile, and chemically unstable; readily oxidized when exposed to heat, oxygen, or light; and decomposed during processing stages and storage as well as within GIT conditions that reduces their antimicrobial potency. Furthermore, essential oils display poor solubility and dispersibility in aqueous food systems and influence sensory attributes of food products [10, 43, 204].

Nisin is a polypeptide composed of 34 amino acids obtained from certain strains of *Lactococcus lactis* and found in two main forms, namely, nisin A and nisin Z. Nisin Z shows a higher stability and dispersibility in food formulations than A type [34]. Nisin as the only GRAS (generally recognized as safe) bacteriocin can inhibit growth of several species of pathogenic and nonpathogenic Gram-positive bacteria such as *Listeria monocytogenes*, *Bacillus* spp., and *Staphylococcus aureus*, protect food products from microbial spoilage, prolong their shelf life, and improve food safety [88, 166]. Nevertheless, there are some problems that restrict direct usage of

nisin and cause remarkable losses in its antimicrobial activity such as low stability against adverse environmental factors as well as proteolytic inactivation, unwanted interaction with food ingredients, and inadequate dispersion in food systems [34, 166]. Moreover, utilizing free form of nisin may create some issues within foods. For example, nisin may negatively influence starter culture activity in cheese matrix and consequently decrease consumer acceptance [23].

Lipid-based nanodelivery systems can solve these problems because they provide targeted and prolonged release, inhibit undesirable interactions and degradation, and minimize appearance of resistant strains of bacteria. These carriers also facilitate passage of antimicrobials through cell membrane, enhance bioactivity of essential oils, and thus reduce concentrations required for exerting antimicrobial activity which leads to preserving sensorial properties and quality of fortified foods [34, 100, 116].

Several studies have demonstrated the beneficial effects of lipid-based nanocarriers on antimicrobial activity, stability, and flavor retention of essential oils and their constituents for food applications. For instance, Balta et al. [18] evaluated antimicrobial potential of nanoemulsions containing geraniol and linalool against some foodborne bacteria *(E. coli*, *Listeria innocua*, and *Pseudomonas lundensis*) by a simulated medium of meat. Both loaded compounds could control the microbial growth. However, they showed a lower efficiency for declining *Pseudomonas lundensis* counts compared to others [18]. In another research by Lu et al. [116], citral essential oil-loaded nanoemulsions exhibited an inhibitory effect on bacterial strains (*S. aureus, E. coli, Pseudomonas aeruginosa, Enterococcus faecalis, Salmonella typhimurium*, and *L. monocytogenes*). Nevertheless, they had a similar inhibition zone diameter and antimicrobial efficiency against both Gram-positive and Gram-negative species [116].

In the study conducted by Artiga-Artigas et al. [10], four essential oils obtained from lemongrass, mandarin, thyme, and oregano oil were incorporated into nanoemulsion systems via microfluidization with the aid of Tween 80 and pectin as emulsifying agents [10]. Chuesiang et al. [33] produced nanoemulsions loaded with cinnamon essential oils by phase inversion temperature technique using MCT and Tween 80. They revealed that droplet size and stability of nanoemulsions were affected by concentration of essential oils, oil phase, and surfactant [33]. In another work, Mendes et al. [133] fabricated nanoemulsion systems for loading *Eugenia brejoensis Mazine* essential oil as an antimicrobial agent by homogenization. Based on their results, nanoemulsions had good characteristics, and physical stability resulted from appropriate emulsifiers and increasing rotational speed. Besides, bactericidal activity was dependent on droplet size, and nanoemulsions with smaller particle sizes were more efficient against *Pseudomonas fluorescens*. When loaded essential oils were also applied in sliced ham, their antimicrobial capability was reduced [133].

The dual incorporation of nisin and garlic extract into nanoliposomes was carried out by Pinilla and Brandelli [162], and antimicrobial effectiveness of loaded nanoliposomes was investigated against some bacterial species (*Salmonella enteritidis*, *L. monocytogenes*, *and S. aureus* and *E. coli*) in whole milk when stored at 37 °C.

Nanoliposomes were equally effective on bacteria, while free form of nisin and garlic extract could not individually inhibit microbial growth. Natural antimicrobial agents also presented a higher ability to reduce *L. monocytogenes* counts [162]. Cui et al. [36] employed soy lecithin-derived nanoliposomes for boosting the stability and antimicrobial activity of clove oil against *E. coli* and *S. aureus*. Loaded essential oils could prevent growth of bacteria. However, as *S. aureus* increased the release rate of clove oil by secreting pore-forming toxins, nanoliposomes showed a higher antimicrobial effect. Moreover, adding loaded nanoliposomes into tofu formulation led to an efficacious inhibitory activity toward *S. aureus* [36].

Sebaaly et al. [187] found that nanoliposomes prepared by ethanol injection method promoted stability of eugenol against UV radiation. Additionally, antioxidant activity of eugenol was preserved after nanoencapsulation [187]. Tian et al. [204] fabricated SLNs bearing citral through high-pressure homogenization approach by a blend of Span 80 and Tween 80 (1:1 ratio) and glycerol monostearate as surfactant and solid lipid, respectively. According to their results, larger amounts of incorporated citral were retained during storage at 37 °C for 12 days in comparison with its free counterpart [204]. Zhao et al. [224] revealed that SLNs were able to promote bioavailability and sustained release properties of Yuxingcao essential oil.

Prombutara et al. [166] nanoencapsulated nisin within SLNs via high-pressure homogenization technique by Imwitor 900 as solid lipid with aid of surfactant and co-surfactant that were Poloxamer 188 and sodium deoxycholate, respectively. Nisin concentration significantly influenced physiochemical properties of SLNs. Release rate of nisin was dependent on medium conditions in terms of pH and salt concentration. Nanoencapsulation of nisin led to a prolonged antimicrobial activity toward *Lactobacillus plantarum* and *L. monocytogenes* [166]. Keivani Nahr et al. [100] entrapped cardamom essential oil into NLCs produced by food-grade ingredients including cocoa butter and Tween 80 and assessed impact of nanoencapsulation on its antimicrobial capacity. Obtained NLCs displayed desirable physiochemical characteristics and a good stability over 30 days of storage. Loaded essential oil was also superior to free form regarding antimicrobial potentials [100]. Lewies et al. [225] proved the efficient bactericidal activity of nisin-loaded NLCs against *S. aureus* and *S. epidermidis*.

3.6 Phytosterols

Phytosterols are one of the most popular bioactive compounds with a high hydrophobicity and can be divided into two main groups including stanols and plant sterols (i.e., β-sitosterol, campesterol, and stigmasterol). Phytosterols possess numerous health benefits such as anticancer, inflammatory, antioxidant, and antidiabetic activities. They can also prevent cardiovascular diseases and arteriosclerosis by decreasing low-density lipoprotein (LDL) cholesterol in serum [17, 39, 195].

Phytosterols especially β-sitosterol have recently attracted great attention in order to develop novel functional foods [154], although low bioavailability, high melting point, and poor aqueous solubility make it difficult to incorporate β-sitosterol

into food systems without a suitable carrier. Besides, they show a high oxidation and crystallization tendency, reducing their functionality. Phytosterols are often applied in esterified forms which can enhance their solubility in fat-rich foods such as spreads without any adverse influence on other food matrices [79, 195]. Nanoencapsulation presents an efficient solution for these obstacles. There are few studies on incorporation of phytosterols into lipid-based nanocarriers and their applications in the food industry. Bagherpour et al. [17] fortified butter with NLCs bearing β-sitosterol prepared by hot homogenization approach, and physicochemical characteristics plus oxidative stability of samples were assessed. Obtained NLCs had a nanometric size, negative surface charge, desirable homogeneity, and high encapsulation efficiency. Also, they were physically stable during long-term storage. No evident change was observed at peroxide and acid values of butter samples containing NLCs and they showed a good oxidative stability. Antioxidant activity of loaded β-sitosterol was maintained in butter matrix over 3 months of storage at refrigerated temperature, while its free form experienced a significant loss [17].

Alexander et al. [8] added plant sterols instead of cholesterol into liposomal formulations. Characteristics of nanoliposomes are influenced by phospholipid and sterol concentrations. Their results revealed that plant sterols significantly increased the particle size and encapsulation efficiency, although nanoliposomes exhibited a low physical stability in presence of plant sterols and undergo phase separation during storage. These authors suggested that optimization of plant sterol to phospholipid ratios and selection of suitable preparation methods can improve storage stability of nanoliposomes containing plant sterols [8]. Panpipat et al. [154] employed different sterol to phospholipid ratios plus various types of β-sitosteryl fatty acid esters with the aim of producing nanodispersions. On the basis of their results, β-sitosterol was less effective in producing homogeneity of nanodispersions compared to its esterified forms. Moreover, nanoparticles obtained from esters of β-sitosterol were smaller and more stable. On the other hand, β-sitosteryl unsaturated fatty acid esters preferred to make nanoemulsions with desirable characteristics instead of nanodispersions which can be satisfactory for pharmaceutical and food sectors [154].

Ribeiro et al. [177] formulated and characterized novel lipid-based colloidal nanodispersions for enclosing phytosterols using various types of triacylglycerols and Tween 20. They found that supercooled emulsions and amorphous particles were created as a result of applying Myritol and trilaurin as liquid and solid triacylglycerols, respectively. These systems could entirely prevent the crystallization of phytosterols as well as lipids. Furthermore, they presented good stability during long-term storage [177]. In a recent study by Soleimanian et al. [195], β-sitosterol-loaded NLCs were fabricated by three different types of lipids including glyceryl behenate, pomegranate seed oil, and propolis wax. They demonstrated a notable impact of type and content of lipids on physiochemical properties of NLCs. Increase in phytosterol content and decrease of lipid content led to larger size and lower values for encapsulation efficiency. Crystallinity of β-sitosterol also diminished upon nanoencapsulation [195].

In the study of Lacatusu et al. [104], a mixture of natural oils including fish oil, grape seed oil, and squalene was used to make NLCs comprising β-sitosterol alone and simultaneously β-sitosterol and green tea extract. Obtained NLCs had a great encapsulation efficiency and surface charge less than −30 mV, indicating stable systems. Dual nanoencapsulation of β-sitosterol and green tea extract not only caused an evident decrease in particle size but also promoted antioxidant efficiency. Loaded β-sitosterol was able to entrap free radicals better than unencapsulated sample. Additionally, NLCs enabled gradual and controlled release of β-sitosterol [104].

3.7 Enzymes

Among the lipid-based nanocarriers, nanoliposomes are the most commonly used system for delivering enzymes in food matrices particularly cheese to shorten the ripening time and reduce production costs. High amount of enzymes are lost by whey when directly utilized in milk to accelerate ripening and consequently raise manufacturing cost of cheese. Moreover, adding free form of enzymes leads to low cheese yield, uneven distribution in curd, and undesirable sensory attributes of final product [47, 85].

Nanoliposomes enable gradual release, more stability, appropriate partitioning into food matrix, and enhanced performance for enzymes and also positively influence taste, flavor, and texture of cheese [121, 136]. Flavourzyme is a mixture of fungal proteases which has desirable effects on flavor and ripening of cheese. Jahadi et al. [86] prepared nanoliposomal formulations for accommodating Flavourzyme by heating method. Then, nanoencapsualted form of Flavourzyme was added into cow milk and produced Iranian white brined cheese. Nanoliposomes did not significantly affect the curd and whey composition as well as cheese yield as compared to control [86]. These researchers in another study found that ripening period had the greatest effect on protein decomposition of cheese samples followed by concentration of loaded Flavourzyme and brine treatment time (brining time). Moreover, 0.3% w/w of loaded enzyme, 1 month of ripening, and brining time for 8 h processed samples with the most proteolytic activities and the highest level of acceptance in sensory attributes. Also, the optimum concentration of enzyme-loaded nanoliposome led to defeat drawbacks related to texture and taste in cheese samples treated with free form [87].

On the other hand, stability and functionality of enzymes dramatically are affected by temperature and pH values within food products, and they are easily denatured and inactivated under harsh environmental conditions. Karami et al. [93] fabricated SLNs entrapping superoxide dismutase as an antioxidant enzyme by cold homogenization technique. Loaded SLNs had desirable properties concerning particle size and encapsulation efficiency. Moreover, nanoencapsulation provided remarkable improvement in stability, enzymatic potency, release behavior, and permeability of superoxide dismutase [93]. In the study conducted by Qi et al. [226], catalase as a hydrogen peroxide-scavenging enzyme was nanoencapsulated

into SLNs. Main components of SLNs were Poloxamer 188, tripalmitin, and soybean phosphatidylcholine which acted as surfactant, oil phase, and stabilizers, respectively. SLNs were highly stable owing to bear a surface charge above −30 mV. Indeed, nanodelivery systems demonstrated protective effects against proteolysis and released catalase sustainably [168].

4 Conclusion and Future Trends

Lipid-formulation nanoencapsulation technologies could be considered as an efficient alternative to overcome the limitations related to direct usage of bioactive compounds especially hydrophobic ones within food systems and also applied to design novel functional foods. They can be prepared without use of organic solvents; provide prolonged release, target specificity, and biocompatibility; protect incorporated compounds against adverse external conditions, chemical reactions, and digestion; improve their stability, solubility, dispersibility, efficiency, and bioavailability which consequently facilitate intestinal absorption; and enhance biological activity of bioactives. However, there are still some challenges in development of nanoformulations regarding toxicological safety, effects on human body, and commercialization. Moreover, it is essential to fabricate lipid-based nanocarriers by using food-grade materials and healthy lipids for food and pharmaceutical practices. Besides, more investigations need to be carried out on stability, release behavior and added level of nanoparticles to preserve sensory attributes especially appearance in food products, promote functionality of bioactive compounds, and ensure safety for in vivo applications. Therefore, these issues must be taken into account for applying nanoencapsulated bioactive compounds in food, pharmaceutical, and cosmetics industries.

Abstract

Conjugated linoleic acid (CLA) is a group of polyunsaturated fatty acids that exist as positional and stereo-isomers of octadecadienoate (18:2). Among these isomers, the most studied two isomers are cis 9, trans 11-CLA and trans 10, cis 12-CLA due to their biological effects. CLA can be naturally synthesized in the rumen of ruminant animals by bacteria *Butyrivibrio fibrisolvens* via the Δ-9-desaturase of trans 11 octadecanoic acid pathway. The major dietary sources of CLA are represented by meat and milk from ruminant animals. Although references to CLA can be traced back to the 1950s, current interest in the health benefits of CLA started in the late 1980s, after it was identified as the anti-carcinogenic component present in fried ground beef. Since then, an extensive literature has documented the anticarcinogenic effects of CLA. In addition, there is some evidence that CLA is also anti-atherosclerotic, has beneficial effects on type 2 diabetes, and may play a key role in helping to regulate body fat. The fact that the richest natural sources of CLA, meat and dairy products, are consumed by people worldwide has very interesting implications for public health.

Keywords

Conjugated linoleic acid · Fatty acids · Animal source foods · CLA and cancer · CLA and human diet · CLA and human health

List of Abbreviations

CLA	Conjugated Linoleic Acid
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
FAME	Fatty Acid Methyl Esters
MUFA	Monounsaturated Fatty Acids
PUFA	Polyunsaturated Fatty Acids
SFA	Saturated Fatty Acids
TFA	*Trans* Fatty Acids

1 Introduction

Anthropology has previously recognized the importance of food and diet variations among time periods. It is possible to identify the profile of meat consumption during human evolution in four periods: the first could be characterized by an opportunist hunting; while in the second, hunting had grown to a bigger scale and lasted 2 to 3 million years; in the third period, men started to domesticate animals and plants, which had began 10,000 years ago; during the fourth and last period studies determined that meat contained compounds which could increase disease risk [1]. Anthropological data have also suggested an important influence of meat consumption in human erect posture. Bipedalism is probably the first and most important characteristic which distinguished humans from their ancestors as it allowed a more efficient locomotion and load carrying, which are important advantages in hunting [2]. Cranial–dental

changes are quite visible when analyzing hominids fossils. Molar teeth size has decreased and the jaws and front teeth have become stronger. Also shearing crests have grown. These changes could be explained through the urgent need of tearing and chewing meat rather than grinding leaves, fruits, seeds, and cereals [3].

Gastrointestinal tract features can also aid in determining dietary preferences considering that the gut of herbivores and pure carnivores suffered different physiological and metabolic adaptations. On one hand, plant-based diets are associated with a sacculated stomach and well-developed caecum and colon, which increased with plant fiber content. On the other hand, a carnivore's stomach is well developed and acidic with a large small intestine. Humans are omnivorous thus fitting in neither category. They have a simple stomach and a relatively long small intestine but also a reduced caecum and colon [4]. The fact that the small intestine is the most prominent organ in the human gastrointestinal tract is due to the need for adaptation to a varied diet, including nutritionally dense foods, with great volume and conducive to being digested in the small intestine.

Meat is an important source of high-value animal protein in many regions of the world. Around the globe, the diets of relatively more urbanized populations are characterized by a higher content of meat, poultry, and other animal products than the less diversified diets of rural communities [5]. Contrary to popular perception, average red meat intakes appear to be moderate and in line with current recommendations in developed countries [6]. Red meat intakes in these countries range from the lowest consumption in Greece at 31 g per day for women and 55 g per day for men to the highest consumption in The Netherlands at 79 g per day for women and 136 g per day for men (see Table 1).

Essentially, meat is basically composed of water, protein, lipids, minerals, and carbohydrates. Lean muscle tissue contains approximately 72–74% moisture, 20–22% protein, 3–5% fat, 1% ash, and 0.5% of carbohydrate. These proportions are largely variable, especially in the lipid content, which depends on species, amount of fattening, inclusion of the adipose tissue, and so on. There is an inverse relationship between the percentages of protein and moisture and the percentage of fat so that meats with high content of fat have lower content of moisture and proteins [7].

Skeletal muscle contains a variable amount of lipids, between 1% and 13%. Lipid content mainly depends on the degree of fattening and the amount of adipose tissue. Lipids can be found within the muscle (intramuscular), between muscles

Table 1 Mean daily intake (g/d) of total red meat (fresh and processed) in selected countries

Countries	Women	Men
Spain	67	127

(intermuscular), and in adipose tissue. Intramuscular lipids are mainly composed of triacylglycerols, which are stored in fat cells, and phospholipids, which are located in cell membranes. The amount of cholesterol in lean meat is around 50–70 mg/100 g. Intermuscular and adipose tissue lipids are mainly composed of triacylglycerols and small amounts of cholesterol, around 40–60 mg/100 g [8].

Triacylglycerols are the major constituents of fat. The fatty acid content mainly depends on age, production system, type of feed, and environment [7]. Monogastric animals such as swine and poultry tend to reflect the fatty acid composition of the feed in their fat. In the case of ruminants, the nutrients and fatty acid composition are somehow standardized due to biohydrogenation by the microbial population of the rumen [9]. The properties of the fat will depend on its fatty acid composition. A great percentage of the triacylglycerols are esterified to saturated and monounsaturated fatty acids. When triacylglycerols are rich in polyunsaturated fatty acids (PUFA) such as linoleic and linolenic acids, fats tend to be softer and prone to oxidation. These fats may even have an oily appearance when kept at room temperature. Phospholipids are present in cell membranes, and although present in minor amounts, they have a strong relevance to flavor development due to their relatively high proportion of PUFA. Major constituents are phosphatidylcholine (lecithin) and phosphatidylethanolamine. The phospholipid content may vary depending on the genetic type of the animal and the anatomical location of the muscle [10]. For instance, red oxidative muscles have a higher amount of phospholipids than white glycolytic muscles.

2 Lipids in Meat
