Lipid contributes substantially to the caloric content of meat. It also has marked effects on mouth-feel and flavor of meat. There are three sources of lipid in meat: the muscle fibers, subcutaneous adipose tissue, and intramuscular (interfascicular, marbling) adipose tissue [11]. Once subcutaneous adipose tissue has been removed, the primary contributor to lipid content of meat is intramuscular adipose tissue.

Pioneering researchers from the seventeenth and eighteenth century such as Robert Boyle, Poulletier de la Salle, Antoine François de Fourcroy, and others began the study of modern lipid chemistry. During the nineteenth century the chemist, Chevreul, identified several fatty acids, suggested the name “cholesterine” for the fatty substance in gallstones, coined the word “glycerine” and showed that fats are comprised of glycerol and fatty acids [12]. During the twentieth century many advances have been made in terms of the understanding of lipid structure and function. Lipids include waxes, oils, fats, steroids, and related compounds ranging from soaps to petrochemicals [13]. Triacylglycerol, which is a neutral lipid, are made up of three fatty acids attached to a molecule of glycerol, and they vary in their physical properties according to the chemical structure of the fatty acid. A phospholipid is a lipid containing phosphoric acid as mono- or diester and is the main building block for cell membranes. Fatty acids are “amphiphilic,” i.e., has a carboxyl group (hydrophilic) at the polar end and a hydrocarbon chain at the nonpolar tail (hydrophobic). Fatty acids consisting of only single bonds are termed

"saturated." If there are carbon–carbon double bonds in a fatty acid chain, the fatty acid is termed "unsaturated." Oleic acid (C18:1) contains one double bond and is termed" monounsaturated." A fatty acid with more than one double bond is termed "polyunsaturated." The polyunsaturated fatty acids (PUFA) predominate in vegetable oils. The two determinants of the consistency of a lipid is the length of the predominant fatty acid chains and the presence or the absence of double bonds [13]. Fatty acids with twelve or more carbon atoms are referred to as long-chain fatty acids and are typical of fats from animal origin.

Meat fat comprises mostly monounsaturated fatty acids (MUFA) and saturated fatty acids (SFA). The most ubiquitous fatty acids are oleic (C18:1), palmitic (C16:0), and stearic (C18:0) acids. Poultry and pork contain somewhat more unsaturated fatty acids (10–15% of total fatty acids) than beef and lamb, and also a notable amount of PUFAs. Linoleic acid (C18:2) is the predominant PUFA (0.5–7%), followed by alpha-linolenic acid (up to 0.5%) [14]. *Trans*-fatty acids (TFA) comprise about 1–2% of total fatty acids across all types of meat; in ruminant meats they represent 2–4%. Pigs have much higher proportions of the major polyunsaturated fatty acid (PUFA) linoleic acid (18:2 n-6) than cattle and sheep [15]. Linoleic acid is derived entirely from the diet. It passes through the pig's stomach unchanged and is then absorbed into the blood stream in the small intestine and incorporated from there into tissues. In ruminants, the fatty acid, which is at high levels in concentrate feedstuffs (grains and oilseeds), is degraded into monounsaturated and saturated fatty acids in the rumen by microbial biohydrogenation and only a small proportion, around 10% of dietary 18:2 n-6, is available for incorporation into tissue lipids.

The second most important PUFA is α-linolenic acid (18:3 n-3), which is present in many concentrate feed ingredients but at lower levels than 18:2 n-6. This is a major dietary fatty acid for ruminants since it constitutes over 50% of total fatty acids in grass and grass products. Again, a high proportion is biohydrogenated to saturated fatty acids in the rumen. A variable proportion of dietary 18:3 n-3 is biohydrogenated (85–100%) but this is more than for 18:2 n-6 (70–95%), so less is available for incorporation into tissues [16]. As with 18:2n-6, proportions in ruminants are higher in muscle than adipose tissue. Muscle contains significant proportions of long chain (C20–22) PUFA which are formed from 18:2 n-6 and 18:3 n-3 by the action of Δ5 and Δ6 desaturase and elongase enzymes. Important products are arachidonic acid (20:4 n-6) and eicosapentaenoic acid (EPA, 20:5 n-3) which have various metabolic roles including eicosanoid production.

The n-3 and n-6 fatty acids are required in the diets of humans as well as other monogastric mammals as they cannot be synthesized de novo. These fatty acids function as carriers of the fat-soluble vitamins (Vitamin A, D, E and K) and play a crucial role in the immune response of both man and animal. Essential fatty acids with 18-carbon molecules include linolenic acid (9-cis-, 12-cis-,15-cis-octadecatrienoic acid; C18:3 n-3) and linoleic acid (9-cis, 12-cis-octadecadienoic acid; C18:2n-6). The two most important 20-carbon essential fatty acids are arachidonic acid (C20:4 n-6), which is formed by desaturation and elongation of linoleic acid, and EPA (C20:5 n-3), which is formed by desaturation and elongation of α-linolenic acid [17]. Meat, fish, and fish oil are the only significant dietary sources of C20:4 n-6

(arachidonic acid) and C22:6 n-3 docosahexaenoic acid (DHA). Meat contains lower concentrations of these polyunsaturated fatty acids when compared with oily fish [18]. The two most readily found n-3 fish oil fatty acids are EPA and DHA.

Cholesterol in meat exists in two forms: as free cholesterol and as cholesterol ester [19]. Free cholesterol is associated primarily with cellular and subcellular membranes of muscle and intramuscular adipocytes. Cholesterol ester, located within the triacylglycerol-rich central lipid vacuole, comprises about 75% of the total cholesterol in adipose tissue. Muscle fibres, which are rich in membranes but contain comparatively little lipid, have approximately 75% of their total cholesterol associated with membranes and the other 25% associated with their neutral lipids. There are two reasons for the minimal effect of intramuscular adipose tissue on the concentration of cholesterol in meat:

1. Each gram of intramuscular adipose tissue contributes only 1.2 mg of cholesterol.
2. Any increase in intramuscular adipose tissue replaces an equal volume of muscle, which contributes as much as 0.65 mg of cholesterol per gram.

Thus, any contribution of intramuscular adipose tissue to total cholesterol is diluted by the amount of muscle it displaces. For this reason, different cuts of meat may vary substantially in the number of calories from fat but will differ only slightly in their cholesterol content [19].

3 Effects of Animal Nutrition on Meat Lipidic Profile

A great research effort has been exerted since the 1980s for the manipulation of the fatty acid composition of meat, to achieve nutritional recommendations, especially an increase in the ratio between PUFA and saturated fatty acids (SFA). More recently, nutritionists recommend that PUFA composition should be manipulated toward a lower *n*-6:*n*-3 ratio. Fats with a higher content of PUFA have lower melting points that affect the fat firmness. Softer fats may raise important problems during processing if the integrity of the muscle is disrupted by any mechanical treatment (chopping, mincing, stuffing, etc.). The major troubles are related to oxidation and generation of off-flavors (rancid aromas) and color deterioration, specifically a trend toward yellowness in the fat [8].

Pigs and poultry are monogastric animals that incorporate part of the dietary fatty acids practically unchanged into the adipose tissue and cellular membranes, where desaturation and chain elongation processes may occur [7]. The extent of incorporation may vary depending on the specific fatty acid and the type of feed. Different types of cereals as well as dietary oils and their effects on the proportions in fatty acid composition have been studied. The use of canola or linseed oils produces a substantial increase in the content of linolenic acid (C 18:3), which is an n-3 fatty acid. In this way, the n-6:n-3 ratio can be reduced from 9 to 5 [20]. Other dietary oils such as soy, peanut, corn, and sunflower increase the content of linoleic acid (C18:2), an n-6 fatty acid. Although it increases the total PUFA content, this fatty acid does

not contribute to decrease the n-6:n-3 ratio, just the reverse. A similar trend is observed in the case of poultry, where the feeds with a high content of linoleic acid such as grain, corn, plant seeds, or oils also increase the n-6/n-3 ratio. As in the case of pork, the use of feeds containing fish oils or algae, enriched in *n*-3 fatty acids such as EPA (C 22:5 n-3) and DHA (C 22:6 n-3) acids, can enrich the poultry meat in n-3 fatty acids and reduce the n-6/n-3 ratio from around 8.4 to 1.7 [15]. The main problem arises from oxidation during heating, because some volatile compounds such as hexanal are typically generated, producing rancid aromas. The rate and extent of oxidation of muscle foods mainly depends on the level of PUFA, but they are also influenced by early postmortem events such as pH drop, carcass temperature, aging, and other factors. Feeds rich in saturated fats such as tallow yield the highest levels of palmitic, palmitoleic, stearic, and oleic acids in pork loin [21]. Linoleic and linolenic acid content may vary as much as 40% between the leanest and the fattest animals [22]. The PUFA content is especially high in phospholipids, located in subcellular membranes such as mitochondria, microsomes, and so on, making them vulnerable to peroxidation because of the proximity of a range of prooxidants such as myoglobin, cytochromes, nonheme iron, and trace elements [23]. Muscle contains several antioxidant systems, for example, those of superoxide dismutase and glutathione peroxidase, and ceruloplasmin and transferrin, although they are weakened during postmortem storage.

The fatty acid profile in ruminants is more saturated than in pigs, and thus the fat is firmer [14]. The manipulation of fatty acids in beef is more difficult due to the rumen biohydrogenation. More than 90% of the PUFA are hydrogenated, leaving a low margin for action to increase the PUFA/SFA ratio above 0.1. However, meats from ruminants are rich in conjugated linoleic acid (CLA), mainly 9-*cis,*11-*trans*-octadecadienoic acid, which exerts important health-promoting biological activity [24]. In general, a good level of nutrition increases the amount of intramuscular fat. On the other hand, food deprivation may result in an induced lipolysis that can be rapidly detected (in just 72 h) through a higher content of free fatty acids and monoacylglycerols, especially in glycolytic muscles [25].

4 Conjugated Linoleic Acid (CLA)

During the 1930s, biological chemists began to realize that the cow could convert dietary nonconjugated fatty acids to a conjugated component. However, the mechanism for this transformation and the location at which it was effected were unknown. By 1950, it was established that there was a species-to-species difference in the unsaturated fatty acid content of body fat from pasture-fed animals. Linolenic acid is the predominant pasture fatty acid. When ruminant animals such as cows and sheep consume this acid, only trace amounts appear in body tissues or milk. On the other hand, the horse, a nonruminant, transfers a considerable proportion of dietary linolenate to its depot fat [26].

Observations that rumen contents could hydrogenate polyunsaturated fatty acids to produce acids with *trans*-unsaturation provided a biological explanation for the

presence of *trans*-fatty acids in the depot fat of sheep and oxen, noted as early as 1928 [27]. Later, scientists from New Zealand [28] examined the *trans*-unsaturated fatty acid content of fat from a selection of ruminant and nonruminant animals. As expected, the depot fats from ruminants (Sambur, fallow deer, ox, and sheep) contained conjugated diene at around the 0.5% level. An unexpected finding was the presence of considerable conjugated diene in the body fat of the nonruminant marsupials, wallaby (3.5%), and quokka (2.9%). Depot fat *trans*-monounsaturated fatty acid content from these marsupials was also exceptionally high, 19% and 21%, respectively. The high conjugated diene and transmonoene content is explained by their possession of a ruminant-like digestion.

The isomer *cis*-9,*trans*-11-18:2 was identified in the depot fat of pasture-fed lambs using Gas Liquid Chromatography analysis [29]. Trivial names for the natural *cis*-9, *trans*-11-isomer have been suggested: firstly [30] was proposed bovinic acid, but this name was considered too restrictive because the isomer is also produced in the rumen of a number of other species of commercial importance. For this reason was later suggested rumenic acid, a name that is now accepted and used [31].

During the early 1980s, Michael Pariza and his colleagues at the University of Wisconsin found that an isolate from grilled minced beef could inhibit carcinogenesis. The anticarcinogenic isolate was shown to consist of isomers of conjugated octadecadienoic acid in which the constituent double bonds are separated by a single carbon-to-carbon bond instead of a methylene group. The isomers were referred to collectively as conjugated linoleic acid for which the acronym CLA is now used [27].

Conjugated linoleic acid (CLA) refers to a group of polyunsaturated fatty acids that exist as positional and stereo-isomers of conjugated dienoic octadecadienoate (18:2). The predominant geometric isomer in foods is the c9t11-CLA isomer, also called "rumenic acid" [24], followed by t7,c9-CLA, 11,13-CLA (c/t), 8,10-CLA (c/t), and the t10c12-CLA isomer. The three-dimensional stereo-isomeric configuration of CLA may be in combinations of cis and/or *trans* configurations (Fig. 1).

CLA is found in foods such as beef and lamb, as well as dairy foods derived from these ruminant sources [32]. Numerous physiological properties have been attributed to CLA including action as an antiadipogenic, antidiabetogenic, anticarcinogenic, and antiatherosclerotic agent (Table 2). In addition, CLA has effects on bone

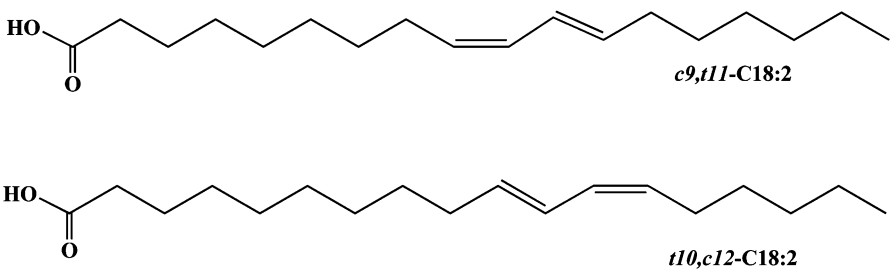

Fig. 1 Main isomers conjugated linoleic acid. Top: C18:2Δ9c,11 t (rumenic acid). Bottom: C18:2Δ10t,12c

Table 2 Physiological properties of CLA

Major function	Physiological model
Body composition	Decrease adiposity in chicks, mice, rats;
	Decrease adiposity in human subjects.
Diabetes	Decrease the onset of diabetes in male rats;
	Aids in the management of metabolic parameters in human subjects with type 2 diabetes;
	Decrease insulin sensitivity in mice.
Carcinogenesis	Decrease chemically induced mammary carcinogenesis in rats;
	Decrease growth of transplantable breast cancer tumor cells in nude mice;
	Decrease growth of transplantable prostate cancer tumor cells in nude mice;
	Decrease chemically induced colon carcinogenesis in rats;
	Decrease chemically induced forestomach.
Atherosclerosis	Decrease atherosclerotic plaque formation in hamsters.
Immune system	Decrease eicosanoid and histamine production;
	Increase onset of lupus in mouse model.

formation and the immune system as well as fatty acid and lipid metabolism and gene expression in numerous tissues [24].

The primary dietary sources of CLA for humans are food products derived from ruminant animals, mostly cattle, including meat fat, milk, cheese, yoghurt, and butter [33]. There are two biosynthetic processes responsible for the formation of CLA. These processes are carried out primarily in ruminant animals but also to a lesser extent in nonruminant animals. The first process is the incomplete biohydrogenation of linoleic acid and linolenic acid in the rumen; the second biosynthetic process is the endogenous conversion of transvaccenic acid, an intermediate of biohydrogenation, to CLA in tissues [34]. The main dietary source of linoleic acid for ruminant animals is concentrated feed consisting mainly of grains and seed oils, whereas the main dietary source of linolenic acid is pasture grasses [35].

4.1 Biosynthesis of CLA

Because potential health benefits have been associated with dietary consumption of CLA, enhancement of CLA concentrations in meat and milk has become an important objective in animal nutrition research. It is generally accepted that CLA in ruminant meat and milk originates from incomplete biohydrogenation of linoleic acid in the rumen [36]. A study performed in 1951 [37] noticed that the body fats of ruminants possessed less linolenic acid than horses on the same high linolenic acid diet and suspected something to have happened in the rumen. Linolenic acid was incubated in rumen fluid, and it was demonstrated the formation of TFA in the rumen. Utilizing rumen contents from fistulated sheep grazing pasture [38], it was confirmed the existence of TFA as a result of rumen biohydrogenation. Later [39] it

was also demonstrated that conjugated dienoic acids accumulated when linoleic acid was incubated with rumen contents, but not when linolenic acid was incubated with it.

4.2 CLA Synthesis in the Rumen

A diverse range of rumen bacterial species have been isolated; they demonstrate a capacity to isomerize *cis*-double bonds of unsaturated fatty acids to form conjugated *cis*/*trans* double bond systems and further hydrogenate these conjugated acids [36]. A study performed in 1967 [40] showed the production of *c*-9, *t*-11 CLA from linoleic acid by *Butyrivibrio fibrisolvens*. When the same bacteria were incubated using linolenic acid as the substrate, *c*-9, *t*-11, *c*-15 C18:3 were produced, in which 18:3 later was found to be hydrogenated to trans vaccenic acid [41]. No *c*-9, *t*-11 CLA was formed from linolenic acid.

The biohydrogenation of linoleic acid and linolenic acid in the rumen occurs in a similar manner. The first reaction in linoleic acid biohydrogenation is the isomerization where the double bond at carbon-12 position is transferred to carbon-11 position forming *c*-9, *t*-11 CLA. It is followed by the rapid hydrogenation of *cis*-9 bond leaving *trans* vaccenic acid. Both these steps are carried out by group A bacteria, while the last step of biohydrogenation of oleic to stearic acid is carried out by group B bacteria [42]. The enzyme responsible for the conjugation of *cis*-9, *cis*-12 double bonds was identified as linoleic acid isomerase (EC 5.3.1.5). It is a particulate enzyme bound to the bacterial cell membrane [36] and demonstrates an absolute substrate requirement for a *cis*-9, *cis*-12 diene system and a free carboxyl group [43], found in both linoleic acid and linolenic acid. Similarly, the linolenic acid is first isomerized at *cis*-12 position to form *c*-9, *t*-11, *c*-15 C18:3, which were then reduced at both the *cis* bonds to produce *trans* vaccenic acid. The final step is similar to that of linoleic acid. A common intermediate during the biohydrogenation of linoleic acid and linolenic acid was found to be *trans* vaccenic acid [42]. Its reduction appears to be rate limiting in the complete biohydrogenation of unsaturated C18 fatty acids resulting in the accumulation of trans vaccenic acid in the rumen [44]. This is the predominant pathway of rumen biohydrogenation of linoleic acid and linolenic acid. Subsequently, a product precursor relationship between *trans* vaccenic acid and CLA was observed both in vitro and in vivo (sheep) with increasing concentrations of LA in the diet [45].

With a low-fiber diet, a change in *trans* octadecenoic acid profile of milk occurred and *trans*-10 octadecenoic acid became the predominant *trans* octadecenoic acid in milk fat [46]. This suggested the hypothesis of another pathway for the ruminal synthesis of *t*-10, *c*-12 CLA involving bacterial *c*-9, *t*-10 isomerase with the formation of a *t*-10, *c*-12 double bond as the first step in the process [36]. The *c*-12, *t*-11 isomerase from *Butyrivibrio fibrisolvens* can hydrogenate *t*-10, *c*-12 octadecadienoic acid [41], thus producing *t*-10 octadecenoic acid. It has been shown that more than 50% of the linoleic acid was converted to *t*-10, *c*-12 isomer of CLA and only 10% was converted to *t*-10 octadecenoic acid by anaerobic *Propionibacterium* isolated from mouse cecum [47]. Another rumen bacteria *Megasphaera elsdenii* YJ-4 have

also been shown to produce *t*-10, *c*-12 isomer of CLA [48]. The *t*-10, *c*-12 isomer was formed from linoleic acid but not from either of the linolenic acid as was the case with *c*-9, *t*-11 isomer of CLA. It is not clear whether *t*-10 octadecenoic acid is desaturated at *cis*-12 position to produce *t*-10, *c*-12 isomer in the rumen or in some other tissues endogenously.

Rumen pH has an important role in maintaining a viable rumen environment suitable for *Butyrivibrio fibrisolvens* involved in the biohydrogenation of linoleic acid and linolenic acid. It has been shown that ruminal pH at 6.0 or above has a positive effect on *trans* vaccenic acid and CLA contents in rumen cultures [49]. It is of higher importance in high yielding dairy and beef animal diets where large amounts of grain are included in the diet and thus decrease the rumen pH below 6.0. Other than its positive effects on *Butyrivibrio fibrisolvens,* how rumen pH affects overall biohydrogenation of unsaturated fatty acids of 18, 20, or 22 carbons in the rumen in relation to CLA and *trans* vaccenic acid has not been investigated in detail. It has been shown that CLA could be increased by supplementing diets with feed sources such as fish oil or marine algae (*Schizochytrium* sp.), which are rich in 20- or 22-carbon fatty acids [50] that do not yield either CLA or *trans* vaccenic acid during biohydrogenation in the rumen. The mechanism by which supplementation of fish oil or marine algae increases concentration of milk fat CLA and *trans* vaccenic acid is not clear. It has been proposed that the longer chain polyunsaturated fatty acids from fish oil inhibit the complete biohydrogenation of C in the rumen by inhibiting the 18:2 growth of bacteria responsible for hydrogenating *trans* vaccenic acid or through the inhibition of their hydrogenases [36] leading to an increased escape of *trans* vaccenic acid from the rumen. Further research is needed on the pathway for rumen biohydrogenation of longer chain poly-unsaturated fatty acids from fish oils and other fatty acids sources of marine origin to clearly define the mechanisms involved in enhancing CLA and *trans* vaccenic acid contents in food products from ruminants.

4.3 CLA Endogenous Synthesis

While the origin of CLA from linoleic acid by *Butyrivibrio fibrisolvens* in the rumen was accepted, it was not sufficient to account for all the CLA present in milk or meat. The levels of CLA in meat and milk from ruminants compared with nonruminants suggest a close association between rumen function and CLA levels in tissue and milk fat.

A study performed in 1996 [51] found that lactating sheep grazing pastures with no supplemental linoleic acid produced a high level of *c*-9, *t*-11 CLA in milk fat. The puzzle as to why the milk fat showed greatly increased absorption in the ultraviolet region when cows were turned out to pasture, even though the pastures are high in LNA and not LA, continued to intrigue the scientists. Two years later another study demonstrated that supplementation of fish oil, which is high in PUFA of 20 or more carbons did not produce *c*-9, *t*-11 CLA or *trans* vaccenic acid as the intermediate during biohydrogenation, and also increased *c*-9, *t*-11 CLA content in the milk of

cows [52]. Basing their research on these preliminary results, it was possible to get to the conclusion that ruminal synthesis of CLA was only marginal and could not account for the amount of CLA present in milk and meat from ruminants [36]. Overall these findings suggested that the CLA formed during the biohydrogenation of linoleic acid in the rumen was not the only source and that another source needed to be explored.

Initially it was proposed that CLA could be synthesized endogenously from *trans* vaccenic acid by Δ9-desaturase. A recent study [53] provides several lines of evidence that, by analogy with rumenic acid, trans-11,cis-13 CLA may originate both from ruminal biohydrogenation and from direct Δ13-desaturation of vaccenic acid in mammary tissue.

An experiment [54] was conducted to examine whether increased CLA in milk of dairy cows fed fresh pasture compared with alfalfa and corn silages was because of ruminal or endogenous synthesis. Eight Holsteins were fed a total mixed ration using alfalfa and corn silages as the forage source in confinement or grazed in a replicated crossover design. The proportion of total fatty acids as CLA (primarily c9, t11-18:2) in g/100 g was 0.44 v. 0.28 in ruminal digesta, 0.89 v. 0.53 in omasal digesta and 0.71 v. 1.06 in milk during confinement feeding and grazing, respectively. Blood plasma CLA was 0.54 v. 1.05 mg/l for the two treatments, respectively. The increased concentration of CLA in milk with grazing likely resulted from increased synthesis through desaturation of t11-18:1 in the mammary gland. Other authors [55] estimated rumen output of CLA in nonlactating cows and then extrapolated the results to lactating cows on the basis of feed intake. They estimated the endogenous synthesis of CLA to be >80% of the total. Another study [56] even estimated 100% of CLA to be derived from endogenous synthesis. It is not surprising, considering the fact that the amount of CLA detected in the blood serum of cows is none or very small [57].

It is possible that a higher proportion of CLA is synthesized endogenously in cows fed all pasture diets compared with cows fed grains, oil seeds, or oils, because LNA, which is high in fresh pastures, does not produce CLA as the intermediate product during its biohydrogenation in the rumen. However, all these studies used an indirect approach to estimate the CLA synthesized endogenously and it may be over- or underestimated under different feeding regimens. A direct approach, which may be difficult, is probably needed to measure the actual uptake of CLA and its incorporation into milk fat by the mammary gland to estimate the mammary synthesis of CLA more accurately.

In other ruminants, information on the proportion of rumen and endogenous origin of CLA is limited. However, the fact that increased CLA content in lamb meat [58] and goat milk fat [59] was associated with high TVA contents indicates that post ruminal synthesis could be the predominant one. A very high correlation ($r = 0.99$) of CLA with TVA in goat milk fat [59] suggests that mammary synthesis predominates over rumen synthesis of CLA.

Several other *trans*-C 18:2 isomers are found in rumen digesta, and milk and tissue lipids [41]. Unlike *c*-9, *t*-11 CLA, no detailed studies have been conducted to study the endogenous synthesis of other isomers of CLA, including *t*-10, *c*-12,

probably because many of them contribute 0.05% or less in milk or meat fat and their biological significance has not been established.

5 CLA in Foods

CLAs are widely distributed in various foods, primarily in dairy products and meat from ruminants. In general, ruminant products have the highest amounts of CLA, while vegetable products and some seafood contain only trace amounts [60].

The wide variation of the CLA content in dairy products reflects the differences in CLA contents of the milk fat. The CLA content in milk fat is markedly influenced by the cows' diet [46], the PUFA content of the feed [61], dietary regimen [62], and the presence of ionophores [63]. The influences of the processing parameters and starter cultures on the preparation of cheese are contradictory [64], and further studies are necessary to evaluate whether the conditions increase the CLA content and change the isomer distribution in cheese. CLA contents in long-ripened propionic-acid-fermented cheeses (e.g., old Emmenthal, or yogurt) with added probiotic cultures appear to be slightly elevated [60]. The content of CLA in dairy products ranged from 0.63% in condensed milk to 1.16% in cow's milk, and from 0.40% in Gouda to 1.70% in Jurassic cheese [60]. These values should not be viewed as representative of one product. The wide variation of the CLA content in dairy products reflects the differences in CLA contents of the milk fat.

Meat from animals such as pigs contains low amounts (0.12%) of CLA because such animals lack a rumen. The CLA in pork may originate from feedstuffs that contain CLA such as meat meal or tallow.

5.1 CLA in Meats

Food sources originating from ruminants are known to have markedly higher CLA concentration than those from monogastric animals. Table 3 shows the CLA concentration of meat from different animal species usually used in the human diet. The

Table 3 CLA content in different meat and meat products (mg/g FAME)

Lamb	5.6
Beef	2.9–4.3
Pork	0.6
Chicken	0.9
Turkey	2.5
Salami	4.2
Cooked ham	2.7
Smoked bacon	0.8–2.7
Smoked ham	2.9

Source: Adapted by [36]

highest CLA concentrations were found in lamb (4.3–19.0 mg/g lipid) and with slightly lower concentrations in beef (1.2–10.0 mg/g lipid). The CLA content of pork, chicken, and meat from horses is usually lower than 1 mg/g lipid. Interestingly, turkey seems to have a relatively high CLA content (2–2.5 mg/g lipid), but reasons for this are unclear [32]. Some data on CLA meat content of animals less common in human diets like meat from elk (1.3–2.1 mg CLA per gram fatty acids), bison (2.9–4.8 mg/g fatty acids), water buffalo (1.83 mg/g fatty acids), and zebu-type cattle (1.47 mg/g fatty acids) are also available [65]. The highest CLA concentration (38 mg/g fatty acids) of all animals was found in adipose tissue of kangaroos [66]. Large variations in the CLA content are not only reported between animal species but also within muscles of the same species.

The CLA concentrations reported in various studies may be underestimated because only the c9,t11–18:2 isomer was determined, and not the total CLA content [67]; however, this isomer accounts for more than 80% of the total CLA, even if a study found that between 76% and 92% (depending on the species) of the total CLA was c9,t11–18:2, while other studies [68] determined a value of 78% in lamb rib loins, and a value of about 59% in beef [69].

A trial performed with the aim to evaluate the effect of the slaughter weight on the CLA isomer content of intramuscular fat in three different kind of lamb muscles, specifically *Longissimus dorsi*, *Triceps brachii*, and *Semimembranosus*, showed that the body weight at slaughter significantly affected the amount of rumenic acid in intramuscular fat of *Semimembranosus* and *Triceps brachii* in Massese lambs, but not in the *Longissimus dorsi*. In particular, the heaviest animals showed the highest amount of rumenic acid [70]. The different behavior shown by LD muscle did not seem to be related either to differences in the stearoyl Co-A desaturase enzyme activity, or to differences in the rumen activity, or to differences in fat deposition. Thus, further studies are needed to verify whether this different behavior among muscles is related to their different metabolism and/or to a different tissue utilization of fatty acids [71].

Grilling rib-eye, sirloin, T-bone, and ground beef to an internal temperature of 80 °C increases both the c9,t11-isomer (mg/g fat) and total CLA (mg/g fat) content of these meats [69], but a significant increase was observed only in the case of the grilled T-bone steak. Results obtained in the same study [69] showed that frying, grilling, microwaving, and baking ground beef patties did not produce any major changes in the CLA content. With the exception of baking, the higher internal temperature (80 °C) generally resulted in higher CLA concentrations. During refrigerated storage of ground beef, oxidative damage occurs but this does not influence the CLA content. Results obtained till now demonstrated that cooking and storage of meat does not negatively alter its CLA content [72].

CLA can be produced with very limited amount by gastric bacterial biohydrogenation in pig resulting in low amount of CLA in pork [73]. However, pork is an ideal candidate for CLA enrichment by feeding chemically synthesized CLA because CLA cannot be further saturated and can be deposited in tissues with relatively high efficiency [73]. The cis 9, trans 11 isomer of CLA could be incorporated by 46.4% in subcutaneous adipose tissue and the cis 11 and trans 13 was

incorporated by 0.74% in intramuscular fat. Feeding pigs with 1% CLA for 47 days significantly increased the CLA content including the cis 9, trans 11 and the trans 10, cis 12 in belly fat [74]. However, results on pig growth performance in response to CLA supplementation are not homogeneous, as reported by [75]. This may be due to a deficit of nutrients in diets containing CLA isomers, as these fatty acids act as repartitioning agents, promoting lean tissue deposition. The high lean tissue deposition and the low body fat deposition of CLA-treated pigs [76] may require an increase in dietary protein content and/or protein quality to maintain protein synthesis and growth in finishing swine. In fact, the utilization of substances with repartitioning effects such as ractopamine required an increase in lysine content in finishing pigs [77]. Consequently dietary CLA supplementation might induce an insufficient nutritional level of an essential amino acid like lysine, the first limiting amino acid in pig diet used for protein deposition.

In a study performed on rabbit meat, it was demonstrated that dietary CLA improved the oxidative stability of rabbit muscle, increasing shelf life, decreasing lipogenic enzyme activity, and reducing plasma triglycerides and total cholesterol [78]. The same authors also found that addition of CLA isomers to rabbit diet modified lipid content and fatty acid composition and reduced lipid oxidation in LL [79]. The increase in CLA content, from about 1.3 to 10.4 mg/100 g of edible meat, suggests that the nutritional quality of rabbit meat for human consumption may be improved.

CLA content very similar to those found in ruminants has been determined in meat obtained from foals slaughtered at 24 months of age [80]; equid meat is a typical red meat, even if it is produced by a monogastric hind-gut fermenter [81]. However, considering another equid such as donkey, in one of the few studies recently performed on donkey meat lipid profile characterization, it was not possible to determine CLA [82].

5.2 CLA in Chicken, Turkey, and Eggs

The content of CLA may be increased by 40 times in breast and thigh meat, by feeding CLA enriched diets to broilers [83]. Despite this high increase in the CLA content in breast and thigh meat, the recommended daily intake for CLA in humans may only be covered by roughly 10% [84]. Furthermore, CLA enriched poultry meat shows deviations in meat quality, increasing toughness and showing also a darker color [85]. This is also confirmed by sensorial evaluation: color and flavor of CLA enriched meat received positive results from the test panel, whereas, texture and juiciness were negatively scored. The toughness of the meat may be explained by the higher proportion of SFA in CLA enriched muscle tissues and the consequent decrease in UFA, which increase the fat melting point [85].

In egg yolk lipids, CLA was not even detected when laying hens were fed a normal concentrate diet [35]. The effects of dietary CLA supplementation on eggs fat profile have been recently reviewed [86]; an interesting result showed that the egg yolk surface from hens fed CLA diets sometimes had relatively dark color with light

spots. Dietary CLA increased the firmness of hard-cooked egg yolk. The texture of yolks from hard-cooked CLA eggs was rubbery and elastic, and the yolks were more difficult to break. It was speculated that the quality changes of CLA eggs were related to the increase of yolk water content, the movement of ions between yolk and albumen through yolk membrane, and the changes of egg yolk pH during storage.

Dietary supplementation of CLA significantly influenced fatty acid profile in egg yolk lipids: myristic, palmitic, stearic, CLA (9-cis, 11-trans CLA and 10-trans, 12-cis CLA) were increased by dietary CLA, while palmitoleic, oleic, linoleic, linolenic, arachidonic, and DHA acids were decreased. Total CLA concentration observed when 5% CLA was fed ranged between 8.5 to 8.6% (Ahn et al. 1999). The decrease in the concentrations of linoleic and linolenic acids in yolk lipids of hens fed CLA probably reflects the relatively low concentration of these fatty acids in the CLA source as compared with soybean oil. Decreases in arachidonic acid and DHA acid in yolk lipids from hens fed CLA also could be related to the low concentration of dietary linoleic and linolenic acids, which serve as precursors to the formation of arachidonic and DHA acids. Another possibility is that CLA may compete with linoleic or linolenic acid for Δ6-desaturase, the rate-limiting step for the conversion of these fatty acids into arachidonic acids or DHA acid in liver microsomes [87].

5.3 CLA in Fish

Several studies demonstrated the cardiac benefits of a regular intake of fish, a source of the long-chain n-3 fatty acids EPA and DHA [88]. A sharp demarcation in the linoleic acid content of fish showed that most marine fish typically had only 1–2% of linoleic acid. This content is so low as to continue to preclude speculation concerning whether the fatty acid of the muscle of this food would or would not contain CLA [89]. The situation changes completely when considering the new developments in farmed fish that accumulate fatty acids from a variety of dietary ingredients in their growth period. The reason is that the diets represent a balance between the cost and efficacy of the ingredients. The need is to provide good quality protein for growth and meet minimal specific needs for “essential” fatty acids, especially in salmonids, plus vitamins and minerals. For salmonids, replacement of the most common dietary fat, fish oil, with vegetable oils has become common lately.

Seafoods are not considered to be important sources of CLA, either, but the term seafood is so loosely used that it is often difficult to learn from brief references whether the source of most of the fat or lipid in the reference is from cold-water or warm-water fish, or from the fish alone [89].

5.4 CLA in Milk and Dairy Products

The CLA content in dairy cows milk fat can be affected by a cow’s diet, breed, age, non-nutritive feed additives, such as ionophores, and by the use of synthetic mixtures

of CLA supplements [90]. Among these factors, the diet is known to strongly influence the CLA content of milk and includes feedstuffs such as pasture, conserved forages, plant seed oils, cereal grains, and animal fat.

The positive effect of pasture-based diets on the CLA content of milk fat has been demonstrated in several experiments [90]. Cows grazing pasture had 500% higher CLA content in milk fat (2.21% of total fatty acids) compared to cows fed a diet containing 50% conserved forage (hay and silages) and 50% grain (0.38% of total fatty acids). Other researchers have also demonstrated that the CLA content of milk increased linearly as the proportion of fresh grass from pasture in the diet was increased.

About 48% to 56% of the total fatty acids in fresh forages consist of C18:3. Fresh grass supplies C18:3 as a substrate for ruminal biohydrogenation. However, the abundant supply of C18:3 from fresh grass only partly explains the large increases in CLA and *trans* vaccenic acid contents of milk fat from pasture-fed cows. Besides this, the high concentrations of soluble fiber and fermentable sugars present in fresh grass may create an environment in the rumen without lowering the ruminal pH that is favorable to the growth of the microbes responsible for CLA and *trans* vaccenic acid production. Ruminal pH is generally relatively high in cows grazing pasture compared to cows fed a combination of conserved forage and grain.

The effects of several feeding strategies on CLA concentration in dairy milk have been recently described; most experiments were conducted on Holstein or Friesian cows. The most common results indicated that CLA in milk is related to the availability of its precursors (oleic acid, linoleic acid and linolenic acid) from ruminal andendogenous synthesis [91]. The average difference in CLA content of milk fat among Brown Swiss, Holstein-Friesian, and Jersey breeds is 15% to 20% when fed similar diets. Brown Swiss cows have inherently higher CLA in milk fat, followed by the Holstein-Friesian and Jersey breeds; data on other breeds are too limited to form any firm conclusions [90].

Microbial fermentation can contribute to increases in CLA content in dairy products through isomerase and reductase reactions in the biohydrogenation pathway. Moreover, the process temperature can also influence the CLA content in dairy products. Dairy products, such as cheese, are the richest sources of CLA, and CLAs are formed in cheese during processing and storage [92]. When the animals were pasture fed, the contents of CLA in milk fat were much higher than that when a fodder mixture was supplied to cows. These data indicate that linoleic acid-enriched feed can increase the CLA contents in milk and cheese through fermentation by ruminal bacteria. The influence of cheese processing, e.g., changes in temperature, microbial fermentation, or ageing, on CLA production are proportional [93]. Existing literature suggests that CLA in milk fat is a stable compound under normal processing and storage conditions, while processing dairy products at >80 °C may slightly elevate the CLA content.

Lactic acid bacteria, bifidobacteria, and some propionibacteria are used as starter cultures in cheese and are able to efficiently convert linoleic acid to CLA. Thus, CLA-enriched cheeses typically originate from CLA enriched milk, and starter cultures also have a great influence on the CLA content [93].

6 Human Dietary Intake of CLA

It is not easy to determine how much CLA humans are currently consuming, and how much should be consumed in order to obtain the health benefits and anticancer effects that have been observed from adding proper levels of CLA to the diet. Rigorous documentation of dietary CLA intake in any population is not available currently. However, several investigators have utilized indirect methodologies to estimate both typical and extreme intakes of CLA in a limited number of populations. Using 3-d dietary records in conjunction with published CLA contents of foods, typical CLA intake has been estimated to be between 52 and 137 mg/day for young men and women in the United States and 430 and 350 mg/day for German men and women, respectively [30]. The use of a semiquantitative food-frequency questionnaire to estimate typical CLA intake in lactating women suggests that CLA intake in this population is 227 mg/day [30].

The CLA and TFA dietary intake in Germany is shown in Table 4; the estimated daily CLA intake was found to be 0.36 g/day for women and 0.44 g/day for men. The CLA intake compares to approximately one-fifth the daily intake of TFA and may reach physiologically active levels.

To date, statements about health promoting effects of CLA are mainly based on animal trials and remain to be proven in humans [36]. In human trials synthetic CLA supplements are usually used and these do not reflect natural isomer composition in foodstuffs. Whether natural CLA sources (meat and milk from ruminants) have a similar impact on human health warrants further research.

Furthermore, estimations of the dietary intakes of CLA isomeric forms by infants, children, and adolescents have not been documented. The dietary CLA intake reflects individual, dietary, and ethnic consumption habits. Finally, examination of the relationships among human dietary intake of CLA isomers, their concentrations in adipose tissue and plasma, and risk of various chronic degenerative diseases (e.g., cancer, diabetes, and obesity) is essential for scientists to better understand the importance of dietary CLA in human health. Thus, enhancing our knowledge concerning CLA intake in various populations must remain a primary focus for research in this area.

Table 4 Estimated CLA and TFA intake in Germany

	Women		Men	
	CLA (g/d)	TFA (g/d)	CLA (g/d)	TFA (g/d)
Milk and dairy products	0.24	0.90	0.28	1.1
Meat and meat products	0.08	0.2	0.11	0.3
Fish	<0.01	<0.01	<0.01	<0.01
Margarines	<0.01	0.1	<0.01	0.2
Cakes and pastries	0.03	0.2	0.03	0.2
Chocolate and sweets	<0.01	0.1	0.01	0.1

7 Cancer and CLA Consumption

The initial observations arousing interest in the biological effects of CLA showed their ability to reduce chemically induced cancers in animal models. In contrast to the many hundreds of phytochemicals that possess varying degrees of anti-carcinogenic activity, CLA is unique because it is a group of fatty acids isomers found in highest amounts in animal products [94]. Furthermore, CLA was found to possess anticarcinogenic activity that turned out be quite potent. The following sections present the published experimental literature that indicates an effect of CLA on cancer inhibition, primarily in animal models of chemically induced cancer.

7.1 Colorectal Cancer (CRC)

The publication of the World Cancer Research Fund/American Institute for Cancer Research [95] raised considerable alarms about the cancer risks associated with red and processed meats, in concluding that they are a convincing cause of colorectal cancer (CRC). There are a number of possible mechanisms for a link between meat consumption and CRC. These include the promotion of carcinogenesis by high-fat intake, the production of carcinogenic heterocyclic amines (HCAs), and/or polycyclic aromatic hydrocarbons (PAHs) during cooking, the formation of carcinogenic N-nitroso compounds (NOCs) either within meat per se or as a result of endogenous processes, and the promotion of carcinogenesis by hem iron [96]. It is also suggested that the high energy density of meat increases the likelihood of obesity, itself a major risk factor for cancer [95]. For each of the mechanisms implicated in cancer formation, there is an approach to reducing any cancer threat. The selection of meat will affect its fat content. It seems that wild animals are overall lower in fat, with a lower proportion of saturated fatty acids and higher proportion of polyunsaturated fatty acids as compared with farmed animals. In general, the selection of animals according to genotype, and diet they are fed on will, profoundly influence not only the total fat concentration in the meat but also the nature of the fats. Obvious modulations include dietary fat intake, but controlling the intake of other nutrients such as vitamin A will also have an influence.

Meat and meat products vary greatly in their fat content according to the animal species, age of the animal, and part of the carcass used. The fat content and fat composition is also affected by animal feeding, a fact that is exploited for modification of the meat fatty acid composition, with the relatively best results in single-stomached pigs and poultry [97]. Data on the average fat content and fatty acid composition of meats and meat products are published as part of food composition tables throughout the world. The fat content of meat has decreased in recent years, with new breeds coming onto the market, and different trimming processes. Of the nutrients considered to have detrimental effects, saturated fatty acids (SFA) provide around 50% of the fatty acids found in meat, while *trans* fatty acids (TFAs) make up only a small component. The rest is mainly made up of monounsaturated fats, with

small amounts of polyunsaturated fatty acids (PUFA), including small amounts of n-3 PUFA, which are likely to be beneficial in cancer prevention [95].

7.2 Breast Cancer

Breast cancer is the clinical expression of the development of tumor tissue initially within a breast, then within different other sites during the metastatic evolution period. This tumor tissue results from a multistep carcinogenic process that probably extends over several decades. This process consists of an accumulation of genetic alterations acquired during a woman's life span, which leads to the neoplastic transformation of normal epithelial cells. Dietary lipids can modulate mammary carcinogenesis at several stages; some of them may contribute to the prevention of acquired genetic alterations through their antimutagenic activity and therefore act at the very early stages of the initiation process. Lipids can also influence tumor promotion [98]. Fatty acids, the main components of dietary lipids, have several properties that make them potential targets for use in a dietary prevention of breast cancer. For a few years, growing interest has focused on particular fatty acids, geometrical and positional isomers of linoleic acid, i.e., conjugated linoleic acids (CLA). These dietary conjugated dienes present interesting anticarcinogenic properties in animal studies of mammary carcinogenesis; furthermore, these properties are unique in that CLA can act at very low concentration, close to that observed in the diet [99].

Whether CLA may be considered as potential targets for use in a nutritional prevention of breast cancer remains an attractive issue. The amount of CLA needed, the duration of intervention, as well as the proper stage in life for such an intervention are not known at present. In humans, only epidemiological studies have been conducted and results are inconclusive. Only 1 study found a negative association between the intake of CLA and risk of breast cancer in postmenopausal women, while other studies reported no effect of CLA intake on protection against breast cancer [100].

7.3 Skin Cancer

Although not nearly equal in extent to the investigations on mammary cancer inhibition, the effect of CLA on skin carcinogenesis has received a fair amount of examination and was the tumorigenic site of the first study to demonstrate an anticancer effect of CLA [94]. From the many hundreds of chemicals in a partially purified extract from fried ground beef, a substance that exhibited anticarcinogenic activity has been identified [101]. Using the classic two-stage mouse epidermal carcinogenesis model, this substance was identified as CLA. In this experiment, synthetically prepared CLA was topically applied 7 d (20 ng/mouse), 3 d (20 ng/mouse), and 5 min (10 ng/mouse) before dermal treatment with 50 nmol DMBA per mouse ($n = 20$/group). One week later, the female CD-1 mice received twice weekly

topical treatments with 6 μg 12-*O*-tetradecanoyle-13-acetate (TPA) until study termination at 16 weeks post-DMBA. Compared with control mice ($n = 30$), CLA-treated mice had an ~15% lower papilloma incidence and 50% fewer papillomas per mouse.

Some years later, results obtained by other researchers [102] demonstrated that CLA has less biopotency against mouse skin carcinogenesis and perhaps a less steep dose-response curve than for mammary cancer inhibition.

7.4 Prostate Cancer

In contrast to the research on breast cancer cell lines, the investigation of CLA on prostate cell lines is limited. A study was carried out in order to examine the antiproliferative effects of different concentrations of a commercial preparation of conjugated linoleic acids (CLA) mixture of isomers [cis -9, trans -11 CLA (c9,t11 CLA): trans -10, cis -12 CLA (50:50)] and their constituent isomers on PC-3, a human prostatic carcinoma cell line, and to study their effects on gene expression (mRNA and protein levels) of different enzymes and oncoproteins involved in oncogenesis and progression of prostate cancer [103]. The trans -10, cis -12 CLA was the most effective isomer (55% inhibition); this isomer seems to work preferentially through modulation of apoptosis and cell cycle control, while c9,t11 CLA isomer affects arachidonic acid metabolism.

8 CLA and Cardiovascular Function

The intake of fat, particularly of saturated fat, is directly associated with the concentration of cholesterol in the blood, and the cholesterol in the blood is directly associated with the risk of ischemic heart disease [104]. A little more than two-thirds of the cholesterol is transported by low-density lipoprotein (LDL) and one-third by high-density lipoprotein (HDL). High concentrations of total cholesterol in the blood will almost always mean that LDL cholesterol is high. High concentrations of LDL cholesterol and low concentrations of HDL cholesterol increase the risk of arteriosclerosis and ischemic heart disease. Many epidemiological studies have found that a high content of meat in the diet is associated with increased risk of ischemic heart disease. The higher risk of ischemic heart disease has early on been ascribed to the contribution of SFA from the meat. PUFA increase HDL cholesterol; if SFA in the diet are replaced by MUFA or PUFA, a fall in total cholesterol and in LDL cholesterol is seen. SFA with a carbon chain length of 12–16 increase total cholesterol and LDL cholesterol compared to the monounsaturated fatty acid oleic acid (C18:1), while stearic acid (C18:0) has a neutral effect on concentrations of total cholesterol and LDL cholesterol [105].

Some studies [106] investigated on the effects of dietary CLA on atherosclerosis. In a study, rabbits were fed semisynthetic atherogenic diets (14% fat and 1% cholesterol) with or without CLA (0.5 g/day per rabbit) for 22 weeks. CLA feeding

was associated with significant reductions in total cholesterol, LDL-cholesterol, and plasma triacylglycerol concentrations. CLA did not affect HDL-cholesterol concentrations per se; accordingly the decrease in LDL-cholesterol resulted in a significant reduction in the LDL-cholesterol/HDL-cholesterol ratio.

Feeding 1% CLA as part of a semipurified atherogenic diet (0.2% cholesterol) had a significant beneficial impact on both the progression and regression of atherosclerosis [107]. The effects on atherosclerosis were observed, even though plasma lipids were unaffected. All levels of CLA significantly reduced total cholesterol and VLDL plus LDL-cholesterol concentrations, whereas HDL-cholesterol was not affected.

Different studies found that CLA reduces atherosclerosis, is hypocholesterolemic, reduces adipose tissue mass; however, epidemiological studies and controlled trials in humans are inconclusive and the methodology used is often questionable [108]. The studies evaluating CLA and atherogenesis, carried out till today in different animal models, are thus inconclusive in predicting how CLA will behave in man; there is at present no evidence in support of the anti-atherogenic effect of CLA. In no species has a consistent, reproducible, dose-dependent effect of CLA been established. Until such data are published, the debate on the involvement of CLA in cardiovascular function and blood lipids will continue.

9 CLA and Obesity

Meat fat has a relatively high content of stearic acid and, hence, is less cholesterol-increasing compared with fats with a lower ratio between stearic acid and SFA with a lower carbon chain length (e.g., dairy fat). The high fat content in the diets of industrialized populations, in connection with low level of physical activity, is directly related to the high and increasing occurrence of obesity and ischemic heart disease [104]. Prevention and treatment of obesity, therefore, is based on a reduced fat intake by exchanging high-fat meat with lean meat. There is some evidence that lean meat can be advantageous in a slimming diet, primarily since a high protein intake seems to increase satiety. Consequently, meat, especially lean meat, does not increase the risk of ischemic heart disease or obesity.

CLA is marketed in the United States as a dietary supplement. The focus of marketing efforts is directed toward the implications that CLA will reduce fat mass and increase lean body mass in humans. The basis for these clinical impressions arises from animal studies that demonstrate remarkable alterations in body fat and lean body mass [109]. There are numerous theories on the mechanisms of alterations in body composition seen in animals ingesting CLA, but few studies have been carried out to address this question. Table 5 lists some of the potential mechanisms by which CLA may reduce fat mass and/or increase lean body mass. Alteration of membrane structure is an overarching potential mechanism that might affect a number of activities such as enzyme and hormonal response, permeability, membrane fluidity, and receptor number and/or function. CLA has a different spatial configuration than the parent linoleic acid molecule, which could produce an altered

Table 5 Potential mechanisms of action of CLA to alter body composition

1. Alter membrane structure or function
2. Alter eicosanoid, arachidonic, and/or prostaglandin metabolism
3. Alter cytokine production or response
4. Alter peroxisome proliferator–activated receptor (PPAR) activity
5. Alter sympathetic nervous system activity
6. Alter growth hormone or growth factors

Source: [109]

membrane structure. CLA may be metabolized to different compounds in the eicosanoid pathway, thus affecting the amounts of arachidonic acid and prostaglandins.

Although there is evidence in animals of the ability of trans-10,cis-12 CLA to reduce adiposity and increase lean mass, such unequivocal data supporting the efficacy of either of the CLA isomers in humans are not available [110]. Before CLA supplementation is recommended, further research on human effectiveness and safety of the different isomers of CLA is required.

CLA is known to alter cytokines [111] and tumor necrosis factor (TNF)-a and other cytokines may play major roles in fat metabolism and the etiology of at least some types of obesity. Increased amounts of CLA in the diet reduce fat mass and increase lean body mass. This is the picture seen with administration of β-3 adrenergic agonists to animals [112] and is postulated to occur in humans [113]. β-3 agonists increase both the metabolic rate and the proportion of energy derived from fat oxidation. CLA has been shown to increase metabolic rate and specifically to increase fat oxidation. Finally, it is possible that CLA might alter the secretion or action of growth hormone, insulin-like growth factor, or other growth factors. Administration of growth hormone results in an increase in accumulation of lean body mass and a decrease in fat mass due to increased lipolysis [114].

A recent study [115] demonstrated that dietary supplementation with CLA isomers to dairy cows resulted in a higher plasma IGF-I and leptin level, but in the conclusions section it was stathed that further investigations are necessary to define the exact mode of action of CLA as well as to understand its role in the regulation of the somatotropic axis regulating liver IGF-I secretion.

The first study performed in humans to evaluate body composition used 20 subjects who were of normal weight to mildly overweight [109]. This was a randomized, double-blind, placebo-controlled trial of CLA, 1.8 g/day, versus placebo for a 3-month period. Body composition measurements were performed using a near infrared apparatus. The initial body weights and percentage body fat measurements for the CLA and placebo subjects were 70.9 kg versus 71.8 kg and 21.3% versus 22.0%, respectively. After 3 months, the placebo group had a body weight of 72.4 kg and body fat of 22.4%. The CLA group had a nonsignificant decrease in body weight to 70.2 kg, but the percentage of body fat significantly decreased by 4.3–17.0%.

Another study [116] evaluated 23 experienced resistance-trained males who were matched into two groups for body weight and total training volume. In a randomized

study design, the CLA group was given six capsules per day of a 60% pure CLA preparation and the placebo group was given olive oil capsules for a total period of 28 days. Subjects also were tested for strength performance with bench press and leg press exercises at the beginning and end of the 28-day period. There were no significant differences in body mass, percentage of body fat, or lean body mass between placebo and CLA subjects. Also, there were no significant changes in strength performance on the exercise tests. However, the trends for both strength exercises favored an improved performance in the CLA group. The length of time that the CLA preparation was given was short compared with the time it was administered in animals, and the doses of CLA given to the humans were much lower on a per kilogram basis.

In a clinical trial performed with the aim to test CLA for the treatment of obesity [109], 80 obese subjects were randomized to CLA versus placebo in a double-blind fashion over 6 months. All subjects were asked to follow a standardized diet and exercise regimen with a modest reduction in calories and a modest increase in exercise. Subjects took 2.7 g of CLA daily and body composition was assessed by underwater weights. Mean body weight at baseline in the CLA and placebo groups was 97.1 kg and 96.9 kg, respectively. The percentage of body fat was 38.8% and 35.7%, respectively. There were no significant changes in either body weight or body fat after 6 months. Both groups lost ~2.5 kg of weight and ~1 kg of body fat. *Post-hoc* analyses of the data revealed a subpopulation of individuals who gained lean body mass. There were twice as many subjects in the CLA group than in the placebo group who gained lean body mass, but the CLA subjects lost body fat on average, whereas the placebo group gained. The difference in body fat change was statistically significant. There were no major side effects or adverse events noted in either group, with the exception of one person in the CLA group who exhibited significant edema and weight gain for a period of several weeks. This resolved when CLA was discontinued, but the subject restarted CLA without the knowledge of the investigators and had no further problems over the last 3 months of the study.

CLA has been demonstrated to affect a wide variety of enzymes and hormones in the body, multiple mechanisms may come into play. Priority areas for future research include attention to the changes CLA produces in membrane structure and function, the effects on prostaglandin and cytokine function, and the effects on sympathetic nervous system activity. Human studies of CLA did not demonstrate a clear effect of CLA on body composition. Because of the contradictory results, raise concern about the possibility of the deleterious effects of trans-10,cis-12 CLA on the lipid profile, glucose metabolism and insulin sensitivity, it is advisable to consider with caution the use of CLA supplements containing high quantities of trans-10,cis-12 CLA, especially in obese patients with type 2 diabetes or metabolic syndrome, which constitutes a considerable proportion of the whole overweight/obese population [117].

However, uncertainty about the appropriate dose for humans, coupled with the possibility that the effects may be best demonstrated during a weight accumulation phase, suggests that dose-response studies are critical. Studies of the usefulness of CLA in the prevention of weight gain would be of major interest. In addition, studies

in growing children may be considered in the future when questions of dose are answered and more information on safety is available.

10 CLA and Diabetes

Diabetes mellitus type 2 is the most prevalent form of diabetes, comprising 90–95% of the diagnosed cases [118]. Individuals who have insulin resistance and a relative insulin deficiency exhibit the elevated postprandial blood glucose levels that typify this disease. Insulin resistance may be improved with weight reduction, dietary management, and/or pharmacological treatments. There are numerous risk factors for the development of type 2 diabetes including the presence of impaired glucose tolerance, ethnicity, age, gender, and genetics; central to all of these risk factors is obesity.

Based on the fact that CLA can reduce adiposity in experimental animals, a study to elucidate the role of CLA in the development of type 2 diabetes in male rats has been performed [24]. Male rats were fed semipurified diets containing no CLA (control), 1.5% CLA, or the antidiabetic thiazolidinedione drug, troglitazone (0.02%) for 2 weeks. Rats fed the CLA or thiazolidinedione diet exhibited significantly reduced ($p < 0.05$) fasting glucose, insulinemia, triglyceridemia, free fatty acid levels, and leptinemia compared with control rats.

Whereas CLA reduces fasting insulin in diabetic animals, it modestly increases fasting serum insulin in nondiabetic swine [119], mice [120], and humans [121]. Because fasting insulin may be used as a surrogate marker for insulin resistance, these data suggest that CLA reduces insulin sensitivity under a normoglycemic state. In agreement, after long-term feeding (8 months) of a CLA-diet, an induction of insulin resistance was observed in male mice; CLA-induced insulin resistance was associated with lipodystrophy. The impact and significance of CLA for reducing insulin sensitivity and/or altering lipodystrophy for people who are normoglycemic is unknown.

Because CLA was able to delay the onset of diabetes in the rat model, CLA as an aid in the management of type 2 diabetes in humans was examined [24]. A double blind, randomized study to determine the effect of daily supplementation with CLA or placebo (safflower oil) on metabolic parameters of diabetes was conducted. Subjects with type 2 diabetes were provided with supplements with CLA or placebo, instructed to maintain a healthy diet using the Food Guide Pyramid and asked not to change their diet or activity habits for the 8-week intervention period. CLA supplementation (6.0 g CLA/day) significantly decreased fasting blood glucose, plasma leptin, body mass index, and weight. Low density lipoprotein levels significantly increased, but less in the CLA-supplemented group than in the placebo group. In addition, body fat (%) was modestly decreased ($p < 0.08$) in subjects supplemented with CLA. Fasting insulin, triglycerides, cholesterol, and high-density lipoprotein were not significantly affected by CLA. According to 3-day diet records, energy intake was not significantly different between groups at baseline or throughout the study. Supplementation with CLA for 8 weeks could be associated with favorable

alterations of several metabolic parameters of subjects with type 2 diabetes. Further work is needed to determine the therapeutic potential of CLA in the management of type 2 diabetes; basing on the available results, it is possible to say that CLA may represent an important agent for the treatment of type 2 diabetes.

11 Conclusions

It is well known that meat contains a large amount of proteins with high biological value. However, in recent years, the bioactivities of certain compounds that are present in meat, even though in minor amounts, have received increased attention because they may have an important nutritional role. CLA is a group of isomers of octadecadienoic acid that is abundant in the fat of ruminants like cattle and sheep. The content may change depending on the breed, feed, and age. CLA has been reported to reduce the risk for certain types of cancer like the colorectal cancer as well as having other activities like antiartherioesclerotic, antioxidative, and also playing certain role in controlling obesity. It has also been found to favorably modulate immune function in humans. Although the consumption of ruminant products contributes to blood concentrations of CLA in humans, it is largely unknown whether these physiological doses might have biological effects in humans.

Because small amounts of CLA (0.5% of diet) have been shown to alter the expression of genes and impact conditions such as carcinogenesis, obesity, diabetes, and atherosclerosis in experimental animals, it is possible that small amounts consumed over a prolonged period of time may exert similar beneficial effects in human beings. Understanding the role of CLA in modulating events associated with macronutrient metabolism suggests that CLA may be a healthy dietary component with the potential for impacting human health in the areas of cancer, obesity, diabetes, and cardiovascular disease. However, more work is needed to fully elucidate the safety and efficacy of isomers and doses that are required for exerting this breadth of potential beneficial effects. It is hoped that with improved understanding of the doses and isomers required, improvements in recommendations may be made to people regarding the intakes of CLA to improve health.

In this context, the role of dietary CLA in human cancer risk is probably the most interesting one. There are some data showing a favorable effect of CLA on human cancer cells. More extensive evidence from human studies is generally lacking, although there are a few epidemiologic studies that have focused on evaluating the role of dairy products in relation to various cancers, and at least one has found an inverse relationship between milk intake and breast cancer.

Among anticarcinogens, CLA is unique for the following reasons:

- It is an animal-derived product with its highest levels found in ruminant meat and dairy products.
- It exerts a potent action through dietary intervention under a wide range of conditions.
- It possesses multiple modes of action.

The time has come to conduct clinical studies with CLA in order to judge its potential as a chemopreventative agent for humans.

Contents

Abstract

Unlike refined grains, whole grains, which consist of entire grain, contain high micronutrients and dietary fiber in their bran and seed. In the literature many studies showed that high-fiber diets may reduce the incidence of chronic diseases such as diverticulitis, diabetes, obesity, heart diseases, and some cancer types. Once upon a time, whole grains were neglected by researchers. Following the determination that dietary fibers are present in the whole grains together with micronutrients and phytochemicals, the focus of the studies has shifted towards observational studies related to whole grains intake. Cereal fibers have proven to have stronger health effects as a result of synergistic effects with phytochemicals and micronutrients in whole grains. This chapter describes the dietary fiber-related health effects of whole grain consumption after mentioning characteristics of dietary fiber and whole grains.

1 Introduction

Nutrition makes a significant contribution to the etiology, prevention, and progression of disease [1–4]. Diets such as the Mediterranean-type dietary patterns, which have high in fruits, vegetables, whole grains, and proteins from plant sources and lower in meat and meat products have been shown to have long-term beneficial effects on health [4–7]. It is not just happenstance that longevity is also characterized by similar dietary patterns, even though the influence of other lifestyle factors cannot be ignored [4, 8]. High levels of dietary fiber, unsaturated fatty acids, antioxidants, and foods that have low energy density are some of the protective components of the diet [4, 9]. The all bioactive components of the diet work together for promoting health.

One of the most important constituents in foods that have beneficial physiological effects in humans is dietary fiber. The consumption of dietary fiber has decreased considerably as a result of the fact that the foods have begun to be processed and refined more in the last two centuries [10, 11]. It has been determined that increased consumption of low-fiber foods in the diet as a result of the transition from high-fiber diets to low-fiber diets in human nutrition may lead to an increase in the prevalence

of chronic diseases such as diverticulitis, diabetes, obesity, heart diseases, and some cancer types [11, 12]. After this hypothesis, there has been an increase in interest and researches related with dietary fiber and foods which are thought to be important sources of dietary fiber [11].

Whole grains are rich sources of vitamins, minerals, and phytochemicals as well as fiber. The phytochemicals of whole grains contain phenolics, carotenoids, vitamin E, lignans, β-glucan, inulin, resistant starch, sterols, phytates, etc. Plant-based foods like fruits, vegetables, and whole grains, which include significant amounts of bioactive compounds, can also meet desirable health benefits beyond basic nutrition to decrease the risk of some diseases [13–15]. Epidemiological studies ensure evidence that whole foods, including whole grains, are protective against a broad range of diseases, and this protectiveness is usually greater than that seen with any individual ingredient [16, 17]. Dietary guidance suggests consumption of whole grains to decrease the risk of chronic diseases such as cancer and cardiovascular disease (CVD) [18]. Epidemiologic studies declare the opinions that whole grains are protective against diabetes, obesity, CVD, and cancers, especially gastrointestinal cancers including gastric and colonic [16, 18]. According to the results of research among a large group of women aged 55 to 69 years, eating at least one serving a day of whole grain foods significantly decreased the risk of mortality from all causes compared with women who ate almost no whole grain products [19, 20].

The protective effect of dietary fiber taken from whole grain foods on diseases is much greater than the individual effect of dietary fiber. It is thought that this is caused by the synergistic effect of phytochemicals with dietary fiber in whole grain foods. Therefore, it is more beneficial that dietary fiber intake by consuming complex food sources such as whole grains for human health.

In this chapter, we describe the definitions and intakes of dietary fiber and whole grains and health effects of dietary fiber intake by consuming whole grains.

2 Dietary Fiber

2.1 Definitions of Dietary Fiber

The definition of dietary fiber was used in 1953 by Hipsley to show the nondigestible constituents which consist of the plant cell wall [21–23]. Since then, the term has evolved and the Codex Committee on Nutrition and Foods for Special Dietary Uses (CCNFSDU) established an internationally has approved the legal definition of dietary fiber in 2009 [23–25]. According to CCNFSDU, dietary fiber is defined as carbohydrate polymers with ten or more monomeric units, which are not hydrolyzed by the endogenous enzymes in the small intestine of humans and belong to the following three categories:

(1) Edible carbohydrate polymers that are naturally present in the food as it is consumed.

(2) Carbohydrate polymers that have been obtained physically, enzymatically, or chemically from food raw material and that have been shown to have beneficial physiological effects on health as proved by scientific evidence are accepted by competent authorities.
(3) Synthetic carbohydrate polymers that have a physiological effect on the health benefit as indicated by generally accepted scientific evidence by the competent authorities [24].

While the expression "dietary fiber" describes the nondigestible carbohydrates and lignin that are intrinsic and intact in plants, the term "functional fiber" expresses the isolated nondigestible carbohydrates that have beneficial physiological effects in human body [26]. When inulin is formed naturally in consumable plants such as onions and chicory, it is defined as a dietary fiber; if it is synthetically produced and added to yogurt, it is categorized as a functional fiber [21–23]. Total fiber is also the sum of dietary fiber and functional fiber, and dietary fiber on food labels includes both dietary and functional fiber [23]. The expression "nondigestible" means both not digested and not absorbed in the human small intestine [26].

2.2 Classification, Sources, and Physiological Effects of Dietary Fiber

According to the solubility of dietary fiber, it is classified into two categories: insoluble dietary fiber (IDF) such as cellulose, part of hemicelluloses, resistant starch, and lignin; and soluble dietary fiber (SDF) such as oligosaccharides, including fructooligosaccharide (FOS), pectins, β-glucans, galactomannan (GM) gums, alginate, and psyllium [23, 24, 27, 28].

2.2.1 Soluble Dietary Fiber

SDF is present in the form of a sticky or viscous, rather than a hard tissue in the food [11, 29]. Although SDF are found in fruits and vegetables, the best sources of SDF are oats and dried beans [30]. FOS, also known as oligofructose and inulin, are collectively entitled as fructans [24, 27]. They are found in plants such as agave, artichokes, asparagus, leeks, garlic, onions, yacon, jicama, and wheat.

Pectin is found in most primary cell walls and is particularly rich in the nonwoody parts of terrestrial plants. It is a linear polysaccharide mainly consisted of about 300 to 1000 D – galacturonic acid monosaccharide units [24, 31]. Although fruits are the major source, pectins represent 15–20% of the fiber in vegetables, legumes, and nuts [24, 32].

The β-glucans are polysaccharides of d-glucose monomers linked by β-glycosidic bonds, which occur most commonly as cellulose in plants, the bran of cereal grains, the cell wall of baker's yeast, certain fungi, mushrooms, and bacteria [24, 31].

GMs are also polysaccharides comprising of a mannose backbone with galactose side groups. They are commonly used in foods as stabilizers owing to their high water binding capacity and their emulsification and viscosity increasing properties.

GM gums, such as fenugreek gum (mannose:galactose; 1:1), guar gum (mannose: galactose; 2:1), tara gum (mannose:galactose; 3:1), and locust bean gum (mannose: galactose; 4:1), change according to their ratios of mannose and galactose [24, 33].

Alginates are unbranched polysaccharides consisting of 1–4 linked β-d-mannuronic acid and α-guluronic acid. Alginate is distributed widely in the cell walls of algae. It is also an exopolysaccharide of bacteria including *Pseudomonas aeruginosa* and commercially available alginates now come only from algae. It is binding with water and it forms which use as thickening agent. These viscous hydrogels are also useful for numerous biomedical applications [24, 34].

Psyllium is the common name used for several members of the plant genus Plantago. The seeds of this plant are used commercially for the production of mucilage. The phrase of psyllium is used for the seed husk, the seed, and the entire plant. The seed husk of Psyllium is a rich source of SDF that is known as psyllium hydrophilic mucilloid, psyllium hydrocolloid, and psyllium seed gum [24, 31].

Some SDF components including oat bran, pectin, and guar gum stimulate fecal excretion of bile acids. On the other hand, wheat bran has no such effect; it promotes a different composition of bile acids than does pectin [35–38]. Some SDFs also reduce serum cholesterol level [38, 39]. Although short-term studies (a single meal or a few days) show that SDFs enhanced glucose tolerance and increased insulin sensitivity in healthy subjects, the results of long-term studies do not support them [38, 40]. Dietary fiber influences colonic function and activities of the microflora. High fiber intakes increase bacterial mass but do not change the microflora composition [38, 41–43]. Colonic bacteria attack fermentable fiber components and then at least a portion of them degrades to short-chain fatty acids and gases [38]. These short-chain fatty acids decrease the colon cancer risks by suppressing toxigenic bacterial reactions [44, 45]. Some studies also express that SDFs prevent type II diabetes owing to the viscosity of the fibers [24, 46].

2.2.2 Insoluble Dietary Fiber

IDFs include cell wall components like cellulose, lignin, and hemicellulose that exist mainly in wheat, most grain products, and vegetables [30]. Cellulose is the best known, most widely distributed, and only truly fibrous component of the plant cell wall. It forms about 25% of the fiber in grains and fruit and about a third of the fiber in vegetables and nuts [24, 32]. It is a polymer that consists of glucose and the β-glucoside linkages. The β-linkages in cellulose are not hydrolyzed by the human intestinal enzymes, so cellulose is accepted as a dietary fiber. Cellulose also has the property of absorbing water (0.4 g water per gram of cellulose), and this explains its ability to increase fecal weight when added to the diet [47].

Hemicelluloses are polysaccharides containing sugars other than glucose, which are associated with cellulose in cell walls. They present in both water soluble and insoluble forms in cell walls. Hemicellulose constitutes about a third of the fiber in vegetables, fruits, legumes, and nuts. The primary dietary sources of hemicellulose are cereal grains [24, 32].

Lignin is a lipophilic phenolic polymer that can absorb bile acids [48]. It is composed of phenylpropane units which are thought to be chemically bound to

the carbohydrates in woody structure [49]. It presents only in small amounts in the diet [26]. Good sources of lignin are foods with a woody component such as celery and the outer layers of cereal grains [24].

Resistant starch (the sum of starch and starch-degradation products that do not digest in the small intestine) performs a function as dietary fiber, after it reaches the large intestine [26, 50]. Legumes are main sources of resistant starch and 35% of legumes starch is escaping digestion [26, 51]. Small amounts of resistant starch are formed by processing and baking of cereal and grain products. Actually, many new functional fibers are resistant starches which are added to processed foods [26].

The function of IDFs is to shorten bowel transit time, to increase fecal bulk, and to render feces softer [30]. The reasons for these are their high water-holding capacities and having insoluble characteristics [48]. Addition of some IDF sources in the diet may also cause a decrease in mineral retention [52].

Although about 75% of the dietary fiber in foods is found as the insoluble fraction, products known as soluble or insoluble fiber sources are often sources in both of these fiber types [30]. The energy value of dietary fiber has detected as 0 kcal g-1 if it is insoluble and 4 kcal g-1 if it is soluble [53].

2.3 Recommendations for Dietary Fiber Intake

Consuming foods with dietary fiber is very important for enhancing bowel function and reducing symptoms of chronic constipation, diverticular disease, and hemorrhoids. There are increasing proofs that a diet rich in these foods can reduce not only high blood cholesterol risk but also hypertension, stroke, and cancer risks [54]. On the other hand, people who consume low dietary fiber and complex carbohydrates and high fat, especially saturated fat, in diets incline to have more heart disease, obesity, and some cancers [30].

General recommendations for dietary fiber intake range between 25 and 35 g per day (g d-1) for adults. The data found in guidelines for dietary fiber consumption of children are the extrapolated data from studies in adults. According to the Dietary Reference Intakes (DRI), the average intake of people of all aged should be 14 g per 1000 kcal; for children 1 to 3 years of age, average intake should be 19 g d-1; and for children 4 to 8 years of age, average intake should be 25 g d-1. The American Academy of Pediatrics suggests dietary fiber intake of 0.5 g per kg body weight for children older than 2 years. In 1995, American Health Foundation developed the rule of "age plus five" which indicates that intake of dietary fiber should be greater than or equal to the age plus 5 g d-1 for children over 2 years [22, 23, 55]. Despite the recommendations for dietary fiber intake, the average dietary fiber intake among people is lower than it should be. It changes from 9.4 ± 4.0 g d-1 to 10.7 ± 3.6 g d-1 in females, and 10.7 ± 4.2 g d-1 to 12.0 ± 4.5 g d-1 in males [23].

Even though many benefits of high fiber diets are also naturally found in the nondietary fiber components such as natural antioxidants, it is best to take dietary fiber from foods in high amounts. But dietary fiber consumption with food is almost

half the recommended level, as can be seen. For this reason, it is thought that the consumption of fiber supplements may be beneficial when used moderately [30].

3 Whole Grains

3.1 Definition and Intake of Whole Grains

According to the guidelines of Food and Drug Administration (FDA), "whole grain" contains "cereal grains that consist of the intact and unrefined, ground, cracked or flaked fruit of the grains whose principal components – the starchy endosperm, germ and bran – present in the same relative proportions as they exist in the intact grain" [56]. The more common whole grain cereals are whole wheat, whole oats/oatmeal, whole grain cornmeal, popcorn, brown rice, whole rye, whole-grain barley, wild rice, triticale, millet, and sorghum, while emmer, farro, spelt, and wheat berries are less common whole grain cereals consumed worldwide [57].

Although American Association of Cereal Chemists International (AACCI) had identified "whole grains" in a similar way with FDA, in 2006 the AACCI expanded this definition to include pseudocereals. Pseudocereals such as amaranth (*Amarantus caudatus*), quinoa (*Chenopodium quinoa* Willd.), and buckwheat (*Fagopyrum* spp.) were included in the definition of "whole grains" because of their macronutrient composition and consumption trends similar to that of cereals. Also, some traditionally and minimally processed forms of whole grains including lightly pearled barley or wheat, bulgur (cracked wheat), and nixtamalized corn are considered whole grains [58, 59].

In April 2013, the AACCI further described a whole-grain product as being one which must include 8 g or more of whole grain per 30 g of product [4, 59]. The FDA acknowledged the whole grain definition created by AACCI but stated that at least 51% of the total weight of the product must be whole grains in order to qualify for whole grain health claims [4, 60]. Also, whole grain food must contain 1–7 g dietary fiber [61].

Whole grains can be consumed in whole, cracked, split, flaked, or ground. They are often milled into flour that is used to make breads, cereals, pasta, crackers, and other grain-based foods. Regardless of how the whole grain is processed, the proportions of bran, germ, and endosperm in a whole grain product must be approximately the same as an original grain [57]. A whole grain can be a complete food such as brown rice or can be also a food ingredient such as whole wheat flour in bread or cereal.

The 2005 Dietary Guidelines for Americans and Healthy People 2010 advises the consumption of at least three servings of whole grain (each equivalent to three ounces) per day [15]. Additionally, dietary guidelines expresses that the recommended grains should come from enriched or whole grain products. Generally, at least half the consumed grains should come from whole grains. Moreover, their consumption is low in the United States (US), mostly owing to taste, cost, and poor eating habits [56]. It is noteworthy that grains intake in Europe and North America is

even lower than in less developed countries, although grains ensure approximately two thirds of the calorie and protein intake in the world [62, 63]. Ninety percent of Americans do not meet the recommendation related with whole grain consumption, and the mean intake of whole grains in the United States is less than one serving per day [15, 64]. Even in Denmark, which has one of the highest whole grain intake in the world, only about 6% of people consume seven or more servings of whole grains [65].

3.2 Biochemical Constituents of Whole Grains and Their Roles in a Healthful Diet

Whole grains are composed of three main parts as starchy endosperm, germ, and bran. In order for a grain to be able to be characterized as a whole grain, it must contain all three parts mentioned above. The bran and germ contain the dietary fiber and most of the biologically active components, whereas endosperm is mainly structure of starch and protein [66]. About 50–75% of the endosperm is starch which is the major energy supply for the embryo during germination of the kernel. About 8–18% of the endosperm is storage proteins along with cell-wall polymers. Relatively few vitamins, minerals, fiber, or phytochemicals are found in the endosperm fraction [61]. The bran contains the aleurone that protects the grain from bacteria, molds, insects, and severe weather [66]. The germ contributes quite small to the dry weight of most grains, for example, 4–5% in wheat and barley. The germ of maize provides a much higher contributor to the total grain structure than that of wheat, barley, or oats [61].

Whole grains, except for rice, are high in dietary fiber and amino acids (arginine, lysine, etc.), low in fat, concentrated sources of starch, high in vitamins, particularly vitamins B (thiamin, niacin, riboflavin, pantothenic acid, etc.), and good sources of minerals (Ca, Mg, K, P, Na, Fe, etc.) [18, 61, 67]. Other components in whole grains associated with improved health status include tocotrienols, lignans, phytoestrogens, phenolic compounds (predominantly ferulic acid and diferulates), phytic acid, and some unique compounds to grain products (avenanthramides, avenalumic acid) [15, 18, 61, 67–69]. They are responsible for the high antioxidant activity of whole grains [61, 67]. The types and varieties of grains effect the concentration of phytochemicals in whole grains [15, 70]. Table 1 shows a comprehensive list of biochemical constituents in some whole grains products.

During the milling process, the bran and germ are separated from the starchy endosperm and then the starchy endosperm is ground to flour. Refined flours have lower nutrients than whole grains because of the higher concentrations of nutrients in the outer part of the grains [62, 63]. Milling process may open up the food matrix, thereby let the release of firmly bound phytochemicals from the grain structure [61]. Milling of grains results in significant nutrient loss [18, 63].

Grains are usually subjected to some types of processing such as cooking and parboiling before consumption in developed countries. Commercial cereals are generally extruded, puffed, flaked to make a desirable product. Most researchers

Table 1 Energy, macronutrient, fiber, some vitamin and mineral contents of common whole grain products [71]

Whole grain products	Serving size	Energy (kcal)	Carbohydrate (g)	Protein (g)	Fat (g)	Fiber (g)	Vitamin E (mg)	Folate (μg)

determined that biologically important compounds, like antioxidants, in the processed whole grains are not removed [61, 72]. According to the results of study with rye, many of the bioactive compounds are stable during food processing, and there can be an increase in their ratios with appropriate processing [61, 73].

Whole grains include significant amounts of bioactive phytochemicals that can provide decreasing the risk of chronic diseases [14, 15, 64, 74]. The phytochemicals in whole grains can be protective or can act synergistically to exhibit these protective effects [19]. The recent evidence shows that the complex mixture of bioactives in whole foods can be more healthful than individual isolated components [15, 74]. The beneficial effects related with whole grain consumption originate due to the presence of the unique phytochemicals in whole grains [15].

According to 2005 Dietary Guidelines, refined and whole grains are important sources of carbohydrates in particular. Carbohydrates provide energy to the body in the form of glucose. Glucose is the only energy source for red blood cells and the preferential energy source for the brain and central nervous system, and preferred energy source for the placenta and fetus during pregnancy. Carbohydrates in grains are mainly found in the form of starches and some fibers. Carbohydrates in grains are mainly found in the form of starches and some fibers. The US Recommended Dietary Allowance (RDA)'s recommendation for daily carbohydrate consumption is 130 g per day for adults and children. If glucose is not present in the diet or glycogen is depleted, which is the body's storage form of glucose, the body will transform protein to glucose for supplying the essential fuel to the brain and protect blood glucose levels [57]. Protein destruction will imperil the life and vital activities.

Compared to refined grains, whole grains are more abundant in nutrients. This is very important in the intake of some components such as folic acid [57]. Refined grain products can be fortified with folic acid and the consumption of folic acid is associated with decreased risk of birth defects, including neural tube defects (NTD), and heart disease [57, 75, 76]. Most whole grain foods, the exception of both hot and cold breakfast cereals, do not need to be fortified with folic acid or other vitamins and minerals. Consumptions of whole grains are more beneficial due to these and similar situations [57].

4 Biological Effects of Dietary Fiber Intake with Consumption of Whole Grains

Epidemiological evidences show that the consumption of whole grains is correlated with reduced risk of chronic diseases such as CVD, diabetes, the metabolic syndrome, and certain cancers. Also, whole grain consumption can play a positive role in weight management [4]. Some examples of similar studies are given below.

Relevant evidence was assessed by Montonen et al. (2003) [77], which high fiber intake with whole grain foods reduced the risk of type 2 diabetes. A cohort consisted of 4316 Finnish men and women aged 40–69 years were followed for 10 years and an inverse association between the intake of whole grain foods and the risk of type 2 diabetes was found. A similar relation was not found for the intake of fiber from

vegetables and fruit. The risk reduction of type 2 diabetes as a result of whole grain intake was approximately 35%.

Newby et al. (2007) [78] examined associations between the consumptions of whole grains, refined grains, and cereal fiber with weight management. It had been observed that compared with subjects in the lowest quintile of whole grain intake, subjects in the highest quintile had lower body mass index and weight and smaller waist circumference. It was determined that whole grains and grain fiber had similar and collective effects on weight, body mass index (BMI), waist circumference changes. It was thought that the cereal fiber and its constituents could in part mediate these relations. In the same study, the associations between the consumptions of whole grains, refined grains, and cereal fiber with both cholesterol and blood glucose level changes were also evaluated. According to the results of study, the consumption of whole grains was inversely related with total cholesterol and LDL cholesterol levels and 2-h glucose amount. Although the effects of cereal fiber on cholesterol and glucose levels were similar with whole grains, the refined grains were increased fasting insulin among women but not men.

Intakes of whole grains and cereal fiber were inversely associated with the risk of chronic diseases. But their relation with total and disease-specific mortality remains unclear. In the study of Huang et al. (2015) [79], it was aimed to evaluate the association of whole cereals and cereal fiber intake with all causes and cause-specific mortality. The study included 367,442 participants that followed from 1995 to 2009. Participants with cancer, heart disease, stroke, diabetes, and self-reported end-stage renal disease at baseline were not accepted to the study. A total of 46,067 deaths were documented over an average of 14 years of follow-up. At the end of the study, it was observed that consumption of whole grains were inversely related with risk of all-cause mortality and death from CVD, cancer, diabetes, infections, respiratory disease, and other causes. When individuals were compared according to their whole grain and cereal fiber intakes, the lowest all-cause mortality risk was found to be 17% for those who had the highest intake of whole grains and 19% for those who had the highest intake of cereal fiber. The lowest disease-specific mortality risk was also determined to be 11–48% for those who had the highest intake of cereal fiber and 15–34% for those who had the highest intake of whole grains. The associations between whole grains consumption with the deaths from CVD, respiratory disease, and infections were not found significant, but the associations between all-cause mortality with deaths from cancer and diabetes were significant ($p < 0.029$). In the result of study, it was determined that consumption of whole grains and cereal fiber could inversely associate with reduced total and cause-specific mortality and cereal fiber was one potentially protective component in whole grains.

The effect of fermented whole grain cereal kernels with a high content of amylose (40%) and/or beta-glucan (4.6%) on postprandial glucose and insulin responses in healthy adults was evaluated by Alminger and Eklund-Jonsson (2008) [80]. For this purpose, a glucose solution or tempe fermented whole-grain barley or tempe fermented whole grain containing 25 g carbohydrates randomly was given to 13 healthy volunteers between the ages of 20 and 75. Blood samples were collected immediately before meal and at 15, 30, 45, 60, 90, and 120 minutes after meal

started. For each individual according to Food and Agriculture Organization/World Health Organization (FAO/WHO) standards, the glycemic index and insulin index of the meals were calculated. It was detected that the lowest peak of insulin response occurred after the high β-glucan oat tempe meal, while the peak of glucose was lowest after the high-amylose/high β-glucan barley tempe meal. During the first 60 minutes after meal, the average blood glucose and insulin responses for both barley and oatmeal dishes were significantly lower than for the reference glucose load ($p < 0.05$). The glycemic indexes calculated for the barley and oat tempe were 30 and 63, respectively. The obtained data suggested that whole grain products that reduce postprandial glucose and insulin responses could be got by fermentation and by using grains with an increased amylose and/or β-glucan content.

Systematic review and meta-analysis of prospective observational studies were performed by Aune et al. (2011) [81] for determining the association between intake of dietary fiber and whole grains with risk of colorectal cancer. For these reasons, PubMed and several other databases up to December 2010 and the reference lists of studies included in the analysis as well as those listed in published meta-analyses were used as data sources. Among them, prospective cohort and nested case-control studies for dietary fiber or whole grain intake and incidence of colorectal cancer were examined. According to the investigated 25 prospective studies, the relative risk of developing colorectal cancer for 10 g daily consumption of total dietary fiber (16 studies) was 0.90 ($p < 0.05$), for fruit fiber (9 studies) was 0.93, for vegetable fiber (9 studies) was 0.98, for legume fiber (4 studies) was 0.62, and for cereal fiber (8 studies) was 0.90. The relative risk of increase in colorectal cancer in the case of three servings of daily whole grains consumption (six studies) was 0.83. In the study, a high intake of dietary fiber, especially cereal fiber and whole grains, resulted in a reduced risk of colorectal cancer.

Chen et al. (2016) [82] who believed that the association between whole and refined grain consumptions and stroke risk remained unclear conducted a study using the MEDLINE and EMBASE databases until February 29, 2016. Seven prospective studies with a total of 446,451 individuals and 5892 stroke cases were examined. Compared to low consumption, the relative risk of stroke in the high consumption was 0.95 for total grains, 0.92 for whole grains, and 0.99 for refined grains ($p < 0.05$). Diets rich in whole grains were inversely associated with ischemic stroke risk whose relative risk was determined as 0.75 ($p < 0.05$). Meta-analysis expressed that the consumptions of whole and refined grain were not associated with total stroke risk, but whole grain consumption was associated with decreased ischemic stroke risk. It was clear that this was caused by the high dietary fiber contents of whole grains.

Although Hollænder et al. (2015) [83] acknowledged the potential role of whole grains in the prevention of CVD, they believed that the results of randomized controlled studies on blood lipids were inconsistent due to the compositional differences of some foods containing dietary fiber. They evaluated the influence of whole grains on changes in levels of total cholesterol (TC), LDL cholesterol, HDL cholesterol, and triglycerides compared with non–whole grain foods by using a meta-analytic approach. In the study which contained systematic literature review of

selected databases, randomized controlled comparisons were performed between whole-grain foods and a non–whole grain control in adults. A total of 6069 articles were screened and data were extracted from most suitable 24 studies. Generally, whole-grain intake reduced LDL cholesterol (weighted mean difference: −0.09 mmol L-1) and TC levels (weighted mean difference: −0.12 mmol L-1) compared to the control ($p < 0.05$). The greatest effect on TC (weighted mean difference: −0.17 mmol L-1) was observed in the whole grain oat consumption. Whole grain foods tended to lower triglycerides compared with the control (weighted mean difference: −0.04), whereas no effect of whole grain foods on HDL cholesterol was observed. Also, no relation was found between whole-grain dose or baseline TC concentration and any of the outcomes, while study duration was positively related with changes of TC and LDL cholesterol levels. Researchers proved that the consumption of whole grain diets lowered LDL cholesterol and TC but did not lower HDL cholesterol or triglycerides. They also indicated that whole grain oats were the most effective grain to lower cholesterol.

Chen et al. (2016) [84] assessed the associations between whole-grain intake and risk of dying from any cause such as CVD, and cancer with a meta-analytic approach. Relevant works on subjects were determined by researching PubMed and EMBASE databases and bibliographies of full publications. In the study, 13 studies about total mortality (104,061 deaths), 12 studies about CVD mortality (26,352 deaths), and 8 studies about cancer mortality (34,797 deaths) were used. Three of these studies were related to whole-grain intake, while the remaining studies were related to whole-grain products intake. Summary RRs were also calculated using the random effect model at the 95% confidence interval and were used as the effect size across studies. In the dose-response analysis which converted the intake of whole-grain products to the amount of whole grain, the summary RRs for an increment in whole-grain intake of 50 g d-1 were 0.78 for total mortality, 0.70 for CVD mortality, and 0.82 for cancer mortality. A similar decrease in the mortality from ischemic heart disease (RR: 0.68) was also observed, but the same case was not observed for stroke (RR: 0.93). Nonlinear relationships between whole grain intake and total ($p < 0.001$) and CVD mortalities ($p < 0.001$) was proven. The relation about cancer mortality ($p = 0.12$) was not nonlinear because these relationships appeared slightly more steep at lower ranges (<35 g d-1) of the intake compared to higher ranges. The findings supporting the significant inverse relations between whole grain intake and mortality related to any cause, CVD or cancer, suggested that whole grain consumption could be increased to improve public health.

Whole grains had attracted attention due to their potential role in weight regulation. A high intake of whole grains was related with smaller weight gain according to prospective cohort studies, while the results from randomized controlled studies were less consistent. Using a meta-analytic approach, Pol et al. (2013) [85] evaluated the influences of whole grains on changes in body weight, percentage of body fat, and waist circumference compared with non–whole grain foods. A systematic literature search was conducted in selected databases and 26 studies comparing whole grains and non–whole grain control consumptions in adults were defined. According to data from 2060 participants, it was found that whole grain intake had

no effect on body weight (weighted mean difference: 0.06 kg) but had a little effect on body fat percentage (weighted mean difference: −0.48%) compared to a control ($p < 0.05$). Whole grain consumption did not reduce body weight compared to control consumption, but it could create a small beneficial effect on body fat. It was thought that the significant differences in body weight and fat were not determined because of the relatively short duration of intervention studies (16 weeks).

Behall et al. (2006) [86] studied the effect of a whole grain diet containing brown rice/whole wheat and/or barley on blood pressure. For this purpose after a 2-week controlled diet, 16 participants consumed a diet which had been replaced by 20% of its energy with whole wheat/brown rice, barley, or half whole wheat-brown rice/half barley during 5 weeks each. Participants were selected from those with systolic blood pressure <140 mmHg, diastolic blood pressure <90 mmHg, and cholesterol levels between 200 and 240 mg dL-1. While the measurements of blood pressure were performed weekly, their weights were determined daily before breakfast. As a result of the study, it was seen that systolic blood pressure decreased by 2.2 mmHg during the control diet and an extra 1.4 to 6.7 mmHg in the whole grain diets. Diastolic blood pressure also decreased by 2 mmHg in the control diet and an extra 2.9 to 3.7 mmHg in the whole grain diets. The replacement of white rice with brown rice, white bread with whole grain bread, and low fiber cereals with barley or whole wheat cereals resulted in reduced systolic and diastolic blood pressure in mildly hypercholesterolemic men and women, and whole grain diets helped to lower blood pressure.

Pancreatic cancer was known as the most fatal cancer type in the United States. The intake of grains and cereals within a large population-based case-control study of pancreatic cancer was evaluated by Chan et al. (2007) [87]. A 131-item semi-quantitative food frequency questionnaire was applied to 532 cases and 1701 controls. Participants were asked to inform their frequency of individual food items intake in the 1 year prior to cancer diagnosis (for cases) or 1 year before interview (for controls). In this study, consumption of whole grain, refined grains, mixed grains, and sweetened refined grains as well as individual grain items were studied. Odds ratio (OR) and 95% confidence intervals were calculated as predictions of relative risk. It was observed that participants who consumed > or =2 servings of whole grains daily had a lower risk of pancreatic cancer as compared to participants who consumed <1 serving per day (OR = 0.60, $p < 0.05$). Similar results were obtained for brown rice (OR = 0.72, $p < 0.05$) and tortillas (OR = 0.56, $p < 0.05$). If the consumption of doughnuts and cooked breakfast cereals were > or =2 servings per week as compared with <1 serving per month, the risk of cancer increased (OR = 1.8 for doughnuts, $p < 0.05$; OR = 1.3 for oatmeal/oat bran, $p < 0.05$; OR = 2.1 for other cooked breakfast cereals, $p < 0.05$). Dietary fiber was inversely related with cancer risk (for highest quartile vs. lowest, OR = 0.65, $p < 0.05$). The data obtained from the study supported the hypothesis that higher consumption of whole-grain or high fiber foods could decrease pancreatic cancer risk. Refined grains consumption was not also associated with risk.

One of the recommended mechanisms for the protective effects of whole grains against chronic disease risk was their gut microbiota effect. Fermentation of soluble

fibers in whole grains could possess a prebiotic effect by altering the composition and/or activity in the gastrointestinal microbiota. To prove this, Costabile et al. (2008) [88] compared the effectiveness of whole grain wheat and wheat bran to modulate the gastrointestinal microbiota by using double blind crossover studies. Thirty-one healthy individuals were chosen randomly to either consume a whole grain wheat breakfast cereal (48 g day-1) or wheat bran breakfast cereal (48 g day-1) daily during 3 weeks. After a period of 2 weeks, the participants consumed the other cereal type for another 3 weeks. It was found that the numbers of fecal bifidobacteria and lactobacilli, which are beneficial for human health, were significantly higher after consuming the whole grain cereal as compared to the wheat bran cereal (9.3 ± 0.4 vs. 8.8 ± 0.4 $\log_{10}$cells g-1 feces, $p < 0.001$ and 8.7 ± 0.2 vs. 8.4 ± 0.2 $\log_{10}$cells g-1 feces, $p < 0.05$, respectively). The 2.5-fold increase in the concentration of ferulic acid (an antioxidant in plant foods) in the blood compared to the baseline was also observed as a result of consuming both cereals.

Erkkilä et al. (2005) [89] examined the relations between dietary fiber and whole grain intakes with progression of coronary atherosclerosis in women due to the fact that increased dietary fiber and whole grain intake was associated with lower risks of coronary artery disease morbidity and mortality. Regular dietary intake was evaluated at baseline with a validated semi-quantitative food frequency questionnaire. Angiographic evaluations were made in a cohort of postmenopausal women with coronary artery disease (CAD) in the Estrogen Replacement and Atherosclerosis Trial (n = 229) at baseline and after 3 years. The relations between baseline and total, cereal, fruit, and vegetable fiber intake and changes in coronary artery diameter and appearance of new lesions were determined. Changes in minimum coronary artery diameter (MCAD) and mean percent stenosis of women who consumed >6 servings of whole grains per week as compared to women who consumed <6 servings per week tended to be smaller after multivariate adjustment ($p = 0.04$ and $p = 0.07$, respectively). Higher cereal fiber consumption than fruit and vegetable-derived fiber was associated with a smaller change in MCAD compared to lower cereal fiber consumption ($p = 0.05$). These findings showed that CAD risk was decreased with a high intake of cereal fiber but not with fruit and vegetable fiber. The results supported dietary recommendations regarding the consumption of foods containing rich fiber, especially whole grain products, among postmenopausal women.

Karmally et al. (2005) [90], who believed that Hispanic Americans had higher risk scores for coronary heart disease than non-Hispanic whites, conducted a study about the efficacy of fiber-rich foods in management of hypercholesterolemia in Hispanics. A total of 152 Hispanic Americans aged 30–70 with baseline low-density lipoprotein cholesterol (LDL-C) levels between 120 and 190 mg dL-1 and triglycerides <400 mg dL-1 joined the study. Participants were randomly chosen to consume 90 g of corn (no brand specified) or oat (Cheerios) cereal per day for the next 6 weeks after consuming a National Cholesterol Education Program Step 1 diet during 5 weeks. The compliance rate among the participants was 100% in the corn cereal group and 99% in the oat cereal group and their body weight was stable during the study. While adding the oat cereal in the diet resulted in significant reductions in total cholesterol (−10.9 mg dL-1; −4.5%) and LDL-C (−9.4 mg dL-1; −5.3%),

there were no significant changes in total cholesterol (1.2 mg dL-1) and LDL-C (1.2 mg dL-1) in the corn cereal group. Also, it was found that every cereal did not have a significant effect on high-density lipoprotein cholesterol (HDL-C), triglycerides, or apo A-1 plasma levels. According to obtained data, the ready-to-eat oat cereal was effective in lowering cholesterol levels of men and women with mild to moderate hypercholesterolemia. An oat cereal can be evaluated as a therapeutic option together with a cholesterol-lowering diet for cure of mild to moderate hypercholesterolemia.

It was thought that whole grains could help in preventing overweight and obesity by increasing satiety and by slowing down starch digestion and absorption. For the purpose of reaching more exact opinions in this topic, van de Vijver et al. (2007) [91] assessed the association between consumption of whole grain foods and dietary fiber with BMI, overweight, and obesity among participants in the Netherlands Cohort Study in a cross-sectional (n = 4237) and in a prospective (n = 1257) setting. A validated semi-quantitative food frequency questionnaire was used for assessing the dietary intake of participants. As the result of the study, the intake of whole grain was found to be inversely associated with BMI in both men and women after multivariate adjustment. Compared to normal weight, the risk of obesity in women and men is lower by 10% (2–16%) and 4% (1–7%), respectively, for each additional gram of dry whole grain consumption ($p < 0.05$). It was estimated that a decrease of 1 unit BMI was associated with a 33 g day-1 increase in dry whole grain intake, and there was a slight inverse relationship between baseline fiber intake and weight gain over 20 years. The results of the study with healthy middle-aged participants showed that men and women with a high whole grain intake had lower BMI, overweight, and obesity risks as compared to men and women with a low whole grain intake.

5 Conclusion

Cereals are a major source of energy in many countries, and surprisingly less attention has been paid to the quality of cereals such as “refined” or “whole” in the different dietary recommendations of different countries. Whereas whole grains have beneficial effects on glucose-insulin homeostasis, certain types of cancers, blood lipids, and gastrointestinal health, especially due to their high dietary fiber contents. When the literature is searched, it is seen that a large mass of evidence on the health outcomes of whole grains has accumulated in the last 10 or 15 years. The associations between whole grain intake and a lower risk of major diseases and death can be explained by several mechanisms. Meta-analysis, which combines the results of many scientific studies, has some weaknesses due to the fact that there are few studies for some endpoints, such as mortality from diabetes and infectious diseases, and it has poor information on the assessment of whole grain intake. Future studies should improve the evaluation of whole grain intake, which is similarly reported, using biomarkers to track compliance in randomized trials, and using validated assessment methods in observational studies. There is a need to further studies related to the biological mechanisms of health effects of whole grains and the

contribution to health of different whole grain types. For example, the numbers of studies suggesting that whole grain oats may be more beneficial in CDVs as comparing to whole grain wheat should be increased, and further research should be conducted in similar fields. For healthy life, whole grain consumption on a daily diet should not be forgotten.

Abstract

The increasing demand on a high-quality gluten-free (GF) products and an increasing prevalence of GF consumers favors the development of research aimed to improve the overall quality of GF products. To obtain a functional GF product providing the additional health benefits, the fortification of GF food is applied. Recently, inulin-type fructans (ITFs) were proposed as multi-task ingredients of GF products, improving their nutritional and health-related properties. In this chapter, the most recent studies on GF products in which ITFs were applied as valuable ingredients affecting the rheological and technological parameters of GF products are presented. The literature data with the successful applications of ITFs in the GF products and with their health beneficial properties, as presented in this chapter, points to a great potential of ITFs in the GF technology. The promising evidences of beneficial impact of ITFs on characteristic of GF goods may contribute to further development and intensified research on new GF products of superior quality that will be dedicated to people suffering from gluten-related disorders.

Keywords

Inulin-type fructans · Inulin · Fructooligosaccharides · Gluten-free diet · Gluten-free products · Prebiotic

List of Abbreviations

AGA	Anti-gliadin
ASD	Autistic spectrum disorders
ATI	Amylase and trypsin inhibitor
BMI	Body mass index
CD	Celiac disease
DGP	Anti-deaminated gliadin
DP	Degree of polymerization
EMA	Anti-endomysium
FODMAPs	Fermentable oligo-, di-, and mono-saccharides and polyols
FOS	Fructooligosaccharides
GF	Gluten-free
GFD	Gluten-free diet
HLA	Human leucocyte antigen
IBD	Irritable bowel disease
IBS	Irritable bowel syndrome
IgG	Immunoglobulin G
ISAPP	The International Scientific Association of Probitics and Prebiotics
ITFs	Inulin-type fructans
JAR	Just-about-right
mRNA	Messenger RNA
MW	Molecular weight
NCGS	Non-celiac gluten sensitivity
QDA	Quantitative descriptive analysis

RDA	Recommended daily allowances
SCFA	Short-chain fatty acids
TLR	Toll-like receptor
tTG	Anti-tissue transglutaminase
WA	Wheat allergy
WDEIA	Wheat-dependent, exercise-induced anaphylaxis

1 Introduction

The term "functional food" is defined as a group of products, which may improve the general condition of the body and decrease the risk of specific diseases [1]. To obtain functional food products that will provide the additional health benefits above those arising from its basic composition, a fortification involving the addition of one or more biologically active compounds or nutrients is applied. Fortification is described as one of the most effective strategies available to improve micronutrient status [2]. Recently, due to the westernization of diet, increasing prevalence of food intolerances, including gluten intolerance, are noted [3]. In gluten-related disorders, nutritional deficiencies of vitamins, minerals, proteins, and fiber are frequently observed [4, 5]. The nutritional deficiencies are mainly associated with a lower nutritional value of the gluten-free (GF) products as compared to the gluten-containing counterparts and because they are rarely fortified [4, 6]. To meet the growing demands of GF food consumers, the enrichment of GF products aimed to improve their palatability and nutritional value seems to be important and reasonable [7, 8]. Recently, inulin-type fructans (ITFs) were proposed as multi-task ingredients of GF products, improving their nutritional and health-related properties [9].

2 Structures, Sources, and Functionality of Inulin-Type Fructans

Generally, fructans are water-soluble mixtures of oligo- or polysaccharides containing at least two adjoining fructose units. The molecule of glucose can be linked by α-(1–2) linkages, similar as in sucrose molecule, at the beginning of chain but it is not obligatory. Fructans can vary based on the degree of polymerization (DP) and chemical structure. In higher plants, five types of fructans can be distinguished based of their structure: inulin-type fructans, inulin neoseries-type fructans, levan-type fructans, levan neoseries-type fructans and mixed levan-type fructans [9] (Fig. 1). ITFs and levan-type fructans are ketose-based fructans with mostly or exclusively β-(2–1) and β-(2–6) fructosyl-fructose linkages, respectively. Therefore, both groups of fructans are mostly linear; however, a small amount of branched units with β-(2–6) and β-(2–1) configuration for ITFs and levan-type fructans, respectively, can occur [10]. Neoketose is a base for both inulin neoseries-type fructans and levan neoseries-type fructans, which are characterized by the presence of glycosidic

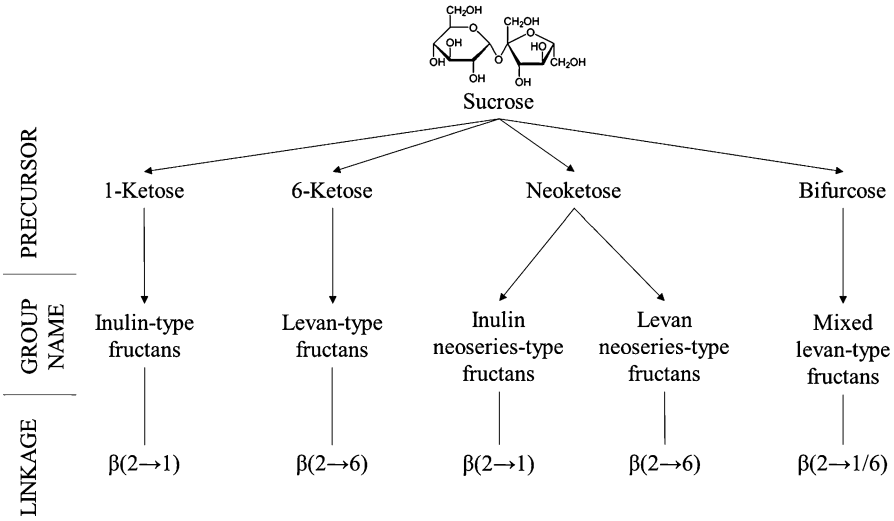

Fig. 1 Representation of fructans' types with their precursors and type of fructofuranosyl linkages

bonds like inulin- and levan-type fructans, respectively, and glucose on both ends of the molecule [10]. Elongation of inulin neoseries-type fructans starts from the C1 of the fructose group and/or from the C6 of the glucose unit of the initial sucrose, while elongation of levan neoseries-type fructans comprises molecules for which the elongation starts from the C6 of the glucose moiety. Mixed levan-type fructans include both types of fructofuranosyl linkages: β-(2–1) and β-(2–6) leading to formation of branched molecules [10].

In plants, ITFs composed of β-D-fructosyl units linked by (2–1) glycosidic bonds consist from 2 to 200 monomers, while ITFs synthesized by bacteria can be much longer reaching even 100,000 units [11]. Based on the length of the chain (DP), ITFs can be divided into long-chain inulin (DP $>$ 10) and short-chain oligofructose (DP $<$ 10) [9, 12]. DP determines the physicochemical properties of ITFs. Among commercially available ITFs, Synergy 1 (Raftilose®, Orafti, Tienen, Belgium) that is a mixture of long- and short-chain fructans have the features of both types of polymers.

The prevalence of fructans in the plant kingdom is very common, and they can be found in approximately 36,000 species [11]. The main taxonomic orders containing the largest amounts of ITFs are *Asteraceae* represented by chicory (*Cichorium intybus*) and Jerusalem artichoke (*Helianthus tuberosus*) – the main sources of ITFs; as well as *Liliales*, including leek, onion, asparagus, and garlic [13]. Tubers and roots of *Asteraceae* are the richest source of ITFs. Plant genotype, cultivar conditions tissue, the developmental stage as well as the conditions of post-harvest storage are factors influencing the chemical structure and yield of ITFs [14, 15]. The majority of ITFs used by food industry is obtained from chicory, containing even 15–20% of inulin. Non-fractioned inulin extracted from chicory roots consists of oligomers and polymers ranged from 3 to 70 DP. The contents of ITFs in different

Table 1 Content (% of fresh weight) and chain length of inulin in various plant

Source	Inulin content	Chain length
Chicory (root)	15–20	DP[a] $< 40 = 83\%$ DP $\geq 40 = 17\%$
Jerusalem artichoke (tuber)	14–20.5	DP $< 40 = 94\%$ DP $\geq 40 = 6\%$
Globe artichoke	2–7	DP $\geq 40 = 87\%$ DP $\geq 5 = 95\%$
Dandelion (leaves)	12–15	
Garlic (bulb)	9–16	DP $\geq 5 = 75\%$
Leek (bulb)	3–10	DP = 12 – majority
Onion (bulb)	1.1–7.1	DP 2–12
Asparagus (modified stem)	2–3	
Wheat (bran)	1–4	DP $\leq 5 = 50\%$
Barley (cereal)	0.5–1.5	
Rye (cereal)	0.5–1	
Banana (fruit)	0.3–1	DP $< 5 = 100\%$

[a]*DP* degree of polymerization

plant sources are summarized in Table 1. Inulin can also be produced enzymatically from sucrose following the transglycosilation and hydrolysis catalyzed by fructosyl-transferase [16]. Synthetic inulin is characterized by a lower polydispersity as compared to plant-derived one [17].

Main role of fructans in plants is related with storing the energy, but they also take part in the osmoregulation and in the response for abiotic-stress [18, 19]. Inulin obtained from chicory is present in a form of white fine powder with a slightly sweet taste due to the presence of both long- and short-chain fractions. The unique chemical structure of ITFs having the furanose conformation and the backbone with the polyethylene oxide determines its higher molecule flexibility as compared to pyranose configuration [17]. The properties of individual fraction depend on DP, determining the versatility of ITFs applications. The short-chain oligofructose is characterized by sweet taste and its sweetness constitutes approximately 35% of sucrose. The technological properties of oligofructose are similar to features of glucose syrup, therefore it can be used to improve the mouth-feel of light-type food products with lower caloric value without compromising sweet taste [20]. Long-chain inulin has neutral taste and it is not sweet but is able to form the gel network when it is mixed at high concentration with water. The aqueous liquid emulsion can be used to replace fat in food production, what is commonly applied in the production of low-fat dairy products with smooth, creamy texture [21]. Fat resembling features are also used in the meat and bakery industries to formulate low caloric products [22–25]. ITFs can be applied not only in the food industry but also for pharma. They can be used as targeted colon deliverer, to stabilize the protein-based pharmaceuticals, to enhance the dissolution rate, and to diagnose kidney failure by urine secretion rate [17, 26, 27].

3 Health-Related Properties of Inulin-Type Fructans

3.1 Prebiotic Effect

B-configuration of ITFs is responsible for their unique properties. ITFs are not hydrolyzed by the enzymes of the upper intestinal digestive tract as they only have the ability to hydrolyze linkages in α-configuration, therefore ITFs reach the colon unchanged [28]. This specific property of ITFs is one of the crucial features which allow considering ITFs as prebiotics. Nevertheless, the definition of prebiotic has evolved many times since 1995, when Gibson and Robertfroid [29] explained prebiotic as "a nondigestible food ingredient that selectively stimulates growth and/or activity of one or a limited number of bacteria in the colon, thereby improving host health" to the final, the most recent definition developed in 2017 by The International Scientific Association of Probiotics and Prebiotics (ISAPP) that simplified it to "a substrate that is selectively utilized by host microorganism conferring a health benefit" [30]. To specify this definition, three criteria should be accepted: prebiotic must be selectively utilized by the commensal microorganisms; have adequate evidence of health benefit for the target host; and must not be degraded by the target host enzymes. ITFs meet all the abovementioned criteria [30]. The fermentation of prebiotics causes changes in the gut microbiota composition. ITFs are preferably degraded by β-fructanoidase synthesized by bifidobacteria [30]. The presence of carbohydrates stimulates the fermentation process leading to an increase in bacterial quantity and fecal mass. The final products of ITFs metabolism are hydrogen, methane, carbon dioxide, lactate, and short-chain fatty acids (SCFA) [31]. SCFA are considered to have beneficial direct and indirect effects on human health. Higher amount of SCFA decrease pH in the intestines inhibiting growth of pathogenic bacteria. Butyrate is the energy substrate for colonic epithelial cells, and it is a key factor in the colonocytes proliferation and development. Water-soluble SCFA can easily pass the intestinal barrier getting into bloodstream, and then spread in the body. Acetate is used by the brain, muscles, and tissue, while propionate is metabolized by liver, reducing the hepatic production of cholesterol [31].

Inulin has been found to stimulate the development of *Lactobacillus* and *Bifidobacterium*, with simultaneous inhibiting of amount of harmful bacteria like *Escherichia coli* and *Clostridium* [32]. The products of fermentation of *Bifidobacterium* are mainly lactate and acetate. The in vitro chemostat study conducted by Langlands and co-workers [33], aimed to evaluate the effect of the prebiotic carbohydrates oligofructose and inulin on the mucosal microorganisms, showed a significant increase ($P < 0.05$) in the number of *Bifidobacterium* and *Lactobacillus* in biopsies taken from the caecum, transverse and descending colon, and rectum. Authors reported a significant increase of eubacteria in subjects consuming fructooligosaccharides (FOS) and inulin but no changes in the total anaerobes clostridia, bacteroides, or coliforms, neither in their proliferation indices [33].

However, the in vitro models do not allow analyzing the complexity of the intestinal ecosystem; therefore to confirm the probiotic effect of ITFs, the in vivo studies and human trial were necessary. Recent in vivo study on inulin

administration in rats' diet of reduced amount of calcium showed a stimulation of bifidobacteria, particularly *Bifidobacterium animalis*, and an increase in SCFA in the groups fed with ITFs [34]. The stimulation of microbiota was dependent on calcium intake, and the positive changes were observed only in animals fed with a recommended amount of calcium. The DP-dependent influence of ITFs on gut microbiota was determined in the study on C57BL/6 J mice [35]. Authors reported that ITFs with lower DP stimulated the intestinal microbiota more efficiently than long-chain inulin. However, in both groups, the growth stimulation of the butyric-producing bacteria was observed. In the group receiving FOS, the dominant bacteria in *Verrucomicrobia* phylum was *Akkermansia muciniphila*, belonging to mucin-degrading species [35].

Numerous human studies, varying the applied dose of prebiotic, the DP, and the duration of experiment confirmed the prebiotic effect of ITFs [33, 36–39]. Randomized, double-blind placebo-controlled study on obese women receiving 16 g of oligofructose-enriched inulin or placebo (maltodextrin) was designed by Salazar and co-authors [40]. After 3 months supplementation, the number of *Bifidobacterium longum*, *Bifidobacterium pseudocatenulatum,* and *Bifidobacterium adolescentis* increased in the ITFs-consuming group. In general, in the obese and overweight human, the SCFA concentration is elevated [41]. In the study by Salazar and co-workers [40], the normalization of the SCFA concentration, with the significant decrease in acetate, propionate and total SCFA content, was noted in the prebiotic group. The increase in *Bifidobacterium* counts was determined in the randomized trial with 4-week intake of 8 g of FOS by 12 healthy elderly volunteers [42]. Prebiotic effect of inulin was also reported in the study of Tuohy and co-workers [39]. Authors reported the significant increase in *Bifidobacterium* in pooled fecal samples collected from ten healthy volunteer after 14-days intake of 8 g of inulin. Small but significant increase was observed also in clostridium group. Inulin intake had no effect on the total bacteria number, *Bacteroides* spp., *Lactobacillus* sp., and *Enterococcus* sp. The authors noticed that the more prominent increase in *Bifidobacterium* was observed in volunteers with a lower initial number of these bacteria [39]. Fecal microbiota composition was weekly monitored in the study with Jerusalem artichoke and chicory inulin-supplemented snacks introduced to 45 volunteers [43]. The increase in the count of *Bifidobacterium* with simultaneous reduction in *Bacteroides – Prevotella* ratio and *Clostridium histolyticum/Clostridium lituseburense* was observed in both experimental groups fed with ITFs [43].

3.2 Dietary Fiber

According to the definition of Institute of Medicine of The National Academies, dietary fiber consists of nondigestible carbohydrates and lignin that are intrinsic and intact in plants [44]. Dietary fibers should be resistant to the enzymes of early sections of intestinal track and should be metabolized in the colon by intestinal microbiota [45]. The interest in dietary fibers is related with a wide spectrum of health beneficial properties, including reducing the risk of type 2 diabetes,

hypertension, cardiovascular disease and helping in the body mass management [46]. The consumption of fibers should consist of 25–38 g per day [47]. ITFs are characterized by the low caloric value (1–2 kcal/g) as well as by β-configuration, allowing to reach large intestine in the intact form in almost 90% determines that ITFs belong to the dietary fiber group, thus they are considered as dietary fiber [20, 48, 49]. Precisely, based on their physiochemical characteristic, ITFs belong to the group of soluble dietary fibers, being better fermentable and viscous [31]. Therefore, ITFs-containing products are labeled as a source of dietary fiber.

3.3 Intestinal Morphology and Gut Function

In general, it is well known that intestinal microbiota has a crucial role in the whole body homeostasis and maintenance of the gut health. Prebiotics, including ITFs, stimulating the development of the beneficial strains of bacteria are considered to improve the gut health in terms of morphological changes, maintenance of intestinal integrity, and alleviating the symptoms of intestinal diseases.

ITFs were applied as a supplement in a study aimed to compare the morphometry of germ-free rats and rats with human fecal microbiota [50]. The height of villi and depth of goblet cells was improved in groups receiving ITFs. Moreover, ITFs had beneficial effect of epithelial mucus layer, especially in a group with fecal microbiota transplantation [50]. The fragility and spontaneous bleeding are considered as a symptom of low-fiber diet due to the reduced amount of SCFA [51]. In other study, 10% of inulin, FOS, and cellulose were applied in the diet of obese mice for 4 weeks to evaluate the effect of fibers on gastroenterology physiology [52]. The authors noticed that in groups fed ITFs, the cecal crypt depth was improved as compared to cellulose-fed and control groups. Additionally, inulin-fed mice had better cecal transmutal resistance. Moreover, a lower expression of colonic mRNA of genes encoding occludin, zonulin 1, AMP kinase, and monocarboxylic transporter 1 was observed in inulin-fed mice, pointing the negative changes in the gut barrier functioning. However, as authors underlined, because the deteriorating in the transmutal resistance and morphological failures were not observed in inulin-fed mice, this mechanism may be more complex and require further studies [52]. Unfavorable effect of ITFs on gut barrier was reported in other studies with animal model [53–55]. However, in the human studies no effect of ITFs on gut barrier was observed [56–58]. On the contrary, Russo and co-workers [59] reported improvement in the circulating level of intestinal permeability markers, such as zonulin and glucagon-like peptide 2 after administration of an inulin-enriched pasta, suggesting the potential role of inulin in the prevention of intestinal disorders [59].

The randomized, controlled trial evaluated the effect of oligofructose on the prevalence of diarrhea in 282 infants aged 6–12 month [60]. Diet supplemented with prebiotics did not affect the prevalence of diarrhea; however, the mean number of days with diarrhea was smaller in the oligofructose group than in the control group. Nonetheless, authors concluded that a prebiotic supplementation cannot be substitutive of breast-feeding [60]. Klessen co-workers [61] analyzed the influence

of inulin on the constipation in ten elderly women and found that in most cases, prebiotic increased the stool frequency from 1–2 to 8–9 per week and modified a stool consistency. In the initial part of this study, the daily dose of 20 g of inulin was applied and after increased gradually up to 40 g per day. In most of women, the inulin dose has no impact on the stool frequency, except of one [61]. Similar findings were reported in the studies conducted on 56 healthy children (age 16–46 weeks) [62]. The authors reported that FOS in a dose of 0.74 g per day taken for 28 days resulted in improved stool frequency and consistency as compared to placebo-fed children. Contrary results were obtained by Bouhnik and co-workers [42] who reported no influence after 4 weeks' supplementation with 8 g FOS on the stool weight, water percentage and stool frequency in six elderly persons.

3.4 Body Mass Management

The increasing evidence of obesity and overweight became a significant problem in the well-developed countries. It is speculated that the increased intake of dietary fibers can help in the body weight management. Thus, a growing number of studies have attempted to develop products with higher content of dietary fibers as well as to answer the question if dietary fibers are actually able to reduce obesity.

Single-blinded, crossover, placebo-controlled pilot study in ten healthy persons taking 8 g of oligofructose or placebo twice a day for 2 weeks was conducted by Cani and co-workers [63]. Morning consumption of ITF significantly improved satiety ($P = 0.04$), while after evening intake, significantly improved satiety and reduced hunger. The energy intake at breakfast and lunch and total daily energy intake were reduced in the group receiving oligofructose as compared to placebo group. Therefore, oligofructose was proposed as dietary supplement in obese people [63]. Similar findings were reported by Genta and co-authors [64], who stated that FOS can help in the obesity management. In their study, 0.29 g or 0.14 g FOS per kg per day in the form of yacon syrup, being a rich source of FOS, were taken for 120 days by 35 obese and slightly dyslipidemic premenopausal women divided into subgroups. The intake of FOS, resulted in reduced body weight, waist circumference, and body mass index (BMI). Moreover, women receiving yacon syrup had lower fasting serum insulin and serum LDL-cholesterol levels and reduced Homeostasis Model Assessment index [64]. Parnell and Reimer [65] examined the effect of oligofructose supplementation on body weight and the concentration of satiety hormones in overweight and obese adults. Forty-eight obese subjects, without any other health problems, ingested 21 g oligofructose or a placebo (maltodextrin) per day for 12 weeks. Supplementation of diet with oligofructose significantly reduced ($P = 0.01$) the body weight, while in the placebo group, the body weight increased up to 0.5 kg. The level of glucose and insulin decreased in the ITFs group and increased in placebo group. The profile of satiety hormone secretion changed after prebiotic intake with increased level of peptide YY and reduced ghrelin, suggesting the contribution in the reduction in energy intake. On the other hand, oligofructose intake did not affect the secretion of glucagon-like peptide 1 [65]. A randomized

double-blind, cross-over intervention with oligofructose (10 g/d or 16 g/d) or placebo for 13 days conducted in healthy adults with average BMI of 24.8 kg/m^3 have evidenced a 11% reduction in the energy intake in the 13th day as compared to the baseline in a group receiving oligofructose [66]. The difference in the energy intake was also noticed between both groups receiving different doses of oligofructose with 2801 kJ and 3177 kJ for 10 g and 16 g of oligofructose, respectively. The reduction of energy intake may be explained by higher secretions of peptide YY and glucagon-like peptide 1 [66]. The most recent randomized double-blind, placebo-controlled trial in obese and overweight children where Synergy 1 (8 g/d) was administered for 16 weeks, showed a significant increase in the feeling of fullness and lower prospective food consumption during breakfast in ITFs group at the end of experiment as compared to the baseline [67]. The energy intake was dependent on age, and 11–12 years old children receiving prebiotic had significantly reduced ($P = 0.04$) energy intake as compared to placebo group, while in younger children (7–10 years old) the difference was not detected. Moreover, the concentration of adiponectin and ghrelin was higher in the group receiving ITFs as compared to placebo [67].

Contrary to that, few studies reported no effect of ITFs supplementation of appetite control, and body weight management. Archer and co-authors [68] substituted fat in sausage patty with inulin and lupin-kernel fiber and evaluated their effect on palatability, perceptions of satiety, and food intake in 33 men. Inulin-enriched patty had no impact on satiety, while lupin-kernel patty was more satiating. However, the total fat intake was 18 g lower in group consuming inulin-enriched patty [68]. Another study with two doses of FOS per day (5 g at breakfast and 8 g 2 h before dinner) where applied to measure satiety [69]. Low morning dose did not affect satiety or food intake during a lunch, while a higher dose influenced satiety in the gender-dependent manner: in women the food intake decreased, however in men increased [69]. Another study also reported that bars enriched with 10 g of different fibers, including inulin and FOS, did not change satiety and food intake in women [70]. These divergent results could be explained by the differences in the DP and/or doses of applied ITFs. Therefore, this issue requires further studies.

3.5 Lipid Profile

Inadequate diet, rich in fat and sugar, with insufficient amount of dietary fiber is suggested to be a factor of cardiovascular diseases, in particular of hypertension, stroke, and heart failure [71]. Therefore, several studies were conducted to assess if changing of dietary habits or dietary supplements could help in reducing the risk of cardiologic conditions. So far, the studies directly evaluating the effect of ITFs on cardiovascular diseases have not been performed; however, their influences on the serum lipid profile have been examined widely.

The study of Letexier and co-workers [72] showed that 10 g of inulin per day significantly reduced the level of serum triglyceride and liver liponeogenesis, but at the same time, it did not affect total cholesterol, HDL- and LDL-cholesterol

concentrations [72]. Other results were obtained by Balcazar-Munoz and co-workers [73] in a 4-weeks randomized placebo-controlled trial in 12 obese individuals who received 7 g of inulin per day. Authors showed a significant decrease in total cholesterol, LDL-cholesterol, VLDL-cholesterol, and triglyceride levels as compared to placebo [73]. The study on healthy men (22 subjects) fed for 5 weeks with inulin-enriched pasta were performed by Russo and co-workers [74] and indicated an increase in HDL-cholesterol by 36% in the group fed with inulin-pasta. At the same time, total cholesterol to HDL cholesterol ratio, concentrations of triglycerides and lipoprotein (a) were reduced by 22%, 23%, and 17%, respectively. In other clinical study, 10% decrease in LDL-cholesterol was reported in type-2 diabetes patients with elevated lipid level after 14 days intake of 8 g/d of FOS [75].

On the other hand, no effect of ITFs on lipid profile was determined in many studies in healthy people [76–78]. The meta-analysis of randomized controlled trial showed that ITFs are able to reduce LDL-cholesterol across all study population, while HDL-cholesterol improvement and reduced fasting glucose trend was noticed only in the type-2 diabetes mellitus subgroup [79]. Therefore, further study on the effect of ITFs on lipid profile, especially studies explaining their dose- and DP-dependent influence are necessary for a definitive conclusion.

3.6 Mineral Absorption

Several in vitro and in vivo studies as well as in human trials have attempted to determine the effect of the intake of ITFs on mineral absorption. Recent in vitro study conducted by Krupa-Kozak and co-authors [80] evaluated the effect of inulin and FOS on calcium uptake and absorption from the calcium-enriched GF bread. The results showed that short-chain FOS improved the cellular calcium uptake from calcium-fortified GF bread. The authors concluded that the absorption of calcium is dependent of DP [80].

Rat model was used to assess the effect of ITFs with different chain length and their combinations on the calcium and magnesium absorption in a 50 male Wistar rats [81]. A significant improvement of magnesium absorption was reported for all ITFs formulations. In case of calcium, only the mixture of short-chain and long-chain ITFs increased absorption significantly; however, the increasing trend was observed also in single formulations [81]. Recent 6-week nutritional experiment on rat model was conduct by Krupa-Kozak and co-workers [34], who aimed to evaluate the effect of inulin of calcium absorption depending on the amount of this mineral in diet. The authors reported that inulin stimulated the absorption of calcium especially in rats fed a diet of reduced calcium level [34]. The results of this study are somehow in agreement with the results of a human trial on adolescent girls consuming a diet supplemented with oligofructose-enriched inulin [82, 83]. Synergy 1 intake in a dose of 8 g per day resulted in the improvement of calcium absorption in girls with normalized calcium intake and in girls with calcium deficiency; however, the beneficial effect was more prominent in the second group [82, 83].

Although the majority of in vivo studies are focused on the evaluation of the impact of ITFs on calcium and magnesium absorption, in one study the effect of 5 week supplementation of mixture of ITFs with different DP (Synergy 1) on iron utilization in piglets fed corn and soybean meal diet was assessed [84]. Final blood hemoglobin concentrations and the overall hemoglobin repletion efficiency of pigs increased significantly ($P < 0.01$) by 28% and 15%, respectively, in pigs supplemented with 4% of ITFs. Changes in the iron utilization were positively ($r = 0.55$ and 0.69, $P < 0.01$) correlated with dietary ITFs concentrations. Also iron concentration in the digesta of proximal, middle, and distal colon were significantly ($P < 0.05$) higher in pig supplemented with 4% ITFs [84].

The effect of ITFs on mineral absorption was evaluated in numerous human trials. Yap and co-workers [85] reported that absorption of iron, magnesium, and zinc were significantly improved in infants fed with inulin-enriched formulations. On the other hand, the retention of calcium and copper were not affected by inulin intake [85].

However, early studies showed that intake of 15 g of oligofructose per day improve the calcium absorption in adolescent girls [86]; numerous studies indicated that the most prominent effect on mineral absorption is observed with oligofructose-enriched inulin as compared to individual ITFs [81, 87, 88]. Supplementation for 6 week with 10 g of Synergy 1 per day resulted in the increase of fractional absorption of calcium and magnesium in 15 postmenopausal women as compared to control [89]. Moreover, the beneficial effect of ITFs was observed also in terms of bone turnover biomarkers, including serum osteocalcin and urinary deoxypyridinoline cross-link [89]. One year interventional randomized, placebo-controlled study showed that 8 g of Synergy 1 significantly improved calcium absorption in a group of 100 adolescents (9–13 years old) [87]. Authors emphasized that the significant increase in true calcium absorption was observed just after 8 weeks of trial, and it was maintained till the end of study in Synergy 1 group. At the end of the experiment, the bone condition parameters were evaluated and showed an improvement in bone mineral content and bone mineral density in ITFs group as compared to control [87].

4 Gluten and the Application of Gluten-Free Diet

4.1 Gluten

Gluten is a mixture of storage proteins found in the endosperm of the mature grain of wheat and some other cereals within the grasses family, including rye and barley. It consists mainly of protein (75–85%) and lipids (5–10%), while most of the remainder is starch and nonstarch carbohydrates, being the residue occurring after washed out the starch granules and other soluble substances from the wheat flour [90]. Gluten proteins are the main source of nitrogen for a growing seedling [91]. Mixture of gluten proteins is composed by monomeric gliadins and polymeric glutenins [92]. Gliadins and glutenins differ in their alcohol solubility. Gliadins are soluble in ethanol-water mixtures, while glutenins are insoluble. Gliadins belong to prolamins

of wheat. The prolamins present in rye, barley, and oats are secalins, hordeins, and avenins, respectively. Gliadins can be subdivided into α/β, γ, and ω-gliadins based on their electrophoretic mobility. α/β and γ-gliadins are low molecular weight proteins (MW 28–35 kDa) with six and eight cysteine residues respectively, whereas ω-gliadins (MW 40–75 kDa) are sulfur poor [90]. The structure of gliadins consists of approximately 300 amino acids with the high percentage of proline and glutamine and low amount of lysine and methionine [90]. The amino acid characteristic is responsible for the harmful effect of gliadins with 13- and 33-mer oligopeptides involved in the alleviated immunological response in celiac patients [93]. The glutenin fraction comprises aggregated proteins linked by inter-chain disulfide bonds; they have varying size ranging from about 500,000 to more than 10 million [94]. Amino acid characteristic of glutenins is similar to gliadins with high content of glutamine and proline [95]. The amount of gluten in wheat grain has changed in time. Genetic modification aimed to improve yielding of crops, result in the arriving of new varieties with multiplied genes also coding the gluten proteins. These changes in the wheat sensitivity are widely reviewed [91, 96].

4.2 Gluten-Related Disorders

A growing popularity of a gluten-free diet (GFD) is related with increasing incidence of gluten-related disorders [97]. In certain group of individuals, the intake of gluten can lead to the development of diseases, which can be divided into two main groups based on the pathogenesis: allergic and autoimmunological. Allergic diseases include wheat allergy (WA), while celiac disease (CD), *Dermatitis herpetiformis,* and ataxia belong to the second group. Nowadays, many cases of patients suffer from hard to diagnose disease, non-fitting to none of defined gluten-related disorders but for who treatment with GFD helps and are enclosed in the so-called non-celiac gluten sensitivity (NCGS).

4.2.1 Celiac Disease

Celiac disease is autoimmunological disease, observed in genetically predisposed individuals, resulting in the villous atrophy as a consequence of presence of gluten in diet. The diagnosed CD patients constitute approx. 1% of general population [98]; however, in many cases CD remain unrecognized or incorrectly diagnosed [99]. CD is observed mainly in highly developed countries due to the westernization of a diet [100]. CD can be diagnosed at every age, not as erroneously thought, only in children. The prevalence of CD is twice more frequent in women as compared to men [101].

Pathogenesis of CD is complex and includes genetic, environmental, immunological, metabolic, and infectious factors [102]. The genetic predisposition is inherited dominantly. Most of person diagnosed with CD contain genes of human leukocyte antigen (HLA): HLA DQ2 and HLA DQ8, placed on a chromosome 6, encoding proteins presenting gluten to lymphocyte CD4+ [103]. Approximately 90–95% of individuals with CD inherit alleles coding HLA-DQ2, while in majority

of the rest, HLA-DQ8 is detected [104]. It is suspected that also other genes may be involved in the pathogenesis of CD. The expression of HLA-DQ is necessary but not sufficient for the development of CD. Breast feeding, time of gluten introduction into the diet of the child, a history of infectious, certain medicals and smoking can be environmental factors contributing to the CD development [105–108]. Groups with higher risk of the incidence of CD include: relatives of CD patients and people suffering from type-1 diabetis mellitus, Hashimoto's thyroiditis, IgA deficiency, and genetic disorders such as Down's syndrome and Turner's syndrome [92].

The immune response to ingested gluten depends on the presentation of gluten peptides for lymphocytes T. In colon, the gluten protein undergoes deamidation by enzyme, tissue transglutaminase, with formation of strongly immunogenic peptides. Intraepithelial lymphocyte infiltrates and immune system stimulation manifested by increased production of interleukin 15 is observed in genetically predisposed individuals [109]. Activation of lymphocytes T, following the gluten peptide recognition, results in damage to the intestinal mucosa by direct action of inflammatory mediators and extracellular matrix metalloproteinases secreted by stimulated fibroblasts, leading to the development of inflammation of the endothelium and lamina propria of small intestine, cryptic hypertrophy, and the atrophy of intestinal villi [103, 110]. One of the consequences of morphological intestinal changes in CD is a limitation of the absorption process. Malabsorption is related to deficiencies of important alimentary nutrients, leading to growth deficit, anemia, vitamin deficiencies, thyroid diseases, mental disorders, fatigue, and infertility.

A wide range of manifestations of CD complicates its diagnosis. Based on the clinical picture, three main types can be distinguished: classic, atypical, and silent [111]. Some of researchers suggest also the addition of a term latent CD and a genetic susceptibility for CD to this classification. Classic CD is manifested by gastrointestinal symptoms such as diarrhea, fatty stools with bad odor, constipations, abdominal pain, loss of appetite, and weight loss. This CD type is diagnosed mainly in children. As compared to classic form, the atypical CD is more common, and it is diagnosed in older children, teenagers, and adults. Except of typical gastrointestinal symptoms, atypical CD can be manifested with verity of extraintestinal symptoms, including anemia, mental disorders, and bone alterations [112–114]. Silent CD is diagnosed accidently in relatives of CD patients or during screening studies [115].

The diagnosis of CD is confirmed by clinical picture, duodenal biopsy, genetic tests, and serological tests. Serological tests include measurements of several antibodies: anti-tissue transglutaminase (tTG), anti-endomisium (EMA), anti-gliadin (AGA) and anti-deaminated gliadin (DGP) [92].

4.2.2 Wheat Allergy

Wheat allergy is a classic form of food allergy being a defense response to a contact with wheat proteins exclusively. Proteins present in other cereals do not cause an immunological response in WA patients. The incidence of WA is estimated at 0.4% of worldwide population, wherein the most frequently is diagnosed in children [91, 116]. The frequency of the WA is age-dependent, in fact in 2 years old children WA incidence was estimated in 2%, while in older children it increased up to 9% [117].

Main signs of WA are skin lesions, typical for food allergies, and gastrointestinal symptoms such as diarrhea, abdominal pain, and constipation [118]. It is possible to distinguish few types of WA depending on the way of exposure to the allergen and the mechanism of immune response. First type is classic WA manifested by the gastrointestinal, respiratory, and skin symptoms; second is wheat-dependent, exercise-induced anaphylaxis (WDEIA), which appears after physical activity; and the last type is the baker's asthma, commonly appearing in the workers of bakeries and mills because of the exposition of the wheat particles irritating the respiratory track. The incidence of WA is the smallest among gluten-related disorders but the consequences of WA can be the most serious ones because of the possible anaphylactic shock, which can be fatal.

Gluten proteins are not the only triggers responsible for allergic reactions in WA. Another wheat proteins belonging to albumin and globulin group have similar ability. Gliadin ω-5 is the main allergen in WDEIA and skin allergies [119], while gliadin α- and γ- as well as protein ATI CM3 (amylase trypsin inhibitors), belonging to albumin group, are responsible for atopic dermatitis [120]. Baker's asthma is a response to the presence of low mass glutenins (α-, ω-gliadins), but the main role in the pathogenesis of Baker's asthma is played by several albumins and globulins, including ATI, lipid transporting proteins, and serpins [121].

Diagnosis of WA is based on the analysis of serum IgE concentration and skin tests. Because of the similarities of immunological epitopes in phylogenetically close varieties, the presence of cross-allergies with allergens of grass and weeds is possible. So far, the most reliable method of food allergies diagnosis is the challenge with allergy-causing food, and then attempt of its elimination from a diet [122]. Therefore, in the diagnosis of WA, gluten-challenge is applied.

4.2.3 Non-Celiac Gluten Sensitivity

Non-celiac gluten sensitivity belongs to gluten-related disorders; however, its characteristic and course does not fit CD or WA [97]. It is suspected that the main cause of NCGS is an imbalanced diet containing foods of high gluten content [123]. NCGS is diagnosed mainly in adults, particularly in female [124]. Individuals with irritable bowel syndrome (IBS) and allergy are particularly vulnerable to incidence of NCGS [125, 126]. High rate of NCGS has been reported in relatives of CD patients, amounting 13% [127]. NCGS patients suffer from symptoms similar to classic CD, including abdominal pain, diarrhea, as well as extraintestinal symptoms such as depression, fatigue, and musculoskeletal pain. In NCGS, symptoms appear in short time after gluten intake. Contrary to CD, NCGS patients do not have elevated concentration of antibodies characteristic for CD (anti-tTG, EMA). There are also no changes in the allergic tests including the measurement of immunoglobulins levels and skin tests. Therefore, the diagnosis of NCGS is based only on the elimination of CD and WA.

Pathogenesis of NCGS is not fully known; however, in its development an important role of the activation of innate immune response, changes in the intestinal barrier functioning and intake of food containing inhibitors of amylases was indicated [100, 127, 128]. It is also suspected that NCGS can be related with a high

intake of fermentable oligo-, di-, and monosaccharides and polyols (FODMAPs) [124]. Persons suffering from NCGS show markedly increased expression of toll-like receptors (TLR) involved in the innate gastrointestinal immune response and lower expression of FOXP3 Treg markers associating with the development of autoimmune diseases such as CD [100].

4.3 Gluten-Free Diet as a Treatment of Other Diseases

Nowadays, a GFD is considered as a treatment alleviating several symptoms and diseases. The attempts have been made to check the possibility of application of GFD in other diseases, in particular a GFD was proposed as a potential treatment for the selected symptoms of irritable bowel disease (IBD). A controlled trial of application of a GFD in patients with IBS-diarrhea indicated that a GFD can reduce the frequency and change the consistency of stool, improve the intestinal barrier functions, and alter rectosigmoid messenger RNA expression of tight junction proteins [129]. Gluten changed the level of various cytokines in peripheral blood mononuclear cells in IBD, and it was concluded that the extent of these alterations were associated with HLA-DQ2 or HLA-DQ8 genotype [129]. To identify the subgroup of IBD patients who potentially respond to a GFD, another approach proposed the evaluation of serum IgG antibodies against gliadin or tissue-transglutaminase in combination with HLA-DQ2 expression [130]. Moreover, an internet-based cross-sectional study utilizing a GFD questionnaire in 1647 patients with IBD reported that among the analyzed group 0.6% and 4.9% of participants were diagnosed with CD and NCGS, respectively [131]. Amongst the respondents, 19.1% had previously tried a GFD, while only 8.2% admitted currently following of GFD. What was interesting, 65.6% of participants reported an improvement of gastrointestinal symptoms after the elimination of gluten from the diet, and 38.3% described symptoms of disease as less frequent and severe [131]. Studies conducted on patients with fibromyalgia both with IBS or CD indicated that a GFD can slightly alleviate the symptoms of those diseases [132, 133].

Emerging evidence suggested the importance of insufficient enzymatic activity, increased gastrointestinal permeability, and the absorption of toxic byproducts of incompletely digested proteins from dairy (casein) and cereals (gluten) in the development of autistic spectrum disorders (ASD) [134]. Therefore, gluten-free and casein-free diets are proposed as a treatment of ASD. The results of the randomized single-blind trials indicated the improvement in the communication, social isolation, repetitive and challenging behavior, and better development in children on a GFD, casein-free diet as compared to those on control diet [135, 136]. On the other hand, another studies reported no significant ($P < 0.05$) differences in verbal and nonverbal communication and behavioral indexes in children following a GFD as compared to controls [137, 138]. The efficiency of a GFD in ASD was widely reviewed [134, 139].

4.4 Gluten-Free Diet as a Dietary Trend

The total occurrence of gluten-related disorders is observed in low percent of the whole population, meanwhile the increasing trend in the GF products consumption and thus production is noticed, projecting that the GF food market will reach 4.89 billion dollars in 2021 [140]. Surprisingly, an emerging number of healthy people begin a GFD, believing that gluten can have harmful health effects [141]. The prevalence of a GFD consumers in US society, who were not diagnosed in any of gluten-related disorders consists at least 0.5% [142]. Another study evaluating this trend showed that the prevalence of CD remained constant (0.58–0.77% of general population), while the amount of a GFD followers increase from 0.52% in 2009–2010 up to 1.69% in 2013–2014 [141]. Authors explained this rising GFD popularity phenomena by the popular opinion that gluten carries negative health effects, therefore a GFD is healthier than a conventional gluten-containing diet, easier access to GF products, and the increasing prevalence of self-diagnosed gluten-related disorders and following of diet without the consultation with physician [141]. Recent prospective cohort study performed in 64,714 women and 45,303 men responding for food frequency questionnaires for 26 years showed no relation between presence of gluten in food and the development of coronary heart disease [143]. On the contrary, authors suggest that a non-necessary GFD application is related with the avoidance of whole grains having beneficial effects on heart conditions, more likely may result in the coronary heart disease development. The authors underline that the promotion of a GFD among people without diagnosed gluten-related disorders should not be recommended [143].

4.5 Controversy Concerning a Gluten-Free Diet

GFD is based on the elimination of gluten-containing foodstuff from a daily regime. The commercially available GF products have higher content of fat and sugar as compared to corresponding gluten-containing counterparts [6]. Studies on children indicated significantly higher energy intakes in CD patients as compared to controls [144]. Additionally, GF products are poor in several important nutrients, especially proteins and mineral components, as well as non-nutritional but physiologically important components, like dietary fiber [6]. For that reason, the efforts have been made to improve the nutritional value of GF products by addition of non-gluten natural additives. Highly nutritional grains, like quinoa, teff, buckwheat, and amaranth, dietary ingredients, and mineral supplements were applied in the development of new gluten-free bakery goods [145–148]. These procedures resulted in improving the nutritional quality as well as augmented the technological properties of GF products.

The difficulty in the proper nutrients balance in the GFD is not the only problem. Recent studies indicated that a GFD can increase the exposure to certain toxins as compared to conventional diet. Fourfold increase in the serum levels of mercury in

CD patients following a GFD as compared to the healthy controls following regular diet was reported by Elli and co-workers [149]. The source of mercury in a GFD is not known; however, these results are worrisome because of the harmful effect caused by mercury, especially in the nervous system [150]. Recently, emerging number of evidence underlie the higher content of arsenic in rice [151]. Rice, rice flour, and other rice products are common replacement of wheat in a GFD; therefore they might elevate the arsenic levels in CD patients, but this must be studied.

Because of all abovementioned controversy of GFD, the proper dietary balance should be established with an assistance of a dietician to keep diversity of the diet [152] and the development of new, high-nutrition, and safe GF products should be explored.

5 Technological Importance of Gluten

Gluten plays an important role in the technology of the cereal-based food products. Due to its unique properties, gluten contributes to batter emulsification and visco-elasticity, provides cohesiveness to dough during processing, retains leavening gases, sets the crumb structure, and imparts elasticity to the bread texture [90, 153]. Gluten properties result of the ability of gliadins and glutenins to aggregate and form a network, the structure of which result from the presence of noncovalent (ionic, hydrogen, and hydrophobic) bonds [90]. The unique physiochemical properties of gluten derive from the presence of both protein fractions, equally affecting the quality of dough. Dough strength and elasticity is related with insoluble glutenin, being more elastic and cohesive. Properties of glutenins are correlated with the presence of disulfide bonds. When these bonds are reduced, glutenins become soluble in aqueous solutions of alcohols, such as gliadins, and they lose the strength features [90]. The soluble gliadin is mainly responsible for the viscosity and extensibility of the dough, because they are inflexible and less cohesive than glutenins. The viscosity is a consequence of high content of proline, allowing the dough to flow and rice [91]. Under conditions providing sufficient dough hydration and when the dough is optimally developed by the mixing process, the disruption of the initially spherical protein particles takes place, together with the stretching and alignment of proteins, which leads to the formation of a three-dimensional structure. By holding gases produced during dough proofing or fermentation, a gluten network allows bread to rise. Finally, during the baking, gluten changes its characteristics from elastic to semi rigid, contributing to the change from dough to crumb. The crumb structure is then formed. These functions of the gluten network give bread its chewy and elastic texture.

Many studies on gluten-free baking products have focused on the design of a GF matrix to overcome the negative impacts of the absence of the gluten network. The replacement of gluten is yet a technological challenge, as it is an essential structure-building protein which is necessary for formulating high-quality cereal-based goods, thus the production of such products is difficult.

A technology of GF baked products is different from the traditional processing of gluten-containing bakery foods. GF dough itself varies considerably from wheat dough, being closer to batter [154, 155]. The consistency of GF dough is greatly dependent on the amount of water or hydration, showing very low consistency during mixing when water adsorption is higher than 90% [156]. For that reason, GF dough does not require kneading, like conventional bread dough, and instead it is blended in a mixer [154]. Therefore, this dough is more like a batter of cake than bread dough [155]. Despite the intensive development of the GF production, many baked GF breads and confectionary products currently on sale are still of inferior quality. The lack of gluten makes it very difficult to obtain an acceptable texture and sufficient volume of baked goods because of the absence of a proper protein network necessary to hold the carbon dioxide produced during proofing [7]. The obtained GF products have a crumbling texture and pale crust [157, 158]. Another problem with GF-baked goods is the reduced volume of obtained loaves due to low carbon dioxide-binding activity during rising. Furthermore, baked GF products, mainly composed of different starches, stale very quickly and are characterized by reduced sensory qualities compared with their gluten-containing counterparts. Gluten is also responsible for the structure of dry pasta and its texture during cooking. A gluten network coagulates during cooking and creates strengthened network, preventing the starch granules to leach [159]. Lack of gluten network results in sticky pasta with poor consistency [159].

The imitation of viscoelastic properties of gluten is a key technological task, and numerous studies have therefore been conducted to overcome this problem. Hydrocolloids and gums, due to their water-binding capacity and ability to form a gel network, were proposed as substitutes for a gluten network to improve of the rheological properties, structure, mouth-feel, acceptability, and shelf life of GF-baked products [160, 161]. Enzymes were applied to improve the quality and extend the shelf-life of GF products [156, 162]. Positive effects were also obtained by using sourdough fermentation as an effective way to improve the texture, flavor, shelf-life, and nutritional value of bread [163].

Recently, Padalino and others [164] studied a range of vegetable flours in the formulation of GF spaghetti and indicated that yellow pepper pasta was the most desirable vegetable flour due to its orange color, homogeneity, and pleasant taste; additionally, yellow pepper pasta decreased the hardness of the pasta, compared to the control. Susanna and Prabhasankar [165] analyzed the inclusion of high protein flours (soya, channa, and sorghum flours) for the production of GF pasta and showed that formulations containing the highest level of soya flour and channa flour, along with hydrocolloids and whey protein concentrate, produced the best cooked pasta characteristics, having the lowest cooking loss, a soft texture, and a pasta with higher protein content compared to the control of *Triticum durum* flour.

Poor structure and texture are not the only problems of GF products. They are also characterized by inferior nutritional qualities. Therefore, to increase their palatability and dietary quality, aside from the typically used corn and rice, a wide range of naturally GF grains (oat, sorghum, and millet) and pseudocereals (buckwheat, amaranth, quinoa, and teff), rich in valuable proteins, minerals, dietary fibers,

and bioactive compounds, were proposed as GF substitutes [8, 145, 146, 166, 167]. Legumes, nut and carob germ, and chia containing important nutrients have been described as valuable components of GF baked products [168, 169]. Another important approach of the GF production is the addition of animal (dairy and egg proteins) and non-gluten plant proteins (zein), as those substances have both a nutritional and a technological role [156, 170–173]. Nowadays, a number of research have been conducted to evaluate the effect of ITFs on the quality and nutritional properties of GF products.

6 State of Art of Application of Inulin-Type Fructans in Gluten-Free Products

6.1 Inulin

The application of inulin and Jerusalem artichoke in the traditional bread of improved technological properties without compromised sensory acceptance [174, 175] has attracted scientists to explore widely this topic. This interest resulted in a number of researches aimed to utilize inulin in traditional bread making [176–179], as well as in other bakery products such as quick breads (scones) [180], pasta [181, 182], different types of cakes [183–185], muffins [24], biscuits [186], and extruded snacks [187].

Although the application of inulin in baked products resulted in decrease technological parameters (lower volume, darkening of the crust, increased crumb hardness, higher rate of staling), but it improved the palatability and flavor, therefore 5% inulin addition was assumed as a compromise between the improvement in nutritional and sensory quality and decreased technological features [177, 188]. However, a recent study indicated that it is possible to optimize the formulation with even 30% incorporation of fibers without compromising the quality of bread [179]. As a sweetener and fat replacement, ITFs were proposed as additive to gluten-containing confectionery products. Muffins with up to 50% fat substitution with inulin were characterized by increased fiber content, moisture, as well as crumb density and springiness [24]. In cakes, even 70% substitution of fat by inulin was possible, resulting in a product with acceptable sensory properties and reduced caloric value [189]. Incorporation of inulin in wheat pasta allowed to obtain pasta with improved nutritional value, without compromising the sensory and cooking quality [182, 190]. On the other hand, Bustos and co-workers [181] showed that inulin is completely lost during cooking and its incorporation into pasta affects negatively its technological properties.

The successful experience of inulin utilization in the traditional cereal products technology contributed to the development of studies on GF foodstuff. As bread is a staple food, consumed daily by the majority of population, thus the majority of research on GF product refers to it. The supplementation of GF bread with different percent of inulin showed that the amount of incorporated inulin plays the main role in changing the properties of GF bread [191]. Volume of loaves increased with the

increasing share of inulin, reaching even 9% increase in bread with 8% inulin addition. This phenomenon can be explained by high water binding capacity of inulin. Unfortunately, bread fortified with higher amount of inulin (8%) was characterized by reduced crumb cohesiveness and springiness and wrinkled crust classifying inulin-rich GF bread as second-grade quality product [191]. The enrichment of GF bread with inulin significantly ($P < 0.05$) reduced the crumb hardening rate as compared to the control non-fortified GF bread. The lower hardening can be attributed to the slower migration of water from crumb to crust. The results of this study showed that the GF bread preparation enriched with 5% of inulin allows to obtain the product with the highest quality.

Hager and co-workers [192] demonstrated that native inulin from chicory determined the rheological properties of fortified GF batter and consequently the quality of GF bread. Moisture content was 5% higher in the GF formulation fortified with inulin as compared to unfortified controls, suggesting that inulin microcrystals led to formation of a gel structure enclosing large amounts of water. During the formation of gel, water is immobilized in inulin macromolecular zones, enclosing large amounts of water, leading to less elastic and more viscous dough [192]. Rheological and viscoelastic properties of GF bread enriched with inulin were a focus of research of Juszczak and co-authors [193]. In their study, the increasing amount of inulin resulted in lower consistency and paste viscosity of the GF batter. The increase of the viscoelastic compliance values and gelatinization temperatures were also reported. Changes in the rheological properties can be associated with the reduced volume of starch granules and limited friction. Water binding capacity of inulin may reduce the swelling of starch granules affecting their size [193].

Chicory-fortified GF bread was characterized by darker crust being a consequence of Maillard reaction, attributed to a larger number of reducing ends formed due to degradation of inulin [192]. On the other hand, as compared to control, the obtained bread had an increased rate of staling and harder crumb, what can play critical role in the consumer acceptance [192]. Contrary results were obtained by Juszczak and co-workers [193], who reported reduction in crumb hardness in parallel with the increasing amount of the inulin addition, suggesting that it can be a method of extension of shelf-life of GF bread.

The addition of inulin to GF bread fortified with bovine plasma proteins were analyzed by Rodriguez Furlán, and co-workers [194]. The enrichment of GF bread with inulin resulted in decreased moisture loss what was attributed to greater number of hydrophilic groups in the inulin molecule and consequently higher water retention [195]. Reduced moisture loss contributed to delay the staling rate of GF bread. Additionally, the incorporation of inulin improved the quality of GF bread crumb by reducing its hardness [194]. It can be explained by uniformity and stabilization of the air bubbles diameter and decreasing the thickness of the walls surrounding the small air cells. The cracked surface of the crust of GF bread disappeared after inulin addition, making it smoother and the volume of loaves increased [194].

Recent studies of Scarini and co-authors [196] aimed to compare the effect of soluble and insoluble fibers addition on the technological and nutritional properties of GF bread, indicated that inulin used at 5% and 10% substitution level decreased

the dough firmness. Addition of inulin at 10% level resulted in GF bread with less compact crumb and the highest cell area of crumb as compared to control GF and GF breads supplemented with other fibers. The texture of loaves was also influenced by inulin addition with lower firmness and increased specific volume of bread in both inulin-enriched formulation. The proteins digestibility increased in GF bread with 5% substitution and then decreased in bread with 10% inulin level [196].

The popularity of confectionary products and their high amount of sugar motivated scientist to develop modified sweets with higher nutritional quality, including dietary fiber. In GF products, as gluten is replaced with fat and sugar to maintain the texture, the problem of unhealthy sweets is especially important. ITFs as fat and sugar substitute were proposed as additives to GF confectionary products. Maghaydah and co-workers [197] demonstrated that different levels of inulin increased moisture of GF cookies in parallel with increasing share of inulin. Moreover, inulin increased the dietary fiber content in fortified GF cookies. Cookies are considered as a good deliverer of nutritional components, especially for children, because of sweet taste, long shelf-life, and low cost. Additionally, the results showed no impact of inulin addition on sensory quality, including flavor, texture, aroma, and softness as well as the technological properties, especially width, thickness, and spread factor [197].

The effectiveness of application of Jerusalem artichoke powder, containing even 50–60% of inulin in dry mass, as a replacement of both fat and sugar in GF biscuits formulation have been reported by Sharoba and co-workers [198]. Jerusalem artichoke powder was used as 25%, 50%, 75%, and 100% substitution of sugar and corn oil in the GF formulation separately, indicating that inulin enriched product can be successfully replaced control biscuits. The inulin-enriched biscuits were characterized by 29% increase in protein and even fourfold increase in fiber contents than control unfortified GF biscuits. Additionally, the caloric value reduced with the increasing amount of inulin. The mineral content, including calcium, magnesium, and iron was 26, 54% and even twofold higher in inulin-rich biscuits as compared to control. The substitution of oil or sugar lower than 75% did not cause significant changes in both physical and sensory properties of biscuits but allowed them to deliver the recommended daily allowances (RDA) of protein, fiber, and minerals [198].

Gularte and co-workers [199] examined the effect of incorporation of both soluble or insoluble fibers and their mixes into a GF layer cake. The addition of blended soluble (inulin) and insoluble (oat fiber) fibers improved the technological properties, particularly specific volume of the fortified cake. Addition of inulin alone resulted in decreased properties of dough, including density and springiness, and reduced the amount of resistant starch [199]. It is well known that the amount of resistant starch is a parameter of concern in carbohydrate-based products [200].

Recent studies aimed to analyze the rheological parameters of chickpea flour-based GF muffins substituted with different concentrations of different biopolymers, including inulin [201]. Authors reported that an inulin-enriched batter was similar to batter supplemented with wheat protein in terms of heating pattern. The value of loss tangent during non-isothermal heating increased, resulting in more clear decreases in

elastic modulus as compared to dissipative modulus at early stage of heating. Higher values of loss tangent are associated with reduced viscoelasticity of batter [201].

Pasta is a staple food based on starches, being a good source of carbohydrates in human diet. Simplicity of cooking, storing, and handling supports the high popularity of this product. Majority of GF pasta is produced of corn and rice starch. Like other GF products, technological properties and nutritional value of GF pasta are poorer as compared to semolina-based product [9]. Therefore, many researchers have attempted to improve the properties of pasta by incorporation of additives having beneficial effect on texture with simultaneous revised impact of human health.

First, the use of inulin was proposed as a supplement of semolina-based pasta. The nutritional quality of inulin-enriched pasta improved by inhibiting the release of sugar during in vitro starch digestion is what reduced the predicted glycemic index by even 15% in formulation with 10% inulin concentration [202]. Inulin influenced the swelling index but did not affect the cooking loss of pasta, adhesiveness, and elasticity. Moreover, the incorporation of inulin reduced firmness of pasta, owing to the ability of inulin to compete with starch for available water, limiting the swelling and gelatinization of starch granules [202].

Contrary results were obtained in term of GF pasta. Mastromatteo and co-workers [203] prepared GF pasta based on maize starch with addition of inulin up to 20%, and they found that enrichment with 5% and 7.5% of inulin resulted in pasta with the highest values of elongation and shear viscosity. Authors stated that the incorporation of inulin over 12.5% increase the firmness of the pasta dough, and finally, too high share of inulin, amounting 15% and 20%, resulted in pasta with such high firmness that made impossible to conduct rheological analysis. However, the dough preparation might affect the rheological properties. The authors applied a pregelatinization process [203]. Consecutive heating and cooling of starch in water condition results in the breaking of amylose and amylopectin chains, and consequently their rearrangement into a crystalline form. It contributes to the retrogradation of starch and starts physical changes in the dough including higher viscosity, improved gel formation and increased degree of crystallinity and exudation of water [204]. The main difference in the starch retrogradation between GF and gluten-containing pasta can be related with the properties of proteins. Gluten proteins have been shown to have no impact on amylopectin; however, glutenin fraction was found to inhibit the starch retrogradation [205]. In contrast, another fractions of wheat protein, including gliadin, albumin and globulin have the ability to improve the retrogradation process [205]. The sensory analysis of dry and cooked gluten-free pasta enriched with inulin showed that these products had an improved quality, wherein the pasta fortified with 5% inulin was characterized by the best sensorial properties, being the most similar to control pasta [203]; however, the higher amount of inulin in spaghetti was associated with a decrease in sensory score, but these products were still acceptable.

Traditional white sauce is based on the wheat flour; however, people suffering from gluten-related disorders can replace it with non-gluten counterparts, such as rice and corn starches [206, 207]. Authors reported that inulin added to the gluten-

and lactose-free, fat-reduced white sauce based on rice starch improved gelatinization of the starch and reduced the viscosity [206]. Additionally, the high water-binding capacity of inulin inhibited starch degradation and hindered the leaching of amylose. Inulin added to sauce limited the formation of bonds between proteins and starch, and consequently, the sauce was more homogeneous. Another study of the same group of authors showed that also a corn starch-based white sauce can be successfully supplemented with inulin [207]. Inulin-enriched white starch-based sauces were characterized by acceptable sensory quality and stability during refrigerating, therefore they were proposed as a suitable substitute for people suffering from CD and lactose intolerance [206].

Tárrega and co-authors [20] studied the effect of fat substitution with different DP inulin on the quality of custard – creamy dessert based on milk or cream and egg yolk which can include also starch or gelatin. The rheological properties of analyzed custard based on hydroxypropyl-distarch phosphate from Tapioca starch and fortified with inulin significantly differed from whole-fat dessert. However, the inulin-enriched custard was characterized by higher thickness, sweetness, and vanilla flavor perception. The formulation with higher amount of inulin as compared to short-chain FOS (ratio 75:25) gave a product with the best texture and pseudoplasticity [20]. Another studies conducted on custard confirmed that inulin can positively influence texture of dessert, due to the water binding capacity of inulin allowing to maintain the thermally stable complexes [207, 208]. The inulin-enriched desserts were characterized by increase of creaminess and sensation of roughness, the improvement of consistency, and simultaneously the decrement of smoothness [20, 208].

In general, dairy products are naturally GF products consumed all over the world. The beneficial effects of dairy fat on human health as well as on the physiochemical and technological properties of dairy products are commonly known [210]. Recently, consumers are looking for low-fat and low-caloric products without compromising the texture and sensory properties of products. Long-chain inulin, having the ability to form crystals, is used as a texture-creator in low-fat dairy products. This ability was used in the studies conducted on acid casein-processed cheese analogs resulting in improved meltability, density, cohesiveness, and viscosity with simultaneous reduction in hardness and adhesiveness [211]. Another study confirmed that substitution of 10% of fat in cream cheese with inulin allow to obtain the product with chemical features similar to control high-fat cheese but with reduced caloric value [212]. Additionally, inulin incorporated into cheese reduced the rate of syneresis in spreads and fresh cheese [212]. Dave and co-workers [213] reported that the inulin percent of substitution of fat can affect the rheological properties of cheese spreads. They showed that 6% fat replacement result in nonacceptable cheese with a mushy texture. However, increasing concentration of inulin (7% and 8% of fat substitution) caused improvement of the spreadability, reaching the parameters close to a control full-fat cheese [213]. Moreover, inulin was applied to improve the nutritional properties of petit-suisse cheese due to the prebiotic effect [214]. Authors reported that inulin added simultaneously with probiotics resulted in the most promising formulation having the potential health benefit.

The stability of inulin in moderate pH condition was used in studies on fermented milk resulting in the increase in the total solid contents leading to increase of the acidity of fermented product. The modified fermented milk was characterized by higher viscosity as compared to control unfortified milk. Additionally, thixotropy of inulin-rich fermented milk increased in parallel with increasing temperature, while hysteresis decreased [215].

6.2 FOS

Short-chain ITFs are characterized by completely different properties as compared to long-chain inulin; therefore, the effect of their incorporation into GF products is diverse. The influence of the addition of ITFs with different DP into GF bread on the physiochemical properties and staling rate was studied by Ziobro and co-workers [216]. The application of FOS significantly ($P < 0.05$) increased GF bread volume in parallel with the increasing amount of the ITF addition. Authors explained it by the competition for unbound water between short-chain ITFs, consisting of mono- and oligosaccharides, and starch, resulting in the delay of starch gelatinization, and consequently the increase of loaves volume. FOS improved porosity and uniformity of bread crumb and reduced staling rate during storage [216]. The authors concluded that FOS can be successfully used to improve the technological quality of GF bread, while the inulin with high DP can be used in bakery technology only to improve the nutritional value, when the improvement in the structure and mechanical properties in not necessary.

Short-chain FOS is characterized by a higher sweetness which can influence the sensory perception of GF products with their application. The study conducted by Morais and co-workers [217] evaluated the effect of different ITFs on the sensory properties of GF bread, using a quantitative descriptive analysis (QDA) performed by a trained sensory panel or consumer tests of CD patients. FOS-enriched GF bread was characterized by better taste and aroma as well as improved appearance parameters such as porosity, texture, and crust color [217].

Cassava starch is used for making special cheese GF bread, popular in the countries of South America [218]. FOS was proposed as a supplement of this special type of GF bread influencing water absorption index and starch solubility. The pasting viscosity decreased with increasing concentration of FOS in GF bread formulation due to higher solubility of FOS as compared to starch. Authors reported changes in GF cheese bread with 9% FOS addition; however, still this amount was not sufficient to consider FOS-enriched bread as a good source of dietary fiber [218].

Addition of 6% of short-chain FOS into custard improved consistency, viscosity, and elasticity of dessert [20, 208, 209]. However, authors stated that these effects were strongly dependent on the presence of carrageenan. High water-binding capacity of water-soluble FOS contributes to increased viscosity [20]. Sensory analysis showed that FOS-enriched custard is characterized by higher sweetness and intensive flavor [20, 208].

FOS can be also used as sugar substitute in low-caloric yoghurt [219]. The increasing concentration of FOS (up to 8%) affects the physicochemical and rheological properties of yoghurt, increasing thixotropy, viscosity, as well as storage and loss moduli. Texture of FOS-enriched yoghurt has been characterized as a weak gel. The authors evaluated also post-acidification of FOS-supplemented yoghurts showing no changes in acidity, what is desirable in modern yoghurts and concluded that FOS was not utilized by applied bacteria (*Streptococcus thermofilus* and *Lactobacillus bulgaricus*) as a carbon source. Survival analysis of consumer acceptance showed that increasing amount of FOS reduced the sensory quality of yoghurt. The addition of approx. 2.6% of FOS was reported as the most accurate for yoghurts [219].

6.3 Synergy Between Inulin and FOS

As short-chain FOS and long-chain inulin differ in their properties, studies were performed aiming to evaluate the effect of a mixture of both fractions to obtain product with improved properties. Commercially available oligofructose-enriched inulin (Synergy 1) was used in a study on GF bread [220]. In general, the technological properties of GF bread supplemented with Synergy 1 were improved. Irrespective of the amount of fructans added to a formulation, breads have higher specific volume which could be attributed to higher CO_2 retention capacity. Additionally, ITFs containing reducing sugars positively affected the crust color of gluten-free bread, what resulted from the formation of brown nitrogenous polymers and melanoidins as the ends products of Maillard reaction during baking [220]. Moisture of Synergy 1-enriched batter and bread was reduced, leading to faster staling. The authors also confirmed the improvement of the sensory qualities of gluten-free breads fortified with ITFs. Irrespective of the amount of fructans added, the enriched breads received higher scores in terms of appearance, color, texture, and taste. The nutritional quality of GF bread was improved after addition of Synergy 1 in term of higher concentration of dietary fiber and reduced glycemic index (from 71 to 48) and glycemic load (from 12 to 8) in formulation with 12% addition of ITFs [220].

Synergistic effect of FOS and inulin was used also to improve the quality of chocolate dairy dessert [221]. Sensory analysis showed that formulation with 7.5% of ITFs and 0.2% guar gum had the best scores in terms of appearance, aroma, taste, texture, and overall acceptability of chocolate dairy desserts. On the contrary, addition of 10% of ITFs decreased dramatically the sensory acceptance of that product. The study indicated that the moderate concentration of ITFs (7.5%) and guar gum (0.2%) was the most appropriate in term of creaminess of chocolate evaluated using a 9-point just-about-right (JAR) scale [221].

Table 2 Summarized effect of the addition of ITFs with diversified DP on the quality parameters of gluten-free products.

Product	Percent of additive	Effect	Reference
Inulin			
Bread	3–8	Increased loaves volume Reduced crumb cohesiveness and springiness Wrinkled crust Reduced hardening	[190]
Bread	9	Increased moisture Increased specific volume Darker crust Reduced hardness	[191]
Bread	4–12	Lower dough consistency and paste viscosity Increased the viscoelastic compliance values Increased gelatinization temperatures Reduced crumb hardness	[192]
Bread	0.5–3.5 PUFI[a]	Reduced moisture loss Reduced staling Increased loaves volume Improved crumb color and porosity	[193]
Bread	5, 10	Reduced dough firmness Improved porosity Increased specific volume Reduced firmness	[195]
Cookies	3–4.5	Increased moisture Increased content of dietary fiber No influence on sensorial quality	[196]
Biscuits	25–100% sugar and oil substitution	Improved protein and dietary fiber content Reduced caloric value Improved mineral content No influence of physical and sensorial quality	[197]
Layer cake	20 or mixed with oat fiber (1:3 ratio)	Decreased density and springiness (inulin alone) Reduced starch resistance (inulin) Improved specific volume (inulin + oat fiber)	[198]
Muffins	5–15	Heating pattern similar to wheat protein-containing dough Reduced viscoelasticity of batter	[200]
Pasta	2.5–10	Reduced predicted glycemic index Reduced firmness Reduced starch swelling and gelatinization No effect on cooking loss, adhesiveness and elasticity	[201]

(*continued*)

Table 2 (continued)

Product	Percent of additive	Effect	Reference
Pasta	5–20	5–7.5% – improved elongation and shear viscosity Over 12.5% – increased firmness Improved sensory quality	[202]
White sauce	2.5	Improved gelatinization Reduced viscosity Reduced starch degradation Improved homogeneity	[205, 206]
Custard	7.5	Increased thickness, sweetness and vanilla flavor perception Improved texture and pseudoplasticity Increased creaminess and smoothness	[20, 207, 208]
Cheese analogs	1–3	Improved meltability, density, cohesiveness, viscosity Reduced hardness and adhesiveness	[210]
Cream cheese	8–12	Cheese with reduced caloric value but with properties similar to full-fat cheese Reduced syneresis rate	[211]
Cheese	6–8	Mushy texture (6%) Improved spreadability (7–8%)	[212]
Petit-suisse cheese	10	Stimulation of growth of probiotic bacteria	[213]
Fermented milk	5	Improved viscosity Increasing thixotropy and decreasing hysteresis parallel with increasing temperature	[214]
FOS			
Bread	3–8	Increased loaves volume (5–8%) Increased hardness (5–8%) Decreased volume and hardness (3%)	[190]
Bread	4–12	Increased loaves volume Delayed starch gelatinization Improved porosity and uniformity Reduced staling	[215]
Bread	0.75	Improved sensory characteristic in terms of taste and aroma Improved porosity, texture and crust color	[216]
Cheese bread	9–29	Increased starch solubility and decreased water absorption index Decreased specific volume	[217]
Custard	7.5	Improved consistency, viscosity and elasticity Higher sweetness and intensified flavor	[20, 207]
Yoghurt	2–8	Increased thiotrophy and viscosity Reduced texture Reduced sensory perception	[218]

(*continued*)

Table 2 (continued)

Product	Percent of additive	Effect	Reference
Synergy 1			
Bread	4–12	Reduced moisture Increased volume and specific volume of loaves Darker crumb and crust color Reduced glycemic index and increased dietary fiber content Improved sensory perception	[219]
Chocolate dairy dessert	5–10	Acceptable sensory properties and creaminess	[220]

[a]A formulation of ultrafiltred and freeze-dried bovine plasma with the addition of inulin (63%)

7 Conclusions

The increasing demand on high-quality GF products and an increasing prevalence of GF consumers favors the development of research aimed to improve the overall quality of GF products. The literature data on the application of ITFs in the GF products and on their health beneficial properties, as presented in this chapter, points to a great potential of ITFs in the GF living. In this chapter, we have presented the most recent studies on GF products in which ITFs were applied as valuable ingredients affecting the rheological and technological parameters of GF products (Table 2). ITFs added to GF products interact with other ingredients and additives, but, in general, they improved the sensory perception of obtained GF products. The evidences of beneficial impact of ITFs on characteristic of GF goods presented in this chapter are promising and therefore, could contribute to further development and intensified research on new GF products of superior quality that will be dedicated to people suffering from gluten-related disorders.

Abstract

As a source of proteins having high biological value, essential nutrients like minerals, vitamins, and surfeit of bioactive compounds, meat is considered as an ideal food for masses. With the advancement of technology and change in socioeconomic status, the consumers have housed high preference for processed and value-added meat products. These products generally lack nutrients like complex carbohydrates that include dietary fiber. Fiber is considered as an important component in diet owing to its multifarious utilities as cardioprotective, weight reducer, management of diabetes, antioxidant, and stress reliever. Its inclusion in diet has been stressed in many studies and incorporation in products particularly high energy-dense products like meat is imperative. For adults, the recommended acceptable intakes of dietary fiber are 28–36 g/day and out of that, 70–80% must be insoluble fiber. Apart from acting as an integral fraction of diet, dietary fiber performs many functions in meat products, viz., improvement in yield, desirable processing attributes, fat reduction, texture modification, etc. Being a by-product of agriculture, these fiber sources are comparatively cheaper and its inclusion on meat products helps in reducing its overall cost of production. Thus, the inclusion of fiber in meat products helps in improving processing and technological functionality with proven health benefits for consumers.

1 Introduction

An increasing awareness among people regarding their health and well-being has propelled the research in food science to a new level. The inclination to natural sources has been increased in recent times owing to many nutritional diseases of affluence that have posed a challenge to both processors as well as medical professionals [1]. However, rapid urbanization and globalization has introduced ready-to-eat, ready-to-cook, and packaged processed products on consumer's platter. These products are rich in fat, salt, and calories but are highly deficient in dietary fiber. Earlier, unrefined grains and vegetables which contain a significantly high amount of fiber were an essential dietary component but the industrial revolution brought a dynamic change in lifestyle resulting in removal of key components from diet, particularly fiber [2]. The extensive study of dietary fiber in recent times could be directly attributed to its multifunctional roles. An improvement in technological and processing characteristics of products along with beneficial physiological effects like lowering blood sugar, cholesterol, improving cardiac health, etc., led the researchers to search new sources of fiber which can be readily incorporated in food products [3].

Meat is considered as a nutrient-dense food item with a high amount of protein, fat, minerals, and vitamins that have a comparatively better bioavailability than other

food stuffs [4]. However, a damaging crusade against meat as a culprit for many health hazards has blemished its image to great extent. The deficiency of complex carbohydrates like dietary fiber in meat has been implicated with an increase in number of diseases like colon cancer and cardiovascular diseases [5]. A solution that has been proposed is enrichment of meat products with various fiber sources. It will not only lead in designing meat product with desired nutritional attribute but also a superior technological advantage attributed to characteristic features of fiber like water- and oil-binding capacity in addition to antioxidant function [6]. A number of studies have already been carried out by using fiber alone or in combinations for formulation of various categories of meat products [7, 8]. This chapter highlights about the functionality of dietary fiber, its physiological and technological significance with a major emphasis on its application in meat products.

2 Dietary Fiber: Definition and Classification

Since 1953 when Eben Hipsely first coined the term dietary fiber, its definition has been revised many a times and till date it is evolving. Initially referred to as unavailable carbohydrate content in foods that lowered the rates of pregnancy toxaemia [9], it included lignin, cellulose, and hemicellulose. Later, investigations regarding correlation of disease incidence and fiber intake led the researchers to recommend increased stool volume and softness through higher dietary fiber intake and hence a new definition was proposed [10]. The most unswerving definition was proposed by Trowell [11] that dietary fiber consists of plant components resistant to digestion by enzymes in alimentary canal of humans, and it includes cellulose, hemicellulose, lignin, oligosaccharides, pectin, gums, and waxes. So thereafter, a categorization of carbohydrates into two basic groups depending upon their digestibility in GIT was done. The first group included starch, fructans, and simple sugars that are easily hydrolyzed and absorbed in small intestine. They are sometimes referred to as nonstructural or nonfibrous polysaccharides. The second group included cellulose, hemicellulose, lignin, and pectin, that are resistant to hydrolysis in small intestine, and are referred to as nonstarch polysaccharides or structural carbohydrates. Contemporary definition of dietary fiber has been proposed by American Association of Cereal Chemists (AACC) and Codex Alimentarius Commission (CAC). According to AACC, 2001, "Dietary fiber refers to the edible part or analogous carbohydrates that are resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine. According to this definition dietary fiber includes polysaccharides, oligosaccharides, lignin, and associated plant substances. Dietary fibers promote beneficial physiological effects including laxation, and/or blood cholesterol attenuation, and/or blood glucose attenuation" [12]. The latest definition proposed by CAC states that dietary fiber are carbohydrate polymers with degree of polymerization not lesser than 3 and are resistant to digestion as well as absorption in small intestine. Further, it possesses properties like capability to increase stool bulk by decreasing intestinal transit time,

reduction of cholesterol, and postprandial glucose levels and fermentable by intestinal microbiota [13].

Dietary fiber can be classified in a number of ways such as on the basis of source from which they are derived (plant, animal, or synthetic), structure (linear, nonlinear, or branched), or solubility. The most acceptable classification is on basis of enzymatic fermentation behavior in a simulated system of that of human alimentary canal. It can be divided into two broad categories, viz., soluble dietary fiber (SDF) and insoluble dietary fiber (IDF). Insoluble fiber comprises cellulose, part of hemicelluloses, and lignin, whereas, soluble fiber constitutes pectins, gums, pentosans, and mucilage [16, 17].

Various components of dietary fiber are presented in Table 1 and classification of fiber on basis of solubility is presented in Table 2.

Cellulose: Cellulose is an unbranched chain of β(1→4) linked glucose monomers and is the most abundant polysaccharide found in nature which forms major constituent of cell walls in green plants and vegetables. The close packing of linear polymers renders it mechanically strong, water insoluble, and resistant to digestive enzymes in human gut. However, a partial microbial degradation in the large intestine may produce beneficial short chain fatty acids. It has an ability to bind water, thereby, increase fecal bulk, and relieve constipation. Two different components of cellulose had been studied by Aspinall [19] on basis of relative hydrolysis. The major portion of cellulose is crystalline component that has noncovalent hydrogen bonds responsible for its immense mechanical strength, resistance to degradation by gut microbes, and water insolubility. Whereas, the amorphous component constitutes a minor portion, i.e., 10–15% and is readily hydrolysable.

Hemicellulose: Similar to cellulose, these are also integral component of plant cell wall. It consists of chain of β(1→4) linked glucose monomers which are smaller in size than cellulose, usually branched and contain a number of sugar moieties like pentose (xylose and arabinose) and hexose units (mannose, galactose, rhamnose) [3, 20]. The main function in human system is binding of cholesterol and promotion of smooth bowel movements.

Lignin: It is a complex polymer that consist about 40 oxygenated phenylpropane units including coniferyl, sinapyl, and p-coumaryl alcohols that have undergone a complex dehydrogenative polymerization [21, 22]. Variable molecular weight and inertness owing to strong intamolecular bonding are characteristic features of this polymer.

Pectin: Composed of galacturonic acid chains connected with α(1→4) bonds, this linear polymer forms important structural component of plant cell wall and outer skin of fruits and vegetables. It is highly water soluble polysaccharide which is easily degraded by the microflora of the colon. A unique gel-forming capability of pectin makes it an ideal constituent of health foods as it decreases the rate of gastric emptying, improves cholesterol and lipid metabolism [23], and prevents and control diabetes in human beings [24]. Further, technologically it is applied in food as a gelling and thickening agent.

Hydrocolloids: It includes a wide range of polysaccharides that are viscous in nature. Majorly formed in secretory cells of plants, these are highly branched and

Table 1 Various components of dietary fiber [1, 14, 15]

Fiber components	Principal groupings	Description	Fiber sources
Nonstarch polysaccharides and oligosaccharides	Cellulose	Principal structural component of cell wall in plants; β-(1, 4) glucose polymer chain; soluble in concentrated acids	Cellulose plants (vegetable, sugarbeet, various brans)
	Hemicellulose	Polysaccharides in cell wall with β-(1, 4) glycosidic linkage	Arabinogalactans,β-glucans, arabinoxylans, glucuronoxylans, xyloglucans, galactomannans, pectic substances
	Polyfructoses	A polysaccharide of fructose that may contain some other sugars too, e.g., β-(2–1)-D-fructosyl-fructose	Inulin, oligofructans
	Gums and mucilages	Secreted by plants at site of injury; may contain rahmnose, arabinose, xylose, galactouronic acid, mannuronic acid, etc.	Seed extracts (galactomannans – guar and locust bean gum), tree exudates (gum acacia, gum karaya, gum tragacanth), algal polysaccharides (alginates, agar, carrageenan), psyllium
Carbohydrate analogues	Pectins	Cell wall components with D-galactouronic acid polymer chains; homogalactouronan, rhamnogalactouronan, xylogalactouronan, etc.	Fruits, vegetables, legumes, potato, sugarbeets
	Resistant starches and maltodextrins	Starch and starch degradation products; contain α-(1,4)-D-glucose polymer chain with α-(1,6)-D- glucose branching	Various plant such as maize, pea, potato
	Chemical synthesis	Synthetic in nature	Polydextrose, lactulose, cellulose derivatives
	Enzymatic synthesis	Produced by enzymatic hydrolysis; may possess prebiotic properties	Neo sugar or short chain, guar hydrolysate fructooligosaccharides, levan, xanthan gum, transgalactooligosaccharides, oligofructose, xylooligosaccharide, curdlan
Lignin	Lignin	Noncarbohydrate cell wall component that resists bacterial degradation; polyphenols like	Woody plants

(*continued*)

Table 1 (continued)

Fiber components	Principal groupings	Description	Fiber sources
		syringyl alcohol, guaiacyl alcohol as main chain	
Substances associated with nonstarch polysaccharides	Waxes, cutin, suberin	Protective in nature too	Plant fibers
Animal-origin fibers	Chitin, chitosan, collagen, chondroitin	Glucosamine linkages may be present	Fungi, yeasts, invertebrates

Table 2 Classification of dietary fiber on basis of water solubility [18]

Class	Examples
Insoluble	Cellulose
Soluble (only in hot water)	Agars, amylose, algins, kappa-type carrageenans (in the presence of K^+ or Ca^{2+}), gelan, konjac, mannan, locust bean gum, low-methoxyl pectins, granular starches, and starch derivatives
Soluble (in water at room temperature but insoluble in hot water)	Curdlan, hydroxylpropyl celluloses, hydroxylpropyl methylcelluloses, and methylcelluloses
Soluble (in water at room temperature and hot water)	Alginates, amylopectins, carboxymethyl celluloses, dextrins, iota-type carrageenan, guar gum, gum Arabic, high-methoxyl pectins, polydextrose, and xanthan gum

bind with water to form gels. This property is utilized in food systems as a gelling agent and thickener, e.g., gums, mucilage, and seaweed extracts (agar, alginate, carrageenan, etc.). The physiological effect of hydrocolloids is exerted by its enzymatic hydrolysis owing to higher soluble fraction of dietary fiber. It is widely used as cholesterol lowering and weight reducing component in diets.

Resistant starches (RS): Starches that escape the enzymatic degradation in small intestine are referred to as resistant starch. Divided into four categories, it has a wide application in food matrix. Type 1 (RS1) is made up of starch granules that are encapsulated by an indigestible plant matrix rendering it physically inaccessible and heat stable [25]. Type 2 (RS2) occurs in its native form such as in an uncooked potato and are resistant to enzymatic hydrolysis due to its compact structure. Type 3 (RS3) represents the most resistant form and are crystallized starches made by unique cooking and cooling of gelatinized starch. Type 4 (RS4) is a starch consisting of chemical bonds other than α-(1,4) and α-(1,6). The chemical modification is induced by esterification, crosslinking, or transglycosylation and is responsible for its limited digestibility in human gut [26].

Nondigestible oligosaccharides: They are found naturally in plants, fruits, and cereals and are synthesized by polymerization of monosaccharides or disaccharides.

They perform similar physiological functions as that of dietary fiber and are highly fermentable in intestine, e.g., fructo-oligosaccharides and galacto-oligosaccharides. Due to their prebiotic properties, its application in food systems is quite promising.

3 Analysis of Dietary Fiber: Methodologies and Modifications

The analytical methods of dietary fiber estimation is varied and have been modified with time. Weende system started way back in nineteenth century and is still adopted in many industries to determine fiber content. The proximate system of analysis relies on determining carbohydrate content by difference. Further through successive acid and alkaline digestion, the extraction of crude fiber was done, but the crude fiber makes up only very small part of whole dietary fiber. During acid–base treatment, hemicellulose and lignin loss occurs, and hence the total fiber is underestimated. Later, with the advancement of chemical analytical protocols, different solvent methods were employed for extraction and measurement of dietary fiber from foods [27]. The protein and starch are removed with various solvents, leaving behind undigested fiber. These methods are divided into many subtypes based on type of solvent used e.g., alcohol insoluble fiber extraction, neutral detergent method, and acid detergent method. The neutral detergent method measuring insoluble fractions and lignin provided a reliable methodology for estimating fiber fractions [28]. However, the relative disadvantage of solvent extraction methods is that there can be damage to the fiber during processing by solvent at many stages, leading to underestimation of total fiber. Currently, the estimation of dietary fiber in foods is carried out by three different methods, viz., nonenzymatic-gravimetric, enzymatic-gravimetric, and enzymatic-chemical. However, enzymatic-gravimetric Association of Official Analytical Chemists (AOAC) method and enzymatic-chemical method are predominately used [29, 30]. Enzymatic-gravimetric method was first introduced by Schaller [31] wherein he presented amylase treatment in preexisting methodology of Van Soest [32]. Later, Prosky et al. [29] adapted the method for insoluble and soluble fractions which is still in use. This method determines mainly a group of polysaccharides, lignin, and some of associated compounds like waxes. The enzymatic treatment removes starch and protein along with precipitation of soluble fiber components by organic solvents. The main disadvantage of this method is that oligosaccharides and some of resistant starches are not quantified, which has been rectified by McCleary et al. [33] in their modified method of fiber determination.

The enzymatic-chemical methods also involve removal of starch and protein as a first step. Thereafter, precipitation with ethanol or dialysis ensures separation of SDF fraction from hydrolyzed starch and sugars [34]. The neutral sugar contents are determined by GLC or HPLC, whereas, total sugars are computed spectrophotometrically. Filtration is carried out to get the residue after hydrolysis of total polysaccharides and quantified as Klason lignin. The nonstarch polysaccharide and Klason lignin in combination gives total dietary fiber value in addition to separate quantification of SDF and IDF contents.

Additionally, mixed treatment methodology for determination of total dietary fiber content yields better results than any single treatment. It involves chemical, mechanical, enzymatic, and microbial fermentation methods in proper combinations. Zong Cai et al. [35] reported that microbial fermentation improved the content of SDF by 15% when used alone, whereas, the yield increased to 35% when used in combination with microfluidization. So, the hybrid methodologies perform better in extraction and separation of dietary fiber constituents than a single treatment process [27].

4 Physiological Benefits and Health Implications of Dietary Fiber

A strong link has been established between dietary fiber consumption and human health through a number of studies carried out on human subjects. A correlational analysis through independent observational studies helped in zeroing down on concept of dietary fiber's role as a potential disease-preventing nutrient [36, 37]. However, the mechanism through which fiber exerts its effect depends mainly on type and composition of that fiber.

(a) **Dietary fiber and cardiovascular health:** Cardiovascular diseases are reported to be the most common cause of death around the globe [38]. Basically, it is a group of etiologies that includes coronary heart disease, hypertension, arrhythmias, strokes, and heart failure [39]. The role of fiber in preventing cardiovascular disease is multifaceted. It acts as reducing agent of hyperlipidemia and hypocholesterolemia through interfering with lipid or bile acid metabolism [2, 40]. Babio et al. [41] reviewed the different sources of dietary fiber on lipid profile and concluded that intake of highly viscous dietary fiber results in decreasing LDL-cholesterol. Highly fermentable dietary fiber like pectin, gums, mucilage, etc., produce short-chain fatty acids (butyric, acetic, propionic), and it further results in rejuvenation of microbiota and reduction in intestinal inflammation which leads to further lowering down of cholesterol in body. On similar lines, Zhang et al. [42] established cholesterol lowering effect of oat bran in ileostomized hypercholesterolemic individuals. Lowering of serum total cholesterol and LDL-cholesterol by 4% and 6%, respectively has been reported by supplementing diet with psyllium [43]. Other mechanisms that have been suggested include inhibition of hepatic lipoprotein production and cholesterol synthesis by fermentation products of dietary fiber. This may lead to increased insulin sensitivity [44]. The dietary fiber may also directly interact with lipase enzyme resulting in reduction of its activity [45], bind with bile salts, thereby preventing lipid emulsification and its absorption in small intestine [46], may act as a barrier between lipase enzyme and fat droplet by forming a protective covering around it [47] or by increasing aqueous phase viscosity leading to disturbance in lipid droplet coalescence and disruption in stomach and intestine [48]. Dietary fiber may also interact with bile acids in small intestine resulting in

lower reabsorption and higher excretion of fat including cholesterol [49]. Further, it may also alter micelle formation and simultaneously limit incorporation of cholesterol in that micelle [50].

(b) **Maintenance of gut health:** Major carbohydrates that reach the intestine and exert their beneficial action are nonstarch polysaccharides, some polyols, resistant starch, and nondigestible oligosaccharides [51]. Dietary fiber undergo fermentation in the large intestine particularly, colon resulting in production of favorable short-chain fatty acids (SCFA), primarily, acetate, propionate, and butyrate. They play a key role in maintaining gut health. Butyrate is preferential fuel for colonocytes that forms a protective lining in colon [52]. Also, SCFA result in lowering pH of colon leading to inhibition of growth of pathogenic microorganisms [53, 54]. The fermentation mass in colon further results in increase in fecal volume and output. Further, absorption of water by dietary fiber adds to fecal buildup [55, 56]. Increased bulk of feces decreases colonic transition time and prevents constipation and production of carcinogenic compounds [57]. Some of the fiber exhibit prebiotic properties, e.g., inulin and fructo-oligosaccharides (FOS) that encourage and stimulate growth of beneficial bacteria like lactobacilli and bifidobacteria in the gut [58]. Dietary fiber also plays a key role in the maintenance of gastrointestinal immunity through increasing T-cell mitogen response and stimulating gut-associated lymphoid tissue (GALT) [59].

(c) **Dietary fiber and its role in prevention and management of diabetes:** Prospective cohort epidemiological studies have concluded a direct link between consumption of fiber in diet and reduction in prevalence of diabetes. Management of type 2 diabetes majorly revolves around glycemic control. Intake of low-glycemic index (GI) diets will control hyperglycemia, and all the fiber-rich diets are low GI in nature. Several events leading to decrease in blood glucose level after consumption of fiber are explained by a number of workers. Lowering of postprandial glucose peak, which leads to decreased insulin demand, and over-exhaustion of the pancreas is facilitated through consumption of fiber. Delayed gastric emptying after consumption of soluble fiber results in lower postprandial glucose and insulin levels and higher consumption of insoluble fiber reduces absorption of carbohydrates in GI tract by increasing passage rate of foodstuffs in gut [60]. Kelley and Mandarino [61] reported that increase in free fatty acids in blood may result in alteration of glucose metabolism through inhibition of GLUT-4 transporters. However, the SCFA produced by dietary fiber in gut results in decrease in serum free fatty acid and may further reduce blood glucose levels. Dietary fiber could limit the transportation of glucose to intestinal absorptive surface by producing contractions and thus result in decreasing postprandial glucose peak [62]. Another mechanism through which dietary fiber can result in preventing diabetes is by stimulating postprandial insulin release via accelerating secretion of incretin hormones, i.e., GLP-1 and GIP and by increasing insulin sensitivity in the tissues [63, 64].

(d) **Dietary fiber and cancer:** Anticarcinogenic and antitumorigenic effects of dietary fiber are well-documented and supported by research on human subjects.

Fermentation of fiber by colonic bacteria results in the production of SCFA which are recognized to be potential players in slowing growth and increasing apoptosis in colon cells. Further, they have a role in decreasing mutations and cancer risk by activation of different drug-metabolizing enzymes [65]. Tang et al. [66] ascertained the relationship between dietary fiber intake and reduction in risk of esophageal cancer in Xingjiang, China, through case-control study. The regular intake of fiber was found to be inversely associated with esophageal cancer risk. Another mechanism proposed for role of fiber in countering cancer risk is that fiber adds to fecal bulk and thereby decreases the interaction between intestinal mucosa and cancer-risk agents present in feces [67]. Also, decrease in intestinal transit time will reduce the production of pathogenic bacteria in colon and eventually limit the production of carcinogens [68].

(e) **Dietary fiber and weight management:** A major predisposing factor for CVD and diabetes is excess weight and obesity. A number of studies have established a strong negative correlation between fiber intake practices and weight control in human subjects. Miller et al. [69] established effect of diet on fat content in body and reported that lean subjects had a higher fiber intake than their obese counterparts. The mechanism that have been proposed for role of fiber in decreasing weight is that it absorbs water and adds bulk resulting in satiety [70]. Hyperinsulinemia that leads to lipogenesis and increased incidence of obesity may also explain the role of fiber in weight management [2]. Fiber-rich diets delay gastric emptying, resulting in slower rate of absorption, and subsequently lesser gain of weight. Sakata [71] proposed that diets rich in fiber may increase chewing time and efforts resulting in various cephalic- and gastric-phase signals and early satiation. It is an established fact that fibers help in controlling and managing weight and subsequently root out the chances of associated ailments like CVD and diabetes.

(f) **Dietary fiber and mineral bioavailability:** Some fiber sources regulate the absorption of minerals in the gut which further affects overall ionic balance in the body. Soluble dietary fibers like pectin, certain gums, etc., helps in the absorption of minerals like calcium, iron, and magnesium [72, 73] by producing SCFA and decreasing intestinal luminal pH [74] and proliferation of epithelial cells in the caeco-colon [75]. Both these factors may lead to enhanced dissolution of insoluble minerals salts in colon. Further, fiber absorbs water and increases its content in colon, solubilize the minerals, and enhance absorption through permeable gut membrane [76].

5 Technological Functionality of Dietary Fiber

For the development of dietary fiber enriched meat products, the technological properties of incorporated fiber play a key role. Apart from providing all the possible health benefits discussed in previous section, fiber sources possess attributes that help in modifying the physicochemical characteristics of meat products. This may

pose a new way for designing and developing meat products for enhanced consumer acceptability.

(a) **Hydration properties and oil-binding capacity:** Water absorption, water-holding capacity (WHC), and swelling are the parameters that encompasses hydration properties of dietary fiber. Water absorption is dependent on substrate pore volume [77] and is determined by water uptake as measured by Baumann apparatus [78]. The amount of water retained by known weight of dietary fiber at specified time and temperature conditions refers to water-holding capacity of that fiber. Due to hydrophilic nature of polysaccharides, fiber holds water molecules in void spaces. This property of dietary fiber is largely dependent on its source, e.g., fiber from cereal by-products have lowest affinity whereas soluble fibers from algae have highest affinity. Other than this, the structure of dietary fiber, percentage of soluble fraction, and presence or absence of charged groups are major determinants of hydration properties. Also, fiber possesses capacity to hold oil that may help in designing novel functional meat products. Oil-holding capacity (OHC) is dependent on surface properties of fiber, overall charge density, and hydrophillicity [79, 80]. Dietary fibers with high OHC may be useful in stabilizing meat emulsion, whereas, superior WHC ensures higher product yield, juiciness, and calorie and salt control in meat products. Further, it may be used as a texture and viscosity modifier in emulsion-based meat products.

(b) **Solubility:** On the basis of degree of solubility in water, fiber may be categorized into insoluble and soluble dietary fractions. The regularity in the structure of polysaccharides decides its fate for enzymatic degradation. Higher degree of irregularity, e.g., β- glucan renders weak linkages in structure and fiber is prone to enzymatic degradation resulting in easy solubilization whereas, regular structure leads to insolubility of fiber, e.g., cellulose. The technological functionality differs for both fractions. Soluble fiber tends to increase viscosity, gel strength, and emulsification as compared to insoluble fiber. As a result, meat product incorporated with SDF is juicy, has a higher cooking yield, and emulsion stability with soft texture. Insoluble fraction tends to increase hardness in meat products with a concurrent reduced gel strength. So, as per the product attributes and demands, the type of fiber to be incorporated may be decided by processors.

(c) **Viscosity:** Ability of dietary fiber particularly SDF to form gels and resist flow behavior determines its viscosity. It is one of the most important technological functionality of fiber that determines its application in various categories of meat products. Water soluble fiber increases viscosity of solution and vice versa [81].

(d) **Antioxidant Properties:** Countering free radicals and delaying lipid peroxidation is one of the most important functionality of dietary fiber, particularly, nonstarch polysaccharides (NSP). It has been reported that several fractions of rice bran possess superior antioxidant properties [82] which are equally effective as ascorbate. This property may be utilized for the extension of storage life of meat products without any addition of synthetic antioxidants.

6 Effect of Fiber Addition on Physicochemical Properties of Meat Products

Effect of addition of dietary fiber in meat products can be visualized through series of change in their functional properties. Different sources of fibers and their possible effects on meat products is summarized in tabulated form (Table 3). Various physicochemical properties, viz., pH, water-holding capacity, cooking yield, etc., are profoundly affected by incorporation of dietary fiber. This in turn affects the processing characteristics of meat products, e.g., an increase in emulsion stability by addition of fiber sources in meat holds immense importance from technological and economic perspective. Further, the change in pH due to fiber source addition affects the overall quality characteristics.

The change in pH of the meat product after addition of fiber is largely dependent on the pH of fiber source. The citrus by-products have comparatively lower pH and when incorporated in meat products, the pH drops significantly. Alesson-Carbonell et al. [83] reported that addition of lemon albdeo in nonfermented dry cured sausages resulted in a decrease in pH owing to the organic acids present in raw albedo. Similarly, with the addition of peach dietary fiber suspensions in low-fat frankfurters, viscosity of meat batter increased. Further, a decline in pH was observed and the decrease was prominent as the level of inclusion of peach dietary fiber increased [84]. Incorporation of *kinnow* rind powder in goat meat patties resulted in lower pH of products as compared to control [85]. On the contrary, Fernandez-Lopez et al. [86] found that there was no decrease in pH in Spanish dry-fermented sausages incorporated with orange dietary fiber. Apart from citrus by-products as a source of fiber in meat products, many other sources have resulted in pH change in different classes of meat products. Yilmaz [87, 88] added different levels (5, 10, 15, and 20%) of rye and wheat bran in low-fat meatballs and observed an increase in pH value as compared to control. Similar findings have been reported by Rao and Reddy [89] and Talukdar and Sharma [90] in chicken loaves and chicken meat patties incorporated with gram flour and wheat and oat bran, respectively. However, Mehta et al. [91, 92] reported that addition of psyllium husk in chicken meat patties and rolls had no significant effect on pH. Similarly, Caceres et al. [93] and Wu and Lin [94] reported that soluble fiber didn't affect the pH of meat products and it was similar to control.

Water-holding capacity is another parameter that is technologically significant in the development of functional meat products. Ability to retain its own or added water ensues increase in emulsion stability and cooking yield. Tunisian beef sausages incorporated with three dietary fibers, namely, VITACEL LC 200, barley beta-glucan concentrate, and VITACEL KF500 potato fiber were developed and its physicochemical properties were studied [95]. The fiber displayed high water and oil-binding capacity resulting in an overall increase in water-holding capacity (WHC) of beef sausages. However, no significant effects ($P > 0.05$) on a_w values was observed. A significant decrease in cooking loss was also observed with an increase in amount of fiber in beef sausages. The reduction in diameter of sausages in

Table 3 Various fiber sources in formulation of meat products and their effects

Type/source of fiber	Type of meat product	Major effects on meat products	References
Highly soluble fiber sources			
Fructo-oligosaccherides	Fermented cooked sausages	40% reduction in fat content Improvement in technological and sensory properties of sausages	[104]
	Sausages	Cooked sausages with 35% less energy value and high amount of soluble dietary fiber without adverse impact on sensory properties Fat reduction close to 40% was obtained	[93]
	Dry-fermented sausages	Fiber had no effect on physicochemical parameters and microbiota evolution during ripening Decrease in lightness value for color and hardness value for texture was observed	[105]
Psyllium husk	Chicken patties	Significant increase in dietary fiber content Increase in emulsion stability and cooking yield Cholesterol content of meat product was decreased significantly	[91]
	Chicken meat rolls	4% level of incorporation of psyllium husk was found to be optimum Decrease in moisture, protein, and fat content of chicken rolls with fiber Fall in texture and tenderness scores on sensory evaluation	[92]
Inulin	Low-fat bologna sausage	With addition of fiber, increase in moisture and decrease in fat content Significant change in textural attributes than control	[106]
	Pork loaves	Improvement in processing quality and functionality of loaves Significant increase in cooking yield and emulsion stability Crude fiber increased by 250% in treated products	[107]
	Sausages	Addition of inulin did not increase crude fiber and textural properties in sausages	[108]
	Mortadella	Textural properties revealed increased hardness values even at lowest concentration of 2.5% Improvement in sensory scores as compared to control	[109]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
	Veal meatballs	Lower concentration of fat and total trans fatty acids as compared to control Meatballs with 20% inulin had lowest moisture, salt, and redness value but highest ash and protein contents	[110]
	Water-boiled sausage	Reduction of fat from 43 to 52% without any loss to sensory quality	[111]
	Cooked meat batters	Better emulsion stabilization with creamy and softer texture	[112]
	Low-fat dry-fermented sausages	Decrease in total calorie counts without any change in sensory acceptability	[113]
Pectin	Cooked ham	Increase in sensory acceptability with addition of fiber	[114]
Alginate	Sausages	Reduction in fat without compromising sensory attributes	[115]
Carrageenan	Mutton kofta	Reduction in fat content with an increase in protein, ash, and carbohydrate content Soft texture with low free fatty acid content	[116]
Konjac flour	Frankfurters	Treated products were better on sensory acceptability scores Better shelf life than high fat control	[117]
Cereals and bran			
Wheat bran	Meatballs	Product with lighter color than control High ratio of unsaturated to saturated fatty acid content	[88]
	Beef patties	Increase in hardness and gumminess of product but decreased springiness and cohesiveness Decrease in protein and increased fat content of cooked beef patties	[118]
	Chicken patties	Increase in water-holding capacity and emulsion stability Higher cooking yield, firmness, total dietary fiber, and unsaturated fatty acid content, whereas, lower sensory attributes, moisture, protein, fat, and cholesterol contents	[90]
Rice bran	Kung-wan: an emulsified pork meatball	Decrease in protein and fat content, however, an increase in carbohydrate content	[119]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
		Decrease in textural parameters of hardness, gumminess, and chewiness Sensory acceptability up to 10% level of inclusion	
	Meat batter	Increase in emulsion pH, emulsion stability, and cooking yield Viscosity of batters containing fiber was higher than control Hardness, cohesiveness, gumminess, and chewiness increased in fiber-added meat batter	[120]
	Emulsion-type sausages	Increase in moisture, fat, and pH Sausages with 3% rice bran had lowest cooking loss and 4% rice bran were hardest in textural analysis	[121]
	Pork meat batter	Increase in emulsion stability and cooking yield Increase in moisture, protein, ash, pH values, yellowness value, textural parameters, viz., hardness, gumminess, chewiness, cohesiveness, and viscosity of meat batter	[122]
	Meat emulsion	Increase in moisture and ash content and yellowness value, cohesiveness, gumminess, chewiness, and sarcoplasmic protein solubility Reduction in total fat content in product	[123]
	Low-fat frankfurters	Increase in moisture and ash content Reduction in fat, cholesterol, energy, and trans-fat levels Increased pH, cooking yield, and TBA values	[124]
	Pork protein gel	Addition of rice bran fiber at 1% level increased moisture, myofibrillar protein solubility, and water-holding capacity Decrease in lightness, redness, and textural values No change in protein on SDS gel electrophoresis	[125]
	Chicken rolls and patties	Decrease in sensory scores of meat rolls and patties with addition of rice bran and psyllium husk combination	[126]
Rye bran	Meatballs	Decrease in total fat, total trans fatty acids, moisture, salt content, weight losses, and redness value	[87]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
		Increase in protein, ash, lightness, and yellowness values	
	Meatballs	Due to particulate nature, rye bran was found to be the best fiber source in meatballs as compared to oat bran and barley fiber No significant difference in firmness as compared to reference after pan frying	[127]
Oat bran	Low-fat beef burgers	Decrease in shear force values with increase in level of fiber	[128]
	Chevon patties	With the increasing level of oat bran, decrease in moisture, protein, and fat content but an increase in ash and total dietary fiber content Increase in concentration of unsaturated fatty acids and decrease in cholesterol, cooking loss, and shear force	[129]
	Light bologna and fat-free frankfurters	Increase in product yield, lightness, and hardness value Decrease in redness value and purge at 3% concentration	[130]
	Meatballs	Substitution of fat by fiber source and it decreased concentration of total fat and trans fatty acids With the increase in amount of oat bran (5%–20%), moisture and fat content decreased and protein and ash content increased No significant effect on sensory properties by fiber addition	[131]
	Beef patties	Significant improvement in cooking yield, fat retention, and moisture content Higher juiciness perception as compared to control	[132]
Oat flour	Beef patties	Decrease in moisture content of raw patties but increased after cooking No effect on protein, ash, and fat content Improvement in cooking characteristics with simultaneous decrease in lightness value No adverse effects on sensory properties	[133]
	Mutton kofta	Decrease in fat content whereas, an increase in moisture, protein, ash, and carbohydrates.	[134]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
		Significant increase in cooking yield No significant detrimental effect on physicochemical and sensory attributes at 8% oat flour inclusion level	
	Chicken kofta	Increase in product yield and decrease in fat Increase in hardness, gumminess, cohesiveness, and chewiness	[135]
Ragi millet/finger millet	Chicken patties	No significant effect on fat and protein content Reduction in shrinkage of patties after cooking Decrease in lightness and yellowness values	[136]
	Chevon patties	Increase in emulsion stability and cooking yield Increase in pH, moisture, water activity, ash, and fat retention whereas, decrease in protein and fat content Significant increase in fiber and calcium content Decrease in instrumental texture profile attributes	[137]
Barley	Pork bologna sausages	Firmer texture and better sensory properties Better purge control and water-holding capacity during storage	[138]
Corn bran	Chevon rolls	Decrease in moisture and protein content while no significant effect on fat and ash content Increase in crude fiber, water-holding capacity, and emulsion stability Increase in polyphenolic content in fiber-enriched rolls	[139]
Fruits, vegetables, and their by-products			
Apple pulp	Fermented sausages	Reduction in energy value of products to 35% and fiber content Sensory and textural properties decreased with inclusion of fiber	[140]
	Chicken nuggets	Decrease in batter stability and cooking yield Reduction in texture and overall acceptability scores Decrease in pH, moisture, dietary fiber, and color parameters	[100]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
Grape fiber	Minced fish muscle	Delay in oxidation in minced horse mackerel muscle during the first 3 months of frozen storage	[141]
	Minced fish muscle	Direct correlation of bound water after thawing and cooking with amount of fiber used Increase in softness and loss of cohesiveness Delay in lipid oxidation parameters	[142]
	Chicken hamburgers	Significant decrease in redness and yellowness values Improvement in oxidative stability and radical scavenging activity Sensory acceptability was not affected by addition of fiber	[6]
	Frankfurters	Increase in protein, dietary fiber, and water-holding capacity Decrease in color values and oxidation levels Frankfurters up to 2% level of inclusion were sensory acceptable	[143]
Tomato fiber	Chopped cooked chicken products	Reduction in pH, increase in water-holding capacity, and increase in product hardness proportional to fiber addition Reduction in lipid oxidation	[144]
	Chicken sausages	Decrease in moisture and an increase in ash content Increase in emulsion stability, cooking yield, and crude fiber content	[145]
Orange	Fermented sausages	Reduction in energy value of products Decrease in sensory and textural properties with inclusion of fiber Best organoleptic quality at 10% pork back fat ad 1.5% orange fiber	[139]
	Dry-cured sausage	Decrease in lipid oxidation parameter, i.e., TBARS value in samples with orange fiber Significant reduction in residual nitrite level	[146]
	Salachichon (Spanish dry-fermented sausage)	pH, water activity, residual nitrite level, and Micrococcus count were affected during dry curing	[147]
	Bologna	Decrease in TBARS values along with aerobic and lactic acid bacteria counts	[148]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
		Decrease in juiciness and increase in hardness perception on sensory analysis	
	Sucuk (Turkish dry-fermented sausage)	Significant effect on lactic acid bacteria, Micrococcus, and pH values Decrease in residual nitrite level and increase in TBARS value Decrease in cooking loss and increase in lightness and yellowness values No statistical difference in sensory scores of texture, color, odor, taste, and general acceptability scores than control	[149]
Carrot dietary fiber	Sobrasaada (dry-fermented sausage)	Decline in all sensory attributes with an inclusion above level of 3% Significant effect on pH and hardness value	[150]
	Chicken nuggets	Improvement in cooking yield and emulsion stability Lower protein, fat, and ash content but higher moisture and fiber than control Hunter color values were higher in treated products, whereas, no change in textural parameters as compared to control	[151]
	Low-salt pork sausages	Improvement in water-binding capacity and marked effects on textural properties Marked increase in whitening with increasing content of fiber	[152]
Peach dietary fiber	Frankfurters	Increase in viscosity of meat batters and water retention Reduction in pH values and no change in protein and collagen content	[84]
	Fermented sausages	Sensory and textural properties decreased with inclusion of fiber	[140]
Lemon albedo	Bologna sausages	Increase in moisture, protein, and fiber content whereas, decrease in fat content Increase in hardness and decrease in juiciness perception	[153]
	Breakfast sausages	Decrease in shrinkage and cooking loss Increased value for lightness	[154]
Citrus fiber	Bologna sausages	Enhancement of oxidative stability, color, and dietary fiber content Negative effect on textural	[155]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
		properties, whereas, no effect on sensory parameters below 2% level	
Sugarbeet fiber	Frankfurters	Slight lowering of sensory scores	[156]
	Frankfurters	Increase in water-holding capacity and total dietary fiber content No significant effect on sensory scores	[157]
	Turkish-type salami	Increase in water-holding capacity and total dietary fiber content with incorporation of fiber No significant changes in appearance, color, texture, or any other sensory scores	[158]
Sugarcane dietary fiber	Low-fat meat batter	Replacement of fat up to 10% level Improved texture and sensory scores Increase in water- and fat-binding properties, dynamic rheology, and reduction of cholesterol contents	[159]
Oyster mushroom	Chicken patties	Decrease in hardness, cohesiveness, gumminess, and chewiness but increase in springiness value as compared to control	[160]
Legume hulls and flour			
Peanut and cowpea flour	Chicken nuggets	Decrease in moisture loss, fat gain, and protein content Decrease in shear force values and energy as compared to control Unacceptable flavor scores at 20% level	[161]
Soy hull	Camel meat patties	Reduction in thickness, fat, water retention, and shear force values Significant effect on chemical composition, cooking yield, flavor, and cooking yield	[162]
Inner pea fiber	Beef patties	Increase in cooking yield and tenderness without adverse effect on flavor	[163]
Bengal gram and black gram flour	Chicken loaves	Reduction in cooking loss and extract release volume and increase in emulsion stability and pH values	[89]
Soybean, Bengal gram, green gram, and black gram flours	Buffalo meat burger	Increase in yield and protein content with simultaneous decrease in shrinkage and fat absorption Roasted flours registered lower TBA values, i.e., enhancement of oxidative stability during storage	[164]

(*continued*)

Table 3 (continued)

Type/source of fiber	Type of meat product	Major effects on meat products	References
Blackeye bean, chickpea, lentil flours, and rusk	Meatballs	Improvement in cooking yield, fat retention, and moisture retention Lower penetration values and higher sensory acceptability scores	[98]
Hazelnut pellicle	Low-fat beef burger	Increase in cooking yield, diameter, and thickness of beef burgers Decreased sensory scores of appearance, flavor, and juiciness as compared to control	[97]
Roasted pea flour	Chicken nuggets	Nonsignificant increase in cooking yield up to 10% level	[165]
Pea fiber	Beef burgers	Improvement in water-holding capacity, cooking yield, and decrease in shrinkage Minimization of production cost without compromising sensory attributes	[166]
Soy flour and moong bean powder	Buffalo meat patties	Reduction of moisture and fat content and increase in protein and fiber content Increase in water-holding capacity and decrease in cooking loss	[167]
Pea flour	Low-fat bologna	Improvement in texture profile values with lower cooking and purge loss Increase in water-holding capacity without compromising sensory attributes	[168]
Bambara groundnut seed flour	Beef patties	No significant effect on proximate composition of raw patties but moisture, protein, and carbohydrate content differed significantly in cooked products Reduction in shrinkage and increase in cooking yield, moisture, and fat retention	[169]
Tiger nut fiber	Pork burgers	Increase in cooking yield, fiber content, fat, and moisture retention Increase in textural parameters like chewiness but negative effects on color attributes	[170]
Chickpea hull flour	Chicken nuggets	Decrease in moisture, protein, ash, color values, total cholesterol, emulsion stability, and cooking yield Improvement in dietary fiber content and textural parameters	[101]
Black gram hull flour	Chicken rolls and patties	Fall in organoleptic quality with an increasing level of black gram hull	[171]

control was reported to be higher as compared to fiber-treated products. Addition of carrageenan or oat fiber increased cooking yield by increasing emulsion stability and water-holding capacity in low-fat frankfurters [96]. Decreasing fat content from 30% to 5% resulted in increased loss during cooking but addition of 2% oat fiber led to reduction in total expressible fluid from 9.6% to 7.6% and from 4.8 to 4.3% in frankfurters with 5 and 12% targeted fat, respectively. Turhan et al. [97] observed improvement in reduction of cooking loss and thickness of beef burgers by addition of hazel nut pellicle and on similar lines increase in cooking yield was observed on addition of bean and lentil flour in meatballs by Serdaroglu et al. [98]. Carrot fiber and dietary fiber suspensions from olive mill wastewater was tried as dietary fiber source in low-fat meatballs by Galanakis et al. [99] and they too were found to be in agreement with other authors for improvement in cooking properties and restriction of oil uptake leading to sustained reduced fat content. But on the contrary, a decrease in emulsion stability and cooking yield was recorded in low-salt and low-fat chicken nuggets incorporated with apple pulp and chickpea hull flour which could be explained by replacement of lean by fiber sources [100, 101]. Similarly, Morin et al. [102] also found an increase in cooking loss in breakfast sausages on addition of carboxymethyl cellulose.

Various other sources of fibers like psyllium husk have been used for increasing fiber content in meat products and a concurrent increase in emulsion stability and cooking yield had been observed. It was attributed due to the presence of soluble dietary fiber in husk that might have entrapped moisture and lead to the formation of a gel during cooking [91, 92]. Similar finding have been reported by Luruena-Martınez et al. [103] who recorded the effect of addition of locust bean/xanthan gum on various quality characteristics of low-fat frankfurters. They observed a significant increase in emulsion stability, cooking yield, and lower jelly and fat separation. Lemon albedo as a source of dietary fiber was used in emulsions by Saricoban et al. [172]. Two types of albedo at five different concentrations, viz., 0, 2.5, 5, 7.5, and 10% were added in emulsions and their functional properties were studied. An increase in emulsion capacity with highest value at 5% level was observed. Similar increasing trend was observed in emulsion stability and viscosity values; however, no change in flow behavior of emulsions was observed other than pseudoplasticity. Addition of fiber as a fat replacer was tried by Pinero et al. [132] and compared with high-fat control (20% fat). They found an increase in cooking yield, fat retention, and moisture content in fiber-added meat products as compared to high-fat control. A decrease in shrinkage of cooked patties from 9.13 to 6.76% with addition of Bambara groundnut seed flour (BGSF) and an increase in cooking yield, moisture retention, and fat retention from 79.1 to 87.2%, 67.5 to 78.05%, and 73.51 to 88.34%, respectively in beef patties was observed [169]. Thus, addition of fiber in various meat products is generally associated with improvement of physicochemical properties, viz., emulsion stability, cooking yield, pH, water-holding capacity, reduction of shrinkage, etc. The change is largely dependent on fiber source and processing characteristics.

7 Fiber Incorporation and Proximate Composition of Meat Products

The overall composition of meat products can be changed with incorporation of fiber. Fiber generally reduces fat content and increases carbohydrate fraction along with dietary fiber component. This has somehow generated a new class of functional meat products with enhanced health benefits. Hydrated oat bran was used by Chang and Carpenter [173] in frankfurters and an increase in moisture and carbohydrate content and a decrease in total fat had been reported by them. This can be attributed to increase water-binding capacity of soluble fiber in oats. On the contrary, formulation of chevon patties with oat bran at different levels, viz., 15, 20, 35, and 50%, resulted in decrease in moisture, protein, and fat content [129]. Soluble and insoluble fiber content in product increased and authors concluded that nutritional value of chevon patties could be enhanced with 15 or 20% oat bran addition. Similar studies were carried out by Yilmaz and Daglioglu [131] and Yilmaz [87] who reported an increase in protein and ash content but a decrease in moisture and fat content with addition of oat bran and rye bran, respectively in meatballs. Rice bran as a source of dietary fiber was used in emulsified meatballs known as Kung-wan in Taiwan by Huang et al. [119]. They reported a significant decline in protein and fat content of meatballs with increasing level of rice bran above 5%. However, an increase in fiber and carbohydrate content was also observed. Similarly, Choi et al. [123] estimated values for protein, moisture, fat, and ash content in meat batter formulations designed with varying levels of grape seed oil and rice bran fiber and found that protein, fat, and ash content in treatments with 2% rice bran fiber were higher than control. The rice bran incorporation in chicken meat rolls and patties at three different levels, viz., 5, 10, and 15% was tried by Mehta [174]. A significant decrease in moisture and protein level was observed in treated products, whereas, an increase in fat, ash, and dietary fiber content was recorded. Utilization of oat flour at three different concentrations in beef patties resulted in decrease in moisture content of raw products and an increase was observed in cooked ones. However, no change in protein, fat, or ash content with addition of oat flour was reported irrespective of cooking or not [133]. Bilek and Turhan [175] used flaxseed flour at 3–15% levels in beef patties and reported an increase in fat and ash content but a decrease in moisture and protein percentage in products. Cereal brans at 5–20% levels in meatballs were utilized as a fiber source by Yasarlar et al. [176] and recorded a gradual decrease in moisture and fat percent while an increase in protein, ash, and dietary fiber with increasing levels of wheat and oat bran. An increase in protein and fiber content of various meat products with the use of legume flours have been reported. Kenawi et al. [167] studied the effect of incorporation of mung bean powder and/or low fat soy flour on proximate composition of buffalo meat patties. They observed that at a level of 10%, both the fiber sources led to reduction in moisture and fat content whereas an increase in the fiber and protein contents. However, a lower protein content in beef patties incorporated with common bean flour [177] and Bambara groundnut seed flour [169] was observed. The change in proximate composition is dependent on the type of fiber incorporated in meat products. Soluble fibers like psyllium husk, oat bran, etc. tend to increase moisture content due to enhanced water-binding capacity, whereas, protein-rich legume flours result in increase

of protein content in final product. A modification can be designed as per product and consumer requirement by the processor.

8 Dietary Fiber and Textural Properties of Meat Products

Texture of meat product is an important attribute that holds technological as well as sensorial importance. Human perception is a key factor in deciding optimum textural quality of meat products; however, to objectify, various instruments are used to measure texture of meat products, viz., Instron Texture Analyzer, Warner Bratzler shear press, and Kramer Shear apparatus. The fiber addition in meat products modifies the texture to a great extent and ultimately affects chewability. There can be both negative as well as positive influence of fiber addition on textural parameters. Addition of tapioca starch, oat fiber, and whey protein in low-fat beef burgers resulted in decrease in all textural parameters [128]. Garcia et al. [109] reported an increase in hardness value of *mortadella*, a Spanish cooked meat product incorporated with inulin when added at 2.5% level; however, in form of gel, it produced same effect at 7.5%. Similarly, an increase in hardness value was reported in pig liver pate developed using three enzymatically extracted fibers along with dry potato pulp and commercial potato fiber (potex) as reference [178]. A gradual decrease in hardness, gumminess, and chewiness of pork sausage with incorporation of hydrated oatmeal was observed by Yang et al. [179]. On the other hand, addition of 2% kimchi powder in breakfast sausages resulted in increased value of harness, gumminess, and chewiness as compared to control [180]. Similar trend has been observed in a number of meat products due to the addition of soy fiber, plasma protein, and various kinds of fiber sources [181, 182]. Incorporation of fiber has resulted in modified textural properties in fish-based products too. A low-fat fish sausage added with swelite (a dietary fiber obtained from inner pea) and fibruline (a dietary fiber obtained from chicory root) was developed by Cardoso et al. [183] and addition of swelite resulted in improved gel strength and hardness whereas, the products from fibruline were poorer in texture than control in terms of cohesiveness and chewability. Wheat bran as a source of dietary fiber was utilized in the formulation of cooked beef patties by adoption of a Box-Behnken design wherein three different variables were studied simultaneously. Wheat bran resulted in higher hardness and gumminess value but a lower springiness, resilience, and cohesiveness without any influence on adhesiveness [118]. Nonconventional fiber sources like grey oyster mushroom at 0, 25, or 50% level were used in chicken patties by Wan Rosli et al. [160] and they found that hardness, cohesiveness, gumminess, and chewiness of chicken patties decreased with incorporation of oyster mushroom whereas, the value for springiness increased.

9 Sensory Properties of Meat Products in Relation with Added Fiber Sources

The consumer acceptability is center to any product formulation and development. It is a complex phenomenon which is judged by sensory evaluation. The different subsets for meat products are generally color and appearance, flavor, texture,

juiciness, and overall acceptability. Tender and juicy meat products attract focus of consumers. Utilization of various fibers has been associated with a change in sensory properties, particularly juiciness and texture. An increase in hardness and decrease in juiciness by the addition of lemon albedo in bologna sausages has been reported by Fernandez-Gines et al. [153]. Similarly, addition of chickpea flour at 2.5 and 5% levels in low-fat pork bologna had no adverse effects on sensory perception. However, textural properties of cohesiveness and graininess increased but juiciness was rated much lower scores than control [184]. However, many fiber sources produced much better sensory perception than control itself, viz., hull-less waxy barley and normal starch barley in pork bologna sausages [138]. According to Kenawi et al. [167], 5% of both low-fat soy flour and mung bean powder resulted in the product with highest values for color, taste, odor, juiciness, and overall acceptability as compared to control. The extent of change in organoleptic quality is largely dependent on the concentration of fiber used in the meat product, e.g., carrot dietary fiber, if added in a concentration above 3% in *sobrassada* resulted in poorer sensory scores than control [150]. In concordance with these observations, cooked beef patties formulated with Bambara groundnut flour at 5% level had no significant effect on sensory attributes but at higher level, i.e., 7.5%, a significant fall in sensory scores for appearance, flavor, and overall acceptability was observed by Alakali et al. [169].

10 Conclusions

With the advancement of technology and reliance on processed products, meat industry is expanding its horizon with introduction of novel value-added products in market. Lack of essential components like dietary fiber can be a great hazard for health of consumers. Thus, its inclusion is needed for portraying meat as a complete food. Further, numerous functional properties like water retention, viscosity, etc. help in formulating the products with higher yield and better sensory acceptability. The technological advancements in developing low-fat, low-salt, high-fiber, and functional meat products can be realized by integrating fiber sources in meat. It is a novel area wherein lot of unconventional fiber sources can be tried for gelling up in meat products.

Abstract

Gum Arabic (GA) is a natural branched-chain multifunctional hydrocolloid with a highly neutral or slightly acidic, arabino-galactan-protein complex containing calcium, magnesium, and potassium. Gum Arabic is dried exudate obtained from the stem and branches of Acacia trees manly *Acacia senegal* and *Acacia seyal*. GA was used by the Ancient Egyptians as an adhesive when wrapping mummies and in mineral paints when making hieroglyphs since the second millennium BC. In modern times, GA is used in foods, pharmaceutical, and many other industries. In this chapter, we describe the structure, chemical, and physical properties of Gum Arabic. In addition, biological properties include antioxidant properties of Gum Arabic, an effect of GA on renal function, blood glucose concentration, intestinal absorption, degradation of GA in the intestine, lipid metabolism, tooth mineralization, and hepatic macrophages. Similarly, pharmaceutical, food, and cosmetic properties of Gum Arabic are discussed.

GA	Gum Arabic
GP	Glycoprotein
GPx	Glutathione peroxidase
HDL	High-density lipoprotein
HSL	Hormone-sensitive lipase
LDL	Low-density lipoprotein
MDA	Malondialdehyde
MGL	Monoacylglycerol lipase
ROS	Reactive oxygen species
SOD	Superoxide dismutase
TAP	2,4,6-Triaminopyrimidine
TC	Total cholesterol
VLDL	Very low density lipoprotein

1 Introduction

Gum Arabic is a natural branched-chain multifunctional hydrocolloid with a highly neutral or slightly acidic, arabino-galactan-protein complex containing calcium, magnesium, and potassium [1]. According to the definition of the Joint Expert Committee for Food Additives (JECFA), Gum Arabic is a dried exudate obtained from the stem and branches of Acacia trees (Fig. 1) [2]. There is more than 1000 species of the genus Acacia Gums; only two are significant for commercial purposes *Acacia senegal* and *Acacia seyal* [3]. *Acacia senegal* is considered the best in quality due to a low quantity of tannins and comprises the majority of global trade [4], whereas *Acacia seyal* produces a lower grade of Gum [5]. Acacia trees are abundant in central Sudan, central and West Africa, and tropical and semitropical areas of the world [6, 7]. Sudan is the leading producer of Acacia Gums worldwide, followed by Nigeria, Chad, Mali, and Senegal [8]. Europe and USA are the most important GA markets, while Japan is the largest Asian consumer.

The use of GA dates back to the second millennium BC when the Ancient Egyptians used Gum Arabic as an adhesive when wrapping mummies and in mineral paints when making hieroglyphs [9]. In modern times, they are used in foods, pharmaceutical, and many other industries [10–13].

2 Structure of Gum Arabic

The chemical composition of GA is complex, and numerous papers have been published on this subject [14]. The backbone of GA is composed of 1,3-linked β-D-galactopyranosyl units. The side chains are composed of two to five 1,3-linked β-D-galactopyranosyl units, joined to the main chain by 1,6-linkages. Both the main and the side chains contain units of α-L-arabinofuranos, α-L-rhamnopyranosyl, β-D-glucopyranosyl, and 4-O-methyl-β-D-glucopyranosyl, the last two mostly as end units (Fig. 2).

Gum Arabic consists mainly of high-molecular weight polysaccharides and their calcium, magnesium, and potassium salts, which on hydrolysis, yield three main

Fig. 1 Gum Arabic formed on a wounded branch of *A. senegal*

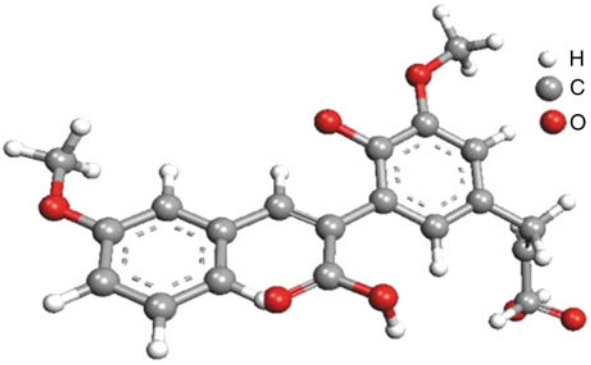

Fig. 2 Structure chemic of the Acacia Gum

fractions of polysaccharides and proteins, including arabinogalactan (AG), arabinogalactan protein (AGP), and glycoprotein (GP), which differ from their molecular weight and chemical composition [15]. The arabinogalactan fraction represents 88% of the total Gum weight has a low molecular weight (Mw, ~300 KDa) and associated little protein content below 1%. The arabinogalactan protein fraction (~10% of the total Gum) has a high molecular weight (Mw) (~1500 KDa) and protein content (~10%). The glycoprotein fraction (<2% of the total Gum) has the lowest molecular weight (Mw, ~250 KDa) and the highest protein content (~20%e50%). Among these fractions, AGP is the most interfacially active component [16, 17], and primarily responsible for the emulsifying properties of GA [18, 19]. This fraction can be adsorbed on the oil–water interface to form a viscoelastic film and reduce the interfacial tension between oil and water because of its amphiphilic characteristics, which is conferred by the hydrophobic protein chains combined to the hydrophilic polysaccharide fragments [17].

3 Chemical Properties of Gums

Chemically, GA is a complex mixture of macromolecules of different size and composition characterized by a high proportion of carbohydrates (D-galactose and L-arabinose) (~97%), and a low proportion of proteins (<3%) [14]. The chemical composition of GA varies slightly depending on its origin, climate, harvest season, tree age, and processing conditions, such as spray dying [20–23]. Many studies have shown some differences between the chemical composition of the GA from *Acacia senegal* and *Acacia seyal* [24–26], the most recent study was conducted by Lopez-Torrez et al. [29]. Both Acacia Gums contained the same amino acids with a higher content of protein in *A. senegal* (2.7%) than in *A. seyal* (1.0%) (Table 1).

Hydroxyproline, serine, leucine, and proline were the most abundant residues and represented more than 55% of the total amino acids in each variety (Table 2). Similar amino acid profiles were identified in previous studies on Acacia Gums from different origins [27–29]. The *A. senegal* Gum samples shown to contain approximately twice the amount of protein compared to the Gum obtained from *A. seyal* [28].

4 Physical Properties of Gums Arabic

The physical properties of GA may vary depending on the origin and age of trees, the exudation time, and climate. Treatment of Gums after collection such as washing, drying, and bleaching in the sun and storage conditions effected the physical properties of Gums [19]. Gum Arabic of excellent quality is tear-shaped,

Table 3 International specifications of Gum Arabic quality FAO [32]

round, with an orange-brown color. After it is crushed or shattered, the pieces are paler in color and have a vitreous appearance. GA has high water solubility and a relatively low viscosity compared with other Gums. GA can get dissolved at water in a concentration of 50% w/v, forming a fluid solution with acidic properties (pH ~4.5). The resulting solution is colorless, tasteless, and does not interact easily with other chemical compounds [30, 31]. The viscosity of GA solutions can be modified by the addition of acids or bases as these change the electrostatic charge on the macromolecule.

The physical properties of Gum Arabic established as quality parameters include moisture, total ash, volatile matter, and internal energy, which were regarding with reference to Gums taken from *Acacia senegal* species in Sudan (Table 3). These parameters can be used to identify raw Gums mostly used as food additives [32, 34, 33]. Gum Arabic is a natural product complex mixture of hydrophilic carbohydrate and hydrophobic protein components [32]. Hydrophobic protein component functions as an emulsifier which adsorbs onto surface of oil droplets, while hydrophilic carbohydrate component inhibits flocculation and coalescence of molecules through electrostatic and steric repulsions in food additives [36, 37].

The moisture content facilitates the solubility of GA carbohydrate hydrophilic and hydrophobic proteins [38]. The total ash content is used to determine the critical levels of foreign matter, insoluble matter in acid, calcium, potassium, and magnesium [39]. The compositions of cations in the ash residue are used to determine the specific levels of heavy metals in the Gum Arabic quality [32, 40]. The volatile matter determines the nature and degree of polymerization of the compositions contained in sugar (arabinose, galactose, and rhamnose) which exhibits strong binding properties to act as emulsifiers and stabilizers in the manufacture of cough syrups in the pharmaceutical industry [2]. The GA internal energy is the required energy to produce an amount of carbon by heating at 500 °C to release carbon dioxide. Optical rotation is used to determine the nature of GA sugars as well as to identify the source of production. Nitrogen content in Gum Arabic determines the number of amino acid compositions with the range of 0.26–0.39% [32].

5 Biological Properties of Gum Arabic

5.1 Antioxidant Properties of Gum Arabic

Oxidative stress is largely occurred through the deregulation of oxidants/antioxidants injury or breakdown of macromolecules of biological nature such as proteins, carbohydrates, lipids, and nucleic acids, ensuing in the imbalances of intracellular homeostasis and consequently the production of several types of reactive oxygen species (ROS) which finally induce more oxidative injury or damage [41]. The antioxidant enzymes activity plays a vital role in the damage of hyperglycemia-related tissue [42]. Previous studies indicated that production of ROS in diabetes might commence the chronic diabetic lesions development on many tissues such as blood vessels [43], eye retina [44], kidneys [45], and neurodegenerative disorders [46].

Superoxide dismutase (SOD) [47], catalase (CAT) [48], and glutathione peroxidase (GPx) [49] are considered the main vital defense tools against reactive oxygen molecules, which are involved in the oxidative damage [50, 51]. In the diabetic patients, the oxidative stress was found to induce various unfavorable effects at the molecular levels in cell physiology [52]. The oxidative stress reduced the concentrations of glutathione (GSH) in patients with type 2 diabetes [52], decreased the activity of CAT [53], reduced the concentrations of renal SOD [54], and increased the level of heat shock protein 70 (HSP70) [55]. The reduction in antioxidant components can cause diabetic complications [56]. The administration of Alloxan by GA was cause a significant reduction of antioxidant enzymes including GPx, CAT, and SOD. The reduction of antioxidant enzymes activities was associated with observable augment in production of malondialdehyde (MDA). The elevation MDA levels ultimately cause oxidative stress, and consequently it mirrors a decreased antioxidant defense potentiality [50, 57].

Several studies indicated that GA is exert a nephron-protective effect against gentamicin (antibiotic) and cisplatin-induced nephrotoxicity in rat [58, 59], and doxorubicin-induced cardio toxicity in rat [60]. Trommer and Neubert [61] indicated that the treatment of GA together with polysaccharides reduced lipid peroxidation. In contrast, Ali [62] revealed that administration of GA to rats at concentrations of 2.5%, 5.0%, and 10.0% in the form of drinking water for eight successive days did not significantly change the levels of free radical scavenger's GSH, acid vitamin C (ascorbic acid, and SOD, or lipid peroxidation). The mechanism of action through which GA improves the antioxidant capacity may be due to the fact that GA contains several types of amino acid residues such as lysine, tyrosine, and histidine, which are commonly considered as antioxidants biomolecules [63, 64]. Moreover, the antioxidant properties of GA in biological systems require a more direct knowledge of the antioxidant capacity [65, 66]. Consequently, the antioxidant activity of GA in biological systems is still an unresolved issue, and therefore it requires a more direct knowledge of the antioxidant capacity of GA that can be obtained by in vitro experiments against different types of oxidant species.

5.2 Effect of GA on Renal Function

The administration of GA in the form of drinking water (15%, w/v) reduces the concentrations of plasma urea and creatinine in adenine-induced chronic renal failure (CRF) in rats. It also decreased the clearance of creatinine and induced significant increases in the inflammatory mediator's concentrations. Further, the treatment with GA significantly ameliorated all adverse effect that induced by adenine. The mechanism underlying the salutary effect of GA in adenine-induced CRF may associate with mitigation of the adenine-induced inflammation and generation of free radicals [67].

Pretreatment of GA (7.5 g/kg/day per oral administration), starting 5 days before mercuric chloride injection, resulted in a complete reversal of Hg-induced increase in blood urea nitrogen, creatinine, thiobarbituric acid reactive substances, and total nitrate/nitrite to control values. Pretreatment of GA prevented Hg-induced degenerative changes of kidney tissues. Thus indicated that GA is an efficient cytoprotective agent against Hg-induced nephrotoxicity [68]. The protective effect of GA on renal function was also confirmed to significantly reduce blood creatinine and urea nitrogen concentrations in diabetic nephropathy patients [69]. Recent studies have shown that GA significantly reduced serum urea and urinary protein. In addition, GA significantly decreased α-SAM and TGF-β1 gene expression in kidney and increased kidney cytokeratin19 and E-cadherin gene expression when compared to STZ-treated group. Therefore, GA may attenuate the development of nephropathy in type I diabetes rat [70].

5.3 Effect of GA on Blood Glucose Concentration

In India, GA is one of the indigenous medicines, and it has many medicinal uses. In Tunisia, the use of GA as hypoglycemic medicinal plants to treat diabetic patients was found to reach more than 70% compared to other medicinal plants [71].

A clinical trial used 40 participants with a daily supplement of powdered GA (10 g/day) for 16 weeks in healthy individuals, prediabetics patients, type 2 DM patients, and diabetic nephropathy patients. The results showed that supplementation of GA significantly decreased fasting blood glucose levels and glycosylated hemoglobin (HbAc1) together with significant reduction of blood uric acid and total protein concentrations [72]. Moreover, supplementation of GA in different forms to the normal or diabetic or fed-high fat diet rat/mice significantly reduced blood glucose levels [83, 85]. The blood glucose lowering propriety of GA may be because GA inhibits absorption of glucose in the intestine via interaction with membrane abundance of sodium-glucose transporter 1 (SGLT1) in experimental mice [69].

5.4 Effect of GA on Intestinal Absorption

The small intestine is a major part of the gastrointestinal tract (GIT) where almost all organic nonelectrolytes and electrolytes absorbed in it different mechanisms which

are operating at the cellular and molecular levels [73]. Concurrent intestinal secretion is a physiological occurrence which is tightly controlled by various mechanisms. This process maintains within the intestinal lumen a condition of variability, dilution, and solubilization that is indispensable to the usual intestinal function of digestion and absorption. The net effects of those mechanisms play a significant role to maintain the normal mammalian small intestine in an absorptive manner. On the other hand, under a certain condition, secretion forces exceed absorption, and a net secretory condition ensues resulting in diarrhea and dehydration. It has been reported that GA enhances small intestinal absorption of sodium in normal experimental rats [74, 75]. GA is also found to increase the absorption of sodium and water in two animal models of diarrheal disease [76]. In normal young rats, the addition of 5 and 10 g/L of GA increased sodium removal rates from the intestinal lumen perfused with oral rehydration solutions containing either 60 or 90 mM sodium. Although GA tended to ease bidirectional fluid movement in those experiments, the net absorption of water was not influenced [77]. At high concentration, GA was associated with increases and expansion of the basolateral intercellular space. Experimental diarrhea was induced in rats by either 1 week of drinking cathartic (magnesium citrate-phenolphthalein) solution to produce chronic osmotic-secretory effects or by jejunal perfusion of theophylline to induce jejunal secretion. The positive influences of the GA on electrolyte and fluids absorption were shown in jejunal perfusion studies in experimental rats that were recovering from chronic osmotic diarrhea induced by cathartic agents [73]. In free living rats, the administration of GA in the form of drinking supplemented ad libitum revealed accelerated recovery when compared to those receiving either water or oral rehydration solutions (ORS) without GA [73]. GA was reported to increase water and electrolytes movement, e.g., water and sodium, from the intestinal lumen to the blood stream [78].

5.5 Degradation of GA in the Intestine

Gum Arabic is mostly indigestible to both animals and humans as it is not degraded in the small intestine. However, it fermented in the large intestine particularly in colon due to the enzymatic action of microorganisms [79]. Several studies have reported that intestinal bacteria can ferment GA to short-chain fatty acid, mainly propionate [80].

5.6 Effects of GA on Lipid Metabolism

Gum Arabic is considered as a dietary supplement that reduces the deposition of body fat. Ingestion of GA was revealed to decrease body mass index (BMI) and percentage of body fat in healthy adult human females [81]. GA has many anti-obesity properties as a dietary supplement in both humans and experimental animals. GA serves as a dietary fiber which helps to reduce body weight and fat deposition. The property of lowering caloric density of the diet of GA is the most potential mechanism involved in the reduction of body weight [82]. In addition, our recent

reports suggest that other complex mechanisms might be involved [83]. The property of lowering glucose and fat absorption of GA is an additional proposed mechanism; nevertheless, this mechanism was debated in earlier reports [84]. GA suppressed diet-induced obesity by altering the expression of mRNA levels of genes involved in lipid metabolism in mouse liver [83]. In addition, GA consumption in the form of drinking water decreased visceral adipose tissue (VAT) associated with downregulation of 11β-hydroxysteroid dehydrogenase type I in liver and muscle of mice [85].

Administration of GA reduced plasma total cholesterol, triglyceride, and low density lipoprotein (LDL) concentrations in human [86] and mice [85]. In agreement with these findings, we reported that GA supplementation decreased plasma LDL, very low density lipoprotein (VLDL), and total cholesterol concentrations, whereas increased HDL concentrations. Numerous mechanisms have been proposed to reveal the hypocholesterolemic effects of dietary fiber [87]. One potential clarification is that dietary fiber increases the viscosity of the intestinal contents, and therefore, interfering nutrient with absorption and micelle formation, which, sequentially, decreases intestinal lipid absorption [88]. Another mechanism suggested that soluble fibers act by disrupting the enterohepatic circulation of bile acids, consequential to increased bile acid excretion, and subsequently reduces plasma cholesterol concentrations [89]. Moreover, the viscosity of fermentable dietary fibers is found to contribute substantially to the lipid lowering effects in rat [90].

Supplementation of GA significantly downregulated hepatic adipose triglyceride lipase (ATGL) mRNA and conserved receptor expressed in brain 2 (SREB2) mRNA expression in mice fed with high-fat diet (HFD) [83, 91]. HMG-CoA reductase (HMGR), the rate-limiting enzyme in cholesterol biosynthesis mRNA expression, was significantly lowered in the GA-treated mice [83]. The dietary fibers have pertained to the hepatic mRNA expression of HMGR in rat [92, 93]. Thus, these results provided insight into how dietary fibers affect lipid metabolism at the gene level. Adipose triglyceride lipase (ATGL), hormone sensitive lipase (HSL), and mono-acyl-glycerol lipase (MGL) are tightly regulated by a nutritional factor. However, under a condition of energy intake, imbalance leads to failure to efficiently control their activity. Consequently, serious metabolic disorders will occur and is believed to be a key mechanism in the development of type 2 diabetes in obesity [94].

5.7 The Effect of GA on Tooth Mineralization

Dental caries is found to occur when the tooth enamel is lost due to an imbalance of the demineralization and demineralization phases, and prevention can be accomplished if the demineralization phase is enhanced [95]. A number of agents have been used for that purpose, including fluoride [96]. Lately, using histopathological methods, it is found that GA can promote demineralization possibly by sustaining other demineralization activities [97]. This supporting function was approved to the rich content of $Mg2+$, $Ca2+$, and $K+$ salts of polysaccharides in GA, and to the

influence of the Gum on Ca2+ metabolism and possibly phosphate. It is also reported that GA contains cyanogenetic glycosides and other numerous types of enzymes such as peroxidases, oxidases, and pectinases that exhibit antimicrobial properties against certain microorganisms such as *Prevotella intermedia* and *Prophyromonas gingivalis* [98].

5.8 Effect of GA on Hepatic Macrophages

Macrophages are known to play a vital role in the regulation of immunological process in all vertebrates. It was reported that the GA activates macrophage by its ability to produce superoxide anions in vitro [99]. While other studies report that GA was competent to blocking the macrophage function completely [100, 101]. Therefore, the scientist inferred that such influences of GA would promise the consideration in the treatment of chronic liver disease, as a disturbed function of Kupffer cells and hepatic macrophages occurs in this kind of disease and is involved in its complications, such as end toxemia [102].

6 Pharmaceutical Properties of Gum Arabic

In recent years, plant-derived polymers have evoked tremendous interest due to their diverse pharmaceutical applications such as diluents, binders, disintegrants in tablets, thickeners in oral liquids, protective colloids in suspensions, gelling agents in gels, and bases in suppository [103].

In the pharmaceutical industry, GA is used as a carrier of drugs since it is considered a physiologically harmless substance. GA has some biological properties as an antioxidant [61, 104, 105] on the metabolism of lipids [106, 107] and in treating many diseases such as kidney [102, 108], cardiovascular [109], and gastrointestinal diseases [110].

Gum Arabic reduces glucose absorption, increases fecal mass and bile acids, and has the potential to beneficially modify the physiological state of humans [111]. GA is slowly fermented by the bacterial flora of the large intestine producing short-chain fatty acids [112]. In addition, GA is able to selectively increase the proportion of lactic acid bacteria and bifidus bacteria in healthy subjects. Previous studies have shown that a daily intake of 25–30 g of GA for 21–30 days reduced total cholesterol by 6% and 10.4%, respectively. The decrease was limited only to LDL and VLDL, with no effect on HDL and triglycerides [113, 114].

7 Food and Cosmetic Properties of Gum Arabic

Gum Arabic is used in textiles, ceramics, lithography, cosmetic, paints, and papermaking [9, 116]. In the food industry, GA is primarily used in confectionery, bakery, dairy, beverage, and as a microencapsulating agent. Acacia Gums are unique among

the various hydrocolloids; they are used notably in food industry because they modify and control the rheological properties of aqueous food systems acting as thickeners, stabilizers, film formers, suspending agents, flocculants, and emulsifiers. *A. senegal* Gum is most widely used in food applications mainly because of its better emulsifying properties than *A. seyal* Gum [115]. In addition, Gum solutions of *A. senegal* are generally less colorful than *A. seyal*. These properties explain differences in the higher price of *A. senegal* Gum compared to *A. seyal* in the international market. Gum Arabic is well recognized as emulsifier used in essential oil and flavor industries such as production of citrus and cola flavor oils for soft drinks [31, 34]. In dairy products, Gum Arabicis is used as a stabilizer in frozen products like ice and ice cream, absorbing water and producing a finer texture. In cosmetic industry, Gum Arabic is used as smoothener in lotions and protective creams, and adhesive in facial masks or face powders [9].

8 Conclusion

Although there are more than 1000 species of the genus *Acacia* Gums, only two are significant for commercial purposes: *Acacia senegal* and *Acacia seyal*. The chemical composition of GA varies slightly depending on its origin, climate, harvest season, tree age, and processing conditions, while the physical properties of Gum Arabic established as quality parameters including moisture, total ash, volatile matter, and internal energy.

GA improves the antioxidant capacity because it contains several types of amino acid residues such as lysine, tyrosine, and histidine, which are commonly considered as antioxidants biomolecules. GA effects renal function through reduction in blood creatinine and urea nitrogen concentrations in diabetic nephropathy patients. GA significantly decreased fasting blood glucose levels and glycosylated hemoglobin (HbAc1) together with a significant reduction in blood uric acid and total protein concentrations. GA increases water and electrolytes movement from the intestinal lumen to the blood stream. GA can be fermented by intestinal bacteria to short-chain fatty acid, mainly propionate. GA, as a dietary fiber, helps to reduce body weight and fat deposition.

In the pharmaceutical industry, GA is used as a carrier of drugs since it is considered a physiologically harmless substance. GA has some biological properties as antioxidant on the metabolism of lipids, and in treating many diseases such as kidney, cardiovascular, and gastrointestinal diseases.

In the food industry, GA is used in confectionery, bakery, dairy, beverage, and as a microencapsulating agent. In dairy products, it is used as the stabilizer in frozen products like ice and ice cream, absorbing water and producing a finer texture. In cosmetic industry, Gum Arabic is used as smoothener in lotions and protective creams, and adhesive in facial masks or face powders.

Abstract

Consumers' awareness on benefits of intake of low carbohydrate foods is increasing day by day. Carbohydrate-rich foods are generally blamed for causing/worsening diabetes and weight gain. However, the presence of resistant starch in carbohydrate-rich foods makes them somewhat suitable for health conscious persons. Resistant starch is of utmost importance to nutritionists and food processors. Resistant starch has assumed great importance due to its unique functional properties and health benefits. Resistant starch provides health benefits such as glycemic control, control of fasting plasma triglyceride and cholesterol levels, and absorption of minerals. Native quality of starch, processing techniques, and storage temperatures affect the resistant starch content in food. Commercial preparations of resistant starch are available in the market. These RS preparations are being used by food industries as an ingredient to lower the caloric value of the food products and also to improve textural and organoleptic characteristics of food. This book chapter will give insights into classification, structure, properties, production, applications, and health benefits of resistant starch.

Keywords

Resistant starch · Classification · Properties · Production technology · Applications · Health benefits

Abbreviations

ANN	Annealing treatment
GI	Glycemic index
HAS	High amylose starch
HHP	High hydrostatic pressure
HMT	Heat moisture treatment
HPT	High pressure treatment
NSP	Non-starch polysaccharides
RDS	Rapidly digestible starch
RS	Resistant starch
SCFA	Short chain fatty acids
SDS	Slowly digestible starch

1 Introduction

Carbohydrates are the main energy source for our body and their energy is used first in the body before protein and fat. Starch is the main form of carbohydrate present in most of the foods. Starch is made up of two major components,

i.e., amylose and amylopectin. These components are present in different ratios in different plants/foods. Quality of starch depends on the ratio and organization of these two molecules in starch granules [1]. Starch is indigestible in its raw form and its digestibility improves to great extent during cooking. Most of the part of starch becomes digestible after cooking; however, some parts remain resistant to digestion. A part of starch present in the diet that escapes digestion and absorption in the small intestine and is fermented in the large intestine of humans, with the production of short chain fatty acids (SCFA), is termed as "resistant starch" (RS) [2]. Resistant starch is present in most of the starchy foods. Resistant nature of the starch depends upon the quality of native starch such as its amylose: amylopectin ratio, compactness, crystallinity, etc. Along with these, behavior and nature of food, cooking methods, temperatures, storage after cooking, and interaction of starch with proteins, lipids, and other carbohydrates are also known to influence the digestibility of starch [3]. American Association of Cereals Chemists and the Food Nutrition Board of Institute of Medicine of the National Academies have defined RS as a type of dietary fiber. There are five different types of RS based on their origin and characteristics. RS is known to positively influence the functioning of digestive tract, gut microbial flora, blood cholesterol, and glycemic index (GI) level and assists in the control of diabetes, protects from colon cancer, diverticulitis, and hemorrhoids through production of SCFA [4, 5].

Due to increasing awareness about healthy and nutritious foods, consumers are now concerned with supplementary health merits of a food and are ready to pay more for healthy food products. International food industry is working on development of innovative functional food products with additional health benefits to fulfill the growing demands for functional foods. Most of carbohydrate-rich foods are known to be high glycemic. Glycemic index (GI) ranks food according to their effect on blood glucose level and high GI food cause fatal health problems such as diabetes and obesity. Development of carbohydrates-based functional foods with low GI is need of the hour. Due to the inverse relation between GI and RS, food nutritionists are looking for use of RS as food fortificant to lower the GI of food. For development of functional foods, fortification is an economically feasible way to deliver the desired component such as RS, in targeted population group. RS is naturally available in different botanical sources, which provides opportunity of its use as a functional ingredient. Food products fortified with RS are becoming popular among consumers. RS is already being incorporated in variety of products such as breads, cookies, muffins, pizza crust, tortillas, breakfast cereals, and snack products. For production of RS at a large scale, various techniques/treatments such as heat, enzymatic, heat with enzyme and chemical treatments are being practiced. Literature/reports on RS have appeared in the past but there is continuous accumulation of newer information as resistant starch continues to attract the attention of researchers. Therefore, it became necessary to update the available information on RS, and this chapter attempts to analyze the information published, especially in the recent past on classification, structure, properties, production technologies, applications, and health benefits of resistant starch.

2 Starch

Starch is the most abundant storage polysaccharide present in form of granules in cereals or legume seed endosperm, tubers (potato and sweet potato), unripe fruits (banana and mango), and in many other plant reserve organs. Depending on the botanical source starch is present in diverse shapes such as round, oval, lenticular, and angular and the granule size generally range between 1 and 100 μm. A starch granule is made up of a number of monosaccharide or glucose molecules that are linked together with α 1–4 and α 1–6 linkages [6]. Starch is made up of two components namely amylose and amylopectin. Amylose is a linear chain of glucose with 6000 degree of polymerization, whereas, amylopectin is highly branched and its degree of polymerization is up to two million. Carbohydrates are stored in insoluble and tightly packed manner in starch granules [7]. Based on the X-ray diffraction spectrum, starches are divided into two forms, i.e., "A type" and "B type." These two types differ in the granule crystalline structures. A-type starches are present in cereals, whereas, B-type starches are present in tubers and other amylose-rich starches. In case of legumes, mixture of both A-type and B-type crystalline structures are present and this mixture is termed as "C-type" structure [8].

Enzymes such as α-amylase, glucoamylase, and sucrose-isoamylase can hydrolyze the gelatinized/digestible starches in small intestine. B-type starches resist enzymatic digestion, whereas A-type starches are slowly digested [9, 10]. Digestibility of starch is affected by a number of factors such as supramolecular structure (packing of crystallites inside starch granules), ratio of amylose to amylopectin, fine structure of amylose, as well as surface characteristics of starch granule [11]. Starch granules being compact structures are insoluble in cold water. Starch gelatinizes at high temperatures (generally above 40 °C) and starches from different sources have different gelatinization temperature. Gelatinized starch contains dissolved carbohydrates, amylose, and low polymerized chains of amylopectin that binds considerable amount of water upon cooling. Amylose and amylopectin chains in gelatinized starch realign upon cooling of starch paste and this process is termed as "retrogradation." Retrogradation occurs at higher rate if the starch paste is stored at lower temperatures. Retrograded starches contain both crystalline and semi-crystalline structures and are hence semi-crystalline in nature. Products of amylopectin retrogradation are less thermostable compared to amylose retrogradation products and their rehydration occurs at the temperatures over 60 °C and 120 °C, respectively.

3 Classification of Starch

Starch is classified based on its rate and extent of digestion and physiological properties. There are three types of starches viz. rapidly digestible starch (RDS), slowly digestible starch (SDS), and resistant starch (Table 1) [12, 13].

Table 1 Classification of starch [13]

Starch fraction	RDS	SDS	RS (Type 1–4)
Digestion timeline (in vitro)/place	Within 20 min, mouth and small intestine	20–120 min, small intestine	>120 min, not in the small intestine, main action in colon
Examples	Freshly cooked food	Native waxy maize starch, millet, legumes	Raw potato, stale bread
Amount (g/100 g dry matter)	Boiled hot potato: 65	Boiled millet: 28	Raw potato starch: 75
Main physiological property	Rapid source of energy	Slow and sustained source of energy and sustained blood glucose	Effects on gut health (e.g., prebiotic, fermentation to butyrate with hypothesized anticarcinogenic effects)
Structure	Mainly amorphous	Amorphous/crystalline	Depending on the type, mainly crystalline

3.1 Rapidly Digestible Starch

Rapidly digestible starch is defined as a "type of starch which is rapidly (within 20 minutes) converted to glucose molecules by the enzymatic digestion" [13]. High levels of RDS are present in starchy foods cooked under moist heat such as potatoes and breads. Major portion of dietary starch is rapidly digestible. More RDS in food is detrimental to health, as it releases glucose to blood at a fast rate which elevates blood glucose level and insulin response [14]. RDS is significantly correlated to GI in literature [15–17].

3.2 Slowly Digestible Starch

Slowly digestible starch is defined as a "type of starch which is converted to glucose after 120 minutes of enzymatic digestion" [13]. SDS is a physically inaccessible amorphous starch that takes long time for digestion and is completely digested in the small intestine. Englyst's in vitro test revealed that raw cereal starches are rich in SDS. However, human testing of normal corn starch (A type) revealed the slow and prolonged postprandial glucose release profile [18]. Slow digestion property of native starches is generally lost during processing of starchy food under moisture [19]. SDS-rich foods as well as low GI foods confer similar health benefits. Such foods delay the occurrence of metabolic syndrome, diabetes, and cardiovascular diseases [20–22]. Retrogradation of partially debranched amylopectin after isoamylase treatment generates SDS [23, 24].

3.3 Resistant Starch

The term "resistant starch" was coined by Englyst et al. to describe a small fraction of starch that resist hydrolysis by α-amylase and pullulanase treatment in vitro [12]. RS resists digestion and absorption in the small intestine and is fermented in the colon. When compared to RDS and SDS, RS is not hydrolyzed to glucose in the small intestine within 120 minutes of being consumed. Amylose amylopectin ratio influences the resistant nature of starch. Digestion of amylose is slow and that of amylopectin is fast after retrogradation. RS is a linear molecule of α 1, 4 D-glucan and is mainly derived from retrograded amylose in cooked starchy food. Large number of factors influences the rate and extent of starch digestion and all of these factors are interlinked which complicate the understanding of resistant nature of starch. With some exceptions such as pea starch, RS content of granular starch is directly correlated with its amylose content [25–27]. Due to this positive correlation as well as other functional and nutritional properties of amylose, agricultural researchers started working on development of crops containing high amylose starches (HAS) [28]. High amylose potato, barley, and wheat have already been developed by some researchers [29–32].

4 Relationship between RDS, SDS, and RS

All the three starch fractions are related to each other. RDS shows inverse relationship with SDS and RS. SDS and RS are structurally more similar in terms of retrogradation and coexist in processed foods [33]. SDS can be made from RDS by several physical, chemical, and physiological methods [34].

5 Classification and Structure of Resistant Starch

Resistant starch is classified into five sub-types viz. RS1, RS2, RS3, RS4, and RS5 (Table 2). Earlier reports described about only three types of RS, i.e., RS1, RS2, RS3, however, over the period of time two more types, i.e., RS4 and RS5, were added to the classification [13, 35–38].

RS1: This type of starch is physically inaccessible to digestion due to its entrapment within whole or partly milled grains or seeds and due to presence of intact cell walls in grains, seeds, or tubers. This type of RS escapes digestion due to inaccessibility of amylolytic and digestive enzymes and passes to small intestine as such [39]. Only proper grinding/milling can make this RS to digest completely in small intestine. Its heat stable nature does not allow it to break down or open up during normal cooking.

RS2: Native starch granules which are protected from digestion due to their conformation/structure are termed as RS2. Raw potato and green banana contain this type of starch. RS2 being crystalline and compact in nature has no access to digestive enzymes and amylases and hence is poorly susceptible to hydrolysis [40].

Table 2 Classification of types of resistant starch (RS), food sources, and factors affecting their resistance to digestion in the colon [59]

RS type	Description	Food sources	Resistance minimized by	Digestion in small intestine
RS1	Physically protected	Whole- or partly milled grains and seeds, legumes	Milling, chewing	Slow rate, partial degree, totally digested if properly milled
RS2	Ungelatinized resistant granules with type B crystallinity, slowly hydrolyzed by α-amylase	Raw potatoes, green bananas, some legumes, high amylose corn	Food processing and cooking	Very slow rate, little degree, totally digested when freshly cooked
RS3	Retrograded starch	Cooked and cooled potatoes, bread, cornflakes, food products with repeated moist heat treatment	Processing conditions	Slow rate, partial degree, reversible digestion, digestibility improved by reheating
RS4	Chemically modified starches due to cross-linking with chemical reagents	Foods in which modified starches have been used (e.g., breads, cakes)	Less susceptible to digestibility in vitro	A result of chemical modification, can resist hydrolysis
RS5	Amylose-lipid complexes	Foods with high amylose content	Not susceptible to hydrolysis by α-amylase	Can resist digestion

Both RS1 and RS2 show slow and incomplete digestion in small intestine. Nowotny observed the resistant nature of raw potato starch in 1937 while working on the enzymatic hydrolysis of raw starch from numerous plant species [41]. He observed the small extent of enzymatic hydrolysis of raw potato starch. Later his results were confirmed by various researchers [42, 43]. Fine-grain high amylose maize starch and coarse grain potato starch showed similar resistant nature. The structure as well as resistance of high amylose maize starch is retained even during processing/preparation of food. Starches from different sources vary in the size of granule. Granule size affects the extent of enzyme adsorption on its surface. However, no relationship was found between the extent of enzyme adsorption and degree of starch hydrolysis [44]. Later the extent of enzymatic hydrolysis was linked to degree of starch crystallization. Starch hydrolytic enzymes first degrade the amorphous region, therefore, resistant nature was attributed to the crystalline region of starch; however, resistant nature of starch is not always linked to its degree of crystallinity. High amylose starches as well as B-type starches are more resistant to enzymatic hydrolysis [43, 45].

In B-type starches only surface of granule is hydrolyzed, whereas in A-type starches deep enzymatic hydrolysis takes place. Starch resistance depends upon the size of blocklets in the granule. Potato starch contains large blocklets formed due to the double helices and are incorporated in crystalline layers of granules and hence potato starch is more resistant compared to cereal starches which contains small blocklets [46–48]. Resistant nature of starch is not dependent on any one factor, but a large number of factors such as granule size, shape, amylose content, crystallinity, and also size of pores/holes in the granule affects the starch resistance [39].

RS3: Physically modified starches are termed as RS3. RS3 is formed during moist-heat processing of food and is basically a retrograded starch or more precisely a retrograded or recrystallized amylose found during cooking of gelatinized starch and in cooked starchy foods that are stored at low or room temperature. RS3 is highly thermostable and is used as an ingredient in a wide variety of conventional foods [40]. Most common examples of RS3 are cooked and cooled potatoes and corn flakes [49]. RS3 is nutritionally important type of RS and has good quality due to high water holding capacity compared to granular starch [50]. During storage of gelatinized starch at low temperature for some time, amylose double helices realign and aggregate to form a highly thermostable B-type crystalline structure. Amylose retrogradation renders α-1 → 4 glucosidic linkages inaccessible to amylase which is responsible for resistant nature of RS3. Being thermostable these aggregates can be rehydrated only at high temperatures, i.e., above 150 °C. Formation of RS3 is highly influenced by storage temperature and duration. Storage of starch paste at low temperature results in more RS3 formation compared to storage at high temperature [51]. Starch crystallinity is also affected by storage temperature. Storage of gelatinized starch at low temperature results in B-type crystallinity, whereas storage at boiling temperature results in A-type crystallinity [52]. Both amorphous as well as crystalline fractions are present in starch gels, wherein amorphous fraction is hydrolyzed by amylolytic enzymes and crystalline fraction remains resistant [53]. Formation of RS3 is hampered by formation of amylose-lipid complexes, which results in less production of RS3 [54]. When starch gels are stored at low temperatures, amylopectin also participates in formation of partly crystallized gels. However, crystallization by amylopectin is quite slow and amylopectin crystallization structures are less thermostable compared to amylose crystallization structures and can be rehydrated at 55–70 °C temperature [36]. Amylopectin crystallization structures are also resistant to amylolytic enzyme activity. Formation of RS3 depends on the botanical origin of starch, amylose content, and procedure used for its preparation. Preparation of amylopectin retrogradation products is a lengthy process; however, this process can be hastened with repeated heating and cooling of starch paste.

RS4: Chemically modified starches are known as RS4 [55]. RS4 is a group of starches in which digestibility is decreased with chemical procedures such as etherization, esterification, or cross-bonding with chemicals. Based on water solubility of RS4 as well as analysis method, RS4 is further divided into four sub-categories [4]. Chemical modification mainly involves conversion, substitution, and cross-linking. During chemical modification enzyme access to starch is blocked by formation of atypical linkages which decrease its digestibility by hydrolytic enzymes [56].

The resistance of acetylated and hydroxypropylated starches is directly proportional to degree of substitution [57]. When compared to native starches, hydroxypropyl distarch phosphate and acetylated distarch phosphate are more resistant to enzyme hydrolysis [58]. The level of resistance in RS4 is directly proportional to the degree of chemical modification. For example, higher the degree of substitution with phosphoric acid, more will be the resistance of monostarch phosphate. The structure as well as composition of starch granules is changed during chemical modification, which in turn increase their resistance to amylolytic enzymes.

RS5: Amylose chains are penetrated by lipids in starch from many plant sources. RS5 is a type of RS which is formed due to amylose-lipid complexes. Generally, these complexes are formed during food processing; however, they can also be prepared under controlled conditions. These type of complexes appeared in high amylose starches, hence formation of amylose-lipid complexes is influenced by the amylose-amylopectin ratio of starch and botanical source. RS5 comprises polysaccharides of water insoluble linear poly α-1,4 glucan that are resistant to hydrolysis by α-amylase [38]. These polysaccharides promote the formation of SCFA, mainly butyrate, the most important SCFA [59].

6 Properties of RS

RS has gained importance because of its nutritional aspects as well as functional properties. RS can be used in a variety of foods due to numerous desirable properties such as swelling, viscosity increase, gel formation, and water-binding capacity (Table 3) [60]. Due to these properties RS can replace flour on one-to-one basis without affecting dough rheology significantly. Other properties of RS include its bland flavor, which upon incorporation in some other food does not change taste of

Table 3 Functional properties and advantages of commercial sources of RS2 and RS3 [59]

Natural sources
Bland in flavor
White in color
High gelatinization temperature
Fine particle size (which causes less interference with texture)
Good extrusion and film-forming qualities
Lower water properties than traditional fiber products
Lowering the calorific value of foods
Increase coating crispness of products
Increase bowl life of breakfast cereals
Functional food ingredients
Useful in products for celiacs as bulk laxatives and in products for oral rehydration therapy
Allow the formation of low-bulk high-fiber products with improved texture, appearance, And mouth feel (such as better organoleptic qualities) compared with traditional high-fiber products

food. RS appear white in color and have fine particle size. Like taste, texture of food also remains unaltered due to its fine particle size. Due to low calorie content of RS (1.6–2.8 Kcal g^{-1}) it can complement reduced fat and low sugar food formulations and can impart special characteristics along with dietary fiber fortification in high fiber food [61]. Low water holding capacity of RS provides good handling during processing, improves crispiness, expansion, and texture in the end product. Other qualities of RS include high gelatinization temperature, good extrusion, and film forming property. Incorporation of RS improves coating crispiness of the product and also enhances the bowl life of breakfast cereals. Food industry is successfully using RS in a range of baked and extruded products. RS is highly suitable in grain-based, low moisture to moderate moisture food systems [59].

7 RS Production Technologies

To fulfill the growing demands for functional foods, food industry is investigating ways to produce innovative functional food products with additional health benefits. With increasing awareness about health and nutrition among consumers, researchers and producers are aiming to develop functional foods with supplementary health merits [62]. Researchers and nutritionists are working together for development of functional foods with low GI. Due to various health benefits such as positive influence on digestive tract functioning, gut microbial flora, blood cholesterol, GI as well as on diabetes control, and being low calorie ingredient RS can be used for fortification of high GI foods to convert them to low GI [63]. Presence of natural sources of RS makes it suitable functional ingredient for fortification purposes [64]. In order to increase the intake of dietary fiber, consumers are ready to pay more for RS-fortified food products. Several techniques are available to alter the GI as well as rate of starch digestion. These techniques involve modification of key functional ingredients using low or no calorie sugars, formation of starch lipid-complexes, or through processing techniques such as heat moisture treatment and extrusion. RS is included in the food to combine physical characteristics of the food such as texture, water holding capacity, processing stability, and nutritional functionality. To preserve the nutritional functionality of RS-containing food, stability of RS during processing is of utmost importance [65]. Various techniques such as heat, enzymatic, heat with enzyme, and chemical treatment are available for manufacture of RS.

7.1 Heat Treatment

7.1.1 Heating Cooling Cycles

Repeated heating and cooling cycles for RS production are being used since long. Another method for RS production involves starch gelatinization followed by enzymatic debranching of gelatinized polymer, deactivation of the debranching enzyme, and isolation of the resultant product by drying/extrusion/cocrystallization. RS produced by using heating-cooling cycles is RS3. Various researchers have

reported the increase in RS3 content by using different combinations of storage duration and heating and cooling temperatures. More RS3 yield is obtained with gelatinization in high pressure autoclave as compared to water bath (90 °C) [66]. High RS3 can be prepared by autoclaving of starch (30% w/v) at 121 °C for 1 h and cooling at room temperature followed by storage at 48 °C for 1 day. Same steps are repeated several times to obtain high RS3 yield. Heating of wheat starch suspension (20% w/w) at 100 °C for 16 h, followed by air drying results in 12.9% RS3 as compared to 10.4% tested as dietary fiber [67]. Boiling and cooling of potatoes at 4 °C for overnight results in 2.8-fold increase in RS yield [68]. RS content increased up to 63% after boiling and cooling of potatoes at 4 °C for 48 h compared to boiled hot potatoes [49]. Gelatinization of starch at 120 °C for 20 min followed by cooling to room temperature yielded high amount of RS [69]. Starch gelatinization at 110 °C, 121 °C, 127 °C, 134 °C, and 148 °C for 30 min to 1 h can increase the RS3 yield even in starches containing normal amylose level [70–72]. Gelatinization of water-starch suspension in 1:3.5 ratio at 134 °C with four repeated heating cooling cycles results in good yield of RS3 [73, 74].

7.1.2 Hydrothermal Treatment

Hydrothermal treatment involves physical modifications that change the physico-chemical properties of starch without altering its granular structure. Annealing (ANN) and heat moisture treatment (HMT) are the main hydrothermal treatments where the temperature and heating time need to be controlled. These treatments are based on the starch to moisture ratio. In ANN treatment, a combination of excess of water (>40%) and temperature below gelatinization is used, whereas HMT takes place under controlled moisture content (10–30%) with high temperature (90–120 °C) [75]. Partial acid hydrolysis enhances the effect of hydrothermal treatment and can result in heat stable granular RS [76]. HMT is natural physical modification technique that is safer than chemical modification of starch. In ANN treatment temperature must be held below gelatinization temperature to retain the initial granular structure of starch. Granular structure is lost due to combination of gelatinization and melting at 40–60% moisture level. Enhanced granular stability due to hydrothermal treatment results in high RS content [65].

ANN treatment is known to enhance the degree of starch crystallinity, strengthen crystalline form of granules, and order starch chains in crystalline as well as amorphous layers. All of this increases granule stability with decreased solubility and swelling capability and hence, in turn, increase resistance of starch granules to amylolytic enzyme [77]. Lee et al. [78] used different combinations of moisture (20–25%) treatment, duration (1, 5, and 9 h), and temperatures (110 °C, 130 °C, and 150 °C) to treat waxy potato starch (0% amylose) and achieved maximum RS yield, i.e., 66.8% with the combination of 20% moisture, 110 °C temperature, and 5-h treatment.

Starch treated with HMT has increased resistance to amylolytic enzymes. HMT of high amylose maize starch at 100 °C temperature and moisture content below 35% leads to crystallite formation along with ordering and binding of amylose chains in the amorphous region which results in lower degree of swelling and hence results in

resistant nature of starch [79]. Chung et al. [80] reported 7.7%, 20.3%, and 5.6% increase in RS yield after HMT of corn, pea, and lentil starches, respectively. Chung et al. [81] compared the effect of ANN and HMT on RS yield and observed that HMT results in higher RS yield compared to ANN. ANN increased RS to 0.3%, 1.3%, and 1.6% whereas increase with HMT was 1.7, 4.7, and 5% in starches of pea, lentil, and navy bean, respectively. An extensive range of botanical sources and a range of HMT conditions were studied by various researchers and they observed numerous changes on granular surface, swelling factor, amylose leaching, gelatinization temperature, X-ray diffraction pattern, crystallization, and gelatinization parameters of starch [82–85].

Most widely used methods to increase RS3 yield are ANN, acid hydrolysis of amylomaize starch, and repeated freeze-thawings [65, 86]. Generally high amylose corn starch is used for preparation of RS3 [87]. ANN treatment (50 °C for 24 h at 50% moisture) increased RS content in pinto bean and black bean to 39.7% and 19.7%, respectively. Jiranuntakul et al. [88] observed that different starches respond differently to HMT. They observed that HMT (25% moisture, 100 °C temperature, and 16 h) increases the RS from 27–40.3% in waxy corn starch, whereas same conditions decrease the RS from 4.7% to 29.7% in normal corn, rice, and potato starch. Zero to seven cycles of boiling and freezing at −18 °C for 23 h to whole wheat flour in water (1:15% w/v) increased the RS content from 1.03% to 8.07% [89].

7.1.3 Extrusion

Extrusion technique is widely used in food processing industry to prepare food products with different shapes. This is a high temperature short time process (HTST) and has the potential to increase the RS content of food product up to certain extent. During extrusion high shear force causes depolymerization followed by thermal cleavage of the starch molecule. As a result straight chains are produced which are more prone for retrogradation into RS3 [90]. RS content of normal corn starch increased from 11% to 20% after acid hydrolysis followed by low or high shear extrusion [91]. Extrusion conditions such as barrel temperature, screw speed, and shear force have more impact on RS yield as compared to starch moisture content [92]. Extrusion of maize starch with 12–18% moisture did not show significant increase in RS content, whereas at 20% moisture level, RS content increased significantly. Origin of starch affects the RS yield during extrusion. Because of high gelatinization temperature and amylose content banana starch is most efficient for production of RS through extrusion, compared to other starches [64]. RS content of wheat starch increase from 0.8% to 2.8%, normal maize starch from 1.5% to 2.1% [93], barley from 2% to 3% [94] after extrusion. Reports on increase in RS after extrusion are conflicting as many studies reported decrease in RS content after extrusion and attributed this to degradation of starch granules under high temperature, pressure, and shear forces [95]. Possible reason for this conflict could be the interaction of starch with other components available in various food matrix.

7.1.4 Heat and Enzyme Treatment

RS production can be increased by using a combination of heat and enzymatic or chemical and enzymatic modification. Enzymes or chemicals can be used to remove amorphous region of retrograded starch. Example of simultaneous heat and enzyme treatment is pullulanase treatment of gelatinized starch and isolation of the product by drying/extrusion. RS production is also achieved by controlled heat treatment of starch, followed by debranching with the help of enzymes, annealing, and drying [96]. Treatment of gelatinized starch with debranching enzyme such as isoamylase or pullulanase results in debranched amylopectin starch. Debranched amylopectin starch is used in formation of reduced-fat food products and can be prepared from any starch containing amylopectin such as common corn and waxy maize starch. In high amylose maize starch, RS content is increased by enzymatic debranching followed by extrusion or drying, where the addition of an inorganic salt or debranched starch before the isolation further increases the RS content [74, 97]. Debranching of potato amylopectin with pullulanase before repeated heating-cooling cycles as well as maize starch debranching increase the RS3 yield [70, 98]. However, to get high yield of RS3 from maize starch autoclaving of starch at 121 °C for 1 h before debranching is required.

7.2 Enzymatic Treatment

Lower molecular mass of starch and amylopectin debranching play a role in enhanced RS production and enzymes are used for both of these purposes [99]. Debranching enzymes such as pullulanase and isoamylase act only on α 1,6 glycosidic bonds at branch points of amylopectin and break these bonds. As a result amylose content of the starch increases which in turn forms tightly packed crystalline structures which is responsible for the resistant nature of starch. Enzymes such as α- and β-amylase can also be used to break the α-1,4 glycosidic bonds. Both enzymes act on different areas of starch molecules, where α- amylase breaks all α-1,4 glycosidic bonds leaving those near the branch points and releases glucose monomers. Whereas β-amylase breaks every other α-1,4 glycosidic bond from nonreducing end of amylopectin or amylose and releases maltose units. In practice, pullulanase and isoamylase are commonly used for RS production compared to α- and β-amylase. As α-amylase breaks almost all the α-1 → 4 glycosidic bonds of starch, it lowers the starch paste viscosity and as a result adversely affects crystal formation. In low viscosity starch pastes fast movement of linear chains causes difficulty in crystal formation [100]. Optimization of α-amylase is required to obtain sufficient yield of RS. Measurement of total dietary fiber content of RS samples through enzyme treatment revealed that the concentration of α-amylase is more critical compared to amyloglucosidase [101]. The α-amylase activity showed inverse relationship with RS content. Poly 1,4-α-D-glucan can also be used for production of readily fermentable heat stable RS of optimal chain length [102]. Pullulanase enzyme can also be used to produce RS with the same cooking quality as that of untreated rice starch or flour. Starches

from potato, oat, barley, sago, corn, wheat, tapioca, and arrow root can be used to produce RS through pullulanase treatment [74].

7.3 Chemical Treatment

Chemical reagents are used to block the enzyme access and as a result modified starch escapes digestion after chemical treatment. Chemical treatment changes the molecular structure of starch which results in high RS production. Acidification, esterification, and cross-linking are the major forms of chemical modification of starch.

7.3.1 Acidification

The purpose of acidification is to first hydrolyze the amorphous parts of starch granules followed by hydrolysis of crystalline region. This process generates short chains of amylopectin which are disorganized by autoclaving followed by acidification. During retrogradation, these chains reorient to form more ordered double helix structures which resist enzyme hydrolysis [103]. Acid modification followed by autoclaving and retrogradation to increase RS yield is reported by several researchers [104, 105]. Acids such as hydrochloric acid, orthophosphoric acid, and sulfuric acid can be used for starch modification [106]. Tester et al. [107] obtained 49.5% RS by treatment of lima bean (*Phaseolus lunatus*) with hydrochloric acid at 1/60 parts of native starch at 90 °C for 1 h. Xie and Liu [108] obtained 68.3% RS yield with chemical treatment of normal corn starch with citric acid followed by dry heating at 140 °C for 7 h and heating at 100 °C in boiling water bath. During acidification by citric acid, citric anhydride substitutes the hydroxyl glucans of starch chains that resist digestion by amylolytic enzymes. Thermal-acid treatment of starch for production of RS needs optimization, as high intensity of this treatment may destroy the resistant structure of starch. Heat and citric acid treatment of normal maize starch increased RS yield to 35.62% [109].

7.3.2 Cross-Linking

Food industry is using cross-linking to improve functional property, freeze thaw stability, and cold storage stability of starch pastes. Cross-linking stabilizes and strengthens starch by randomly adding inter- and intramolecular bonds [110, 111]. Seib and Woo [112] and Woo and Seib [113] have described the use of various cross-linking techniques for increasing RS yield in normal starches derived from several botanical sources. Starches are chemically modified by treating with multifunctional reagents that form ether or ester linkage between hydroxyl groups of starch molecule [111]. Chemically modified starches show resistance to enzyme hydrolysis in both raw as well as gelatinized form [114]. During chemical modification, starch resistance is improved by substitution of starch hydroxyl group with citryl, acetyl, octenylsuccinyl, and hydroxypropyl [108, 115–118]. Cross-linking of starch with phosphate showed contradictory results as some authors [113, 119] reported decrease in digestibility of starch and some authors [58, 118, 120] reported either slight or no change in the digestibility of starch. These contradictions

could be due to the difference in the origin and property of starch and the conditions used to modify starch. For production of cross-linked starches bi-or-polyfunctional reagents such as sodium trimetaphosphate, phosphorous oxychloride, or mixed anhydrides of acetic acid and dicarboxylic acid like adipic acid are used. Kahraman et al. [121] reported use of reagents such as sodium triphosphate or its mixture with sodium tripolyphosphate for cross-linking glucans for RS production. Factors such as source of starch, reaction conditions like time, temperature, pH, and type and concentration of cross-linking reagent affect the chemical and functional properties of cross-linked starches [111, 122]. Woo and Seib [113] reported positive correlation between RS content and reaction time. Temperature and pH both increase the RS content of cross-linked corn and wheat starch, where cross-linking is more subjective to pH than temperature-induced modifications. Cross-linking of corn and wheat starch yield 80.4% and 83.9% RS, respectively [123]. Wheat and corn starch has different optimum conditions for production of cross-linked RS. For production of cross-linked wheat starch 38 °C temperature and pH 12 and for cross-linked corn starch 70 °C temperature and pH 12 are optimum treatment conditions [121]. Carlos-Amaya et al. [124] reported increase in RS from 21.49% to 29.14% in banana starch with dual modification using cross-linking and esterification. Starch may appear as swollen granules, combination of starch fragments, as well as dispersed starch molecules or completely dispersed starch molecules based on the degree of gelatinization. Ratio of starch fractions viz. RDS, SDS, and RS is determined by the degree of starch gelatinization and the structural changes in starch caused by physical or chemical treatment [125].

Chemically modified starches have been utilized as food additives, thickening or gelling agents, and fat replacers. Hydrothermal treatments increase the accessibility of chemically modified starches to the amylolytic enzymes. However, the level of digestion is determined by the origin of starch and degree of substitution with chemical groups [120]. Di-starches are modified RS with high dietary fiber content ($\geq$ 70% w/w) and their resistance to the activity of amylase show direct correlation with degree of chemical substitution [113]. Acetylated retrograded starches also come under chemically modified starches and their quality is influenced by degree of substitution and raw material used for esterification [126]. Hydroxypropylation, roasting with glycine, and cross-linking with epichlorohydrin also increase starch resistance to amylolytic enzymes [125].

7.4 Hydrostatic Pressure Treatment

Hydrostatic pressure treatment (HPT) is a nonthermal food processing method where food is processed at high hydrostatic pressure (HHP) ranging from 200 to 600 MPa. Water is used as a pressure transmitting medium in this process [127]. During HPT, starch microstructure is influenced by factors such as pressure level, method of pressure application, time, temperature, constitution of food, and phase state of food [128–132]. High pressure treatment at 120 to 600 MPa for 30 min converted the C-type X pattern of starch to B-type in mung bean [131]. Potato starch being more resistant to pressure than rice, corn, or tapioca starch yields low RS at equal

HHP level [133]. Among the continuous and two-cycle (200 and 600 MPa) HPT, HHP at 600 MPa significantly alters the microstructure and lowers the RS content of rice starch in comparison to HHP level 200 MPa [134]. Two 15-min cycle of high hydrostatic pressure treatment at 200 MPa could be beneficial to increase RS content. Zhang et al. [135] reported 11.7% RS yield of high amylose maize starch (50% amylose content) gelatinized at high pressure and temperature (10.3 MPa, 110 °C) and retrograded for 24 h.

8 Improving RS Production in Plants

In view of the industrial application and the nutritional benefits of resistant starch, researchers around the globe have been working to increase the RS content of the plants. The approaches for increasing the RS content in plants includes natural selection, conventional breeding, as well as transgenic. All these approaches are based on biosynthetic pathways of starch metabolism. The key enzymes for starch biosynthesis are AGPase, starch synthases, and branching enzymes. Generation of the sugar nucleotide ADP-glucose is catalyzed by AGPase. Starch synthases catalyze the polymerization of glucose residues resulting in formation of α-1,4 glucans. Branching enzymes cleave α-1,4 glucans and reattach the cleaved chain to an α-1,4 glucan chain by an α-1,6 glycosidic linkage thereby forming a branch.

In 2000, Gerhard et al. developed very-high-amylose potato starch by manipulating starch branching enzymes through genetic engineering [29]. They simultaneously inhibited two isoforms of starch branching enzyme to below 1% of the wild-type activities which resulted in altered starch granule morphology and composition. In these potatoes amylopectin was found to be absent, whereas the amylose content increased to levels comparable to the highest commercially available maize starches. Slade et al. used TILLING (Targeting Induced Local Lesions in Genomes) approach and identified mutations in the form of single nucleotide polymorphisms (SNPs) in starch branching enzyme IIa genes (SBEIIa) [136]. They combined these new alleles of SBEIIa through breeding which resulted in the development of high amylose durum and bread wheat varieties containing 47–55% amylose and having elevated resistant starch levels compared to wild-type wheat. Recently in 2014, Sparla et al. applied the TILLING approach on barley and identified 29 new alleles in five genes related to starch metabolism known to be expressed in the endosperm during grain filling: BMY1 (Beta-amylase 1), GBSSI (Granule Bound Starch Synthase I), LDA1 (Limit Dextrinase 1), SSI (Starch Synthase I), SSIIa (Starch Synthase IIa). A line having a nonsense mutation in SSIIa exhibited a twofold increased amylose/amylopectin ratio [137].

9 Commercially Available RS Products

Starch Australia Ltd. introduced the first commercial RS, i.e., Hi-maize. Later other companies introduced new commercial starches to market using different preparation technologies. The commercial RS prepared by different companies vary in

percent RS content. Other commercial RS are CrystaLean® (RS3), Novelose®240 (RS2), Novelose®260 (RS2), Novelose®330 (RS3), Eurylon® (RS2), Amylomaize VII (RS2), and Neo-amylose (RS3) (Table 4). CrystaLean is RS3 produced by starch retrogradation of high amylose maize starch ae-VII hybrid. National Starch and Chemical Co. (USA) introduced Hylon-VII, a natural high amylose maize starch. Most of the above RS3 products are prepared by amylose retrogradation of high amylose corn starch using repeated heating and cooling cycles under controlled moisture and temperature conditions. These processes lead to manufacture of granular form of concentrated RS containing up to 47–60% RS content. A highly crystalline RS3 namely Actistar Act*-RS3 has also been prepared using maltodextrins as starting material. Due to the starting material and process used for the production, Act*-RS3 tastes very natural. High amylose corn starch is also being used for the production of Fibersym HA, which is being used in a wide array of lower-net-carbohydrate food products. Fibersym HA provides more than 70% dietary fiber and is used in the preparation of food products such as pizza crust, breads, tortillas, cookies, muffins, breakfast cereals, snack products, and nutritional bars. Potato starch is used for the production of Fibersym 80ST. Fibersym 80ST has slightly higher water holding property which influences the properties of finished food products like cookie spread and muffin volume. Nutriose FB06 and Fibersol-2 also contain high RS content and provide 85% and 90% fiber content, respectively. Fibersym 80ST, Fibersym RW, Fibersym HA, and Fibersol-2 are all RS4 preparations and are available in the market. RS preparations without altering the organoleptic properties of food products reduce the availability of some saccharides. RS fortification does not alter the quality of product and organoleptic properties of extruded, baked products and confectionary remains unchanged [59, 138].

10 Applications of RS

Potential physiological benefits and unique functional properties of RS have attracted the attention of nutritionists and food processors. With ever increasing awareness of consumers towards health and nutritious food, they are concerned with supplementary health merits derived from regular ingestion of RS along with traditional nutritional aspects of food [139]. Looking into this, food processors, researchers, and producers are working on development of improved foods with slow digestion and additional health benefits. RS is one such ingredient which is being used for fortification of food products to enhance the nutritional value and health merits of food. RS being naturally present in broad range of starchy foods makes it convenient to use it as a functional ingredient for fortification purposes. RS-fortified food products are gaining popularity among consumers and consumers are even ready to pay more for such food products to increase their dietary fiber intake [140]. At commercial level, RS containing starch ingredients are available in name of "resistant starch." Most of these RS-enriched products are fully digestible and act as RS supplier [108]. In mid-1990s the first ever commercially available RS product was reported. However, nowadays RS-rich powders are prepared by large number of

Table 4 Commercially manufactured resistant starches commonly used in various foods [59].

Brand name of commercial RS	Type	RS/TDF% content	Physiological and/or health benefits	Manufacturer
Hi-maize	RS2	30–60% TDF	Prebiotic properties. Lowers fecal pH. Increases the level of SCFA (in particular butyrate which may reduce cancer risk). Increases bowel action with its mild laxative effect. Increases the bowels' beneficial microflora	National Starch and Chemicals co., USA
CrystaLean	RS3	19.2–41% RS	Prebiotic effect. Increases proportion of butyrate. Increases cell proliferation in proximal colon (in rats). Provides soluble dietary fiber and prebiotic effects. Low glycemic index	Opta food ingredients Inc., USA
Novelose 240	RS2	47% RS	Lowers glycemic response when used as a substitute for flour and other rapidly digested carbohydrates	National Starch and chemicals co., USA
Novelose 260	RS2	60% RS	Lowers glycemic response when used as a substitute for flour and other rapidly digested carbohydrates	National Starch and chemicals co., USA.
Novelose 300	RS3	<30% TDF	Lowers glycemic response when used as a substitute for flour and other rapidly digested carbohydrates	National Starch and chemicals co., USA
C*Actistar	RS3	53% RS	Health benefit potential. Prebiotic effect. Source of butyrate. Supports the immune system. Reduced glycemic response. Low calorific value. Easily fermentable RS. Very well tolerated.	Cerestar (Cargill company)
Fibersym™ HA	RS4	>70% TDF	Acts as prebiotic, reduces the glycemic and insulin response of healthy individuals as well as type 2 diabetics	MGP ingredients, Inc. (Atchison, Kans.) and Cargill
Fibersym™ 80ST	RS4	80% TDF	Acts as prebiotic, reduces the glycemic and insulin response of healthy individuals as well as type 2 diabetics	MGP ingredients, Inc. (Atchison, Kans.) and Cargill
Nutriose FB	–	85% TDF	Low calorific value	Roquette, Freres, France
Fibersol 2	–	90% TDF	Probiotics effect, intestinal regularity, and blood sugar regulation	ADM/Matsutani

(*continued*)

Table 4 (continued)

Brand name of commercial RS	Type	RS/TDF% content	Physiological and/or health benefits	Manufacturer
Hylon^{R} VII	RS2	23% TDF	Increases level of SCFA	National Starch and chemicals co., USA.
Neo-amylose	RS3	87 or 95% RS	Prebiotic. Protects against inflammatory intestinal disease. May protect against colorectal cancer. May help control blood glucose levels in diabetics	Protos-biotech. (Celanese ventures GmbH)

companies employing various technologies. RS cannot be replaced by traditional insoluble fiber in a RS-fortified food product, due to the high quality of RS-enriched final product [141]. RS is being used in the preparation of moisture-free food products. Cross-linked RS prepared from starches of maize, tapioca, and potato are being used for formulation requiring pulpy texture, smoothness, flowability, and low pH and high temperature storage [142]. Baked products, pasta products, as well as beverages are fortified with RS to improve their textural properties and nutritional quality. Most of the fat in imitation cheese was successfully replaced with RS, without adversely affecting the meltability or hardness of RS. In such cases, RS provides dual benefits, one being reduction of fat in a food product and another being health benefits conferred by RS itself. Nowadays large number of RS/fiber-fortified products such as high fiber breads, biscuits, and breakfast cereals are available in the market. The availability of techniques to prepare RS tolerant to processing made it possible to prepare RS-rich food products. Dry pasta products containing up to 15% RS can be prepared, without affecting dough rheology during extrusion. In comparison to unfortified pasta, RS-fortified pasta appears light in color and has a firm texture in the same time as that of unfortified pasta [74]. RS added opacity to the beverages. It is being used in thickened opaque health drinks in which insoluble fiber is desirable. RS is superior to other fibers, due to its bland taste, which imparts less gritty mouthfeel and masks flavor to much lesser extent. However, other fibers have a strong flavor, coarse texture, and poor and dry mouth feel.

11 Health Benefits of RS Consumption

Health awareness is increasing at a fast rate among consumers. To meet the growing demand of consumers for functional foods, international food industry is investigating ways to produce innovative food products with additional health benefits. Carbohydrate-rich foods are main part of our diet and most of the carbohydrate-rich foods are high glycemic. Therefore, development of carbohydrate-rich foods with low GI is need of the hour. High GI foods adversely affect health by spiking

blood glucose level and cause insulin disturbance. Carbohydrate products with low GI can improve the control of obesity and diabetes and subsequently can reduce the risk of cardiovascular diseases [62]. However, all RS types are not effective to control cholesterol level. The composition and properties of RS determine the extent of production of SCFA by bacterial fermentation of RS in the large intestine [143]. RS confers physiological benefits of soluble fiber and has a positive impact on colonic health by increasing crypt cell production rate or decreasing colonic epithelial atrophy in comparison with no fiber diet. Consumption of carbohydrate-rich foods was highly recommended, until recently. However, due to change in the viewpoint on nutrition, in developed countries, nutritional quality of food is expressed by the tendency of reducing calorific value of food. Civilizational changes also contributed to increase in dietary fiber intake that is required for proper functioning of body. RS being a natural food component, attracted much attention. Dietary fiber including RS with little calorific value confers several health benefits like laxation, blood cholesterol attenuation, and blood glucose attenuation.

11.1 RS: A Type of Dietary Fiber

Dietary fibers are "the edible part of plants or analogous carbohydrates that are resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine" [144]. Champ et al. [145] defined dietary fiber as "a part of plant present in the form of a chemical substance which has indigestibility in the small intestine and/or has beneficial digestive and physiological effects and metabolic fate." Dietary fiber comprises of non-starch polysaccharides (NSP), lignin, RS, and nondigestible oligosaccharides. Dietary fiber majorly consists of NSP and lignin. NSPs include majorly cellulose and hemicelluloses (glucan, gums, and pectin). NSP are completely resistant to amylolytic enzymes. In the small intestine, soluble dietary fiber such as β-glucan and arabinoxylan leads to the formation of viscous solution and hence, increase viscosity in the intestine, which in turn slows intestinal transit, delays gastric emptying leading to slow glucose and sterol absorption [146]. Lignin, cellulose, and hemicelluloses are insoluble dietary fibers with high water-holding capacity which contributes to increased fecal bulk. Dietary fibers that are not fermented in the body are excreted in the feces. Dietary fibers are essential for body and they help in regular bowel movement, blood cholesterol attenuation, and blood glucose attenuation.

11.2 RS Improves Probiotic Bacteria

Prebiotic property of RS is of great interest. Prebiotics are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth as well as activity of one or more number of bacterial species residing in the colon and as a result improve host health. Prebiotic and probiotic have a symbiotic relationship. One of the best example of prebiotic is fructo-oligosaccharide, others being inulin,

oligofructose, RS, and inulin type-fructans [140, 148]. RS plays a role as prebiotic as well as symbiotic [148]. Probiotics enhance the epithelial barrier, increase adhesion to intestinal mucosa, and concomitantly inhibit the pathogen adhesion, competitive exclusion of pathogenic microorganisms, production of anti-microorganism substances, as well as modulation of the immune system [149]. RS is known to promote the growth and activity of probiotic bacteria in the colon and also can interact with other prebiotic dietary fibers such as β glucan [145, 150, 151]. RS ingestion helps in extending the viability of some probiotic organisms in the colon. RS acts by protecting some of the ingested organisms on their path to colon and increase the initial levels of bacterial species once they reach the colon. RS acts as a substrate for probiotics in the colon [147]. High amylose starch (HAS) being source of RS2 also acts as prebiotic and prevents the development of nonreversible insulin resistance, lower plasma cholesterol, and triglyceride concentration compared to diet rich in amylopectin starch [152]. RS affects fecal bulk and SCFA metabolism, hence has direct impact on colonic health [74]. RS3 has a high rate of fermentation by intestinal microflora which leads to production of SCFA containing high concentration of butyrate, which has positive impact on colon health [153]. In comparison to RS3, RS4 is inaccessible to enzymes due to chemical modification of starch. Large number of microorganisms and enzymes residing in the colon digest and metabolize most of the biopolymers. RS is hydrolyzed to glucose by bacterial amylase, which is further metabolized into organic acid (e.g., lactic acid) and gases (CO_2, H_2, CH_4) [65, 154]. Among the SCFA, butyrate acts as a main nutrient for colonocytes and deficiency/lack of butyrate increase the risk of colonic diseases such as colon cancer. Compared to all other dietary fibers, RS produces high concentration of butyrate, hence is very much important for human health. RS being source of butyrate in colon prevents the risk of colorectal cancer. Butyrate acts as a source of energy for epithelial cells and inhibits the malignant transformation of such cells in vitro. The rate of fermentation of RS in the colon determines the site of production of SCFA [144]. RS can also be beneficial to adults suffering from colonic lesions. Overall RS has the potential to lower the risk of many diet-related diseases and improve the human health [98, 155].

11.3 Hypoglycemic Effect of RS

FAO recommended increased intake of low GI foods with emphasis on diabetics and subjects with impaired glucose tolerance [156]. GI is a ranking of food/food products with respect to their influence on postprandial glycemia [1]. Hypoglycemia occurs as a side effect in diabetes mellitus patients and can occur in other diseases as well. RS-rich foods have slow digestion rate. This property of RS is of much importance to type II diabetic patients, due to its slow rate of glucose release as well as the time it takes to metabolize. The starch inaccessibility to digestive enzymes (such as α-amylase, isoamylase, and pullulanase) in starchy foods is responsible for reduced postprandial blood glucose and insulin response. Along with RS, diets rich in SDS are also good for health of diabetics as well as nondiabetic persons [13, 157]. Whole

grains containing high concentration of dietary fibers are a good example of low GI food, as they release glucose at slow rate [158]. Processing technique can lower the starch digestibility and can increase the SDS and RS content in cereal grains and can hence enhance the nutritional value of cereal grains. The outer layer and germ of wheat, barley, rye, and oat grains is rich in many bioactive compounds such as dietary fiber, antioxidants, phenolics, lignin, vitamin, and minerals [159]. Such compounds are effective in reduction of risk of cardiovascular diseases, cancer, diabetes, obesity, coronary heart disease, and other chronic diseases [160]. Food industry is focusing on producing functional foods with low GI using these cereal whole grains.

11.4 Hypocholesterolemic Effect of RS

Asp et al. [161] investigated the role of RS in relation to its hypocholesterolemic effect and protective effect against colorectal cancer. RS affects lipid metabolism, where total lipid, total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), very-low-density lipoprotein (VLDL), intermediate density lipoprotein (IDL), triglycerides, and triglyceride-rich lipoprotein are all affected by RS [4]. Feeding of rat with RS diets containing up to 25% raw potato raises the cecal size, cecal pool of SCFA, absorption of SCFA in colon and lowers the plasma cholesterol and triglycerides [74]. Martinez-Flores et al. [162] observed hypocholesterolemic properties of cassava starch extruded with 9.7% RS. Such starches can be used in food to improve overall cardiovascular health. RS ingestion decreased the serum cholesterol level in rats fed with cholesterol-free diet [163]. Some contradictory reports on the role of RS in altering triglycerides and cholesterol levels are available, which emphasize the need of more research in this particular area to obtain a clear picture on effect of RS on lipid metabolism in humans.

11.5 RS Plays a Role in Energy and Weight Management

RS releases energy partially in small intestine as glucose and partially in large intestine as fermentation by-product such as acetate, which in turn provide balanced energy for long time after consumption. Energy value of RS is quite low and is calculated to be approximately 8 kJ g^{-1} (2 kcal g^{-1}) in comparison to energy provided by completely digestible starch, i.e., approximately 15 kJ g^{-1} [164]. RS has been reported to play a role in modification of fat oxidation, as satiety agent, and in weight management [4, 165, 166]. Mobilization and utilization of fat stored as an indirect result of reduction in insulin secretion is enhanced with RS-rich diets [167]. Compared to fully digestible carbohydrates, RS-enriched foods provide few calories along with lower glucose response. RS reduces the total and regional body fat accumulation. Diet enrichment with RS is a natural, endogenous way to increase

gut hormones which are effective in reducing energy intake [168]. RS fortification may be a very effective natural approach to treat obesity.

11.6 Reduction of Gallstone Formation

High secretion of insulin due to consumption of digestible starch-based food is leading to gallstone formation [74]. The occurrence of gallstone formation is quite less in Southern India where whole grains are preferred over flour, compared to North India, where majorly flour is used [169]. The lesser occurrence could be due to the high intake of dietary fibers and RS in South India. The dietary fiber intake in the USA, Europe, and Australia is two- to fourfold lower compared to India and China, where high starch diets are consumed. These results are correlated with the difference in the number of gall stone cases in these countries [74, 170].

11.7 Enhanced Absorption of Minerals

Studies on rat as well as human have shown that RS increase ileal absorption of a number of minerals. RS consumption enhances absorption of only calcium in humans, whereas in rats fed with RS-rich diets, increase in absorption of calcium, magnesium, zinc, iron, and copper was observed [151]. Consumption of diet containing 16.4% RS increases calcium and iron absorption in infant pigs [171]. Schulz et al. [172] reported increase in calcium and magnesium absorption by enhancing mineral solubility in the cecum and/or large intestine in rats by RS2 consumption [172]. Feeding raw potato starch to rat enhanced the fermentation in the distal part of digestive tract, resulting in increased absorption of calcium, magnesium, zinc, and copper owing to hypertrophy of the cecal wall and cecal acidification [173].

11.8 Other Health Benefits

RS reduces inflammatory bowel diseases such as ulcerative colitis and other large bowel problems such as diverticulitis and constipation [4]. As RS is involved in the production of SCFA, particularly, butyrate in vivo, it may prove a useful adjunct to traditional treatments of ulcerative colitis. Diets rich in RS2 as well as RS3 normalize the cell function-like activation of colonic cell proliferation, restoration of apoptotic response and uptake of SCFA, increased cecal level of butyrate, improved cecal and distal macroscopic and histological observations in rats with chemically induced colitis [174]. RS affects immune function through production of pro-inflammatory cytokines and expression of number of receptors on T- and B-lymphocytes that are required for initiation of immune response [175, 176].

12 Future Trends

The increased number of research papers that have appeared on RS is testimony to the importance of RS. RS in food is an active area of research. Research is being carried out on various aspects of RS, such as its increase in food through processing techniques, production of RS-fortified food, studies on health benefits of RS in vitro and in vivo, etc. Due to keen interest of researchers and nutritionists, several commercial preparations of RS are available which can be used to increase fiber content of food. More efforts are required for production of RS resistant to thermal processes during processing. Although several health benefits of consuming RS are reported, further studies are required for development of RS preparation with optional characteristics to claim specific health benefits such as improved blood health and lowering the GI. Although some figures have been proposed for specific health benefits, in general, it is very difficult to suggest a figure for RS consumption for general health benefit. Overall RS consumption has been decreased due to modern food processing practices. However, due to desirable functional and physiological properties of RS, there is an increasing trend to incorporate commercial preparation of RS in processed foods. In developed countries, where processed food daily intake is considerable, RS will provide dual benefit, one being dietary fiber and another being bioactive functional food component to increase gut hormones that reduce energy intake and hence treat obesity. As the demand for healthier food increases owing to its physiological benefits, RS can form essential ingredient of innovative foods to be developed in future.

Future may witness the more tailor made starch derivatives with multiple modifications. Buttriss and Stokes [140] reported development of insoluble resistant maltodextrins with similar functionality as that of RS. More such resistant components may appear in future. Nondigestible chemically modified starch derivatives may have increased application in food formulations [16]. As extrusion also enhances RS concentration of native starch, more extruded products with high RS can be expected in future [177].

13 Conclusions

Due to research on its different aspects (physical, chemical, and physiological) good understanding of RS has been achieved. Reports show that the consumption of RS has declined over the last few decades, possibly due to intake of low fiber foods and fast foods. Looking into this trend, food scientists have developed number of RS/dietary fiber-rich products easily available in the market. RS is ideal for fortification of ready to eat cereals, snacks, pasta, noodles, baked foods, and fried foods. These products can be labeled simply as "starch conferring additional nutraceutical benefits." Processing conditions can be altered to increase its content in food. Alterations in number of heating-cooling cycles, pH, temperature, time, freezing, and drying, etc., alter the RS content. Products prepared with RS incorporation have better crispness, mouthfeel, color, and flavor compared to those prepared with traditional

fibers. RS has assumed great importance due to its physiological properties that can reduce the risk of several diseases, including colon cancer and diabetes and also is useful in controlling obesity and diabetes. RS-fortified products have better consumer acceptability because of its unique physiochemical properties.

Gluten-Free Cereals and Pseudocereals: Nutrition and Health

29

Mario Fernández de Frutos, Bartosz Fotschki, Ricardo Fernández Musoles, and José Moisés Laparra Llopis

Contents

Abstract

Cereals constitute a staple food for large groups of population worldwide. However, the protein fraction of cereals continues receiving increasing attention from the clinical community because of its close involvement in both the development of immunological processes and intestinal disorders. Thus, together with constant technological innovations to the increasing demands of the consumer, makes necessary to optimize food formulations promoting health outcomes. In this context, beneficial health implications are being reported based on the advantageous nutritional profile of gluten-free cereals, but mostly pseudocereals. The latter represent a good source of proteins (albumins/globulins) reducing the

intake of prolamins. Additionally, pseudocereals provide an optimal lipid profile (ratio of saturated versus unsaturated fatty acids) and bioactive compounds with a potential significant impact on the consumer's health. Currently, the underlying mechanisms by which these beneficial health effects occur still remain unsolved. Moreover, some recent data point to metabolic effects beyond their nutritional value. These could have an important impact on immunological processes, although studies on these aspects result inferential. Future research should approach epidemiologic studies and toward consolidating the mechanisms of action, especially in the human body.

1 Introduction

At present, continuous social development and commercial globalization are motivating the increase in food production, where constant technological innovations are needed to respond to the increasing demands of the consumer of high quality food, which is the closest thing to a fresh product with a processed minimum, healthy and nutritious. The important socioeconomic changes in most countries have led to a substantial change in dietary habits favoring an increase in the consumption of animal fats and proteins. This tendency is reflected in an increase in the incidence of diseases, directly or indirectly, associated with alterations of the hepatic homeostasis that give rise to a wide spectrum of pathologies related to the metabolic syndrome, obesity, and type 2 diabetes (T2D).

For the past two decades, the interest of researchers, the food industry, and consumers has focused on those foods that, in addition to containing essential nutrients, have bioactive components that promote health and/or prevent chronic diseases. Here, we can find cereals that have been cultivated worldwide from ancient times [1, 2]. In the case of cereals, in addition to playing an important nutritional function, they are responsible for multiple beneficial effects for health [3]. This has led to propose health claims for the consumption of whole grains in USA (1999) and, as of 2002, in England and Sweden [4]. The rich composition of whole grains or their fractions, along with their high dietary fiber content, have motivated many nutritional interventions that have focused on highlighting their potential for healthier, more nutritious foods [5, 6]. Thus, recent studies support the relationship between regular intakes of whole grains and the lower risk of diseases such as T2D, obesity, cardiovascular disorders, metabolic syndrome, and cancer [7–9].

The protein fraction of cereals has received much attention from the clinical community because of its close involvement in both the development of immunological processes and intestinal disorders. With the increasing development of immune function measuring systems and better understanding of the potential role of cereals in immunometabolic (i.e., obesity, T2D, nonalcoholic fatty liver disease)

[10–12] diseases, people became aware and more selective about food supply. Here, gluten-free cereals and pseudocereals emerged as advantageous alternatives to wheat in innovative healthier and nutritive goods [6, 13–15].

A healthy diet helps protect us from malnutrition as well as immune-metabolic disorders. Cereals are recognized as an essential food within a healthy diet and are recommended for frequent consumption. However, despite the recognized health benefits of cereal consumption, cereals are often considered as grains that provide a great deal of nutrients, forgetting to mention specific health benefits.

This chapter summarizes recent research on pseudocereals providing comprehensive information to better estimate their potential contribution to human health. Beyond its economic, nutritional, and environmental importance, cereals have played a key role in the history of mankind. Animal and human trials support the beneficial effects derived from whole grains consumption, mostly referring to wheat and its derivatives, rice, and maize. Otherwise, pseudocereals belong to a group of nongrasses, which can be consumed as seeds or flours; even kernels can be used to produce diverse food products. The consumption of these grains has experienced a significant increase in recent years worldwide. Thus, general features of those gluten-free cereals and their specific characteristics in comparison to most common cereals are presented.

2 Gluten-Free Cereals and Pseudocereals

According to recent statistics, world cereal trade in 2017–18 has been lifted by 8 million tons to a record 403 million tons, implying an 8.7 million ton (2.2%) expansion from 2016–17 [16]. The world's most important cereals in the diet are corn, wheat, and rice. Barley, oats, and rye are cereals whose consumption is not so widespread [17]. Other cereals such as sorghum and millet are mainly used for animal consumption, intended for human consumption in some regions [18]. Notably, pseudocereals (amaranth, quinoa, and buckwheat) receive increasing attention and are consumed with great acceptance due to their advantageous nutritional profile [3].

2.1 Food Uses

Good nutrition is our source of energy to live and be active, as well as the first defense against disease. Here, vegetal kingdom satisfies a considerable part of the nutritional needs for the human being; in this context, cereals have been part of the diet of most cultures and civilizations for millennia. Cereals constitute an agronomically important crop from the environmental point of view and an economic source of protein, both in human and animal feed. Pseudocereals show out to substitute wheat in different respects, but mainly due to their high protein concentration, minerals, vitamins, and fatty acids [3]. These grains have been part of human food for centuries, although as they have been neglected by food industries and nutrition,

Table 1 Several types of products prepared with most commonly used gluten-free cereals [15, 21, 24]

Gluten-free cereal	Amaranth		Quinoa		Buckwheat		
	Grain	Flour	Whole	Flour	Grain	Flour	Kernels
Product	Toasted, popped, extruded, milk	Bread, rolls, cakes, muffins, pancakes, cookies, noodles	Broths, soups, stews, rice-like products	Porridge, coarse bread, pasta, cookies	Unpeeled, semolina, omelets	Biscuits, cookies, bread, cakes	Tea

current knowledge is still limited. The advantageous nutritional features of these grains make them good candidates as part of strategies, both conventional and modern breeding approaches, in order to provide a public health benefit with the ultimate goal of overcoming deficiencies worldwide [6, 19]. Currently, it is assumed the high nutritional value of pseudocereals; however, the study to what extent these grains impact nutritional status resulted inferential.

Gluten-free cereals are incorporated into wheat-based products up to a certain proportion to improve the nutritional value of the resulting product [6, 20]; however, it still constitutes a great technological challenge. Traditional processing methods for these cereals include hand-operated wooden or stone pestle and mortar, which still are used today in certain regions. Today, processing occurs mainly based on applying the dry- and wet-milling processes. The latter are decided according to the objective to obtain flours at a high extent or fractions where there can be found other defined components. Gluten-free cereals can represent a good source of other ingredients of technofunctional importance (i.e., kernels, saponins, oils). There are numerous scientific publications that define the physicochemical and functional properties of the major components of pseudocereals [21–23].

Gluten-free cereals are being used in a wide variety of foods, devoted to human, pets, and animal feed. Commonly, they are used in several ways, either as seeds, whole or plain grain, and flour (Table 1). The transformations that occur in the distinct components of the flours derived from these cereals during the processing and cooking of foods improve their nutritional value, favor the reduction of "antinutritive" components, and, in some cases, the formation of bioactive compounds that can contribute significantly to the reduction of metainflammatory diseases [15, 25–28].

2.2 General Features of Most Commonly Consumed Pseudocereals

2.2.1 Quinoa

Chenopodium quinoa is a highly nutritious grain that has been cultivated from ancient years in South America. The origin of quinoa appears to be in the Andean

mountains. During recent times, there has been an increased interest worldwide for this grain in the United States, Europe, and Asia. Quinoa has been selected by the Food and Agriculture Organization of the United Nations (FAO) as one of the crops destined to significantly contribute to food security in the next century.

Quinoa seeds contain a higher percentage of bran than common cereals that makes feasible the carriage of higher levels of protein and fats in these [29]. One of the aspects that could limit the widespread utilization of quinoa is the relatively high amount of saponins that appear in the outer layer of the seeds and are considered as "antinutritional" factors. These are also rich in carbohydrates representing the most part of total fraction of nutrients. There can be found monosaccharides such as xylose, arabinose, fructose, and glucose, and disaccharides such as maltose and mainly sucrose [30]. Starch also represents an important source of carbohydrates in the grain. Dietary fiber in quinoa exhibits a composition where it composed mainly of cellulose, hemicellulose, beta-glucans, and lignin. Notably, quinoa carries a significant higher protein fraction compared to other cereals. Here, there can be found protease inhibitors affecting gastrointestinal proteolytic enzymes [25]. The genetic background is identified as a major cause for the variations in content and quality of these proteins. Additionally, environmental conditions and cultivation methods also contribute significantly to these variations [31, 32]. Lipid content in quinoa is composed mainly of unsaturated fatty acids (85%), particularly linoleic (~52%), oleic acid (~25%), as well as saturated palmitic acid (~10%) [33, 34]. In a global perspective, quinoa presents a favorable profile of polar lipids (phospholipids) (25.2 g/100 g total lipids) with potential benefits on inflammatory processes, cancer, cardiovascular diseases, neurological disorders, liver diseases, and antioxidant carrier [35]. This phospholipid profile is particularly important since quinoa constitutes a good source of bioactive compounds such as phytosterols, flavonoids, and tocopherols [36, 37].

2.2.2 Amaranth

There can be found up to 26 *Amaranthus* species, but the three grain species known as amaranths include *Amaranthus hypochondriacus* L., *Amaranthus cruentus* L., and *Amaranthus caudatus* L. These were domesticated in Central America (Tehuacan, Mexico) over 4000 years BC.

Amaranth seeds are of high nutritional value, the carbohydrates representing the major part of the total nutrient fraction in the seed. Starch is the most abundant component in the seeds accounting for up to 65% to 75%, while dietary fiber accounts for only 5% [38]. One of the most interesting advantages of amaranth starch is the production of very small granules (0.75–3 μm) that exhibit extremely high water-absorption capacity [39] providing unique functional properties to food. Numerous studies have shown that amaranth starch exerts important physiological functional properties due to its high digestibility [40]. The nutritional value of amaranth is closely connected to its high protein content and amino acid profile. They display a characteristic protein distribution of about 40% albumins, 20% globulins, 25–30% glutelins, and 2–3% prolamins [41, 42]. Amaranth is considered an essential candidate in special diets for patient with coeliac disease; however, the

Table 2 Fatty acid profile in gluten-free cereal and pseudocereals

Fatty acids (g/100 g)	Gluten-free cereal and pseudocereals[a]					
	Amaranth	Barley	Buckwheat	Quinoa	Rice bran	Wheat
Palmitic (16:0)	18.5–23.8	18.5–21.0	18.2–19.5	9.7–11.4	18.6	15.4
Stearic (18:0)	3.2–4	–	2.18	0.6–0.79	1.75	–
Oleic (18:1)	22–33.3	15.2–15.6	36.4–37.1	24.8–25.6	42.4	22.3
Linoleic (18:2)	38.2–44.8	24.0–52.4	34.8–35.5	52.3–52.8	34.8	54.2
Linolenic (18:3)	0.2–1.0	2.6–5.5	1.93	3.9–7.0	1.1	3.5
Other	7.08–11.3	5.4–6.8	3.8–10.6	2.44–6.8	1.23	4.6

[a]References: [47, 66–69]

recently identified participation of defined globulins in immunological processes [10] warrants further investigation. It has been reported that cooking and popping of seeds decreases the fraction of albumins and globulins [43]. But the immunomodulatory potential of the resulting peptides and other structures has not yet been clarified. For amaranth, the lipid fraction is mainly localized in the germ and seed coat. The oil content of amaranth is commonly estimated between 5% and 9% [44, 45], although a study reported values up to 19.3% [46]. These discrepancies could be caused by differences in the extraction and purification methods employed as well as by environmental factors such as temperature and latitude that influence the composition of the oil of amaranth seed [44]. Amaranth constitutes a good source of linoleic (C18:2), oleic (C18:1), palmitic (C16:0), and stearic (C18:0) acids (Table 2).

Amaranths are also of high nutraceutical value as they are important sources of phytochemicals and antioxidants [47–49]. Origin, accession, and location constitute key aspects determining the content of, for example, tocopherols [47, 48]. Otherwise, after different abiotic stresses, the expression of amaranthin-like genes results enhanced. Amaranthin is a homodimeric lectin that was first discovered in the seeds of *Amaranthus caudatus* and serves as a model for the family of amaranthin-like lectins. Molecular modeling studies have unraveled the structure of amaranthin-like proteins and their carbohydrate-binding sites. Their particular structure allows to interact with the proliferative region of normal human colonic epithelium and neoplastic lesions of the colon. However, a causal association of these lectins to physiological proliferation processes still results inferential.

2.2.3 Buckwheat

Despite the name, buckwheat (*Fagopyrum esculentum* Moench) is not related to wheat, but to sorrel, knotweed, and rhubarb. Native to the steppes of Central Asia and Siberia, it was spread to West being introduced to Turkey and Poland and later expanded to Central and South Europe. Today, the expansion of buckwheat reached Great Britain, Canada, and EE.UU.

Considerable pharmacological evidences both in vitro and in vivo support positive effects of *Fagopyrum* buckwheats such as antitumor, antioxidant, anti-

inflammatory, hepatoprotective, and antidiabetic [50]. These activities are mostly associated to their particular nutrient composition. Carbohydrates represent (~70%) the major proportion of buckwheat's endosperm, among these the main component is starch that comprises 55% of the total fraction [51, 52]. The starch present in buckwheat seeds has a different composition to the rest of cereals, with a higher concentration of amylose and lower of amylopectin and also a significant fraction resistant (35%) to digestion considered as a dietary fiber [53]. The buckwheat's starch capacity to retain water has been established as higher than that of wheat and corn starch [54]. Factors associated to low digestibility of buckwheat starch are small granule size, amylose content, starch-protein interactions, and lipid complexes. Buckwheat proteins exhibit an amino acid profile more nutritionally favorable than wheat. Notably, a more balanced concentration of amino acids is found, except for glutamine and proline [55]. The established higher composition of individual protein fractions such as albumins and globulins in buckwheat in comparison to wheat [55] supposes a significant difference in their potential immunomodulatory features. Meanwhile, globulins from wheat exert a clear inflammatory effect; the beneficial pharmacological effects described for buckwheat suggest different bioactive effects derived from buckwheat's globulins. Nowadays, the very low concentration of glutelins and prolamins in buckwheat makes it a good crop to be part of gluten-free diets [42]. In relation to other gluten-free cereals and pseudocereals, buckwheat provides lower oil content (~2–3 g/100 g) [44]. Otherwise, buckwheat shares with quinoa and amaranth a lipid profile rich in ϖ-3 (linoleic) and ϖ-6 (linolenic) acids as well as oleic acid. Notably, fatty acid content in buckwheat is influenced by seeding time in addition to environmental factors and variety [56]. For buckwheat, neutral lipids represent 85% of the total content, while polar lipids are found in proportions up to 15%. Similarly to other grains, buckwheat seeds are a good source of antioxidants such as tocopherols, phenols, and flavonoids, specially quercetin and rutin. This characteristic favored the interest and use of buckwheat hull by food industries. In addition, groats have also been used for porridges. Other bioactive compounds identified in buckwheat seeds are D-chiro-inositol, myo-inositol, and fagopyritols, which play an essential role in insulin sensitivity lowering glucose blood levels and blood pressure.

2.3 Health Implications

The nutrient content and profile alone does not describe the quality or physiological and health implications sufficiently (Fig. 1). Digestibility, available lysine, net nutrient utilization, and efficiency ratio are some other parameters that help to better estimate the nutritional value of the gluten-free cereals and pseudocereals. In general, the protein quality of pseudocereals is close to that of casein. Significant differences in starch digestibility for pseudocereals are found [25]. Rice and maize are low in protein, fiber, and folate that contrast those concentrations in pseudocereals [3, 57].

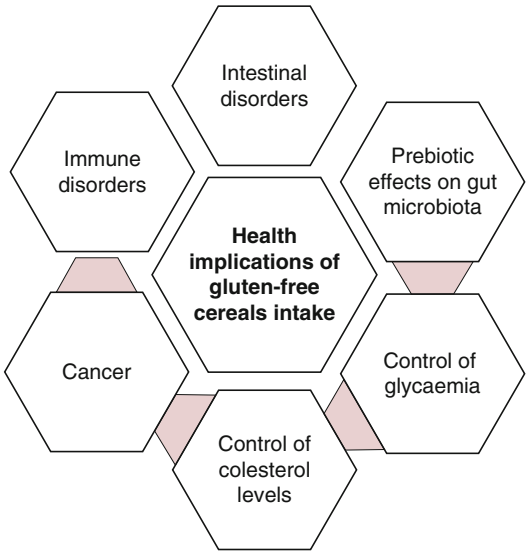

Fig. 1 Health-related outcomes associated to gluten-free cereals intake

2.3.1 Digestibility

The importance of proteins in gluten-free grains relies on their quality. The amino acid composition in pseudocereals provides to them a significant advantageous nutritional profile due to the high content of essential amino acids. Particularly, methionine, lysine, arginine, tryptophan, and several sulfur-containing amino acids are found at higher concentrations than in other gluten-free cereals. Because of the high proportion of lysine in globulins, pseudocereals provide about twofold higher amount of this amino acid than wheat or maize. Thus, they represent an excellent tool to fulfill the nutritional requirements for populations at risk such as children [58, 59]. There can be found several studies in relation to the impact of processing methods on protein quality. A literature search reveals that pseudocereals proteins remain stable, preserving their high quality and digestibility, after washing, cooking [60], and popping [43]. However, a recent study reported a decreased digestibility of quinoa proteins when using an extraction medium with pH values ranging from 8 to 11 [27]. These conditions could have an important impact during preliminary treatments to eliminate of saponins from quinoa by using a "washing" step.

2.3.2 Immunity

Pseudocereals, contrary to common grains such as wheat, contain low or no storage prolamin proteins [61], which are the main storage proteins in cereals and the toxic proteins in celiac disease (CD). Thus, these grains received increasing attention as safe and suitable for CD patients as part of the gluten-free diet. Otherwise, high proportions of pseudocereals proteins are constituted by albumins (40%) and globulins (20%) [59]. Two main classes of globulins can be differentiated in amaranth: 7S (conamaranthin) and 11S (amaranthin) storage globulins [62]. The 11S globulins (salt-soluble proteins) are one of the major storage protein fractions in amaranth.

Amaranth 11S globulin has a molecular mass around 398 kDa, and under reduced conditions, it shows characteristic bands of the acidic (36−32 kDa) and basic (24−22 kDa) subunits of 11S proteins. Additionally, a 59−55 kDa band corresponds to the nonprocessed proglobulin with structural characteristics similar to other 11S globulins [63]. Similarly, in quinoa, the 11S (chenopodin) and the 2S globulin account for 37% and 35% of the total protein content, respectively [64].

Among the different buckwheat proteins, there has been identified a 13S globulin seed storage protein with significant allergenic potential (Fagag1, 61.2 kDa, accession number AF152003, Genbank) usually present as a hexamer linked by disulfide bond [65].

The broad umbrella of heterogeneous conditions identified for reactions to gluten have revealed the need to establish an international consensus and new nomenclature and classification for these; including CD, nonceliac gluten sensitivity, and allergy affecting up to 10% of the general population [70]. Gluten or the epitopes triggering these disorders are found in all *Triticum* species; wheat, spelt wheat, einkorn wheat, emmer, durum wheat as well as rye, barley, triticale, and oat. Nowadays, cereal grains that are considered safe to CD patients are rice, maize, millet, and sorghum. However, recent immunological studies have identified several immunogenic components of the globulin fraction, α-amylase/trypsin inhibitors [10, 11]. The different downstream signaling pathways triggered by these globulins engage the chemokine receptor CXCR3 and either MyD88-dependent or independent signals associated to the Toll-like receptor (TLR)-4. The potential physiological benefit derived from an inhibited amylase activity favored the use of these globulins for type 2 diabetes and obese patients. Notably, these pathologies constitute important risk factors for nonalcoholic fatty liver disease (NAFLD) that today has become the most common liver pathology worldwide affecting an estimated 15–30% of most populations. Thus, 10–20% of subjects with NAFLD develop the severe variant of nonalcoholic steatohepatitis (NASH), hepatic inflammation, and the development of liver fibrosis with high liver-related morbidity and mortality, part of which is due to the development of hepatocellular carcinoma. However, current evidence for a causal association as well as definition of the potential role of globulins from pseudocereals within these disorders has largely been inferential. Buckwheat leaf and flowers are source of α and β amylase inhibitor activity [71, 72]; however, extracts from buckwheat inhibit proinflammatory signals in macrophages (264.7 cells) stimulated with the prototypical TLR4 agonist; lipopolysaccharide (LPS) from Gram negative bacteria [73]. Dietary buckwheat has been associated to prevention of lymphocyte immunosenescence in aged mice [74]. Taken together these studies, there could be hypothesized the more preserved prevention of reactive oxygen species derived from TLR4 stimulation. In this sense, inclusion of flours from pseudocereals into bread formulations as substitute of wheat improved the nutritional iron status [6]. Systemic iron homeostasis is tightly regulated by the liver through synthesis of hepcidin, which associates to inflammatory stimuli regulated by immunological transcription factors such as the proliferator-activated receptor-γ coactivator-1α (PGC1α) that participates in the regulation of metabolic, but also immune activation. Thus, scarce existing studies suggest innate immune-mediated alleviating effects on iron homeostasis dysregulation.

This effect is important not only from a nutritional point of view, but also because nutritional iron is an effective modulator of the TLR4 signaling. For example, it has to be kept in mind that activation of aryl hydrocarbon receptor mediates suppression of hypoxia-inducible factor-dependent erythropoietin expression. The flavonoids content of buckwheat has been indicated to interact with the aryl hydrocarbon receptor at intestinal level increasing its expression [75], thus also influencing TLR4-mediated response(s).

2.3.3 Metainflammation

Inflammation constitutes a physiological process necessary to keep functional appropriate cellular response(s). The innate branch of immune system has a crucial role in determining proper inflammatory homeostasis. Notably, a low-grade inflammation represents a common feature to many metainflammatory diseases such as NAFLD and associated comorbidities such as T2D and obesity. The scarce studies existing show the positive effects reducing inflammatory conditions within the gut-liver axis [6]. Notably, pseudocereals were used with lower proportions (5–25%) in relation to wheat flour. It was demonstrated that amaranth albumin proteins are capable to form disulfide bonds with gluten proteins [22]. The data do not allow drawing out definitive conclusions about the modulatory effect of proteins bioactivity. Otherwise, open a new way to further research in order to produce innovative food formulations from which there could be expected more controlled physiological effects. The literature search reveals continuous and intense research efforts in the baking industry to incorporate gluten-free cereals and pseudocereals [22, 63, 76].

2.3.4 Prebiotic Effects

Currently, the close association between the beneficial effects attributed to prebiotics and prevention of gastrointestinal disorders is well accepted. Prebiotics are non-digestible food ingredients that beneficially affect the host by stimulating the growth and/or activity in specific intestinal bacteria. The latter, through the production of short chain fatty acids, are able to modulate the intestinal inflammatory environment [77]. Fermentation of prebiotics exert important metabolic consequences in liver-related disorders contributes to lipid and cholesterol synthesis in the liver as well as regulating the expression of different transcription factors.

Pseudocereals provide significantly higher amounts of dietary fiber than wheat and related cereals [3]. Despite nutritional benefits, pseudocereals have been shown favorable to the adaptability of yeast and most lactic acid bacteria of technological interest [78, 79]. Preclinical studies demonstrated that enterobacteria and other potential commensal harmful bacteria do not benefit from this prebiotic effect of buckwheat [80]. In addition to metabolic effects, it has been reported the participation of defined receptors (i.e., aryl hydrocarbon receptor) in the buckwheat-mediated controlled of the proliferation of *Bacteroides* spp. [75]. This association between the modulatory potential of buckwheat on microbiota composition and receptors with an important role in cancer progression could open the way to nutraceutical uses of defined components from pseudocereals.

2.3.5 Control of Glycemia

Typical Western diet is characterized by fast digestion and absorption of carbohydrates determining a high postprandial glucose and insulin responses, additionally influencing the risk of liver and biliary tract cancers, although convincing evidence is currently lacking [81]. Current data demonstrate higher glycemic values for gluten-free breads as well as pasta than for their respective counterparts [82, 83]. To date, scarce data support the positive effects of amaranth oil and seeds at controlling insulin responses [84]. The effects of buckwheat on glycemic response(s) remain controversial [85, 86]. Studies on the digestibility of pseudocereals starch predict a poor glycemic value of those [25, 87]. In line with these studies, there have been reported delayed fluxes of glucose release that are reflected in delayed AUC curves of postprandial glucose in rats [88]. These effects were accompanied of an upregulated hepatic expression of the PPARγ receptor that is a key regulator of whole body glucose homeostasis and substrate distribution for energy expenditure. Taking into consideration the influence of other nutrients than starch in the modulation of glycemic values (i.e., protein, fiber and fat), pseudocereals constitute promising "ingredients" to optimize food for populations at risk [45, 89]. Technological features of pseudocereals as well as their behavior during household processes can also greatly impact its glycemic value.

2.3.6 Control of Cholesterolemia

Information from human trials supporting the cholesterol-lowering activity of pseudocereals is scarce [90–92]. The main hypotheses to explain the potential contribution of pseudocereals to the hypocholesterolemic effect are based on their nutritional profile. Otherwise, distinct experimental approaches have been performed to support the cholesterol-lowering activity of quinoa [92, 93], amaranth [14, 94], and buckwheat [90, 91]. Some of those have also focused on the impact of processing treatments (i.e., heat-expanded amaranth) [14] or to what extent can alterations on lipid homeostasis [94] be controlled through pseudocereals intake. Overall, the underlying mechanisms to explain the hypocholesterolemic effects of pseudocereals remain unclear. For example, it has been proposed that buckwheat cholesterol-lowering activity could be derived from its poor digestibility [95, 96] in contrast to the commonly assumed high quality of its proteins. An interesting hypothesis is also the assumption of metabolic effects beyond the changes in lipid homeostasis derived from its nutritional profile [97]. Probably, at least in part, these effects could occur through an increased energy expenditure promoting oxidative metabolism. The existing uncertainties warrant further research in this sense.

3 Conclusion and Future Perspectives

Cereals have been associated to human diet from ancient times. Domestication of cereals was facilitated by polyploidization events that led to genetic determinants, which excluded potentially adaptive alleles. At present, an intense and continuous social development, as well as commercial globalization, motivates the increase in

food production, where constant technological innovations are needed to respond to the increasing demands of the consumer of high quality food. Thus, important socioeconomic changes in most countries leading to a substantial change in dietary habits favor the appearance of metainflammatory diseases (i.e., NAFLD, T2D, obesity). Here, the strong social demand of gluten-free products increased worldwide and even gluten-free foods started being consumed by many other groups of population than those with immunological imbalances such as celiac patients. Several distinct reasons are considered for this switch on "food choice" and consumer's behavior; nutritional quality and health benefits beyond this nutrition are mostly considered. Pseudocereals represent a good option both from a nutritional and technological point of view to improve the nutritional profile of food, while reducing the intake of defined food ingredients associated to intestinal and immunological disorders. Three distinct grains are majorly known as pseudocereals; quinoa (*Chenopodium quinoa*), amaranth (*Amaranthus cruentus*), and buckwheat (*Fagopyrum esculentum* and *Fagopyrum tartaricum*). These grains offer good technofunctional options to use them as substitutes of wheat flour, thus producing gluten-free foods. Moreover, ascription to the gluten-free diet is commonly associated to nutritional deficiencies. Here, the inclusion of pseudocereals improve the nutritional profile and reduces the risk of deleterious effects on the nutritional status.

Pseudocereals consumption has been associated to a wide spectrum of beneficial effects beyond its mere nutritional value in relation to immune regulation including prevention of intestinal imbalances in gut microbiota composition and inflammatory disorders. Many of these effects could derive from their potential to stimulate innate branch of the immune system because of their particular composition on globulins, but also to its prebiotic effect and potential capacity of other naturally occurring biologically active compounds. Although the scarce data existing encourage the use of pseudocereals as adjuvant in nutritional intervention strategies, a complete description of the underlying molecular mechanisms and processes implied is still unknown. This manuscript has been limited to those existing studies where key aspects such as bioavailability of the different compounds as well as concentrations used could result close to the effective physiological ones. The retrieval from literature revision highlights the need to clarify these aspects in order to pave the way for a full translational and transferable usage of pseudocereals into the clinical practice and society to improve self-management strategies of diseases.

Contents

Abstract

Extensive structure elucidation resulted in detailed information about anthocyanins, betacyanins, carotenoids, and chlorophylls, the major natural pigments in plant-derived foods. Modifications of the basic skeleton form a broad diversity of structures for anthocyanins and carotenoids. The chromophores responsible for the pleasant colors and the factors affecting them have been delineated. Identification of sources and determination of the composition in foods have also been widely pursued. Stability and influencing factors, alterations during

processing and storage of foods, and stabilization methods have been studied as part of the effort to retain the natural color of foods and to substitute artificial food dyes with natural colorants, this substitution being justified by concern about the safety of artificial colorants and by the potential health benefits of the natural colorants. Carotenoids have been the most investigated in terms of health effects, involving epidemiological, in vitro, animal, and human intervention studies. A wide range of biological activities have been attributed to anthocyanins, based mainly on cell culture and animal studies; human clinical studies are lacking. Investigations of the potential health benefits of betacyanin and chlorophyll are in their initial stages.

1 Introduction

The natural color of foods of plant origin is due primarily to four groups of pigments: the green chlorophylls, the yellow-orange-red carotenoids, the red-blue-purple anthocyanins, and the red betacyanin. A few animal-derived foods are colored by carotenoids. These pigments are also incorporated into food products by direct addition or indirectly through animals' feed.

Although earlier investigations were motivated by the color, recent studies have been stimulated by potential health effects. These possible health benefits, along with consumers' concern about safety, have led to efforts to replace artificial food dyes with natural colorants. This is not an easy task, however. Natural colorants are usually less stable, more costly, and not as easily utilized as synthetic dyes, besides having weaker tinctoral strength, interaction with food components, and limited range of hues [1, 2].

2 Anthocyanins

2.1 Chemical Structures, Properties, and Occurrence

Anthocyanins are water-soluble pigments belonging to the family of compounds called flavonoids. They are glycosides or acylglycosides of six commonly found aglycone anthocyanidins: pelargonidin, cyanidin, delphinidin, peonidin, petunidin, and malvidin (Fig. 1). Cyanidin is the most commonly occurring anthocyanidin in nature. Anthocyanidins are flavylium (2-phenylbenzopyrylium) structures with varying hydroxyl and methoxyl substituents. They consist of two aromatic rings (rings A and B) linked by a three carbon heterocyclic ring (ring C) that contains oxygen. Eight conjugated double bonds carrying a positive charge on the

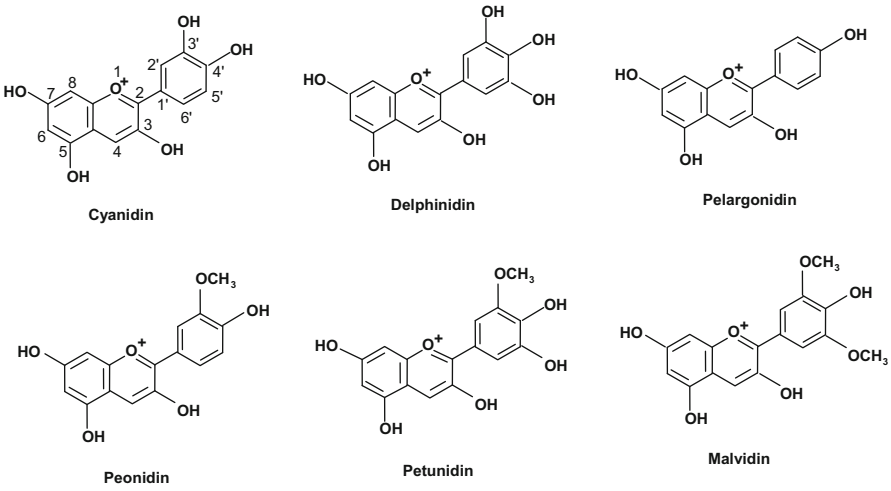

Fig. 1 Six anthocyanins commonly found in foods

heterocyclic oxygen constitutes the chromophore responsible for the intense color of anthocyanins. The color of anthocyanin-rich fruits and vegetables vary from vivid red as in strawberry, purple as in eggplant, and dark blue as in blueberry.

Anthocyanins are known to vary in the number and position of hydroxyl groups; the degree of methylation of these hydroxyl groups; the identity and number of sugar moieties and the positions at which they are attached; and the extent of sugar acylation and the identity of the acylating agent [3–5]. The most commonly encountered sugar is D-glucose, but anthocyanidins can also be conjugated to L-rhamnose, D-xylose, D-galactose, arabinose, and fructose [6], as well as rutinose (6-*O*-α-L-rhamnosyl-D-glucose), sophorose (2-*O*-β-D-glucosyl-D-glucose), gentiobiose (6-*O*-β-D-glucosyl-D-glucose), sambubiose (2-*O*-β-D-xylosyl-D-glucose), xylosylrutinose, and glycosylrutinose [3, 7]. Sugar is typically attached at C-3 on the C-ring (3-glycoside) or at both C-3 and C-5 on the A-ring (3,5-diglycoside). Glycosylation at C-7 on the A-ring and C-3′, C-5′, and C-4′ on the B-ring (not at both C-3′ and C-4′) have also been demonstrated.

The sugar moieties may be acylated with aromatic acids such as *p*-coumaric, caffeic, sinapic, ferulic, gallic, and *p*-hydroxybenzoic acids and/or aliphatic acids such as malonic, acetic, malic, succinic, or oxalic acids [8, 9]. The acyl substituents are usually bound to the C-3 sugar, esterified to the 6-OH, or less frequently to the 4-OH of the sugars. Anthocyanins with complicated acylation patterns on different sugar moieties had also been reported [10, 11].

In aqueous medium such as foods, anthocyanins undergo reversible structural transformations with pH (Scheme 1), with concomitant change in color [1, 12, 13]. The red favylium cation predominates at pH below 2. At pH 3–6, rapid hydration of the flavylium cation occurs at C-2 to form the colorless carbinol pseudobase. The carbinol by ring-opening tautomerization gives rise to the (*Z*)-chalcone, which can

Scheme 1 Structural transformations of anthocyanins with pH

isomerize to the (*E*)-chalcone. At slightly acidic to neutral conditions, deprotonation of the flavylium cation generates the blue quinoidal base.

Anthocyanins are found in fruits (especially berries), vegetables, nuts, grains, roots, and flowers [14–18]. Major sources are purple grapes, cherry, plum, raspberry, strawberry, blackberry, blueberry, black currant, cranberry, chokeberry, red cabbage, and red wine [17–20].

The anthocyanin composition of foods is affected by several factors, such as cultivar/variety [21–29], maturity [23, 24, 28], cultivation practices [27, 30], growing area or season/climate [28, 31, 32], and storage conditions [33]. Amarowicz et al. [34] reviewed extensively the influence of postharvest processing and storage on the contents of flavonoids (including anthocyanins). They concluded that for most of the subclasses in question, the effect of storage and processing on the polyphenol content is negligible in comparison with the differences between different varieties of plants.

2.2 Stability and Alterations During Processing and Storage of Food

Various factors affect anthocyanin color and stability, such as the chemical structure and concentration of the anthocyanin, temperature, pH, light, oxygen, presence of enzymes, proteins, metallic ions, other flavonoids and phenolics, ascorbic acid, and sugar [5, 6, 35–40].

Generally, hydroxylation induces a bathochromic shift and reduces stability, whereas methylation has the opposite effects [35, 41]. Glycosylation of the anthocyanin, especially in C-3, increases stability and solubility in water. The superior color stability of red raspberry products compared to that of processed strawberry and blackberry has been attributed to glycosylation with the disaccharide sophorose [42]. Acylation of sugar moieties also improves stability. Diacylation in the red radish anthocyanin as compared to the monoacylated anthocyanins in red-fleshed potato might be responsible for its greater stability [9]. Diacylated anthocyanins may be stabilized by a sandwich type stacking caused by hydrophobic interactions between the planar aromatic residues of the acyl groups and the positively charged pyrylium nucleus, thus diminishing the formation of the pseudobase [43]. In monoacylated anthocyanins, only one side of the pyrylium ring can be protected against the attack of water [44].

Utilization of anthocyanins as food colorants and functional ingredients has been limited by their low stability and interaction with other compounds in the food matrix. Grape-skin extract has been used as a colorant for a long time. Research has been directed toward the search for better sources and enhancement of extraction efficiency and stability. Examples of possible sources of anthocyanins as colorants are red radish [9, 45–48], red cabbage [23, 36, 49], black carrots [50, 51], red [48, 52], and purple sweet potatoes [29, 52–54].

Because anthocyanins with complex patterns of glycosylation and acylation exhibit remarkable stability to pH changes, heat treatment, and light exposure [55, 56], attributed to copigmentation, self-association, and metal complexing [10, 44, 57],

stabilization efforts have been directed along this line. In nature, anthocyanins are protected by these stabilizing mechanisms [43, 58, 59].

Copigmentation can occur through two mechanisms: (a) intramolecular interaction, which is based on the stacking of the hydrophobic acyl moiety covalently bound to sugar and the flavylium nucleus [56, 60]; and (b) intermolecular interactions in which anthocyanins interact via van der Waals interactions (vertical π-π stacking) between the planar polarizable nuclei of the anthocyanin with colorless copigment (e.g., phenolics) [61, 62]. The anthocyanin-copigment complexes adopt a sandwich-type stacking that stabilizes the favylium cation chromophore and partially protect it from the nucleophilic attack of water, thereby preventing color loss [10, 58]. This molecular association usually produces an increase in absorbance (hyperchromic effect) and a shift to longer wavelength of the visible absorption maximum (bathocromic effect) [43, 65]. A recent review revisited copigmentation, providing a comprehensive description of the nature of binding (the dispersion and electrostatic components of π-π stacking, the hydrophobic effect, and possible hydrogen-bonding between pigment and copigment), and of spectral modifications occurring in copigmentation complexes [7].

Many factors influence the magnitude of copigmentation, including the structures and concentrations of the anthocyanin and copigment, their molar ratio, the pH, temperature, and ionic strength [40, 61, 63, 64]. The effects of these different factors were demonstrated in commercial anthocyanin extracts [57]. At a given pH, color stability was mainly dependent on the structures of anthocyanins and of colorless phenolic compounds. Colorants rich in acylated anthocyanins (purple carrot, red radish, and red cabbage) exhibited great stability due to intramolecular copigmentation. Protection of the red chromophore was greater for diacylated anthocyanins in red radish and red cabbage. For colorants without acylated anthocyanins (grape-marc, elderberry, black currant, and chokeberry), intermolecular copigmentation played a key role; colorants rich in flavonols and with the highest copigment/pigment ratio showed remarkable stability.

Anthocyanins with ortho-dihydroxy system in the B-ring form complexes with certain metal cations, such as AL, Fe, Sn, and Cu [65–67]. Glycosides of cyanidin, delphinidin, and petunidin can form such complexes, but those of malvidin, pelargonidin, and peonidin cannot.

Ascorbic acid accelerates anthocyanin degradation [68, 69]. Initially thought to be due to a direct interaction between the two molecules, it is now believed that it is hydrogen peroxide formed from the oxidation of ascorbic acid that attacks the C-2 position of the anthocyanin, provoking the cleavage of the pyrylium ring and producing colorless esters and coumarin derivatives [37].

Monomeric anthocyanin combines with bisulfite at the pH of most foods and beverages to form a colorless sulfonic acid addition adduct. Addition of the sulfonate adduct was shown to take place at the C_4 position [70], interrupting the conjugated double bond system at the center of the molecule. Polymeric anthocyanins will not undergo this reaction since the 4-position is unavailable, being covalently linked to another phenolic compound [71].

Thermal processing reduces the anthocyanin content of foods [e.g., 26, 27, 29, 38, 72–78]. Monoacylated anthocyanins showed higher resistance against heat treatment (steaming, pressure cooking, microwaving, and frying) than di- and nonacylated anthocyanins [29]. In black currant, cyanidin-3-rutinoside was the most stable to heat treatment at 95 °C; cyanidin and delphinidin rutinosides were the most stable during storage for 12 months at 8 °C [79]. Cyanidin-3-rutinoside was also best preserved in processing purees and low-sugar jams prepared from strawberry cultivars [27]. Pelargonidin-3-glucoside had the most losses.

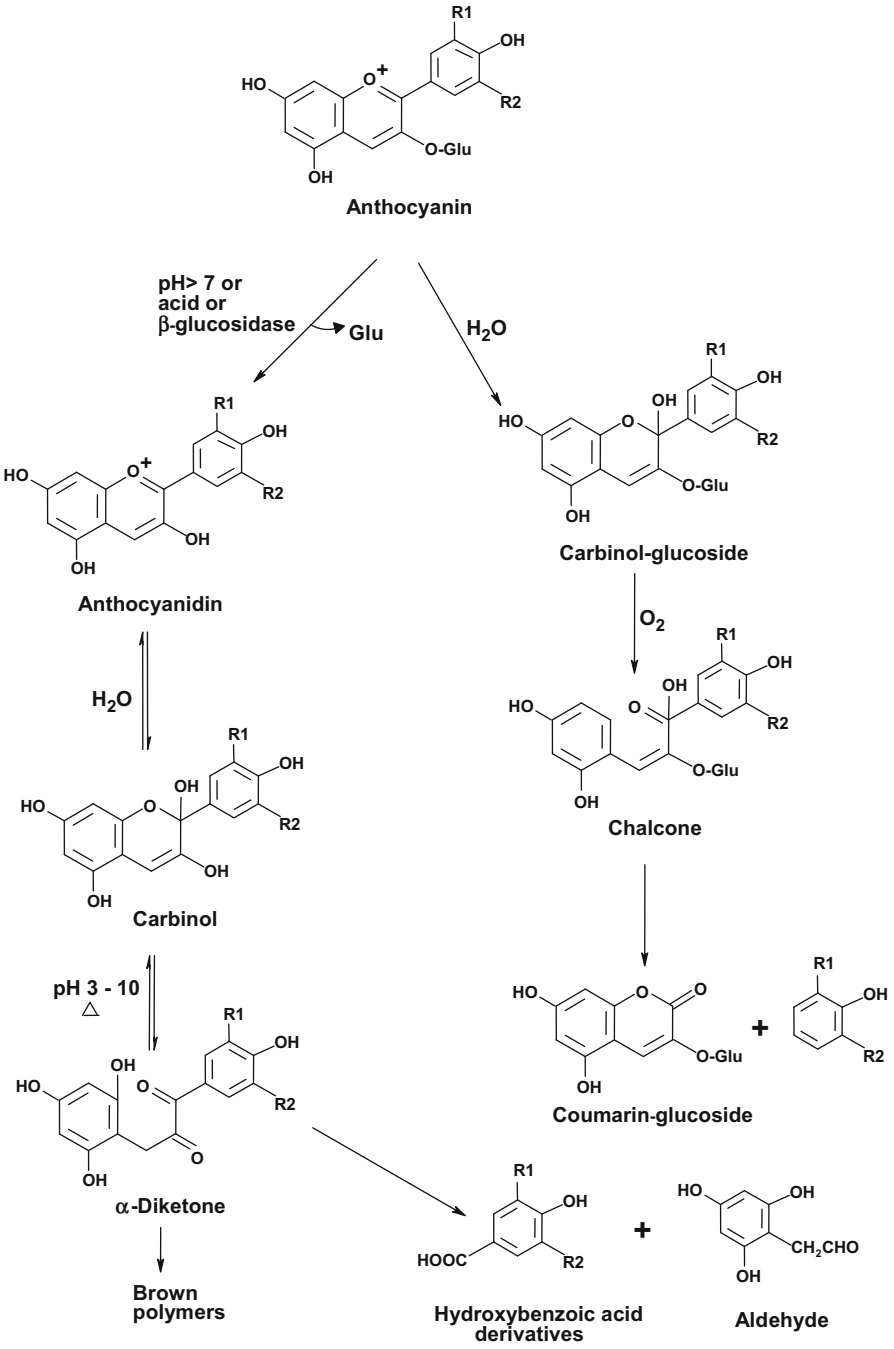
Suggested pathways for anthocyanin alterations during processing involve polymerization (browning) or cleavage (loss of color) [37]. In alkaline or acid medium, or in the presence of the enzyme β-glucosidase, anthocyanin is hydrolyzed, releasing the anthocyanidin, which can be transformed first into the carbinol base and subsequently into α-diketone (Scheme 2). The latter can polymerize, forming brown products, or fragment into an aldehyde and a derivative of hydroxybenzoic acid, both of which are colorless. On the other hand, anthocyanin can also be converted to carbinol and later into chalcone, and finally cleaved into a coumarin derivative and a compound corresponding to the B ring. Coumarin 3,5-diglycoside is a common product of the degradation of anthocyanins (3,5-diglycosides). The degradation depends on the anthocyanin present and the temperature.

In heat-treated (over 6 h at 95 °C, pH 3.5) elderberry and strawberry pigment isolates, acylated anthocyanins initially underwent hydrolysis, splitting the acylglycoside moieties from the flavylium backbone, forming anthocyanidin (aglycone) [80, 81]. Pentoses were more readily split off than hexoses. Opening of the pyrylium ring then followed. Finally, phenolic acids (4-hydroxybenzoic acid from pelargonidin and protocatechuic acid from cyanidin) and phloroglucinaldehyde (from both cyanidin and pelargonidin) were formed as terminal degradation products, residues of the B- and A-ring.

Stabilization methods for anthocyanins include the addition of copigment compounds, such as polymers, phenolic compounds, and metals; exclusion of O_2 during processing and storage; encapsulation techniques [39, 82]. In model beverages, the addition of polyphenols delayed color fading, the most notable improvement being observed with green tea extract [83]. In blackberry juice, the addition of sugars, especially trehalose, improved anthocyanin stability during thermal processing [77].

Encapsulation has been considered of great potential for protecting natural pigments [84], such as anthocyanins [85]. Microencapsulation/encapsulation of anthocyanins has been investigated to develop natural colorants with improved stability, solubility, dispersibility, and bioavailability [51, 86–89]. In black soybean anthocyanin, a combination of copigmentation and nanoencapsulation can be an effective technique for improving the color and antioxidant stability of anthocyanin.

Anthocyanins and their interactions have a decisive role in the color intensity and the stability of wine. Copigmentation appears to account for between 30% and 50% of the color in young wines [58]. Evolution of the red wine color during aging is a complex process that is attributed to copigmentation and to the progressive conversion of the original athocyanins into new, more stable pigments [90, 91].



Scheme 2 Structural alterations of anthocyanins during processing and storage of foods based on [37] and [41]

3 Betacyanins

3.1 Chemical Structures, Properties, and Occurrence

Betalains are water-soluble nitrogen-containing pigments, consisting of the red to red-violet betacyanins and yellow-orange betaxanthins. They are immonium conjugates of betalamic acid with *cyclo*-dopa[cyclo-3-(3,4-dihydroxyphenylalanine)] and amino compounds, respectively. The bathochromic shift of 50–70 nm of betacyanins compared to betaxanthins is due to the aromatic ring of cyclo-dopa. Glycosylation of betanidin results in a hypsochromic shift of the resulting betacyanin with glucose attached at C-6 being less effective than that linked to C-5 [92]. Esterification with aliphatic acyl moieties had little impact on the maximum absorption of betacyanins [93, 94].

Khan and Giridhar [95] presented a list of betalain-accumulating plants reported so far, highlighting pigment occurrence and accumulation pattern, and reviewed betalain biosynthesis. Stintzing and Carle [41] focused on the technological aspects and human health effects.

For a long time, beetroot was considered the sole source of betacyanin for use as food colorant, betanin (betanidin 5-*O*-β-glucoside) being the most abundant pigment. Recent years have seen an increased search for other sources, such as *Ullucus tuberosus*, one of the most widely grown and economically important root crops in the Andean region of South America [96]; *Basella rubra*, commonly known as Malabar spinach, a leafy vegetable that accumulates pigments in its fruits [97]; cactus pear (*Opuntia ficus-indica* and *O. stricta*) [98–102]; red-purple pitaya *Hylocereus polyrhizus* [93, 94, 99, 100, 103–106]; and *Amaranthus* species [92, 107–110].

3.2 Stability and Alterations During Processing and Storage of Food

Betalain stability is increased by high pigment content, high degree of glucosylation, and acylation, low a_w, low pH, antioxidants, chelating agents, low temperature, darkness, and nitrogen atmosphere [104]. Degrading enzymes (peroxidase, polyphenol oxidase, glucosidase), low degree of glucosylation and acylation, high a_w, metal cations, pH <3 or >7, high temperature, light, O_2, and H_2O_2 lowers stability. Glycosylation increased the half-life of betanidin and isobetanidin by about 17 times in O_2-saturated solutions, a behavior attributed to the lower oxidation-reduction potential of betanidin as compared to betanin [111]. Betacyanin stability may also be heightened by substitution with aromatic acids, the 6-*O*-substitution being more effective than 5-*O*-substitution, due to intramolecular stacking, since the U-shape folding of the molecule may protect the aldimine bond from hydrolytic attack [112].

Betalains have been reported to be stable over a broad pH range, from 3 to 7; the pH optimum for betanin is between 4 and 6. Elevated temperature shifted this optimum towards 6 [113]. In the presence of oxygen, betanin was most stable

between pH 5.5 and 5.8; under anaerobic conditions, lower pH values (4.0–5.0) were more favorable [114]. Betanin stability decreased linearly with increasing oxygen concentration [115]. Light and oxygen were observed to have additive effects, the betanin degradation being 15.6 and 14.6%, individually, rising to 28.6% with the simultaneous presence of both [116]. Since betanin undergoes water-dependent hydrolysis, a_w is a crucial factor for betanin susceptibility to aldimine bond cleavage [107–109, 117]. Improved betanin stability was found at lower a_w, the most effective being below 0.63 [118]. In a stability study of encapsulated beetroot pigments, betanin degradation was greatest at $a_w = 0.64$ [119].Greater betanin stability was explained by decreasing mobility of the reactants at lower a_w and by dilution effects at higher a_w.

Metal cations (Fe^{2+}, Fe^{3+}, Sn^{2+}, Al^{3+}, Cr^{3+}, Cu^{2+}) have been shown to accelerate betanin degradation [120–122]. EDTA can prevent metal-catalyzed betanin degradation by pigment stabilization and complex formation with metal ions [120].

Considerable decomposition may be catalyzed by betalain degrading enzymes. Several polyphenoloxidases were isolated from red beet [123, 124]. A betalain oxidase in red beet was reported to catalyze betanin degradation to cyclo-Dopa-5-*O*-β-glucoside, betalamic acid, and 2-hydroxy-2-hydro-betalamic acid [125].

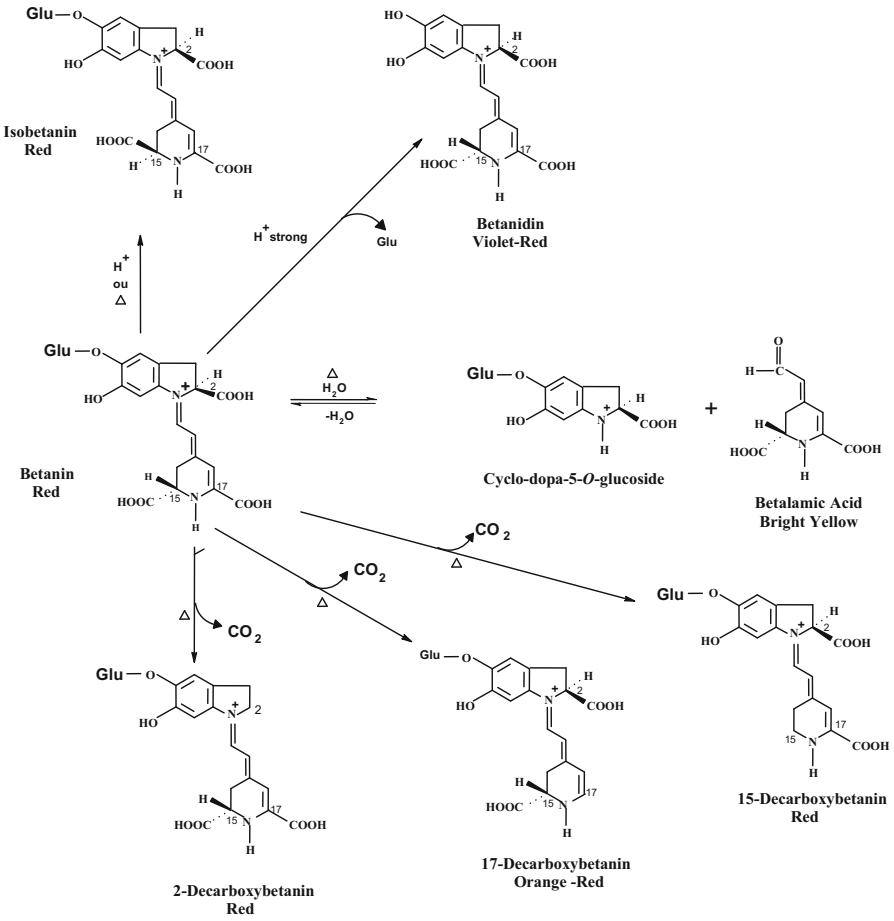
Betalain degradation on thermal processing has been reported in many papers [e.g., 103–105, 113, 115, 121, 126, 127]. The color shift to orange of red beet juice on thermal treatment was explained by the formation of yellow and orange-red degradation products [127].

Betacyanin undergoes isomerization, deglosylation, hydrolysis, decarboxylation, and dehydrogenation, with or without concomitant chromatic changes [117]. Betacyanins are generally accompanied by their respective isobetacyanins, the ratio depending on the food source. However, isomerization can be induced by both acidic [128–130] and alkaline conditions [128]. It has also been observed during thermal treatment of red beet juice [127, 131], the betanin/isobetanin ratio decreasing from 25:1 to 9:1 and 2.5:1 in raw, blanched, and sterilized red beet juice, respectively [131]. On the other hand, thermal treatment of purple pitaya juice elevated the betanin/isobetanin ratio [104]. Betanin and isobetanin exhibit the same chromatic properties.

Under strongly acidic conditions [128], at high temperature [132], or in the presence of β-glucosidase, the glucose moiety of betanin may be cleaved. This deglycosylation results in a bathochromic shift of about 4 nm [117] and an increased susceptibility towards oxidation [41].

At pH above 6 or during thermal processing, betanin undergoes cleavage to the bright yellow betalamic acid and the colorless *cyclo*-Dopa-5-*O*-β-glucoside [129]. This was found to be more pronounced during heat treatment in purified solution than in red beet and purple pitaya juice [133]. Acylation with aromatic or aliphatic acids may protect the aldimine bond from cleavage [112, 133].

Recondensation of betalamic acid and *cyclo*-Dopa derivatives occurs after short-term heating [115, 134]. This regeneration is partial [131, 134] and is greater at pH 6 in the absence of oxygen [114]. No recondensation was observed at pH 7. Ascorbic, isoascorbic, metaphosphoric, and gluconic acids improved the regeneration of red beet juice pigments after heating [135].



Scheme 3 Structural alterations of betanin during processing and storage of foods based on [127]

Betanin may be decarboxylated at the C-2, C-15, and/or C-17 positions, the carboxyl groups differing in their susceptibility toward decarboxylation [133]. Decarboxylation at either C-2 or C-15 do not alter the betanidin chromophore, thereby maintaining the chromatic characteristics of the original betacyanin. On the other hand, 17-decarboxy betanin exhibit an orange hue [117]. Monocarboxylated betanin, phyllocactin (malonyl-betanin, and hylocerenin (3′-hydroxy-3′-methyl-glutaryl-betanin) were shown to be considerably more stable toward degradation than nondecarboxylated betacyanins [114, 136]. Isobetanin undergoes decarboxylations similar to those of betanin (not shown in Scheme 3).

Yellow neobetanin (14,15,-dehydrobetanin) was shown to be a natural constituent of red beet [137, 138] and prickly pear [92, 139]. However, neobetanin formation upon thermal treatment of red beet juice under aerobic conditions has been confirmed [127]. Moreover, dehydrogenation of phyllocactin and hylocerenin on

thermal treatment of purple pitaya juice resulted in the formation of the corresponding yellow neo-derivatives [103]. Thus, dehydrogenation had been held responsible for the noticeable color (hypsochromic) shift during heat treatment of red beet juice and purple pitaya juice [103, 104, 117, 127].

On prolonged thermal treatment, a diversity of betacyanin degradation products may ensue by multiple decarboxylation or by combined decarboxylation and dehydrogenation of both betanin and neobetanin [117]. Mixtures of mono-, di-, and tridecarboxylated betacyanins, together with their corresponding neobetacyanins, were identified in purified extracts of red beet and purple pitaya [106, 140]. Main products were 17-decarboxy-betacyanin, 17-decarboxy-isobetanin, 2-decarboxy-betanin, 2,17-bidecarboxybetanin, and 2,17-decarboxyisobetanin, and 14,15-dehydrogenated-neobetanin. Heating of betanin, phyllocactin, and hylocerenin resulted in decarboxylated neoderivatives together with the corresponding decarboxylated betacyanins [133]. Thus, neobetanin is also decarboxylated in a manner similar to that of betanin and isobetanin (not shown in Scheme 3). Generation of neobetanin, neophyllocactin, and neohylocerenin was observed during heat treatment of red beet and purple pitaya juice [103, 127].

4 Carotenoids

4.1 Chemical Structures, Properties, and Occurrence

The lipophilic carotenoids are generally C_{40} tetraterpenes/tetraterpenoids formed from eight C_5 isoprenoid units joined head to tail, except at the center where a tail-to-tail linkage reverses the order. The most distinctive structural feature is a centrally located, conjugated double bond system. The basic linear and symmetrical skeleton is modified in many ways, including cyclization, hydrogenation, dehydrogenation, introduction of oxygen containing groups, migration of the double bonds, rearrangement, chain shortening or extension, or combinations thereof, resulting in a wide array of structures.

Carotenoids may be acyclic (e.g., lycopene, ζ-carotene) or may have a six-membered ring at one (e.g., γ-carotene, δ-carotene) or both ends (e.g., β-carotene, α-carotene) of the molecule, except capsanthin and capsorubin which have five-membered rings. Hydrocarbon carotenoids (e.g., β-carotene, lycopene) are known as carotenes, and the oxygenated derivatives are called xanthophylls. Common oxygen-containing substituents are hydroxyl (as in β-cryptoxanthin), keto (as in cantha-xanthin), epoxy (as in violaxanthin), and aldehyde (as in β-citraurin) groups.

Plants are able to synthesize carotenoids de novo. Thus, along with the principal carotenoids, low levels of their biosynthetic precursors and derivatives are found in plant-derived foods, making the carotenoid composition variable and usually complex [141]. The carotenoids are located in subcellular organelles (plastids), mainly associated with proteins in the chloroplasts and deposited in crystalline form or as oily droplets in chromoplasts [142].

Carotenoids are not as widely distributed in foods of animal origin and the composition is simpler. Unable to carry out carotenogenesis, animals are limited to absorbing dietary carotenoids, which are accumulated unchanged or slightly altered to form carotenoids typical of animal species.

Hydroxycarotenoids in ripe fruits are mostly esterified with fatty acids [143–147]. In a few fruits, particularly those that remain green when ripe (e.g., kiwi) [148], limited or no esterification of carotenols occur. In green leaves [149], carotenols are unesterified; those of corn [150, 151] are mostly unesterified. Lutein, the principal carotenoid, occurs free or esterified in one (monoester) or both hydroxyl groups (diester) in nasturtium [152] and marigold [153] flowers, with the esters predominating. Esterification occurs progressively during maturation and appears to be important physiologically. Acylation increases the lipophilic character of the xanthophylls, facilitating their accumulation in the chromoplasts [148]. Moreover, in red and hot chili peppers, mono- and diester carotenoids showed greater processing stability than the nonesterified counterparts [154].

Astaxanthin is the main carotenoid of some fish, such as salmon and trout, as well as crustaceans. It may be found free, esterified in one or both hydroxyl groups with fatty acids, or as a complex with proteins (carotenoproteins) or lipoproteins (carotenolipoproteins) [155]. Crustacean astaxanthin is a mixture of the three ester forms.

Carotenoids in which the carbon skeleton has been shortened by removal of fragments from one or both ends of the usual C_{40} structure are called apocarotenoids. Natural examples are bixin, the major pigment of annatto, and crocetin, the main coloring component of saffron. As with epoxy carotenoids, apocarotenoids are initial products of the oxidative degradation of carotenoids. Thus, traces of these compounds are often found in foods. For example, β-Apo-8′-carotenal, β-Apo-10′-carotenal, and β-citraurin are common minor carotenoids of citrus fruits.

The conjugated double bond system comprises the light-absorbing chromophore that confers the carotenoid's attractive color and is mainly responsible for their special properties and many functions [141]. As the light yellow ζ-carotene, a carotenoid should have at least seven conjugated double bonds in order to have perceptible color, phytoene (three conjugated double bonds) and phytofluene (five conjugated double bonds) are colorless, whereas lycopene (11 conjugated double bonds in an acyclic structure) is red. The monocyclic γ-carotene and the bicyclic β-carotene, although having the same number of conjugated double bonds as lycopene, are red-orange and yellow-orange, respectively. This is because cyclization takes the π electrons of the ring double bond out of plane with those of the chain due to steric hindrance between the ring methyl group at C-5 and the hydrogen at C-8 of the polyene chain. Hydroxyl substituents do not affect the chromophore; thus, both α-carotene and its dihydroxy derivative lutein are pale yellow. Similarly, the monohydroxy and dihydroxy derivatives of β-carotene, β-cryptoxanthin and zeaxanthin, have the same color as β-carotene. Capsanthin with a conjugated double bond system consisting of nine double bonds in the polyene chain, one double bond in the β-ring, and the carbonyl group double bond, and capsorubin with its nine conjugated double bonds in the polyene chain extended by the double bonds of two

carbonyl groups, give the intense color of red pepper. Astaxanthin, which has nine conjugated double bond in the polyene chain extended by two double bonds in β-rings and two carbonyl group double bonds, is responsible for the vivid red color of cooked shrimp, lobster, and crabs. In the raw crustaceans, astaxanthin is complexed with protein, transforming the color to blue, black, or grey. Heating denatures the protein and the red color of free astaxanthin ensues. Astaxanthin also gives the reddish color of salmon and trout flesh.

In nature, carotenoids exist primarily in the all-*E* configuration. An exception is bixin, which occurs naturally in the *Z*-form. Theoretically, each carbon-carbon double bond in the polyene chain of carotenoids may exhibit *E*-*Z* isomerization. However, some double bonds are prevented from undergoing this isomerization because the *Z*-configuration is sterically hindered [156, 157]. The *Z*-isomers of β-carotene [158–160] and zeaxanthin [160–163] commonly found in foods are the 9-*Z*-, 13-*Z*-, and the 15-*Z*-isomers. Carbon-carbon double bonds located in the cyclic part of the carotenoid structure, as the C-5,6 double bond in β-carotene, are also sterically hindered and are not isomerized. However, this double bond in the acyclic lycopene is unhindered and 5-*Z*-lycopene is found in tomato and tomato products, along with the 9-*Z*-, 13-*Z*-, and the 15-*Z*-isomers [164–167]. Being unsymmetrical, all-*E*-α-carotene [158], β-cryptoxanthin [158], and all-*E*-lutein [160–163, 168] give rise to 13′-*Z*- and 9′-*Z*-isomers in addition to 13-*Z*-, 9-*Z*-, and 15-*Z*-isomers in foods.

The carotenoids most commonly encountered in foods are β-carotene, α-carotene, β-cryptoxanthin, lycopene, lutein, and zeaxanthin (Fig. 2) [169–174]. Rich sources of β-carotene are some palm fruits, some squash cultivars, green leafy and non-leafy vegetables, carrot, orange-fleshed sweet potato, cantaloupe, mango, and apricot. β-Carotene is sometimes accompanied by α-carotene, as in carrot, some varieties of squashes, pumpkins, and palm fruits. β-Cryptoxanthin is the main carotenoid of orange-fleshed fruits, such as papaya, tangerine, orange, loquat, persimmon, and tree tomato. Lycopene-rich foods are tomato and tomato products, pitanga, pink-fleshed guava, red-fleshed papaya, and watermelon. The richest sources of lycopene, however, are the Asian gac (*Momordica cochinchinensis*) fruit [175, 176] and the Spanish sarsaparilla [147]. Corn and corn products and some varieties of squash are the major dietary sources of zeaxanthin/lutein. Leafy and other green vegetables are the main sources of lutein.

The different factors affecting the carotenoid composition of the fresh produce have been extensively investigated, such as cultivar/variety, maturity, climate or season, geographic site of production, agronomic practices, part of the plant utilized, harvesting, and postharvest handling [141, 148, 173, 174, 177–179].

4.2 Stability and Alterations During Processing and Storage of Food

Carotenoid stability is affected by the nature of the carotenoid (carotene or xanthophyll, *E*- or *Z*-isomer, esterified or unesterified) and the food (fruit, root, leaf, juice, puree), disruption (peeled, sliced, shredded) of the food matrix, oxygen, light,

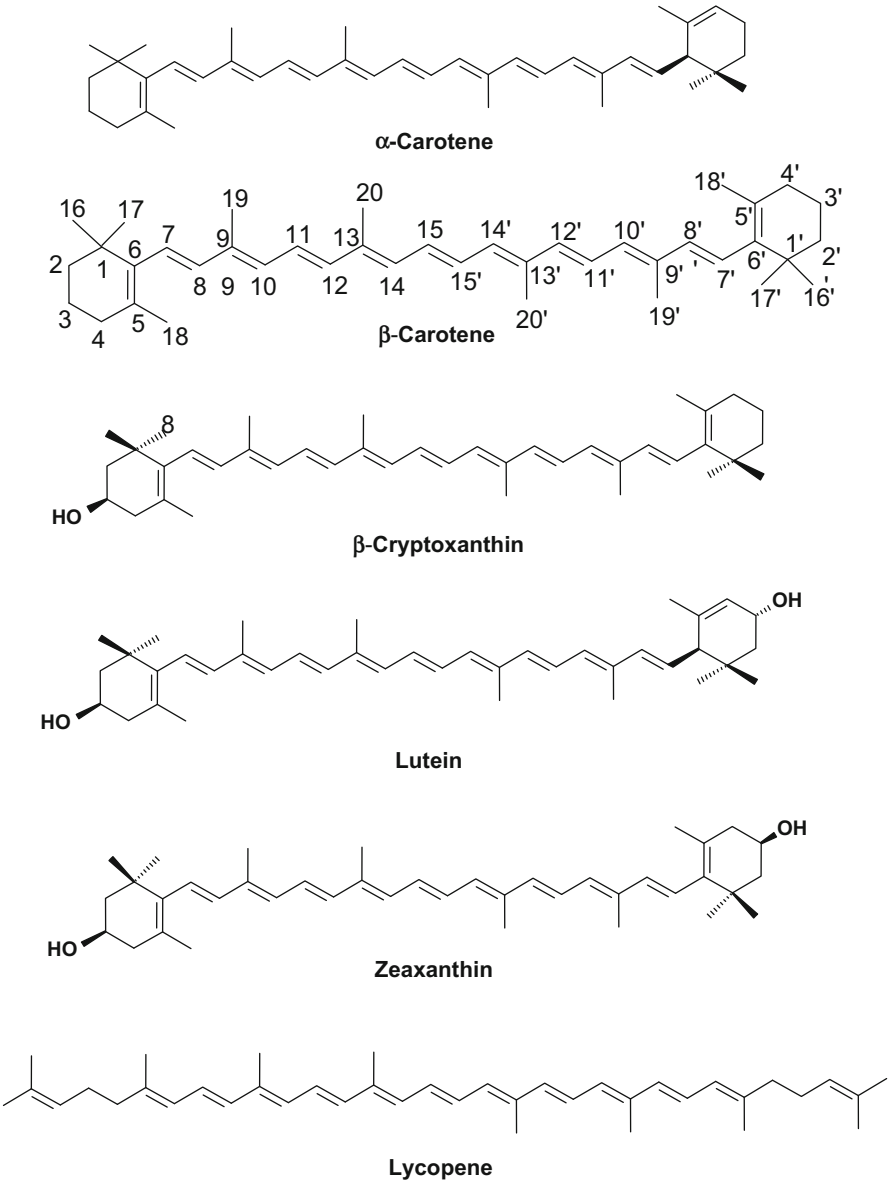


Fig. 2 Carotenoids commonly found in foods

processing method and condition (especially temperature and duration), and storage condition and duration, water content/activity, atmosphere, oxidizing enzymes, antioxidants, metal catalysts and prooxidants, and free radical initiators and inhibitors [174, 180, 181, 182, 183, 184, 185].

Considering the individual effects along with the interplay of many influencing factors, results of the numerous studies on the effects of home and industrial processing may sometimes appear conflicting. Moreover, in spite of the great progress in carotenoid analytical capability, existence of some errors in the analysis and in the calculation of retention or loss cannot be ruled out. Isomerization and oxidation of carotenoids during analysis and/or during storage of samples may also be attributed erroneously to the processing and storage of foods.

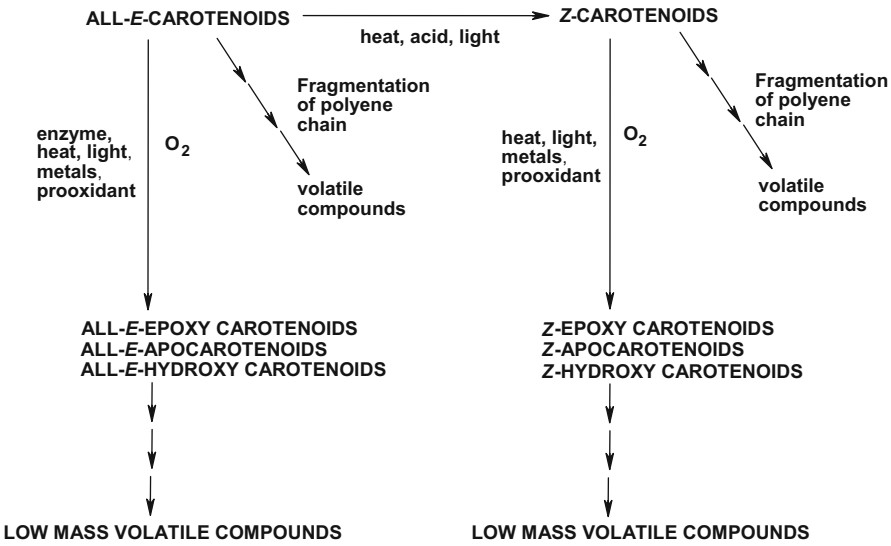
Carotenoid degradation is known to increase with the destruction of the food cellular structure, greater surface area or porosity, duration and severity of processing conditions, duration and inadequate conditions of storage, permeability of packaging material to O_2, and exposure to light. Processing and storage effects on food carotenoids had been reviewed [179–187], with tomato, carrot, and pepper as the most investigated foods.

In paprika and chili powder, mono- and diesters showed greater processing stability than their nonesterified counterparts [154]. This was probably due to the more lipophilic nature of the esterified carotenoids, resulting in their better integration into membrane structures, thereby protecting them from thermal degradation. Capsanthin, capsorubin, zeaxanthin, and β-cryptoxanthin mono- and diesters exhibited similar stabilities, whereas the susceptibility to degradation of the nonesterified carotenoids varied considerably.

A review of earlier studies [180] drew some conclusions, which continue to be supported by recent studies [174]. Carotenoids differ in their susceptibility to degradation. Moreover, their stability differs in different foods even when the same processing and storage conditions are used. The main cause of carotenoid loss during processing and storage of foods is enzymatic or nonenzymatic oxidation. Enzymatic oxidation of carotenoids can occur to a greater extent than thermal decomposition in many foods. Whatever the processing method chosen, retention of carotenoids decreases with longer processing time, higher processing temperatures, and cutting or maceration of the food. The heat treatment in blanching may provoke some losses of carotenoids, but the inactivation of oxidative enzymes will prevent further and greater losses during processing and storage. Because the carotenoids are more concentrated in the peel than in the pulp, peeling and juicing result in substantial losses of carotenoids, often surpassing those of heat treatment. Exclusion of oxygen (through vacuum or hot filling, oxygen-impermeable packaging, or inert atmosphere), protection from light, and storage at low temperatures all protect carotenoids from decomposition.

Alteration or loss of carotenoids during processing and storage of foods occurs through physical removal (e.g., peeling), geometric isomerization, and enzymatic or nonenzymatic oxidation [174, 181].

Isomerization of all-E-carotenoids to the Z-isomers carotenoids is promoted by acids, heat, and light. The release of organic acids during slicing, pulping, or juicing of fruits can be sufficient to provoke this isomerization, but it occurs to a greater extent during cooking or thermal processing, as shown for various carotenoids in many foods [158, 162, 186, 188–195]. During typical cooking of tomatoes, β-carotene and lutein isomerized to a greater extent than δ-carotene, γ-carotene, and



Scheme 4 General scheme for the oxidative degradation of carotenoids reproduced from [174]

lycopene [196]. Individual carotenoids and their isomeric forms also behaved differently during production and storage of canned tomato juice [197]. Notably, tetra-*Z*-lycopene was drastically reduced and isomerized to other geometric forms, including all-*E*-lycopene.

The technological, analytical, and nutritional implications of the occurrence of carotenoid Z-isomers in food were reviewed by Schieber and Carle [198]. Pronounced *E*-*Z* isomerization leads to a decrease in color intensity and the ability to quench singlet oxygen [199, 200]. It also results in loss of provitamin A activity and alteration of bioavailability and metabolism.

Enzyme-catalyzed oxidation takes place prior to heat treatment, during peeling, slicing, and pulping. It can also occur in minimally processed food and in unblanched frozen food during thawing [141, 174].

Nonenzymatic oxidation (also called autoxidation) is accompanied by isomerization, and both the *Z*- and *E*-isomers are oxidized [201, 202]. Oxidation initially involves epoxidation, cleavage to apocarotenals, and hydroxylation [201, 203, 204]. Subsequent fragmentations result in a series of compounds of low molecular masses, similar to those produced in fatty acid oxidation. Cleavages at different sites of the polyene chain can also directly produce short volatile fragments [174]. An overall carotenoid degradation scheme is shown in Scheme 4.

Epoxidation of β-carotene commences with oxygen attack in the terminal double bond of the conjugated double bond system on one side of the molecule, and then on the other side, forming β-carotene-5,6-epoxide and β-carotene-5,6,5′,6′-diepoxide, respectively. Rearrangement of the 5,6- to the 5,8-epoxide yields β-carotene-5,8-epoxide and β-carotene-5,8,5′,8′-diepoxide [201, 203–207].

Epoxidation of lycopene occurs both at the terminal conjugated double bonds and at the isolated double bonds with the formation of lycopene-1,2-epoxide and lycopene-1,2,1′, 2′-diepoxide, along with lycopene-5,6-epoxide and lycopene-5,6,5′,6′-diepoxide [202, 208, 209]. Combinations of these epoxides and cyclization result in a greater number of products and a more complicated epoxidation scheme.

Introduction of the 5,6-epoxide moiety and transformation of this group to the 5,8-furanoid is a common reaction in foods. A good example is the conversion of violaxanthin to auroxanthin, as observed in bottled mango juice [210], mango juice and canned mango slices [211], and orange xanthophylls [212–214].

Cleavage of β-carotene results in β-apo-carotenals (β-apo-15-carotenal, β-apo-14′-carotenal, β-apo-12′-carotenal, β-apo-10′-carotenal, and β-apo-8′-carotenal). A similar scheme takes place with lycopene, forming apo-15-lycopenal, apo-14′-lycopenal, apo-12′-lycopenal, apo-10′-lycopenal, apo-8′-lycopenal, and apo-6′-lycopenal [202, 215].

Both Z- and epoxy-β-carotenes were detected in corn oil containing β-carotene, oxidized in the Rancimat at 110 °C from 1 to 14 h [216]. Likewise, some Z- and epoxycarotenoids were found in cashew apple juice heated at 60°C and 90 °C [217].

Volatile compounds are generated from carotenoids by direct cleavage of the carotenoid polyene chain, sequential cleavage, and transformation of the initial volatile [174]. These are mostly aldehydes, ketones, alcohols, hydrocarbons, furan, and pyran [218–221]. Now devoid of color, they contribute to the desirable flavor of foods and beverages, as in wine and tea, but also to off-flavor, as in dehydrated carrot.

A prominent change during ripening of fruits is the enhanced biosynthesis of the vividly colored carotenoids and their oxidative cleavage to volatile compounds that contribute to the typical aroma/flavor of ripe fruits. There is similarity between the volatile compounds resulting from autoxidation and the enzymatic oxidation of carotenoids during ripening [174].

The utilization of carotenoids as colorant additives and functional ingredients in foods and beverages can be problematic because of their insolubility in water, instability, and low bioavailability. The first two problems have been addressed by the formulation of water-dispersable market products, as colloidal suspensions, emulsions, or dispersions in suitable colloids. In recent years, attention has centered on encapsulation and nanoencapsulation [174].

5 Chlorophylls

5.1 Structures, Properties, and Occurrence

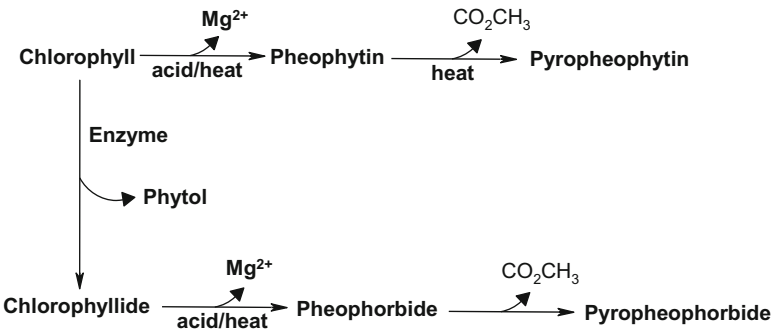
Chlorophyll a and b are the typical green pigments of higher plants, occurring in an approximate ratio of 3:1 in lettuce leaves [222] and in five commonly consumed Mediterranean leafy vegetables [223], but with a ratio of 1:2 to 1:4 in different varieties of the tree tomato fruit [224]. Chlorophylls are porphyrins, which are macrocyclic tetrapyrrole pigments in which the pyrrole rings are joined by methyne

bridges and the double bond system forms a closed, conjugated loop [37]. A centrally located magnesium atom is coordinated with the nitrogen of the four pyrroles. Chlorophyll a has a methyl group and chlorophyll b has a formyl group at C-3. Both have a vinyl and an ethyl group at the C-2 and C-4 position, respectively; a carbomethoxy group at the C-10 position of an isocyclic ring; and a phytol group esterified to propionate at the C-7 position. Phytol is a 20-carbon monounsaturated isoprenoid alcohol. Chloropyll a appears blue-green and chlorophyll b yellow-green [225]. The chlorophyll molecule has a hydrophilic part, the macrocycle, and a hydrophobic segment, the phytol. The closed circuit of conjugated double bonds is the chromophore that allows them to absorb light.

5.2 Stability and Alterations During Processing and Storage of Food

The green color of vegetables and fruits, due to the presence of chlorophyll, is affected by aging, enzymes, weak acids, oxygen, heat, and light. Degradation of chlorophyll occurs during ripening of fruits, senescence of green vegetables, and thermal processing of foods [226]. Epimerization is the first alteration observed when chlorphyll is exposed to heat [37, 227, 228]. Mild heating is sufficient to induce the inversion of the C-10 carbomethoxy group located in the isocyclic ring, forming isomers designated as chlorophylls a′ and b′.

The chlorophyll degradation route is shown in Scheme 5. It has long been known that the olive brown color of cooked and canned vegetables is due to the formation of pheophytin, the most common alteration of chlorophyll reported in thermally treated green vegetables, such as spinach [229], broccoli [230], pepper [194], squash, green beans, peas, leek, broccoli, and spinach [231]. Industrial processing resulted in 55–75% loss of chlorophyll a and 50–89% of chlorophyll b, and an increase in pheophytin a and b in both broccoli florets and stems [230]. Disrupting and breaking the cell walls, heat induces the release of acids, decreasing the pH. Under acidic condition, the magnesium atom is replaced by hydrogen to form pheophytin.



Scheme 5 Alterations of chlorophyll during processing and storage of foods

The green chlorophyllide is formed by the removal of phytol, catalyzed by the naturally occurring enzyme chlorophyllase. Prolonged heating causes elimination of the carbomethoxy group at C-10, giving rise to pyropheophytins, as observed in heat processed green vegetables [232].

Chlorophyll b was reported to be thermally more stable than chlorophyll a [37, 233, 234], the higher thermal stability of the former being attributed to the electron-withdrawing effect of its C-3 formyl group [235]. However, in a study on the effect of microwave and conventional cooking methods on chlorophyll pigments of six green vegetables, chlorophyll a was found more heat resistant compared with chlorophyll b, except in peas [231].

A similar early stage degradation occurs in degreening senescent leaves, consisting of the transformation of chlorophyll to chlorophyllide, pheophorbide, and pyropheophorbide, catalyzed respectively by chlorophyllase, Mg-dechelatase, and pheophorbide a oxygenase [226, 236, 237]. Pheophorbide a undergoes oxygenolytic opening of the porphyrin macrocycle, catalyzed by pheophorbide a oxygenase; subsequent reactions produce flourescent chlorophyll catabolites. The latter undergo catabolism to nonflourescent chlorophyll catabolites. This general catabolic pathway in senescent leaves was found to be also active in olive fruits during maturation [238].

Efforts to retain the green color in processed foods include: acid neutralization, high temperature short-time processing, enzymatic conversion of chlorophyll to chlorophyllide, and commercial application of metallo complex [37]. Pheophytin and pyropheophytin will complex with copper and zinc ions to form complexes with more attractive green color and are more stable to light. While pheophytin and pyropheophytin were found in conventionally processed green beans, in Veri-green canned beans, the green color was maintained due to the formation of the more stable zinc complexes, Zn-pheophytin a and Zn-pyropheophytin b [239]. The Veri-green process is a patented procedure in which blanching of green vegetables is undertaken in the presence of zinc salts [240].

6 Health Benefits

Of the natural pigments, the most studied in terms of human health are the carotenoids. Their best established function is the provitamin A activity, but they have been credited with other health-promoting effects, such as immunoenhancement and reduction of the risk of developing chronic degenerative diseases, such as cancer, cardiovascular diseases, cataract, and macular degeneration [241–245].

Carotenoids' action against diseases has been widely attributed to their antioxidant activity [246–248]. However, nonantioxidant mechanisms have been increasingly reported for these bioactive compounds such as retinoid-dependent signaling, modulation of carcinogen metabolism, regulation of cell growth, inhibition of cell proliferation, enhancement of cell differentiation, stimulation of intercellular gap junction communication, gene regulation, modulation of DNA repair mechanisms, induction of detoxifying enzymes, hormonal and immune system modulation, and filtering of blue light [241, 242, 244, 249, 250].

Lycopene's possible role in human health has drawn considerable attention [251–256], especially in relation to prostate cancer [257–260]. Lycopene has also been associated with reduced risk for lung [261], pancreatic [262], colorectal [263], and digestive tract cancer [264].

Lutein and zeaxanthin selectively accumulate in the macula of the human retina [265, 266], and most epidemiological studies have shown that dietary intake or plasma or retina levels of lutein and/or zeaxanthin are associated with reduced risk of age-related macular degeneration, the major cause of irreversible blindness in the elderly [e.g., 265, 267–272]. These two carotenoids have also been consistently linked to the reduction of the risk for cataract [267, 270, 273, 274]. A meta-analysis of six studies showed, however, that dietary lutein and zeaxanthin were significantly related with reduced risk of late macular degeneration, but not with decreased risk of early macular degeneration [275]. Supplementation with lutein could improve visual function in patients suffering from macular degeneration and cataract [276, 277].

For the protective role against macular degeneration and cataract, lutein and zeaxanthin may act in two ways: (1) as filters of damaging blue light, and (2) as antioxidants quenching excited triplet-state sensitizers or singlet oxygen and scavenging harmful reactive oxygen species like lipid peroxides or the superoxide radical anion [278].

Dietary intake or serum levels of lutein and/or zeaxanthin have also been inversely associated with cardiovascular diseases [279–281]. Based on their survey of coronary mortality in 16 countries, Connor et al. [282] concluded that a diet low in foods containing folate and lutein/zeaxanthin might be the major contributing factor to increased coronary risk observed in the countries of Central and Eastern Europe.

As enumerated in review articles, a wide range of biological activities have been attributed to anthocyanins, such as antioxidant, antiallergic, anti-inflammatory, antiviral, antiproliferative, antimicrobial, antimutagenic, antitumor activities; microcirculation improvement; and peripheral capillary fragility prevention [4, 13, 20, 283, 284]. Anthocyanins are associated with low prevalence or alleviation of some diseases/disorders such as cancer, cardiovascular diseases, diabetes, obesity, and cognitive decline.

Antidiabetic properties include lowering of blood glucose levels by protecting β-cells, improving insulin resistance, increasing insulin secretion, improving liver function, inhibiting carbohydrate hydrolyzing enzymes, antioxidant capacity, and regulation of adipocyte function [283, 285].

Anticancer activity has been attributed to the additive effect of multiple mechanisms, such as antimutagenic activity, anti-inflammatory activity, antiproliferative effect, inhibition of DNA damage, inhibition of carcinogen activation, induction of phase II enzymes for detoxification, cell cycle arrest, inhibition of COX-2 enzymes, induction of apoptosis and antiangiogensis [13, 283, 286, 287].

Prevention of cardiovascular diseases encompasses increasing serum antioxidant capacity, strong inhibition of lipid peroxidation, active oxygen radical scavenging, capillary permeability, vasorelaxation, reduced plasmatic total cholesterol and hepatic triglyceride levels, inhibition of atherosclerotic plaque progression, improving endothelial dysfunction, inhibiting oxidized LDL formation [288, 289].Neuroprotection and vision improvement have also been cited for anthocyanins [283, 284].

The numerous reported biological activities and health-promoting effects of anthocyanins have been based mostly on in vitro cell studies and animal studies. Properly designed human clinical trials need to be carried out to provide definitive evidence.

Potential health-promoting activities (antioxidant, anti-inflammatory, anticancer, antilipidemic, antimicrobial activities) have also been attributed to betalains [290–292], but investigations are very much at the initial stage. Studies on the possible health effects of chlorophyll (anticancer, antimutagenic, and anti-proliferative activities; inhibition of heme-induced cytotoxic and hyperproliferative effects) are even more limited [293–296].

7 Concluding Remarks

The impressive work that has been accomplished on the chemical and technological aspects of natural pigments and colorants of foods, particularly anthocyanins, betacyanins, carotenoids, and chlorophylls, has provided a wealth of information on a wide range of important topics, including structures, chemical properties, stability, alterations during processing and storage, and stabilization methods. The potential health-promoting effects of carotenoids have been investigated for some time, but because of some inconsistent or inconclusive results, more human clinical studies are needed. The wide range of biological activities indicated by cell culture and animal model research for anthocyanins require confirmation by more human studies. Currently, at an initial stage, investigation of the health benefits of betacyanin and chlorophyll should be continued.

Contents

Abstract

Lycopene is the most abundant carotenoid found in human serum and has been recognized as the most effective antioxidant among all the carotenoids. Lycopene has 11 conjugated double bonds in its structure. However, lycopene occurs naturally in the all trans form in the dietary sources, found in as many as 18 different isometric forms in human serum and prostate cells mostly in cis form. However, the absolute concentrations of individual carotenoids within specific lipoprotein classes have not been reported; relative distribution of β-carotene, α-carotene, and lycopene among the very low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL) was similar, with 58–73% in LDL, 17–26% in HDL, and 10–16% in VLDL when separated by conventional sequential flotation ultracentrifugation and quantified by high-performance liquid chromatography. Lycopene has also been found helpful in

elimination of xenobiotics through stool or urine. Lycopene alters hormone and growth factor signalling including IFG-1 (31.5% decrease in serum IFG-1 levels) which is associated with cell proliferation. However its stability is a critical factor for its functional aspects. Physical and chemical factors like elevated temperature, exposure to oxygen and light, metallic ions (e.g., $Cu2^{+}$ and $Fe3^{+}$), extreme in pH, and active surfaces affect its stability.

Keywords
Lycopene · Metabolism · Functional · Antioxidant · Carotenoids

Abbreviations

BV	Biological value
CDP-ME	Methylerythritol cytidyl diphosphate
CDP-MEP	4-Diphosphocytidyl-2-C-methyl-D-erythritol-2-phosphate
CTP	Cytidine 5′-triphosphate
DMAPP	Dimethylallyl pyrophosphate
DXR/IspC	DXP reductoisomerase
HDL	High-density lipoprotein
HMBPP	4-Hydroxy-3-methyl-butenyl 1-diphosphate
IFG-1	Growth factor-1
IPP	Isopentenyl pyrophosphate
IspD	CDP-ME synthetase
LDL	Low-density lipoprotein
LOOHs	Hydroperoxides
MEcPP	2-C-Methyl-D-erythritol-2,4-cyclodiphosphate
MEP	2C-methyl-D-erythritol 4-phosphate
MVA	Mevalonic acid
PUFAs	Polyunsaturated fatty acids
VLDL	Very low-density lipoprotein

1 Introduction

Fruits and vegetables play a significant role in human nutrition, especially as sources of vitamins, minerals, and dietary fiber. Tomatoes are important for both, its large consumption and richness in health-related food components. It is one of the most versatile vegetable crops, ranking second around the world after potato [1]. Lycopene, the carotenoid pigment responsible for the red color, is the most distinctive compound present in tomatoes and has been recognized as the most effective antioxidant among the carotenoids. The unique quality about the composition of tomatoes and tomato products with respect to other fruits and vegetables is their high content of lycopene, the acyclic carotenoid containing 11 conjugated double bonds. There is a small amount of lycopene in few other fruits such as watermelon, pink guava, pink grapefruit, strawberry, and papaya, but tomato products are the major source of lycopene in human diet. Varietal effect is also prominent, and lycopene

content depends upon the variety, climatic conditions, and harvesting stage of tomato.

In addition to lycopene, violaxanthin, neoxanthin, lutein, zeaxanthin, α-cryptoxanthin, β-cryptoxanthin, α-carotene, β-carotene, γ-carotene, neurosporene, phytoene, phytofluene, cyclolycopene, b-carotene 5, and 6-epoxide are other carotenoids commonly cited in tomato and tomato-derived products [2]. Lycopene is the most abundant carotenoid found in human serum and, therefore, most important in terms of net antioxidant activity [3]. However, lycopene occurs in all *trans* form in dietary sources; it is always present in *cis* form in human tissues. The reason for particular interest in lycopene is its pharmacological effect and potential use in prevention of various metabolic diseases. Therefore, it is now regarded as a neutraceutical or functional food ingredient.

2 Biosynthesis of Lycopene

Lycopene belongs to the carotenoid family which are the red, yellow, and orange pigments found in dietary sources principally in fruits and vegetables. It was first isolated by Millardet in 1876 who called it "solanorubine" [4]. It was again isolated by Schunck in 1903 in pure form and named as "lycopene" [4]. It has an aliphatic hydrocarbon chain with 13 double bonds in its structure, and the molecular formula is $C_{40}H_{56}$ (Fig. 1). Lycopene has 11 conjugated double bonds in its structure, which makes possible to assume 2048 geometrical configurations theoretically. However naturally only 72 *cis* isomers of lycopene are found and are structurally favorable ingredients. Scientists are conducting clinical trials to know the exact pharmacokinetics of lycopene in the human body.

Carotenoid synthesis in plants occurs by various biosynthetic precursors naturally found in plants. It is basically de novo synthesis of carotenoids in plants which is affected by the presence of these biosynthetic precursrs. Maturation or ripening in fruits and fruit vegetables is generally accompanied by enhanced "carotenogenesis," the carotenoids increasing markedly both in number and quantity. Exposure to sunlight and high temperature enhance carotenoid biosynthesis, so the tropical foods are generally colored by carotenoids contrary to fruits of colder regions that are mostly colored due to anthocyanins [5, 6].

Isopentenyl pyrophosphate (IPP), an isoprenoid, is the biological precursor for all carotenoids including lycopene. Isopentenyl pyrophosphate is synthesized from acetyl-coenzyme A by a well-established pathway via mevalonic acid (MVA) (Fig. 2). Isomerized form of IPP which is known as dimethylallyl pyrophosphate (DMAPP) acts as a starter molecule for chain elongation. When the DMAPP is produced after isomerization of IPP, it again condenses with a molecule of IPP to form geranyl pyrophosphate (C_{10}) which further condenses with a molecule of IPP to form farnesyl pyrophosphate (C_{15}) and finally produces geranylgeranyl pyrophosphate (C_{20}) by similar elongation. The presence of enzymes which influence the chain elongation is not clear, but the mevalonic kinase and 5-phosphokinase which are present in the chloroplast fragments are

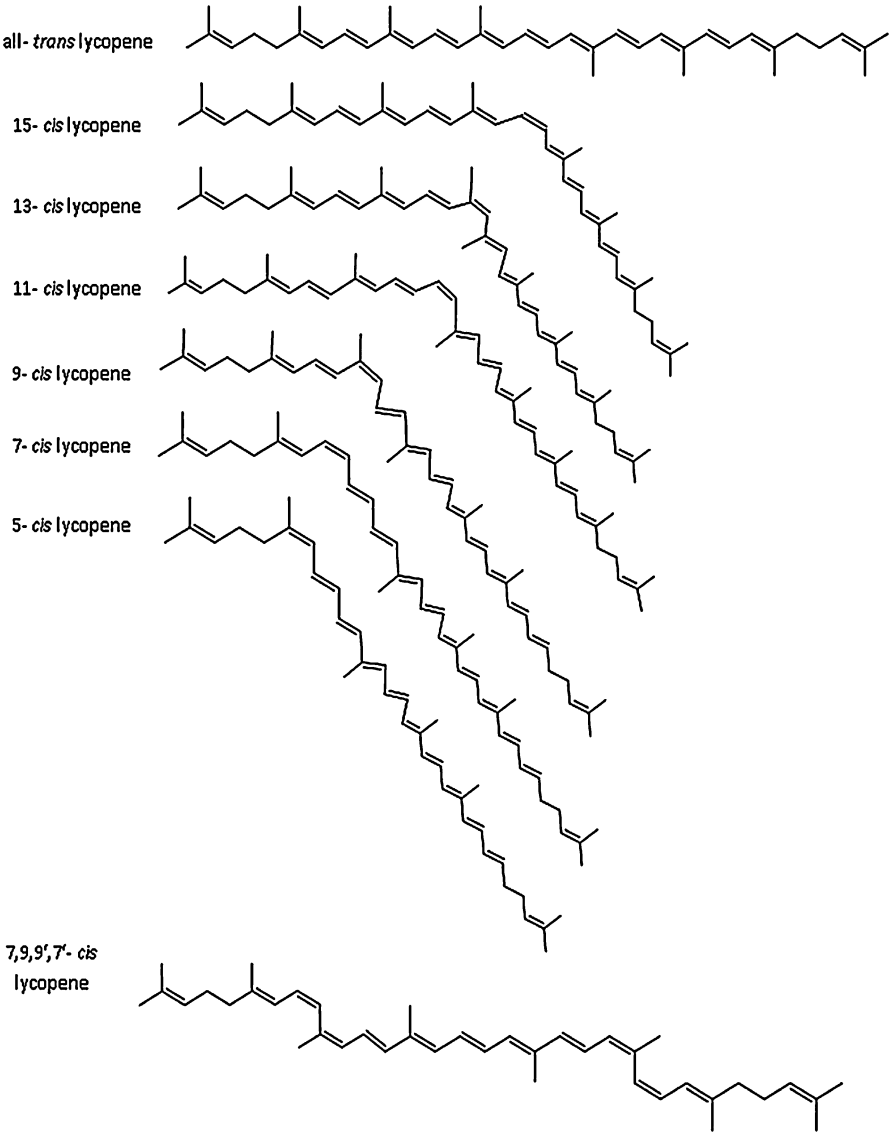

Fig. 1 Common lycopene isomers

believed to be the core enzymes which affect this chain elongation process [7]. Phytoene which is the first (C_{40}) compound is believed to be a carotenoid precursor. Phytoene is stepwise dehydrogenated to phytofluene, ζ-carotene, and neurosporene (Fig. 3). Cyclization begins at neurosporene level, and it leads to the formation of various cyclic carotenes including lycopene (Fig. 4).

During postharvest transport or storage, carotenoid biosynthesis may continue, raising the carotenoid content, provided that the fruit, vegetable,

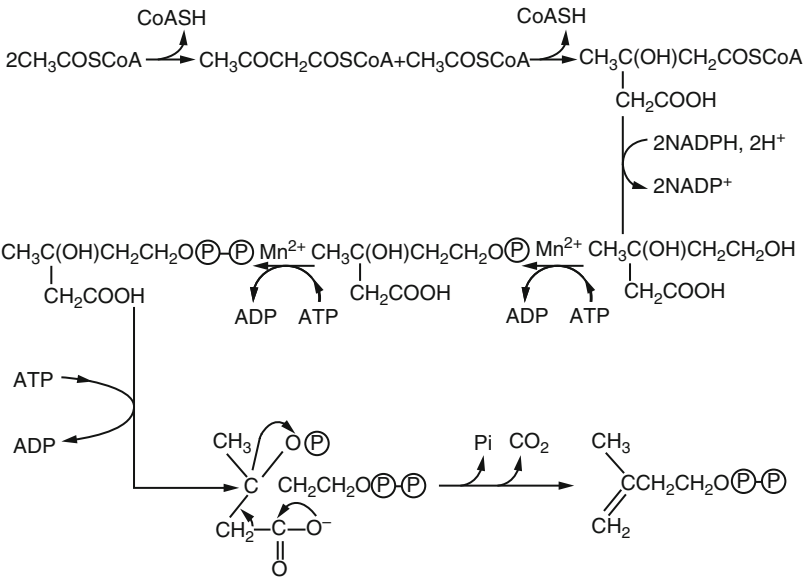

Fig. 2 Conversion of acetyl-CoA into IPP

or root is kept intact, preserving the enzyme system responsible for "carotenogenesis" [6].

For decades, the MVA pathway was thought to be the only pathway for the biosynthesis of IPP and DMAPP. However, the 2C-methyl-D-erythritol 4-phosphate (MEP) pathway was discovered in the 1990s [8–10]. This pathway is initiated with a thiamin diphosphate-dependent condensation between D-glyceraldehyde 3-phosphate and pyruvate to produce DXP which is then reductively isomerized to MEP by DXP reductoisomerase (DXR/IspC). Subsequent coupling between MEP and cytidine 5′-triphosphate (CTP) is catalyzed by CDP-ME synthetase (IspD) and produces methylerythritol cytidyl diphosphate (CDP-ME). An ATP-dependent enzyme (IspE) phosphorylates the C2 hydroxyl group of methylerythritol cytidyl diphosphate, and the resulting 4-diphosphocytidyl-2-C-methyl-D-erythritol-2-phosphate (CDP-MEP) is cyclized by IspF to 2-C-methyl-D-erythritol-2,4-cyclodiphosphate (MEcPP). IspG catalyzes the ring opening of the cyclic pyrophosphate and the C3-reductive dehydration of MEcPP to 4-hydroxy-3-methyl-butenyl 1-diphosphate (HMBPP). The final step of the MEP pathway is catalyzed by IspH and converts (HMBPP) to both IPP and DMAPP. Thus, unlike the MVA pathway, IPP/DMAPP isomerase (IDI) is not essential in many MEP pathway-utilizing organisms [8].

The 2C-methyl-D-erythritol 4-phosphate (MEP) pathway, in charge of the essential biosynthesis of isoprenoids, represents a promising and selective target for developing new drugs against tuberculosis. To date, only fosmidomycin, a molecule that targets the second enzyme of the MEP pathway, has reached clinical trials, but recent advances elucidating the structure and kinetics of the MEP enzymes are likely to change this scenario [11, 12].

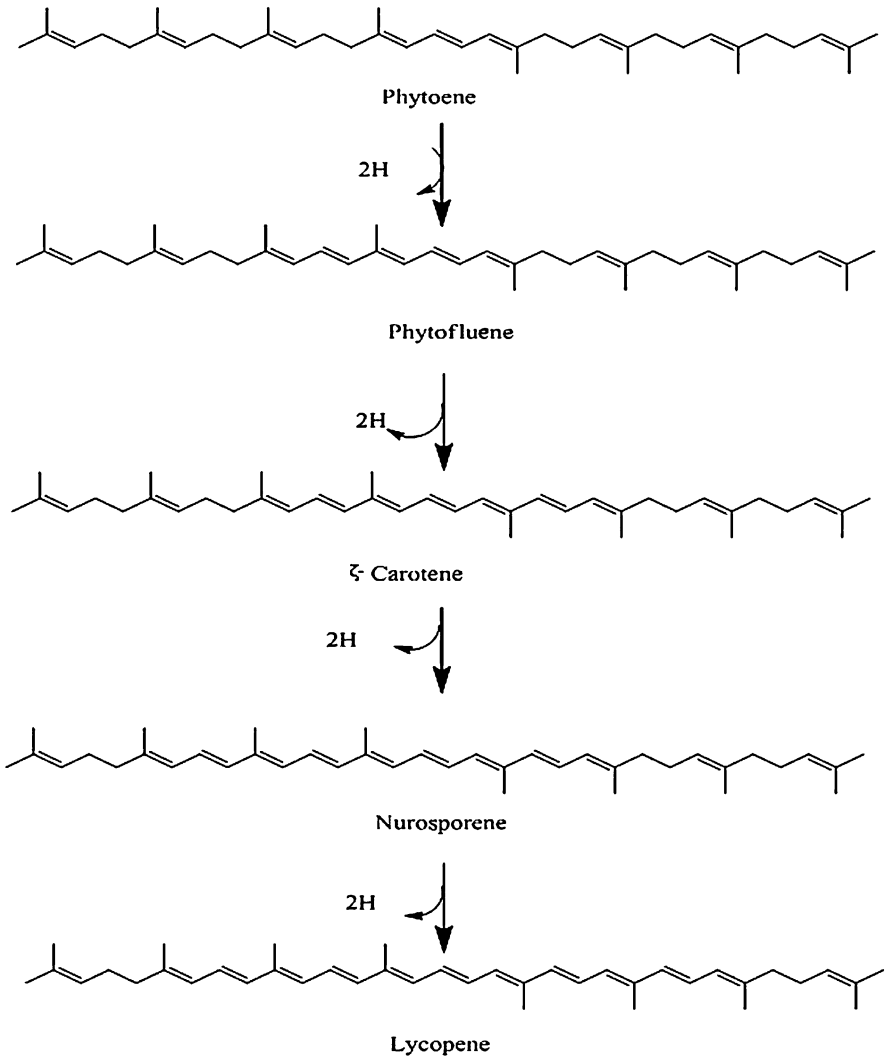

Fig. 3 Stepwise dehydrogenation of phytoene to lycopene

3 Absorption and Metabolism Aspect of Lycopene in the Human Body

As it has been discussed earlier that, however, lycopene occurs naturally in the all *trans* form in the dietary sources, it is mostly found in *cis* form in the human tissues. This supports the hypothesis that it is readily absorbed in *cis* form and present in the same configuration in human tissues. Lycopene was found in as many as 18 different

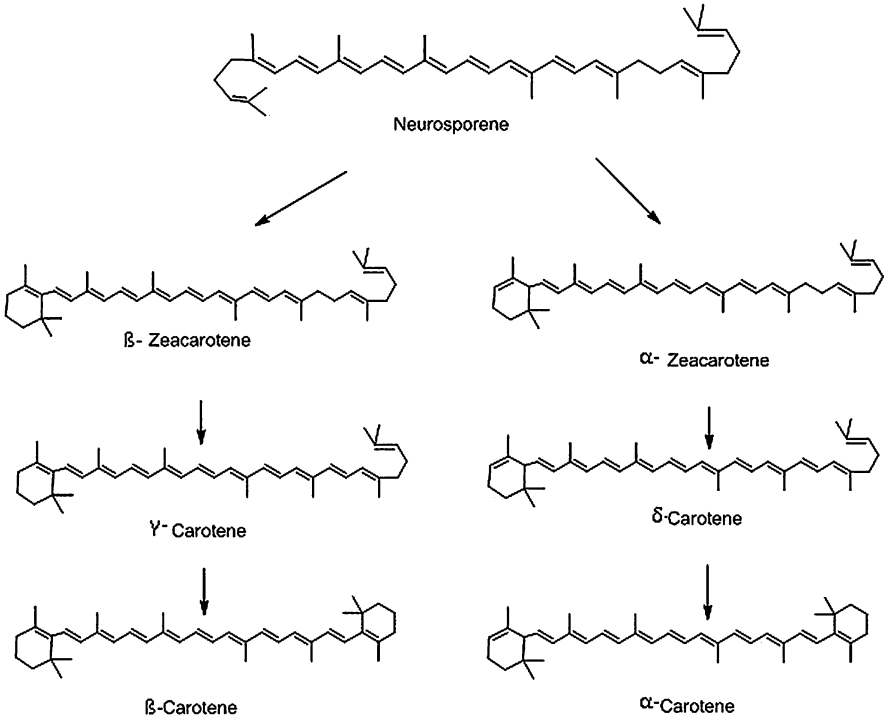

Fig. 4 Conversion of neurosporene to α-carotene and β-carotene

isometric forms in human serum and prostate cells. According to the study of Boileau et al. [13] when ferrets were given oral dose of only 9% *cis* isomers, the *cis-trans* isomer ratios showed that *cis* isomers are more readily taken up by micelles and making them more readily absorbed. However, the diet was containing only 9% *cis* isomers, mucosa (58.8%), lymph (77.4%), and blood (52%), and tissues contained significantly more *cis*-lycopene isomers than the stomach (6%) or intestinal content (17.5%). Studies by Boileau et al. [13] also suggested that mucosal cells contain 41% more *cis*-lycopene. In-vitro the mucosal cells were having more of *cis*-lycopene, in vitro trials were conducted to understand the mechanism of lycopene isomer uptake by bile acid micelles. However the complete mechanism of preferential absorption of *cis* isomers of lycopene is not clearly understood it was hypothesized that the introduction of one or more double bonds into a lycopene molecule reduces its length and thus fits well into micelles with greater ease. Alternatively, it has also been suggested that linear all *trans* isomers may more readily aggregate within the intestine and form crystals greatly reducing their uptake by micelles [14]. The hypothesis was also supported by the study of [15] when male F344 rats were fed lycopene-containing diet for 8 weeks; they also achieved similar lycopene concentration in tissues.

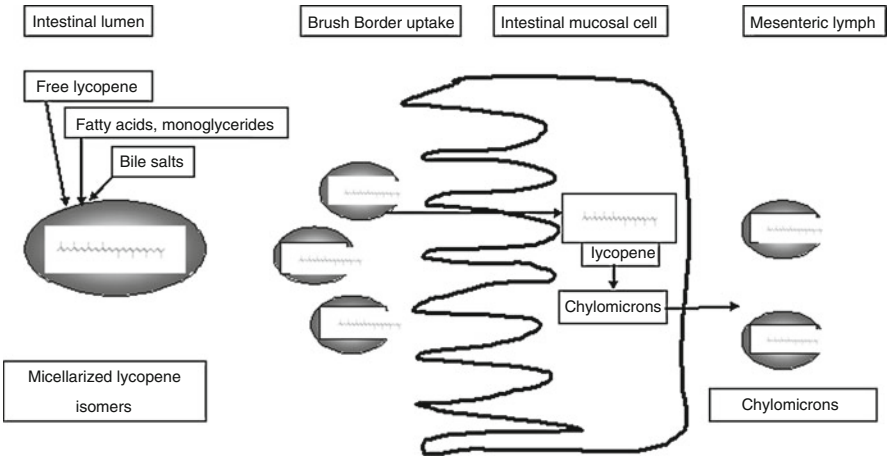

Fig. 5 Uptake of lycopene through mucosal cells

All the carotenoids appear to be absorbed by duodenal mucosal cells by passive diffusion, similar to that of cholesterol and triglyceride lipolysis (Fig. 5). Physical matrix in which they are ingested is the critical and important factor which affects their bioavailability and their dissolution in bulk lipids. Studies by Hernell et al. [16] indicated that the ultimate structure produced during lipid digestion is a discoidal mixed lipid micelle composed largely of bile salts, free fatty acids, monoglycerides, and phospholipids with a diameter of 80 Å. The carotenoids are included in micelles according to their structure and micellar lipid composition. Carotenoids are taken up by the intestinal mucosal cells through the bile acid micelles. Bile acid micelle formation is influenced by the fat intake, and hence lycopene or some other carotenoid absorption is increased when it is taken with fat or a meal containing fat [17].

Lycopene in the mixed lipid micelles is then taken up by the duodenal brush border enzymes through passive diffusion. Different carotenoids and fat-soluble vitamins like vitamin E compete with each other during absorption. Canthaxanthin and lycopene reduced the 0–24-h plasma β-carotene response when given concurrently compared to administration of β-carotene alone [18]. Lycopene exits the mucosal cell in chylomicrons, which are secreted via the mesenteric lymph system into the blood. The distribution of carotenoids among the various lipoproteins classes therefore appears to be determined by the physical characteristics of the individual carotenoid and the lipid composition of the lipoproteins. However, the absolute concentrations of individual carotenoids within specific lipoprotein classes have not been reported; relative distribution of β-carotene, α-carotene, and lycopene among the very low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL) was similar, with 58–73% in LDL, 17–26% in HDL, and 10–16% in VLDL when separated by conventional

sequential flotation ultracentrifugation and quantified by high-performance liquid chromatography [19].

4 Lycopene and Its Role in Detoxification Pathway in Humans

Cytochrome P-450 enzyme in animals constitutes one of the primary defense systems against natural toxic chemicals from plants which are the major sources of dietary toxins. The induction of cytochrome P-450 enzyme prevents acute toxic effects from foreign chemicals but also results in oxidant by-products that damage DNA. Cytochrome P-450 enzyme helps in detoxification via two different pathways called phase I and phase II detoxification pathways. The study showed lycopene significantly induced phase I enzymes in a dose-dependent manner and doubled hepatic quinone reductase (QR), a phase II enzyme. Lycopene has also been found helpful in elimination of xenobiotics through stool or urine. Xenobiotics are pharmacologically, endocrinologically, and toxicologically active substances that must be metabolized and degraded to such compounds so that it can be eliminated through human excreta. Xenobiotics are also metabolized by cytochrome P-450 enzyme phase I and phase II pathways.

Lipid oxidation is a normal biological process by which we obtain energy from fat. Deleterious lipid oxidation occurring in the body is called peroxidation of polyunsaturated fatty acids (PUFAs) and produces hydroperoxides (LOOHs). Uncontrolled oxidation of lipids in biological membranes is a major contributor in several diseases such as heart disease, cancer, and neurodegeneration. The elevated level of LOOHs was observed during instances of cellular injury and found correlated to the disruption of cellular membranes, inactivation of enzymes, and damage to DNA and protein molecule. Initiation and propagation of lipid peroxidation was studied in isolated microsomes of the liver. The reaction was catalyzed by iron and microsomal NADPH-cytochrome P-450 reductase enzyme. This enzyme is reported to produce superoxide anion formed by addition of an extra electron onto the diatomic oxygen molecule. Aust and Svingen [20] suggested that lipid peroxidation in microsomes of the liver occurs in two stages. In initiation stage cytochrome P-450 reductase catalyzes reduction of ADP-Fe + 3 which is subsequently reacting with oxygen molecule to form a ADP-perferyl radical. The perferyl radical is then responsible for initiating lipid peroxidation and formation of lipid peroxides.

Oxidative DNA damage could be a major risk factor for the development of tumors, so that dietary antioxidants are able to decrease such damage in vivo which would be expected to have cancer prevention effects. Hence, antioxidant substances when present in foods at low concentrations compared with those of oxidizable substrate markedly reduce, delay, or prevent the oxidation of the substrate [21]. Due to the safety concerns over synthetic compounds, research has been focused on novel antioxidant components present in foods.

5 Mechanism Responsible for Health Benefits of Lycopene

There are five mechanisms that researchers proposed which may account for the beneficial effects of tomato phytochemicals and their metabolite. Firstly, lycopene is the strongest antioxidant compared to other commonly consumed carotenoids. Decreased DNA damage has been reported in white blood cells after 15 days of supplementation of tomato and tomato juice. It accounts for about 50% of carotenoids in human serum. Among the common dietary carotenoids, lycopene has the highest singlet oxygen quenching capacity in vitro (Table 1). Another outstanding feature is its high concentration in the testes, adrenal gland, and prostate. Lycopene uptake varied with individuals, but peak serum concentrations were always reached between 24 and 48 h. The carotenoid was eliminated from serum with a half-life of 2–3 d. The increase in peak serum concentrations was dose-dependent but not linear with the dose.

Secondly, lycopene alters the biotransformation of xenobiotics; cooked tomatoes and lycopene alter hormone and growth factor signaling in prostate cells. This includes alterations in insulin-like growth factor-1 (IFG-1) activity. IFG-1 stimulates cellular proliferation and decreases apoptosis, which is a mechanism by which normal cell death happens. Eating cooked tomatoes was associated with a 31.5% decrease in serum IFG-1 levels in a case-controlled study of 112 men. Beneficial alterations of IFG-1 concentrations and its ability to stimulate cell division have also been found in rats and healthy men. An in vitro study showed lycopene and tomato polyphenols including quercetin, kaempferol, and rutin, to interfere with IGF-1 signaling, thus preventing the growth factor from stimulating cell proliferation. In a number of cancer cell line including breast cancer cells and endometrial and prostate cancer cells, lycopene halted cellular replication in vitro. Lastly, lycopene and its metabolites may help fight some cancers by increasing connexin 43 levels. Connexin 43 is a molecule involved in cell-to-cell communication, which is important in the regulation of uncontrolled, rapid cell growth. In a metastatic prostate cancer cell line, lycopene did not increase connexin 43; however, it did in another prostate cancer cell line, a breast cancer cell line, and oral cancer cells. The inhibition

Table 1 Comparison of antioxidant capacities of carotenoids

Carotenoid	Rate constant for quenching of singlet oxygen $K_q \times 10^9$ (mol^{-1} s^{-1})

Bixin	14
Canthaxanthin	21
Zeaxanthin	10

Source: Data from Di Masio et al. [22] and Miller et al. [23]

of connexin 43 in these cell lines was associated with an inhibition of cell growth, suggesting that upregulation of connexin 43 may be important to the anticancer action of lycopene. Since a synergistic effect appears to exist between tomato phytochemicals, recommending the consumption of supplements made from whole tomatoes and/or the consumption of two to four or more servings per week of tomato products may reduce the incidence of prostate cancer and health-care costs in our aging population.

In contrast to other carotenoids, its serum values are not regularly reduced by smoking or alcohol consumption but by increasing age. Remarkable inverse relationships between lycopene intake or serum values and risk have been observed in particular for cancers of the prostate, pancreas, and to a certain extent of the stomach. In some of the studies, lycopene was the only carotenoid associated with risk reduction. Its role in cancer risk reduction still needs to be clarified. Patients with HIV infection, inflammatory diseases, and hyperlipidemia with and without lipid-lowering treatment may have depleted lycopene serum concentrations [24].

6 Stability and Functional Aspects of Lycopene

Stability is a critical aspect of lycopene functionality. As a highly conjugated polyene, lycopene can undergo two types of changes: isomerization and oxidation. Physical and chemical factors known to contribute to the degradation of other carotenoids are also reported to affect in case of lycopene. These include elevated temperature, exposure to oxygen and light, metallic ions (e.g., Cu^{2+} and Fe^{3+}), extreme in pH, and active surfaces [25, 26].

Cis and *trans* isomers of lycopene have distinct bioactivity and biostability. In general *cis* isomers are more soluble in oil and hydrocarbon solvents than their all *trans* counterparts. They are less prone to crystallization than *trans* isomers due to their kinked structures. They are less intense in color which affect consumer's perception of food quality. All *trans* configurations predominate in fresh tomatoes and gradually isomerize to *cis* configurations upon processing and storage. Isomerization of lycopene has been shown to take place both in food systems and in model systems. *Trans*-to-*cis* isomerization typically occurs during isomerization. The storage of processed foods favors reversion from *cis* to *trans* because the *cis* isomers are in a relatively unstable state compared to the *trans* isomer, which is relatively a stable ground state. Mostly the 5-*cis*, 9-*cis*, and 15-*cis* isomers are found in human serum when assessed using nuclear magnetic resonance (NMR) spectroscopy. With its acyclic structure, a large array of conjugated double bonds and important hydrophobicity lycopene exhibits a range of unique and distinct biological properties. Of these properties its antioxidant potential is of particular interest. The system of conjugated double bonds allows lycopene molecule to quench the singlet oxygen and also other free radicals. In an in vitro study by Boileau et al. [13], it was found an effective singlet oxygen quencher. Under appropriate conditions, it has been found effective as an antioxidant at lower concentrations not only against O_2^- but also against lipid peroxidation and a highly destructive hydroxyl radical HO.

The antioxidant properties of lycopene most likely contribute to limit the risk of some diseases [3].

Various factors such as heat, processing conditions, heat, oxygen, light, dehydration, and storage conditions affect the lycopene stability and *cis*-to-*trans* isomerization of lycopene isomers. Time-temperature combination in heat processing of lycopene is crucial and affects its isomerization and degradation. Besides time-temperature combination reaction medium, physical matrix and environmental conditions also affect the stability of lycopene. Basically two types of changes occur, isomerization and degradation, due to the parameters described above. As is has been discussed in earlier sections that majority of lycopene is present naturally in the all-*trans* form in fruits and vegetables. However, the absorption and bioavailability of the *cis*-lycopene is better than the *trans* isomers. During the heat processing, *trans* isomers gradually change into the *cis* form. It has been observed that all *trans*-lycopene isomerizes into mono- or poly-*cis* form due to changes in seven of the conjugated double bonds initially during the thermal processing followed by degradation of lycopene content. It has been reported by Hakette et al. [27] that degradation of lycopene started at a temperature as low as 25 °C. At this temperature degradation of lycopene occurs mainly due to oxidation, and isomerization occurs at a very low rate. Isomerization of lycopene from *trans* to *cis* form occurs on a faster rate at a temperature above 75 °C [27, 28]. According to the study of Lee and Chen [29], no significant change occurs in the lycopene content during the first 12 h of heating at 50 °C. However, at 100 °C heating for 9 h, isomerization of lycopene from all *trans* to mono-*cis* form followed by degradation of mono-*cis* to di-*cis* and poly-*cis* form of lycopene occurs. Thus it can be concluded that the isomerization of mono-*cis*-lycopene to di-*cis*-lycopene is the main phenomenon during heating in initial phase followed by conversion to poly-*cis* form and subsequent degradation. At the temperature above 100 °C, lycopene was found highly unstable, and severe deduction was noted in the lycopene content at higher temperature above 100 °C. No lycopene was detected after 10 min at heating over 100 °C.

The exposure of light also induced similar kind of changes in the all *trans*-lycopene. According to the study of Lee and Chen [29] and Shi et al. [30, 31], all *trans*-lycopene first changes into 9-*cis*, 13-*cis*, and 15-*cis* isomers, and then degradation of lycopene occurs. It has been also found during the study that *cis* isomers are less stable than all *trans* isomers under light exposure. Lee and Chen [29] studied the stability of lycopene standard at 25 °C for 6 days at illumination intensity (2000–3000 lx). All *trans*-lycopene was found to decrease with an increase in illumination time, and total loss of lycopene was measured as 94% after 144 h of illumination exposure.

Lycopene stabilization was found three times higher in the presence of oxygen than under inert conditions. Vacuum and N_2^- packaging of tomato powder were found highly effective to reduce the oxidation changes of lycopene. According to the study of Sharma and Le Maguer [32], vacuum pack and dark storage combination showed the lowest lycopene loss. Auto-oxidation of lycopene is irreversible and leads to fragmentation of molecule. During the storage *cis-trans* reversion of lycopene is also reported. During storage *cis-trans* re-isomerization and auto-oxidation

of lycopene are the main reasons of loss in lycopene content. Auto-oxidation produce acetone methylheptenone, levulinic aldehyde and glycoxal also which is responsible for loss in color and typical hay like odor [33].

7 The Linkage of Health and Food Choice

Health is one reason consumers mention when they are asked about factors that influence their food choices correspondingly; nutrition experts emphasize that the degree of healthy eating needs to be judged on the level of diet. Whereas no single food product can be categorized as health promoting or not, this is true that from a nutrition point of view, information about fat, vitamin, and other nutraceutical contents of food tend to be categorized, for example, all fruits and vegetables are rich sources of vitamin C and carotenoids or other pigment contents which are of health-promoting value. Functional food is regarded somewhere between medicine and conventional food, but there is no common shared definition of functional food. Japan has its own legislation of "food for specified health uses," called FOSHU, in which functional foods are clearly regarded as food products that are eaten as part of an ordinary diet. In Europe, the definition suggested by an EU-funded concerted action project has widely been used. According to this definition, functional foods are "satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects in a way that is relevant to either an improved state of health and well-being and/or reduction of risk of diseases" [34].

Traditional nutritional education has emphasized the role of a health-promoting diet. Following nutritional guidelines will result in reduced risk to develop obesity and other chronic lifestyle-related diseases, such as cardiovascular disease, diabetes, and cancer. The message on the benefit of a healthy diet may be hard to convey to the consumer, as the end result is unsure and achieving the possible reward takes several years or even decades. Functional foods offer a new kind of positive health benefit to the people. Instead of avoiding certain kind of foods, these food products promise positive physiological effect on bodily functions or even a reduction on risk level of diseases through eating a single product. Functional food effects are easier to understand for the consumer since they contain results that can be instrumentally measured, such as lowering the level of cholesterol in the blood, decreasing the blood pressure, or increasing the density of bone mass [35, 36].

The beneficial health effect of functional foods is due to the presence of a myriad of bioactives that render their effects via a number of mechanisms. The diseases of concern include coronary heart disease, certain types of cancer, type 2 diabetes, brain health and mental disorders, immune response, inflammation, obesity, and arthritis, in association with oxidative stress and metabolic syndrome. The substances that may influence such diseases often originate from plant sources and sometimes animal sources and microorganisms. Examples include carotenoids such as alpha- and beta-carotene; lutein; astaxanthin; lycopene; fucoxanthin; dietary fiber; beta-glucan; soluble fiber; long-chain omega-3 fatty acids; phenolics such as phenolic acid; phenylpropanoids; catechins; anthocyanidins; flavones; flavanones;

proanthocyanidins; lignans; sterols and stanols; pre-, pro-, and syn-biotics; and soy isoflavones. Some proteins and biologically active peptides also come under the category of functional foods.

8 Regulatory Aspects of Functional Foods

The success of a functional food depends to a large extent on the regulatory framework in which it is allowed to be marketed. From country to country, the method of regulating the labeling and composition of functional foods varies enormously. The most important issue that must be considered related to functional foods is "the nature of the ingredient." What specific health benefit does it actually confer on the consumer? A whole host of the products in the market profess to be functional, ranging from vitamin- and mineral-enriched products to the products containing added fiber ingredients and pre- and probiotics. Is there really a distinction between vitamin added for fortification and a vitamin added for its perceived functional qualities?

Health claims of a product describe the relationship of a diet to the specific disease, and only 11 health claims are approved by the FDA. An example is healthful diet with adequate folate may reduce a women's risk of having a child with brain or spinal cord defect. Health claims traditionally have been approved based on the concept of "significant scientific agreement" which the FDA has recently defined in a guidance document as an agreement among qualified scientific experts that a substance-disease relationship exists based on a sound body of scientific evidence. The level of scientific evidence must be strong enough that it would unlikely to be reversed by the further study [37].

Nutritional claims describe the level of a nutrient or dietary substances in a product using terms such as free, high, and low, or they compare the level of a nutrient in a food to that of another food, using terms such as more reduced, etc. An accurate quantitative statement (e.g., 200 mg of sodium) that does not characterize the nutrient level may be used to describe any amount of a nutrient present [37]. Structural and functional claims are statements of health-promoting or nutritional benefit allowed on dietary supplement labels. They are not allowed to mention disease conditions; they must describe the support or maintenance of the normal functioning of the body. "Cranberry supports the health of urinary tract" is an example of a model structure or functional claim.

9 Conclusion

Lycopene not only has the pharmacological and nutritional effect in humans and animals but also has promising health benefit too. However its potential health benefits have been known since the late 1950s; recently clinical and functional aspects of lycopene and its metabolic fate have been stimulated their potential use in the prevention of the chronic diseases. There has been a growing interest in the

role of lycopene in a variety of ailments in humans including some cancers and heart diseases. Recent studies have shown that consumption of lycopene-rich foods reduces the risk of such diseases. Lycopene is also a more potent antioxidant than all other carotenoids found in human serum. However, it has no pro-vitamin A activity, but it efficiently quenches the singlet oxygen and prevents degeneration of proteins and DNA. Heat treatment has shown improved bioavailability of lycopene after cooking, which means it is more easily absorbable by the body in the heat-processed tomato products. Heat processing affects *trans-cis* isomerization of tomato products. The loosely bound lycopene in tomato products is released during heat processing, while the degree of isomerization is directly correlated with temperature and duration of heat processing. Recent scientific and epidemiological data has proven the anticancer properties of lycopene. The US National Research Council of the Academy of Sciences, World Cancer Research Fund International, American Cancer Research Institute, and WHO have strong documentary proofs and made similar recommendations for possibility of reducing cancer risks. Considering the possible health benefits of lycopene and functionality, it has a brighter scope for the functional food domain and food processing industry.

Sweet Potato: Bioactive Compounds and Health Benefits

32

Remya Mohanraj

Contents

Abstract

Sweet potato, a delicious root vegetable, possesses high nutritional value. It is reported to exhibit anticancer, antidiabetic, and anti-inflammatory activities and to be a natural alternative to estrogen therapy. Sweet potatoes are a rich source of phytochemical compounds, and plant-derived compounds always have been an important source of several clinically useful biomolecules. This chapter aims to focus on the health benefits and phytochemical composition of sweet potato with special emphasis on 4-ipomeanol. 4-Ipomeanol, produced by infected sweet potatoes, is a potential anticancer agent. Earlier studies revealed that bioactivation of 4-ipomeanol to a cytotoxic metabolite occurred particularly in tissues that are abundant in specific P450 mixed function oxidase enzymes. Based on the above

rationale, 4-ipomeanol was the first agent to undergo clinical development as an anticancer agent especially against lung cancer. 4-Ipomeanol as a potential prodrug for P450-directed gene therapy of liver and brain cancers has also been investigated. Recent findings suggest that ^{18}F-labelled 4-ipomeanol could be used in imaging tumors and monitoring enzyme/prodrug interactions.

Keywords
Sweet potato · 4-Ipomeanol · Anti-cancer activity · Phytochemical composition

1 Introduction

Sweet potato (*Ipomoea batatas* (L.) Lam, Convolvulaceae) (Fig. 1) is a root vegetable rich in starch and sweet to taste [1, 2]. It ranks as the seventh important staple crop in the world and in developing countries, it is ranked as the fifth following rice, wheat, maize, and cassava [3]. The skin may be red, purple, brown, or white in color. The flesh color ranges from white, yellow, and orange to purple [4].

Sweet potatoes are native to South America. Columbus introduced it to Europe from where it eventually spread to other parts of the world [5]. From time immemorial, this root tuber that possesses an abundance of pharmacologically active ingredients occupied a significant position in human nutrition and animal feeding. Several reports point out to the use of sweet potatoes in traditional medicine. The leaves are used by Akan tribes of Ghana to treat type 2 diabetes [6]; in Brazil, they are used in the treatment of inflammatory and/or infectious oral diseases [7]. In regions of Kagawa, Japan, sweet potatoes are used to treat anemia, hypertension, and diabetes [8]. The stems are used for treatment of prostatitis [9]. In addition to the above, sweet potatoes are reported to be alterative, aphrodisiac, astringent,

Fig. 1 Purple-skinned sweet potatoes

bactericide, demulcent, fungicide, laxative, and tonic. It is a folk medicine for asthma, bugbites, burns, catarrh, ciguatera, convalescence, diarrhea, dyslactea, fever, nausea, renosis, splenosis, stomach distress, tumors, and whitlows [10]. In Mexico, the leaves are used for the treatment of inflammatory tumors, and their decoction is used in baths and gargles for tumors of the mouth and throat [11].

Reed [12] described the plant as a tuberous-rooted perennial that is usually grown as an annual. Slender, prostrate stems form a running vine up to 4 m long and produce milky juice. Lateral stem branches that arise from the short stem are usually not branched. Leaves are ovate-cordate and borne on long petioles, palmately veined, angular or lobed, green or purplish depending on the variety. Fowers white or pale violet, axillary, funnel-shaped, borne singly or in cymes on short peduncles. Pods are round with 1–4 flattened, hard-coated, angular seeds per pod [12].

Keeping the above background in mind, this chapter aims at providing an insight into the health benefits and recent advances in phytochemical composition of sweet potato tubers with special emphasis on 4-ipomeanol, an anticancer agent.

2 Health Benefits

Sweet potato is a staple food in many parts of the world and is a drought-tolerant crop that holds promise in improving food and nutrition security [13]. Sweet potatoes are especially significant because of their abundant nutraceutical components. This tuberous root is a rich source of carbohydrates, dietary fiber, vitamin A (as β-carotene), vitamin B6, vitamin C, manganese, copper, potassium, and iron [14]. Red sweet potatoes have been reported to have 12.98% of glucose and therefore gain recognition as a good energy source. Besides this, sweet potatoes contain 2.78% crude fiber as an added advantage for the consumers. In essence, sweet potatoes are not only a good food diversification but also a food alternative that bestow food security and promote health [15].

Sweet potatoes offer a near-balanced diet for the human body in that they possess significant amounts of carbohydrates in comparison with other starchy foods such as rice, maize, and sorghum porridge [16]. They encompass a broad range of macro- and micronutrients, generous amount of vitamin C, reasonable amounts of vitamin B complex (vitamins B1, B2, B5, and B6) and folic acid, as well as an adequate amount of vitamin E [17, 18].

A colossal advantage is that the sweet potato crop could be made accessible throughout the year in tropical and subtropical areas where warm conditions abound. This offers a leverage in case drought poses a challenge for staple crops such as cereals. The competence of sweet potatoes in being drought tolerant after establishment raises its yield potential higher than that of other staple crops [13].

The US Food and Drug Administration summates the nutritional facts of sweet potatoes as follows [19]:

Serving size (gram weight/ounce weight)	1 medium (130 g/4.6 oz)
Calories	100
Calories from fat	0
Total fat	0
Sodium	70 mg
	3% DV
Potassium	440 mg
	13% DV
Total carbohydrate	23 g
	8% DV
Dietary fiber	4 g
	16% DV
Sugars	7 g
Protein	2 g
Vitamin A	120% DV
Vitamin C	30% DV
Calcium	4% DV
Iron	4% DV

Percent Daily Values (% DV) are based on a 2,000 calorie diet

In the class of different varieties of sweet potatoes, orange-fleshed sweet potato is reported to possess high amounts of β-carotene, a precursor for vitamin A. It has been recorded that the amount of β-carotene is directly proportional to the intensity of orange color of the sweet potato flesh [17, 20, 21].

Leighton [21] tested for β-carotene in different South African orange-fleshed sweet potato varieties and concluded that β-carotene concentration varied with depth of color.

Alam et al. [22] analyzed the nutritional composition of nine varieties of orange-fleshed sweet potatoes. They also analyzed the total carotenoids and total polyphenol content. Each variety showed a significant variation in the nutritional composition. The quantification of total carotenoids and total polyphenol content was done using spectrophotometry, and the proximate composition was done using AOAC. The results obtained indicated that the total polyphenol content varied from 94.63 to 136.05 mg gallic acid equivalent/100 g fresh weight. The obtained results also indicated that total carotenoids content ranged from 0.38 to 7.24 mg/100 g fresh weight. Dark orange-colored flesh varieties had a higher content of total carotenoids as compared to their light-colored counterparts. These findings suggest that the sweet potato varieties studied are rich in proteins and carbohydrates, low in fat, and high in polyphenol and carotenoids. Therefore sweet potatoes could serve as an excellent source of dietary antioxidants which could potentially prevent free radical damage and also prevent vitamin A malnutrition [22].

Sanoussi et al. [23] assessed the mineral composition of ten selected cultivars of sweet potatoes (01 cream, 02 white, 03 yellow, and 04 orange flesh-colored) using standard spectrophotometry, in order to establish a scientific basis for efficient

valorization and sustainable utilization of these crops in Benin. The mineral composition of the tubers on dry weight basis ranged from 0.53 to 0.73 mg/100 g for iron; 0.23 to 0.27 mg/100 g for zinc; 23.04 to 29.97 mg/100 g for calcium; 21.30 to 25.40 mg/100 g for magnesium; 42.00 to 46.33 mg/100 g for phosphorus; 308.67 to 328.67 mg/100 g for potassium; and 29.00 to 34.00 mg/100 g for sodium. The mineral salt recorded in highest amount in all the samples was potassium, which could contribute on an average up to 19.78% and 15.83% of the recommended dietary allowance of children and adults, respectively [23].

2.1 Cardioprotective Effects

Studies from Harvard University School of Public Health reveal that sweet potatoes are a tremendous source of B6 vitamins, which promote breaking down of homocysteine. It is noteworthy that homocysteine contributes to the hardening of blood vessels and arteries. As an exceptional source of potassium that lowers blood pressure and maintains fluid balance, sweet potatoes play a significant role in improving heart health (American Heart Association) [19].

Phytochemical screening of aqueous tuber extract of *Ipomoea batatas* conducted by Shafe et al. [24] showed the presence of tannin, saponin, flavonoid, terpenoid, alkaloid, anthraquinones, reducing sugars, and cardiac glycosides. The administration of tuber extracts lead to a decrease in the activities of serum creatine and lactate dehydrogenase. The results obtained suggest a potential cardioprotective effect of the aqueous tuber extracts of sweet potato [24].

2.2 Regulation of Blood Sugar

According to sources from North Carolina State University, sweet potatoes help regulate the levels of blood glucose. Linus Pauling Institute at Oregon State University reported that sweet potatoes are an excellent source of manganese which helps the body metabolize carbohydrates and thus maintain healthy blood sugar levels [19].

2.3 Immune Booster and Anti-inflammatory Properties

Mercy Margaret et al. [25] prepared the aqueous extract of *I. batatas* and evaluated the in vitro anti-inflammatory activity of the extracts by membrane stabilizing method. Phytochemical analyses of the extracts revealed the presence of phenols, flavonoids, tannins, anthraquinones, and reducing sugars. The results indicated that the anti-inflammatory potential of the extracts could be attributed to the presence of phenols and flavonoids in the extracts [25]. Vitamins A and E present in sweet

potatoes also support a healthy immune system and are powerful disease-fighting antioxidants [19].

2.4 Benefits for the Gastrointestinal System

The high fiber content of sweet potatoes helps in retaining water. Also, magnesium, which is present in sweet potatoes, aids in digestion. They are soothing for the stomach and intestines. B-complex vitamins, vitamin C, beta-carotene, potassium, and calcium present in sweet potatoes are beneficial in curing stomach ulcers. Additionally, the roughage in sweet potatoes alleviates constipation and the resultant acid formation, which diminishes the chance of ulcers [26].

2.5 Benefits for Respiratory System

Sweet potatoes are effective in providing relief from asthma by clearing congestion of the nose, bronchi, and lungs. This property could be attributed to its typical aroma. In addition to harboring vitamin C, iron, and other nutrients, sweet potatoes are capable of warming up the body which help to cure bronchitis [26].

2.6 Cancer Prevention

Many scientific investigations have revealed that eating sweet potatoes have the potential to decrease the risk of breast, colorectal, gallbladder, and kidney cancer. In a 10-year study for evaluating the risk factors for kidney cancer death, 47,997 males and 66,520 females aged 40 years and older were included. Researchers concluded that eating sweet potatoes and potatoes regularly was associated with a decreased risk of kidney cancer [27]. The various health benefits of sweet potatoes are summarized in Fig. 2.

3 Bioactive Compounds from Sweet Potato

Sweet potatoes harbor an immense amount of bioactive compounds which contribute to the health benefits conferred by them. Earlier research studies have pointed out that bioactive compounds are different in orange-fleshed sweet potato and white-fleshed sweet potato. Phytochemical screening conducted by Shekar et al. [28] revealed high percentage of carbohydrate, reducing sugar, and phenolics in white-fleshed sweet potato and increased levels of total protein, flavonoids, anthocyanins, and carotenoids in orange-fleshed sweet potato. In orange-fleshed sweet potato, it was also observed that the rate of starch and cellulose degradation was lesser during storage, which pointed out to a strict regulation of gene(s) involved in starch

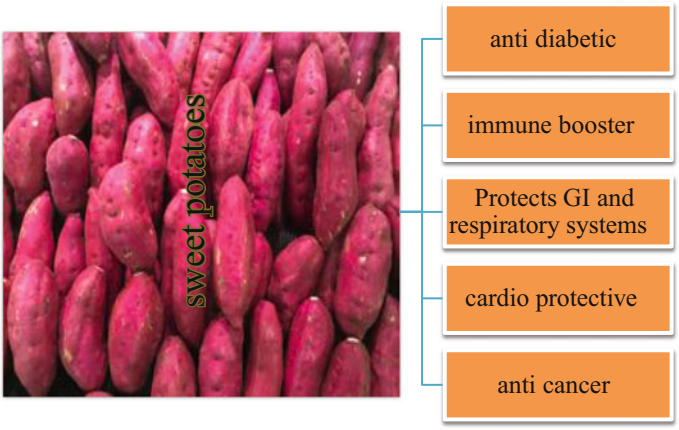

Fig. 2 Health Benefits of Sweet Potatoes

degradation. These researchers also conducted comparative proteomics which displayed a cultivar-dependent expression of proteins along with evolutionarily conserved proteins [28].

Phenolic compounds and carotenoids have been reported to be present in sweet potatoes. Phenolic compounds, such as phenolic acids and anthocyanins, are quite predominant in the purple-flesh variety. In orange fleshed varieties, α-carotene, β-carotene, and β-5 cryptoxanthin are predominant. Sweet potato is an abundant source of dietary fiber, minerals, vitamins, beta-carotene, phenolic acids, and anthocyanins. These bioactive compounds confer distinctive flesh colors to sweet potatoes such as cream, yellow, orange, and purple [29].

The tubers of sweet potato are rich in polyphenols such as anthocyanins and phenolic acids. They also possess vitamins A, B, and C [30]. Sucharitha et al. [30] reported that the root of *Ipomoea batatas* contains phytoconstituents like flavonoids, carbohydrates, and tannins.

Phytochemical components such as alkaloids, saponin, tannins, steroids, anthocyanins, flavonoids, and anthraquinones were extracted by Anbuselvi and Muthumani [14] using different solvents like ethyl acetate, methanol, chloroform, and acetone.

Park et al. [31] determined the phytochemical diversity, including carotenoids, flavonoids, anthocyanins, and phenolic acids, in sweet potatoes of varying flesh colors (white, orange, and purple). They also made an attempt to identify the hydrophilic primary metabolites from the different varieties. As a result of their study, they reported that in orange-fleshed varieties, carotenoid content was considerably higher among which β-carotene was the most plentiful. Only purple-fleshed sweet potatoes showed the presence of anthocyanins. The levels of phenolic acids and flavonoids were higher in purple-fleshed varieties as compared to the other two varieties [31].

Oluyori et al. [32] conducted phytochemical screening of the peels of sweet potatoes and reported the presence of tannins/phenolic compounds, terpenoids, reducing sugar, cardiac glycosides, alkaloids, and lipids.

Rosas-Ramírez and Pereda-Miranda [33] carried out the purification of the chloroform-soluble resin glycosides from the roots of yellow-skinned sweet potatoes. This was done using preparative-scale HPLC, and six oligosaccharides, batatin VII, and batatinosides VII–IX, with novel structures were collected, along with previously known resin glycosides pescaprein I and batatinoside IV. Each structure was characterized using high-field NMR spectroscopy and FAB mass spectrometry [33].

Studies carried out by Kang et al. [34] indicated that sweet potato extracts inhibited excessive production of pro-inflammatory mediators such as NO, iNOS, COX-2, and TNF-α and thereby attenuated neuroinflammatory responses in LPS-activated BV-2 microglia. The results suggested that the anti-neuroinflammatory potential of sweet potato extracts may be related to its strong antioxidant properties and its regulatory actions on pro-inflammatory cytokine such as TNF-α. These results suggest the sweet potato extracts might be developed as a promising candidate for the treatment of neuroinflammation-mediated neurological disorders [34].

3.1 Anthocyanins

It has been reported that the purple-fleshed sweet potato anthocyanins protects against acetaminophen induced hepatotoxicity in mice [35].

Cuevas Montilla et al. [36] compared different Japanese purple sweet potato cultivars and reported a remarkable variation of anthocyanin profile. Ten major pigments with non-, mono-, or diacylated structures of 3-*O*-(2-*O*- -D-glucopyranosyl- -D-glucopyranoside)-5-*O*- -D-glucosides of cyanidin and peonidin were characterized by ESI-MS^n and NMR analyses.

Aldi et al. [37] reported that purple sweet potato peel has high levels of anthocyanins, which are powerful antioxidants. They conducted a study aimed at determining immunostimulatory effect of purple sweet potato peel. They observed parameters like the activity and capacity of peritoneal macrophages, the total number of leukocytes, and the percentage of leukocytes and spleen weights relative. The results indicated that the ethanol extract of purple sweet potato peel posses immunostimulatory effect that increased the activity and capacity of peritoneal macrophage cells, the total number of leukocytes, and number of neutrophil segments [37].

3.2 Phenolics

Jung et al. [38] used chromatography to isolate different polyphenolic compounds possessing potent antioxidant activities, from methanolic and hydromethanolic extracts of sweet potato tuber flour. The isolated compounds

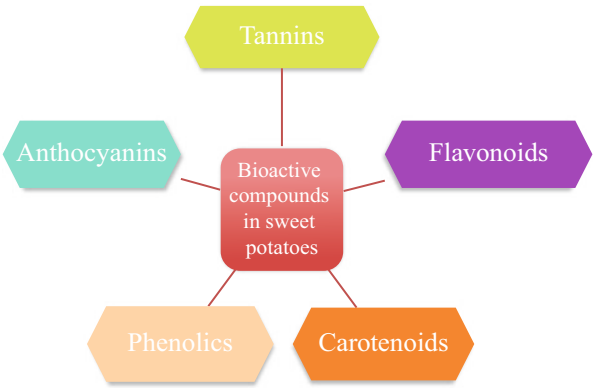

Fig. 3 Bioactive components of sweet potatoes

were 4-*O*- caffeoylquinic acid, 1,3-di-*O*-caffeoylquinic acid, and 3,5-di-*O*-caffeoylquinic acid [38].

Pochapski et al. [39] carried out phytochemical screening that showed positive results for triterpenes/steroids, alkaloids, anthraquinones, coumarins, flavonoids, saponins, tannins, and phenolic acids. Total contents of alkaloids, anthraquinones, and phenolic compounds in 100 g of the dry sample were reported to be 345.65, 328.44, and 662.02 mg, respectively [39].

Hesam et al. [40] reported that sweet potato contains endogenous amylases along with the high starch content. The two predominant amylases are α- and β-amylases. Since sweet potato is a promising source of β-amylase, they focused their investigation on the properties of β-amylase from white-flesh sweet potato grown in Iran as a potential source for industrial applications [40]. The various bioactive components of sweet potatoes are given in Fig. 3.

4-Ipomeanol a furanoterpenoid produced from infected sweet potatoes has been proven to possess anticancer properties. The following is a detailed description of this wonderful yet less known compound from sweet potatoes.

3.3 4-Ipomeanol

4-Ipomeanol is a stress metabolite produced in response to general damage to sweet potatoes [41]. Clark et al. observed that organisms like *Plenodomus destruens*, *Diaporthe batatatis*, *Diplodia tubericola*, *Fusarium solani*, and *Ceratocystis fimbriata* induced accumulation of relatively high concentration of 4-ipomeanol (5–236 μg/g) in sweet potato [42]. However, it has been recently reported that 4-ipomeanol can also be produced in vivo in the root tubers of *I. batatas* without specifically being infected [43, 44].

3.3.1 Physical and Chemical Properties

The various physical and chemical properties of 4-ipomeanol is given in Table 1 [42, 45]. The structure of 4-ipomeanol is shown in Fig. 4 [46].

Table 1 Various physical and chemical properties of 4-ipomeanol [42, 45]

S. No.	Properties	Data
1	Molecular formula	$C_9H_{12}O_3$
2	Molecular weight	168.18978 g/mol
3	H-bond donor	1
4	H-bond acceptor	3
5	Rotatable bond count	4
6	Topological polar surface area	50.4
7	Description	Colorless to yellowish color oil in state
8	Specific optical rotation	+7.86 deg at 25 deg C/D
9	Flash point	>150 °C
10	Maximum absorption	211 nm
11	Rf value	0.65 [methanol/benzene (1:10)]
12	GC-MS NIST number	131689

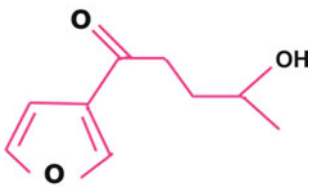

Fig. 4 Structure of 4-ipomeanol [46]

3.3.2 In Vitro Production

A procedure for isolation of 4-ipomeanol from infected sweet potatoes was described by Boyd and coworkers [47]. 4-Ipomeanol was also synthesized chemically from diethyl 3,4-furandicarboxylate in a five-step process [48]. Krauss et al. [49, 50] used another approach for the chemical synthesis of 4-ipomeanol in four steps starting from commercially available furan-3-carbaldehyde. They also synthesized analogues of 4-ipomeanol from furan-3-carbaldehyde and furan-2-carbaldehyde [49, 50]. A protocol for in vitro bioproduction of 4-ipomeanol from the rhizogenic callus of *I. batatas* was reported for the first time by Remya and Subha [43, 44].

3.3.3 Covalent Binding Property

The cytochrome P450 system present in animal bronchial Clara cells activates 4-ipomeanol. Localized cytotoxicity is elicited by the resulting metabolites by their binding to specific macromolecules [51]. Possibility of an influence by differences in species and strain in the covalent binding of 4-ipomeanol was studied by Dutcher and Boyd [52]. Investigation of three strains of rat, Hartley guinea pigs, albino New Zealand rabbits, golden Syrian hamsters, and six strains of mouse divulged that lungs were the main target for 4-ipomeanol covalent binding and toxicity. In addition to pulmonary damage, liver and kidney necrosis was reported in the hamster and the mouse strains. Principal site of damage was found to be the

lung in rats, guinea pig, and rabbits. In all the six mouse strains studied, covalent binding of 4-ipomeanol was approximately twice as high in kidney as in lung; there was some lung damage and remarkable renal toxicity [52]. Though birds (Japanese quail, chickens), devoid of Clara cells in their respiratory tracts, do not exhibit pulmonary toxicity after 4-ipomeanol, they develop severe hepatic injury [53].

Following [14C] 4-ipomeanol administration to rats, Boyd et al. demonstrated that radioactivity was concentrated in the lungs, and 90% was covalently bound [54]. Outcome of another study by Boyd showed that electron-dense granules which later became necrotic were found specifically localized over Clara cells following the administration of [14C] 4-ipomeanol to rats, mice, and hamsters. On the contrary, it was observed that the adjacent ciliated bronchiolar cells and other major pulmonary parenchymal cells were neither radiolabeled nor necrotic. When animals were pretreated with piperonyl butoxide, an inhibitor of cytochrome P450, there was a considerable reduction in covalently bound radioactivity, and there was no necrosis in the Clara cells [55]. Covalently bound 4-ipomeanol was most heavily concentrated over the apical cap of Clara cells where the cytochrome P450 enzymes are concentrated [56, 57]. Studies implied that formation of a reactive metabolite was essential for covalent binding and that it was localized in lung proteins. It was also observed that pretreatment with diethylmaleate helped increase covalent binding of the reactive metabolite of 4-ipomeanol in both the lung and liver and reduced the LD50 value. The "vital macromolecules" to which the reactive metabolite of 4-ipomeanol is covalently bound are tissue proteins and not nucleic acids. This was revealed by studies that showed that hot trichloroacetic acid or perchloric acid dislodged nucleic acids and the insoluble material left behind was mainly protein [56, 58, 59].

3.3.4 Therapeutic Potential

4-Ipomeanol has been proven to have exhibited both in vitro and in vivo antitumor activity against non-small cell lung cancer (NSCLC), and therefore was suggested as an antitumor agent specific to lung cancer [60, 61]. The clinical development of 4-ipomeanol as a lung cancer-specific agent was based on its organ-specific toxicity in preclinical studies in mammals [62]. In animals like rabbits, rats, guinea pigs, female mice, and dogs, preferential activation of 4-ipomeanol occurs in the lung Clara cells. To a lesser extent the compound is also activated by type II pneumocytes abundant in cytochrome P450 isoenzymes [55]. It could be observed that toxicity is predominantly pulmonary, due to the binding of active intermediate to nucleophilic macromolecules, leading to bronchiolar epithelial necrosis preferentially involving Clara cells [53, 55, 63]. In preclinical toxicity studies, 4-ipomeanol has produced dose-dependent pulmonary toxicity [63]. The primary sites of 4-ipomeanol binding in mammals are lungs and proximal renal cortical tubules [51, 64]. In male rats administered with radiolabeled 4-ipomeanol, radioactivity was highest in lung tissue followed successively by intestines, liver, and kidney [54].

Rowinsky et al. [65] observed cytotoxic effects in the human lung, liver, and kidney, presumably because all these organs contain the isoforms of cytochrome P450 that could metabolically activate 4-ipomeanol. These results suggested that

clinical evaluation of 4-ipomeanol in humans should be extended to include liver cancers, and renal cancers, in addition to lung cancers [65]. Phase I study on 4-ipomeanol in patients with non-small cell lung cancer (NSCLC) was performed by Kasturi et al. [66].

It was noticed that 4-ipomeanol may be preferentially activated in the human liver rather than the lung, and these results formed the basis for evaluating the clinical activity and for evaluating the toxicity of 4-ipomeanol in patients with advanced hepatocellular carcinoma [67].

Studies on the human CYP4B1 isozyme revealed that its metabolic activity toward 4-ipomeanol is <1% of the rate of rabbit CYP4B1 [68]. Expression of rabbit CYP4B1 in rat and human glioma cell lines made these cells highly susceptible to 4-ipomeanol [69]. Mohr et al. demonstrated that the CYP4B1/4-ipomeanol prodrug-activating system is effective in inducing cell death of hepatocellular carcinoma cells at low 4-ipomeanol concentrations. It was proposed that this system might be useful for augmentation of standard chemotherapy or gene therapy [70].

Constanze et al. demonstrated that a proline residue at position 427 in human CYP4B1 is important for 4-ipomeanol bioactivation. They developed a novel human suicide gene system that could be used for adoptive cellular therapies by modifying the human CYP4B1 enzyme for efficient activation of 4-ipomeanol [71].

Cytotoxicity induction by 4-ipomeanol (4-IM) in combination with ionizing radiation in cells transfected with a fusion protein of rabbit cytochrome CYP4B1 under influence of EGR1 (radiation inducible promoter) was investigated by Hsu et al. [72]. The results indicated that EGR1-CYP4B1/4-IM system is a feasible radiation-gene therapy system that may allow effective control of cytotoxicity by therapeutic radiation fields.

Cytotoxic properties of cytochrome P450 4B1 (CYP4B1)-activated 4-ipomeanol for prodrug-activated gene therapy was reported by Jang et al. [73].

Roellecke et al. recently conducted a study that was aimed at developing a clinically relevant self-inactivating lentiviral vector for systematic co-expression of CYP4B1 as an ER-located protein. The study lead to the development of a novel human suicide gene systems that is based on human CYP4B1 and 4-ipomeanol. 4-Ipomeanol was found to induce apoptosis in primary T cells co-expressing mutant CYP4B1 and the divergently located MACS selection and chimeric antigen receptor genes [74].

Recent studies on 4-ipomeanol have revealed its potential to be used as an imaging agent as well for gene prodrug activation therapy. (18)F-Labeled 4-ipomeanol could be used to image tumors and monitor enzyme-activating anticancer prodrugs [75].

4 Conclusion

Sweet potatoes are rich source of nutrients and bioactive components. They have been proven to exhibit anticancer, antidiabetic, cardioprotective, antimicrobial, immune boosting, and hepatoprotective properties. Among the various secondary

metabolites from sweet potatoes, 4-ipomeanol holds promise as a potential anticancer agent and offers prospects for further research. Further research in the direction of utilizing 4-ipomeanol to its maximum potential in the treatment of different types of cancers through effective bioactivation, enhancement of metabolic stability, structure modification, inclusion of biomarkers, evaluation of its utility in imaging of specific types of tumors, and other techniques is essential.

Anticancer Properties of Lycopene

33

Kazim Sahin, Cemal Orhan, Nurhan Sahin, and Omer Kucuk

Contents

Abstract

Lycopene is an acyclic isomer of beta-carotene, found in red-colored fruits and vegetables, including tomatoes, and their processed products, watermelon, papaya, guava, carrots, red grapefruit, and sweet potatoes. It is synthesized by plants or autotrophic bacteria but not by animals. This work provides an up-to-date

overview of mechanisms linking lycopene in the human diet and cancer, considering epidemiological, clinical studies, and experimental data. Dietary lycopene supplementation may reduce the risk of cancers of many organs such as prostate and at the same time retard the growth of tumors. The main protection properties of lycopene against cancer include antioxidant, anti-inflammatory, anti-inhibitory of cancer cell proliferation, anti-apoptotic, increased gap-junctional communication, interferences in insulin-like growth factor 1 receptor signaling pathways, and cell cycle progression and, the ability to improve the metabolic profile. In this context, lycopene has been shown to exert a protective effect in humans or animals with cancers including prostate, breast, gastric, colon, pancreatic, renal, and several other cancers in many studies, although the obtained results are sometimes inconsistent, which warrants further studies focusing on its bioactivity. In this chapter, lycopene supplementation in cancer prevention is reviewed and possible mechanisms of action are discussed in detail.

ROS	Reduction oxidative stress
SOD	Superoxide dismutase
TNF-α	Tumor necrosis factor-alpha

1 Introduction

There is a relationship between diet-related factors, especially nutritional factors in foods and the risk of cancer [1–3]. Consumption of many bioactive substances naturally found in foods, especially antioxidant compounds such as lycopene, is related to a lower risk of cancer [4]. Lycopene, a natural pigment synthesized by plants and microorganisms, is mostly found in tomato products, watermelon, papaya, guava, and pink grapefruit [5]. Lycopene prevents the growth of tumors and inhibits tumorigenesis through a variety of mechanisms, such as cell cycle arrest and/or apoptosis stimulation, modulation of growth factor signaling, modulation of redox status, alterations in cell growth-related enzymes, improvement of gap junctional communication, and inhibition of inflammation [5]. Moreover, in studying the relation of lycopene to cancer prevention, we have found that lycopene improved the nuclear factor erythroid 2-related factor 2 (Nrf2)/heme oxygenase-1 expression and reduced NF-κB/cyclooxygenase-2, preventing the inflammatory cascade and stimulating antioxidant signaling. Lycopene treatment also reduced carcinogenesis associated rises in the phosphorylated mammalian target of rapamycin (p-mTOR), phosphorylated p70 ribosomal protein S6 kinase 1 (S6 K1), phosphorylated 4E-binding protein 1 (p-4E-BP1), and protein kinase B [6]. In this chapter, we review the latest data from in vitro, animal, and human studies to evaluate the protective effects of lycopene in cancer prevention and its mechanisms of action.

Table 1 Dietary source of lycopene [7–9]

Source	μg/g wet weight
Raw tomato	8.8–42
Tomato juice	86–100
Tomato sauce	63–131
Tomato ketchup	124
Pink grapefruit	3.6–34
Pink guava	54
Watermelon	23–72
Papaya	20–53
Rosehip puree	7.8
Apricot	<0.1

2 Lycopene

Lycopene, found in tomatoes, red fruits, and vegetables, including carrots, watermelons, apricot, papayas, guava, and strawberries, and discovered in 1999 by Nguyen and Schwartz, is a tetra-terpene from the carotenoid family [7]. Processed tomato products such as tomato sauce, tomato paste, and ketchup are more concentrated lycopene sources than unprocessed tomatoes. The lycopene-rich sources are shown in Table 1 [7–9].

Lycopene's chemical name is 2,6,10,14,19,23,27,31-octamethyl 2,6,8,10,12,14,16,18,20,22,24,26,30-dotriacontatridecaene. Its formula and molecular weight are C40H56 and 536.85 [8, 9]. Physicochemical properties of lycopene are shown in Table 2. Its structural formula is shown in Fig. 1.

The lycopene consists of eight isoprene units comprising 40 carbon and 56 hydrogen atoms [10]. Lycopene is an unsaturated hydrocarbon with 11 conjugates and 2 unconjugated double bonds, which are highly reactive with oxygen and free radicals [11, 12]. Lycopene in natural plants presents mainly in trans configuration. Conversely, induced via chemical reactions, light, and thermal energy, it can also form cis-trans isomers including 15-, 13-, 11-, 9-, 7-, 5-cis isomers [13]. A study presented that the 5-cis isomer of lycopene is the greatest stable one followed by the all-trans, 9-cis, 13-cis, 15-cis, 7-cis, and 11-cis isomers [14]. Heat processes applied to tomato and tomato products increase isomerization to lycopene cis form and increase bioavailability [13–15].

3 Molecular Targets/Mechanisms of Action of Lycopene in Cancer Prevention

Various studies have shown that lycopene has a protective influence against oxidative stress, an important factor in cancer formation [9]. This may be because lycopene is the most effective singlet oxygen quencher among carotenoids

Table 2 Physicochemical properties of lycopene [9].

Molecule	Lycopene
Structure	IUPAC name	(6E,8E,10Z,12Z,14E,16E,18E,20Z,22Z,24E,26E)-2,6,10,14,19,23,27,31-Octamethyldotriaconta-2,6,8,10,12,14,16,18,20,22,24,26,30-tridecaene
Formula	$C_{40}H_{56}$
Molecular weight (g/mol)	536.87264
Solubility	Ethanol and methanol, soluble in chloroform, hexane, benzene, carbon disulfide, acetone, petroleum ether and oil, insoluble in water
Melting point (°C)	172–175
Stability	Sensitive to high temperature, acids, catalyst, light, oxygen, metal ions. Store at −70 °C. Combustible. Incompatible with strong oxidizing agents

[16]. Moreover, it was reported that lycopene is an antioxidant 10 times more potent than alpha-tocopherol and twice as potent as beta-carotene [17]. Consumption of tomato or tomato products reduces oxidative DNA damage [18], oxidative stress sensitivity in lymphocytes [19], and lipid peroxidation [20]. Lycopene intake also increases the production of superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GSHPx) enzymes [21, 22]. In an animal model, animals reared under the stress conditions had lower lycopene concentration in sera and tissue samples, SOD, CAT, and higher MDA levels than unstressed birds. Variations were observed in serum and tissue lycopene and MDA concentrations and antioxidant enzymes as dietary lycopene level increased [21]. Lycopene may also scavenge peroxynitrite, resulting in oxidized lycopene products [23].

Lycopene also induces phase II detoxification enzymes to protect cells from ROS [24, 25]. It activates the transcription system of the antioxidant response elements/electrophile response elements (ARE) transcription system by disturbing cytosolic connections between the main ARE-activating Nrf2 and the inhibitor Keap1 [24]. In another study, increased lycopene in the diet inhibited Keap1 expression in muscle and improved Nrf2 expression, which was augmented by 150% and reduced by 40%, in response to stress [21].

Besides antioxidant effects, other important mechanisms that explain the anticarcinogenic effect of lycopene are: (i) upregulation of gap-junctional gene connexin 43 (Cx43), (ii) the inhibition of cancer cell proliferation and stimulation of differentiation by regulating the expression of cell cycle regulatory proteins, (iii) regulation of the IGF-1/IGFBP-3, (iv) inhibition of 5-lipoxygenase (5-LOX), (v) regulation

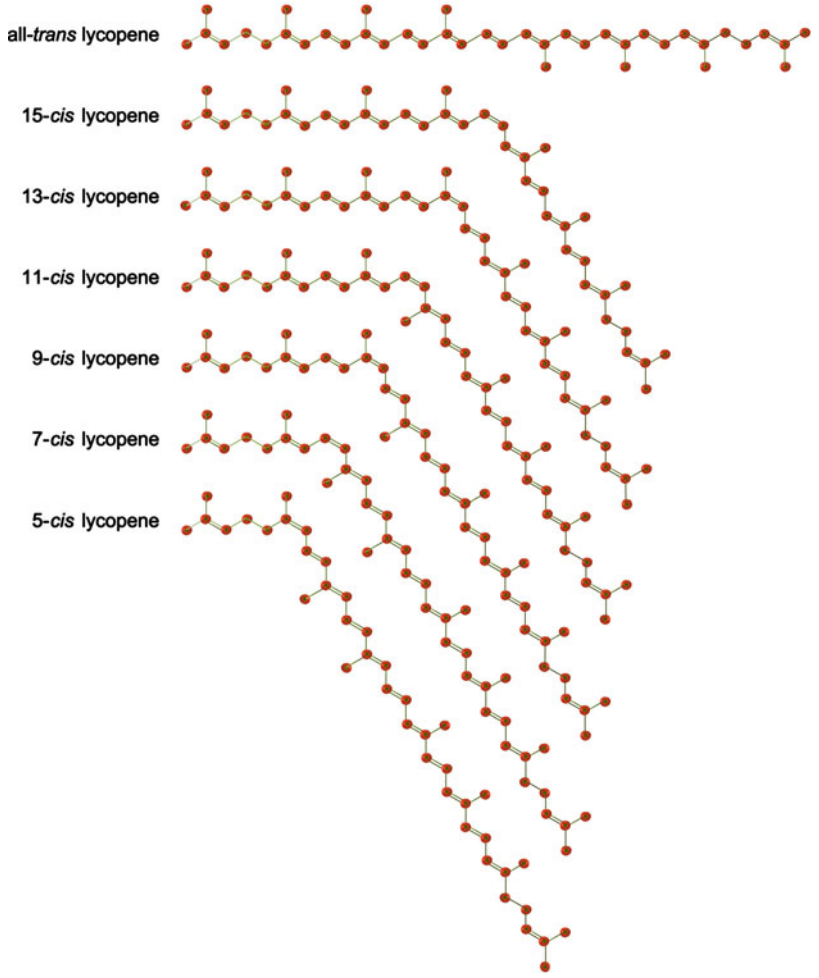

Fig. 1 Structure formula of lycopene

of carcinogenic metabolizing enzymes, (vi) modulation of immunity, (vii) regulation of carcinogen-metabolizing enzymes, and (viii) decrease of oxidative stress by reducing ROS-producing enzymes (Figs. 2 and 3).

Improved Cx43 expression and rises in gap-junctional intercellular communication (GJC) have been observed to arise after human cells were treated in culture with various carotenoids including lycopene [26]. This effect is intensely associated with the capacity of these carotenoids to suppress neoplastic transformation in model cell culture [26, 27], which is an effect shared by retinoid [28]. Diminished expression of connexins, considered as tumor suppressor genes, has been demonstrated in human tumors compared to normal tissue [29–31]. Stahl et al. [32] reported that lycopene

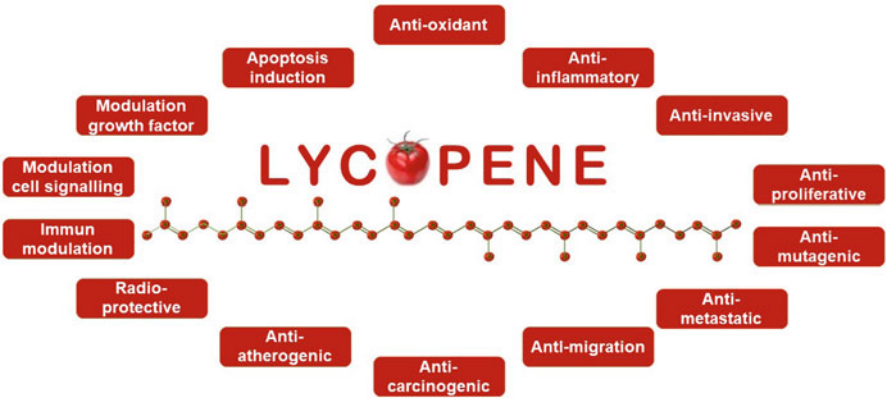

Fig. 2 Mechanism of lycopene in the prevention of chronic diseases

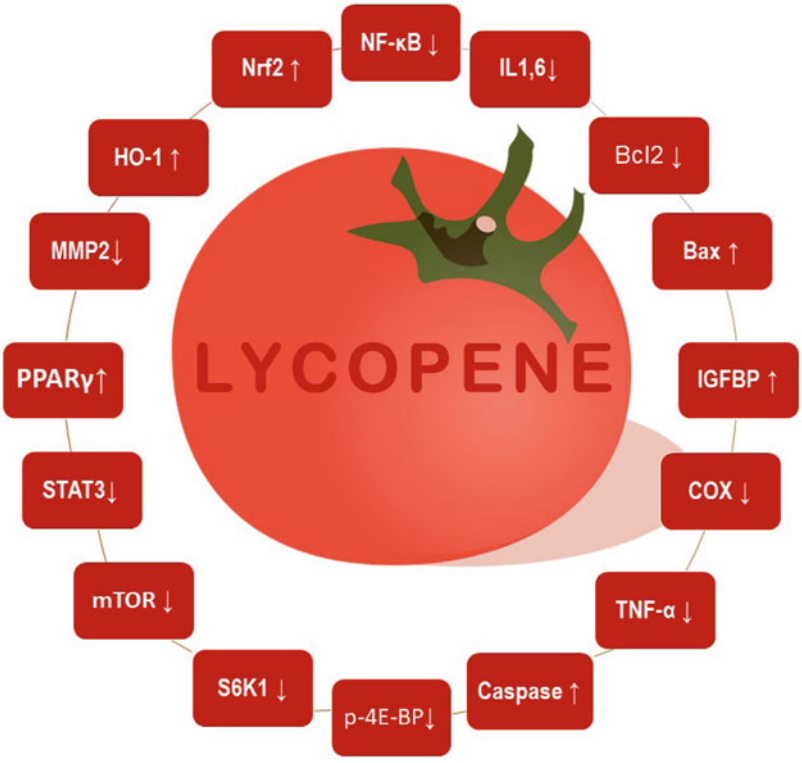

Fig. 3 Molecular targets of lycopene

improved GJC fetal skin fibroblasts after 1 and 3 days of treatment. In addition, Cx-43 expression was basically upregulated by lycopene administration in KB-1 human oral tumor cells, and to a much-reduced extent with β-carotene, thus preventing proliferation and increasing GJC [33, 34]. On the other hand, lycopene acts at multiple points to inhibit VEGF-mediated angiogenesis and suppresses Akt activation by preventing phosphorylation of the molecule [35]. Lycopene also inhibits the NF-κB pathway by inhibiting nuclear translocation and NF-κB DNA binding [36]. Lycopene also acts to inhibit invasion and metastasis via reducing plasma levels and activity of MMP-2 and -9 [37].

Lycopene treatment inhibits tumor formation by affecting various cellular processes such as cell cycle progression and signal transduction pathways [38]. Nahum et al. [39] reported that reduction of cyclin D1 expression by lycopene supplementation and consequent inhibition of cell cycle progression in the G0/G1 phase are significant mechanisms for the decrease of mitogenic effect of IGF-1. Lycopene supplementation significantly reduced serum IGF-1 levels in humans with colon cancer [40]. One study reported that accumulation of lycopene and vitamin E in the tumor and macroscopic estimation of tumors by magnetic resonance imaging presented a significant increase in necrotic area with lycopene plus vitamin E in a prostate cancer model [41].

Lycopene acts via its anti-inflammatory effects to prevent cancer. For example, lycopene inhibits the mRNA and protein expression of the proinflammatory cytokine IL-8 through the NF-κB inactivation. Moreover, lycopene administration was revealed to result in reduced p38MAPK ERK1/2 and JNK phosphorylation and increased PPARγ expression, resulting in improved PTEN activity and the inactivation of AKT [42]. Lycopene treatment has been shown to induce NF-κB inactivation by inhibiting the phosphorylation of IKKα and IKBα. It was also reported that lycopene inhibits TNFα, COX-2, iNOS, and IL-6 secretion [37, 43] (Fig. 3).

Lycopene treatment may suppress levels of nonphosphorylated β-catenin protein and Akt activation, and increase the phosphorylation of β-catenin, which were linked with decreased cyclin D1 expression [35]. Therefore, lycopene treatment inhibits Wnt/β-catenin pathways through the linking along the Akt/GSK3β/β-catenin [44]. The 5-LOX signaling pathway is another potential pathway for lycopene anticancer activity. In one study, it was estimated that the acyclic tomato carotene lycopene and its natural dihydroxy analog lycophyll is bound by the high affinity in the superficial cleft at the interface of the beta-barrel and the catalytic domain of 5-LOX [45].

4 Lycopene in Cancer Prevention

4.1 Breast Cancer

In the etiology of breast cancer, which is most common in women, environmental factors, nutrition, and exercise play an important role. Studies have reported that carotenoids including lycopene reduce the risk of breast cancer perhaps due to their

capability to scavenge DNA damaging free radicals, inhibit cell proliferation, induce apoptosis, and suppress angiogenesis [46, 47]. For example, in an *in vitro* study, treatment with a lycopene-rich extract from red guava (LEG) influenced the viability of human breast cancer cells (MCF-7) but not murine fibroblast cells (NIH-3T3). Additionally, LEG showed low cytotoxicity against BALB/c peritoneal macrophages and no hemolytic activity. LEG triggered a decrease in the cell proliferation and induced cell cycle arrest, DNA fragmentation, alterations in the mitochondrial membrane potential, and morphologic variations linked to granularity and size in MCF-7 cells; nevertheless, it failed to cause any noteworthy damage to the cell membrane or display necrosis or apoptosis [48]. In another cell study, mammary tumor cell lines were cycle-arrested at G1/S phase after treatment with 10 μm lycopene for 48 h by increasing breast cancer-1 (BRCA1) and breast cancer-2 (BRCA2) expression in estrogen-receptor (ER) positive cell lines (MCF-7 and HBL-100) and decreasing them in ER-negative cell lines (MDA-MB-231) [49]. In addition, expression of bcl-2 was reduced by 88% and cell cycle progress was blocked at G(2)/M phase after treatment with lycopene in MCF-7 cell line [50]. Peng et al. [51] also reported that lycopene caused MCF-7 cell contractility and breakage, suggesting that its aggressiveness has decreased in a dose- and time-dependent manner. Additionally, lycopene treatment caused a reduction in cell proliferation and a rise in apoptosis, and it could also upregulate p53 and Bax expression in the cells. Furthermore, lycopene could also increase the expression of p53 and Bax mRNAs in MCF-7 cells [51]. Nahum et al. [52] reported that lycopene treatment inhibits cell cycle progression by inhibiting the level of cyclin D and retention of p27 in cyclin E-cdk2, and inhibiting CDK activities. Assar et al. [36] found that lycopene inhibits breast cancer cell growth at physiologically applicable concentrations of 1.25 μM. This also resulted in a 30–40% decrease in the inhibitor of IκB phosphorylation in cells. In addition, inhibition was detected at the same rate as lycopene for NF-κB activity [36].

In animal studies, it was shown that lycopene inhibits the occurrence and growth of the chemically induced breast cancer [53–55]. In a study, our research group has presented data showing inhibition of mammary cancer incidence, tumor weight and tumor volume by lycopene (70, 48 and 18%), genistein (60, 61, and 35%) and their combination (40, 67 and 65%) were observed in rats, respectively [54]. Combination of lycopene and genistein treatment was more effective in preventing DMBA-induced mammary tumors and regulating the apoptosis-associated protein expression than the treatment by each agent alone [54].

Numerous case-control trials have found associations between the lycopene and mammary cancer in humans. Nevertheless, the results remain inconsistent. Eliassen et al. [56] reported that significant preventive effects with breast cancer were detected for α-carotene, β-carotene, lutein+zeaxanthin, lycopene, and total carotenoids. When the data obtained from case control studies, lycopene decreased breast cancer by 29.0% [46, 57]. A case-control study with 508 breast cancer cases and 508 controls nested in the same cohort was performed and their plasma lycopene levels were not changed. In another nested case control study, 1452 breast cancer cases and 5239 women showed age-adjusted relative risks for breast cancer

increased by lycopene intake 1.0, 1.15, 0.93, 0.97, and 1.01 [58]. In a study comparing lycopene levels in mammary adipose tissue, lycopene was found to be inversely associated with breast cancer risk when adjusted for age, smoking status, and menopausal status [59, 60].

4.2 Lung Cancer

Lung cancer, one of the most common cancers in the world, will be the main cause of cancer deaths in 2020. Studies show that lung cancer patients have lower retinol, α-tocopherol, β-carotene, lycopene, β-cryptoxanthin, selenium, and zinc concentrations [61]. Epidemiological studies have shown that the lung cancer incidence is inversely correlated with fruit and vegetable intake [62, 63]. Tomato and tomato products have also been associated with a lower risk of lung cancer (Table 3) [14]. Lycopene, a bioactive compound of tomato, has been postulated to prevent lung tumorigenesis by cell cycle arrest and/or apoptosis induction, modulation of growth factor signaling, modulation of redox status, cellular changes, alterations in cell growth-related enzymes, and increase in GJC [64].

In an in vitro study, apo-10′-lycopenoic acid has been reported to inhibit the normal human bronchial epithelial cells (NHBE), immortalized normal bronchial epithelial cells (BEAS-2B), and nonsmall cell lung cancer cells (A549) by reducing cyclin E levels, inhibiting cell cycle progression from G (1) to the S phase, and improving cell cycle regulators p21 and p27 proteins [65]. In the same study, pulmonary tumor growth was reduced from a mean of 16 tumors per mouse to an average of 10, 7, and 5 tumors, in a dose-dependent manner, in groups supplemented with apo-10′-lycopenoic acid at 0, 40 and 120 mg /kg [65]. In addition, apo-10′-lycopenoic acid treatment results in nuclear transcription factor Nrf2 accumulation in BEAS-2B human bronchial epithelial cells [66]. In these cells, Nrf2 activation involves the induction of phase II detoxifying/antioxidant enzymes including HO-1, NAD(P)H: quinone oxidoreductase1, glutathione S-transferases, and glutamate-cysteine ligases.

Clinical trials have shown that high intake of lycopene reduces lung cancer risk by approximately 20–30% [67, 68]. In a study in which human plasma and isolated LDL and lycopene solutions were treated with cigarette smoke, depletion of all (E)-lycopenin was higher in plasma than 5 (Z)-lycopenin or beta-carotene. However, LDL was found to be more sensitive to both all (E)- and 5 (Z)-lycopenin than to beta-carotene [69]. Shareck et al. [70] reported that the ORs linked with upper versus lower tertiles of intake were 0.66 for β-carotene, 0.70 for α-carotene, 0.65 for β-cryptoxantin, 0.75 for lycopene, and 0.74 for C vitamins. In a study conducted in Spanish women (130 cases, 206 control), high lycopene consumption was found to be inversely correlated with lung cancer when smoking status, E and C vitamins, and total flavonoid consumption and other carotenoids were adjusted [71]. In another case-control study, a significant inverse relationship between serum lycopene levels and lung cancer mortality after adjusting for cigarettes and serum levels of other

Table 3 Summary of the effect of lycopene in different types of cancer

Cancer	In vitro/in vivo studies	Lycopene formulation	Mechanistical effects	References
Breast cancer	Human breast carcinoma cell line MCF-7	Synthetic 0, 2, 4, 8, and 16 mM 200 mL culture medium	Reduced cell proliferation and increased apoptosis,upregulated the expression of p53 and Bax mRNAs in MCF-7 cells	Peng et al. [51]
Breast cancer	Female Wistar rats	Synthetic 20 mg/kg	Inhibited of tumor growth and expression of apoptosis associated proteins	Sahin et al. [54]
Breast cancer	female Wistar rats	Synthetic 15 mg/kg BW	Decreased tumor proliferation and increased survival rate of treated animals	Jain et al. [184]
Breast cancer	MCF-7 breast cancer cells	0, 2, 4, 6, 8, and 10 μM of lycopene	Modulated cell cycle proteins such as beta tubulin, CK8/18, CK19, and heat-shock proteins in MCF-7 breast cancer cells	Uppala et al. [185]
Breast cancer	Female rats	Synthetic 50 mg/kg of diet	MDA↓, NO↓, SOD↑, CAT↑, GPx↑	Al-Malki et al. [186]
Lung cancer	Mouse model	10, 40, and 120 mg/kg diet of apo-10′-lycopenoic acid	Inhibited the growth of normal human bronchial epithelial (NHBE) cells	Lian et al. [65]
Lung cancer	BEAS-2B human bronchial epithelial cells	10 mM, Apo-10′-lycopenoic acid, apo-10′-lycopenol and apo-10′-lycopenal	Induced both the nuclear accumulation of Nrf2 protein and the induction of phase II detoxifying/antioxidant enzymes,	Lian and Wang [66]
Colon cancer	Human colon cancerHT-29 cells	Synthetic 0, 0.1, 0.5, 1, and 2 μM	Inhibited the phosphorylation of Akt, glycogen synthase kinase-3β (GSK-3β), and ERK 1/2 proteins in human colon cancer HT-29 cells	Lin et al. [44]
Gastric cancer	Male Wistar rats	Synthetic 50, 100, and 150 mg/kg BW	Increased blood IL-2, IL-4, IL-10, TNF-α levels and reduced IL-6 level and enhance blood IgA, IgG, and IgM levels in gastric cancer rats Decreased MDA and increased blood and gastric antioxidant parameters (SOD, CAT and GSH-Px)	Luo et al. [86]

(*continued*)

Table 3 (continued)

Cancer	In vitro/in vivo studies	Lycopene formulation	Mechanistical effects	References
Liver (hepato carcinoma)	SK-Hep-1 cell line	Synthetic 10 μM	Decreased the activities and protein expression of MMP-2 and -9; increased the protein expression of nm23-H1 and the tissue inhibitor of MMP (TIMP)-1 and -2; suppressed protein expression of Rho small GTPases; inhibited focal adhesion kinase-mediated signaling pathway, such as ERK/p38 and PI3K-Akt axis	Yang et al. [187]
Pancreas	Rat pancreatic acinar AR42J cells	Synthetic 2, 10, 20,100 nmol/L	Inhibited the decrease in Ku70 in whole-cell extracts and nuclear extracts, induced by G/GO in AR42J cells	Seo et al. [188]
Renal cancer	Male Sprague-Dawley rats	Synthetic 10 mg/kg	Improved against renal damage caused by Mtx, presumably via antioxidant and anti-inflammatory activities	Oguz et al. [189]
Prostate cancer	Human	Natural (derived from tomato, red watermelon, pink grapefruit, papaya, guava, rose hip canned)	Decreased the risk of prostate cancer	Giovannucci et al. [190]
Prostate cancer	Human	Synthetic 15 mg (twice daily)	Reduced IGF-1 level; increased IGFBP-3 level; decreased tumor growth	Kucuk et al. [161]
Prostate cancer	TRAMP:Bco2 mice	Tomato powder,384 and 462 mg lycopene·kg diet	Lowered incidence of prostate cancer	Tan et al. [191]
Prostate cancer	Human study	Natural, 30 mg of lycopene daily	Lowered PSA level in patients with nonmetastatic prostate cancer	Paur et al. [163]
Prostate ccancer	LNCaP cells	Synthetic 2.5–10 μM	Involved the activation of the PPARγ-LXRα-ABCA1 pathway, leading to reduced cellular total cholesterol levels	Yang et al. [192]
Prostate cancer	LNCaP cancer cells	Synthetic 10 μM	Inhibited DU145 cell proliferation via PPARγ-LXRα-ABCA1 pathway	Yang et al. [151]

Prostate cancer	DU145 prostate cancer cells	Lycopene and apo-12′-lycopenal	Unaltered the levels of the gap junction protein, connexin 43, decreased cell apoptosis rates	Ford et al. [156]
Ovarian cancer	NOD/SCID mice	2.0 ve 5.0 μM lycopene	Decreased the expression of the ovarian cancer biomarker, CA125	Holzapfel et al. [177]
Ovarian cancer	Laying hens	200 or 400 mg of lycopene	Reduced the expression of NF-κB while increasing the expression of nuclear factor erythroid 2 and its major target protein, heme oxygenase 1	Sahin et al. [176]
Photocarcinogenesis (exposed to UV-A radiation)	Human dermal fibroblasts GT-F	Synthetic, 0.5–1.0 μM	Suppressed the increase of collagenase metalloproteinase 1 (MMP-1) mRNA expression	Offord et al. [193]
Skin cancer	Human foreskin fibroblasts and metastatic melanoma	Synthetic, 10 μM	Inhibited PDGF-BB induced fibroblasts migration, attenuated PDGF-BB induced phosphorylation, and reduced PDGF-BB induced signaling.	Chiang et al. [194]
Skin cancer	Albino rats	Lycopene extract from tomatoes vehiculated in nanoemulsions	As lycopene is involved in the synthesis of prostaglandins and phospholipids components of cell membrane	Butnariu and Giuchici [195]
Skin cancer	NMRImice (ears)	(~ 0.05%) lycopene extract	Reduced inflammatory infiltrate in higher extension, which supports the beneficial potential of lycopene.	Ascenso et al [196]
Skin cancer	ICR mice	Synthetic 10–40 mg/kg BW	Reduced the tumor incidence and volume, inhibited the formation of ROS and MDA, protected against the loss of GSH, affected the activities of several oxidant enzymes in skin, translocated higher levels of NF-E2-related factor 2	Shen et al. [134]

(*continued*)

Table 3 (continued)

Cancer	In vitro/in vivo studies	Lycopene formulation	Mechanistical effects	References
Skin cancer	SENCAR mice	Synthetic	Decreased the epidermal thickness, reduced the number of mice with mutation in 61 codon of Ha-ras (anti-initiation effect)	Kowalczyk et al. [197]
Skin cancer	SKH-1 hairless and immunocompetent mice	Red tomato powder	Lowered tumor numbers, metabolomic analyses elucidated compounds derived from tomato glycoalkaloids (including tomatidine and hydroxylated-tomatidine) as significantly different metabolites in skin after tomato exposure	Cooperstone et al. [133]
Skin cancer	SKH-1 hairless mice	Synthetic	Attenuated UVB-induced cell hyper-proliferation and promoted apoptosis, accompanied by decreased cyclin-dependent kinase 2 (CDK2) and CDK4 complex in both human keratinocytes	Chen et al. [132]

carotenoids were observed [72]. On the other hand, there was no significant relationship between lycopene and lung cancer in VITAL study [73].

4.3 Gastric Cancer

Gastric cancer, the fourth most common cancer in the world, is the second leading cause of cancer death. Regular and high intake of fruits and vegetables, and the bioactive substances contained therein such as lycopene, can decrease the gastric cancer risk [74]. These bioactive compounds including lycopene have been observed to increase in the serum and tissues of those who consume them, and high serum levels of lycopene and other carotenoids decrease risk of gastric cancer [75]. In another study, it was reported that lycopene inhibits gastric tumorigenesis by upregulating GSH-dependent hepatic detoxification systems including GSH, GPx, GST, and GR [76]. The combined use of S-allylcysteine, found in garlic, and lycopene decreased gastric cancer via induction of apoptosis by regulating Bcl-2, Bax, and caspases [77]. In an *in vitro* study, lycopene exhibited antiproliferative action in HGC-27 cell lines by enhancing LC3-I, p-ERK expression. In addition, lycopene treatment significantly decreased tumor weight in gastric cancer nude mice model [78]. In clinical trials, lycopene supplementation did not affect the risk of gastric cardiac cancer but reduced the risk of gastric noncardiac cancer by $<33\%$ [79]. In a cohort study, the overall relative risk of gastric cancer for fruits and vegetables were 0.82 and 0.88 [80]. In another case-control study, it was reported that consumption of tomato and tomato products had strong preventive effects on stomach cancer development and its incidence [81]. Moreover, serum lycopene concentrations were lower in patients with *H. pylori* [82]. In a case-control study with 723 gastric cancer patients and 2.879 matched controls in Italy, a significant trend was observed in the reduction of cancer risk due to raw tomato consumption after adjusting for age, gender, education, calorie consumption, alcohol intake, and smoking [83]. In a study involving 191 cases and 570 age-matched controls, the odds ratio for gastric cancer in the highest versus lowest quartile of prediagnostic lycopene was found to be 0.55 [84]. However, Zhou et al. [85] reported that only β-carotene and α-carotene consumption reduced gastric cancer risk. Luo and Wu [86] showed that lycopene treatment to gastric cancer-induced rats mainly up-regulated the redox status and immunity with reduction the risk of gastric carcinoma.

4.4 Liver Cancer

Liver cancer is the fifth most common cancer type in the world. [87]. The most important risk factors for this cancer are hepatitis B and hepatitis C viruses, chronic liver diseases, alcoholism and long-term aflatoxin exposure and other chronic infections [88, 89]. Phytochemicals are powerful potential therapeutic agents for a

multitude of chronic diseases such as cancer, diabetes, and neurodegenerative diseases. It has been reported that supplemental phytochemicals including lycopene and resveratrol are beneficial in the liver cancer treatment [87]. In addition, there is a noteworthy contrary link between serum lycopene, retinol, and retinol-binding protein 4 (RBP4) levels with fibrosis phase in the liver. Serum β-carotene and lycopene are also closely related with their relevant liver levels [90]. In addition, lycopene treatment inhibited metastasis both in vitro and in nude mice in hepatoma SK-Hep-1 cells [91, 92], while the Nrf2-ARE system in HepG2 cells was active [93]. In an experimental study, it was reported that lycopene decreased the number of liver tumor-bearing mice by 49.7% and decreased the average number of tumors per mouse by 88% [94]. Hepatocytes treated with lycopene and beta-carotene are protected from the effects of carcinogenic aflatoxin at both cellular and molecular levels [95]. Conversely, in a study conducted with Long-Evans Cinnamon (LEC) rats, it was stated that lycopene treatment did not diminish spontaneous liver cancer for 70 weeks. In another study, it was found that NADPH oxidase 4 (NOX4) expression and intracellular ROS levels in SK-Hep-1 cells inhibited by 64.3% with lycopene treatment at the highest level in 2.5 μM [96]. In a study, we reported that lycopene supplementation improved the liver CAT, SOD, GSHPx and decreased the NF-κB/COX-2. In addition, lycopene treatment decreased the rises in p-mTOR, p-S6 K1, p-4EBP-1, and protein kinase B [6]. Lycopene treatment is effective against the preneoplastic foci in the liver [97]. Lycopene treatment prevents liver tumor formation in rats spontaneously developing liver tumors and in rats with induced tumor formation with DEN and high fat diet [98]. Cheng et al. [99] showed that treatment of apo-10′-lycopenoic acid in a dose dependent is effective in preventing migration and invasion, suppression of angiogenesis and of liver cells by inhibition of MM-2 expression and activation.

Lycopene supplementation for 26 weeks inhibited the tobacco carcinogen 4-(*N*-methyl-*N*-nitrosamino)-1-(3-pyridyl)-1-butanone (NNK)-induced expressions of α7 nicotinic acetylcholine receptor in the lung and NF-κB and CYP2E1 in the liver and reduced the NNK-induced mortality and pathological lesions in both the lungs and livers [100]. Moreover, lycopene treatment for 24 weeks reduced liver NK-κB p65 and STAT3, IL6, and inflammatory foci in mice. Conversely, lycopene treatment in BCO2-KO were related with decreased hepatic endoplasmic reticulum stress-mediated unfolded protein response through reducing ER(UPR)-mediated protein kinase RNA-activated like kinase-eukaryotic initiation factor 2α activation, and inositol-requiring 1α-X-box-binding protein 1 signaling. Lycopene in BCO2-KO mice inhibited Met mRNA, β-catenin, and mTOR complex 1 activation related with augmented liver microRNA (miR)-199a/b and miR214 levels [101]. In another study, it was reported that lycopene decreased levels of ALT, AST, ALP, LDH in mice during initial stages of *N*-nitrosodiethylamine (NDEA)-induced liver cancer. Lycopene treatment of NDEA mice also resulted in decrease of AFP, HIF-1α, VEGF, CD31, MMP-2, and MMP-9 expression in comparison with NDEA group alone [102].

4.5 Pancreatic Cancer

Pancreatic cancer is the eighth most common cause of cancer death in Europe and the fourth in the United States [103]. Chronic pancreatitis is thought to be related with high intake of alcohol, tobacco smoke exposure and obesity, consumption of animal protein and fat and antioxidant deficiencies [104]. Fruits and vegetables may have a role in the inhibition of pancreatic cancer because they comprise potentially protective substances such as carotenoids, tocopherols, and other phytochemicals [103, 105]. These bioactive complexes play a protective role contrary to free radical damage to DNA, improve immune properties, and inhibit IGF by binding to IGF receptors [103, 106]. In a case-control study, there was a substantial contrary relationship between lycopene consumption and pancreatic cancer after adjustment for age, body mass index, smoking, calorie intake, and education [107]. Huang et al. [108] reported an inverse link between lycopene uptake and risk of pancreatic cancer in Caucasians; this association was found to be insignificant in the mixed population. Another meta-analysis study showed that alpha-carotene and lycopene could reduce the risk of prostate cancer [109]. In another case-control study (44 matched controls and 22 pancreatic cancers), it was reported that lycopene levels were lower in cases than in controls, after adjusting for smoking, education, and serum levels of other carotenoids [110]. However, Jeurnink et al. [103] reported that contrary relations with pancreatic cancer risk were detected for serum β-carotene, zeaxanthin, and α-tocopherol [103].

4.6 Colorectal Cancer

There is an inverse relationship between the lycopene intake or tomato products and colorectal cancer [111, 112]. For example, in in vitro study, it was reported an important decrease in the number of viable cells in human colon adenocarcinoma cells (HT-29) and human colon carcinoma cells (T-84) after 48 h of treatment by lycopene. In the same study, it was also demonstrated that lycopene induced cell cycle arrest followed by decreased cell viability in the common of cell lines after 96 h as compared to controls. Moreover, lycopene has been shown to prevent cell proliferation in HT-29 cells with IC50 value of 10 μM. Lycopene also inhibited Akt activation and β-catenin levels in human colon cancer cells [113]. Lycopene inhibited leptin-mediated cell invasion and MMP-2 expression in HT-29 cells [44]. In addition, lycopene plays an important role in leptin-mediated MMP-7 expression and cell invasion of MAPK /ERK and PI3K/Akt signaling pathways. Lycopene could effectively inhibit the phosphorylation of Akt, glycogen synthase kinase-3 (GSK-3p), and ERK1/2 proteins. Huang et al. [114] tested the lycopene and gold nanoparticles (AN) effects on the inhibition of the HT-29 cells. They reported that their combination (AN 10 ppm plus lycopene 12 μM) and nanoemulsion (AN 0.16 ppm plus lycopene 0.4 μM) caused in a 5- and 15-fold rise in early

apoptotic cells of HT-29 compared with the control treatment. Also, the nanoemulsion decreased the caspases 8, 3, and 9, PARP-1, and Bcl-2, while Bax expression was improved. A fivefold decrease in the migration ability of HT-29 cells was detected for this nanoemulsion when compared to control, with the invasion-related markers being reversed through the upregulation of the epithelial marker E-cadherin and downregulation of Akt, NFκB, MMP-2, and MMP-9 [114].

In an animal study, we presented that 5% of the dietary tomato powder decreased the aberrant crypt foci (ACF) ratio and also decreased adenocarcinoma growth and azoxymethane (AOM)-induced colorectal cancer formation in rats. Moreover, tomato powder supplementation shows chemopreventive action by modulation Nrf2/HO-1 pathway in colon tissue while preventing COX-2 levels and inducing apoptosis via the NF-κB pathway [115]. In an in vivo study, lycopene has been shown to be correlated with anticancer effects by suppression of COX-2, PGE2, and phosphorylated ERK1/2 proteins [116]. However, postinitiation treatment with lycopene did not reduce the development of ACF in male B6C3F1 mice [117]. In contrast, lycopene treatment throughout the postinitiation stage decreased ACF growth but not colon tumors in female Fischer 344/NSIc rats [118].

A meta-analysis showed that an inverse relationship was detected between lycopene intake and the colon cancer [112]. In a clinical study, the serum lycopene level was detected to be lower in the patients with colorectal cancer than in the control subjects [119]. However, a study stated that no important relationship was determined between colorectal cancer risk and lycopene consumption in a cohort study, middle-aged men smokers [120]. Case-control studies have reported a 60% decline in the risk of colorectal cancer linked with higher intake of tomatoes [121–123].

4.7 Skin Cancer

UV light penetrates different skin layers and can cause skin damage by affecting specific biological structures at each level. These effects depend on penetration depth, absorption, wavelength, and structural properties affecting reflection and light scattering, molecular patterns, and pigmentation [124]. Carotenoids including lycopene can be used to reduce the adverse effects of UV light that cause damage to the skin. A linear relationship between lycopene consumption and a prevention of UV-induced erythema formation and a reduced risk of nonmelanoma skin cancer were shown [9, 125–127]. In addition, plasma lycopene levels were associated with lycopene levels in skin and a positive effect was found between the β-carotene in the serum and the β-carotene in the skin. However, plasma-skin associations were lower and not significant for lutein, zeaxanthin, and β-cryptoxanthin. More skin lycopene is destroyed compared to β-carotene when skin is exposed to UV light [128]. Consumption of products rich in lycopene and synthetic lycopene for 10–12 weeks decreased the sensitivity toward UV-induced erythema in volunteers [129, 130]. Andreassi [131] reported that lycopene intake could protect skin against the effects of UV-B radiation, particularly when linked with vitamins C and E. Another

study reported that lycopene did not affect the apoptotic status and necrotic and viable cells in unirradiated cells. Nevertheless, irradiated cells were subjected to a rise with lycopene in both dead and viable subpopulations compared to unexposed irradiated cells [127] by resulting in overexpression of Bax gene.

Chen et al. [132] demonstrated that lycopene pretreatment reduced UVB-induced cell hyperproliferation with apoptosis and reduced cyclin-dependent kinase 2 (CDK2) and CDK4 complex both in human keratinocytes and SKH-1 hairless mice. While FOXO3a is phosphorylated in response to UVB irradiation and is involved in cytoplasm, lycopene treatment rescues this sensitization. Gene ablation of FOXO3a showed a lycopene-induced reduction in cell hyperproliferation, CDK2 and CDK4 complexes, a critical role for FOXO3a in the lycopene-stimulated antiproliferative effect of keratinocytes during UVB irradiation. Furthermore, loss of AKT induced more enhanced lycopene-induced FOXO3a dephosphorylation, while the loss of mTORC2 by transfection with RICTOR siRNA induced levels of AKT phosphorylation comparable to those obtained with lycopene. Conversely, overexpression of AKT or mTORC2 decreased the lycopene effects on AKT phosphorylation as well as on the expression of FOXO3a, suggesting that lycopene is due to negative modulation of mTORC2/AKT signaling [132]. In an animal study of mice exposed to 2240 J/m2 UV-B irradiation and fed with red tomato powder diet for 35 weeks, the number of tumors was found to be significantly lower in mice consuming red tomato diet [133].

Shen et al. [134] reported that pretreatment with lycopene for oxidative stress and skin cancer induced by DMBA/12-O-tetradecanoylphosphoryl-13-acetate (TPA) in female ICR mice significantly delayed tumor growth and decreased the tumor incidence and volume. In addition, lycopene prevented the production of ROS and MDA, thereby inhibiting the loss of glutathione and activating antioxidant enzymes in the skin of mice. Furthermore, animals treated with lycopene showed higher levels of Nrf2 into the nucleus compared with control animals [134]. On the other hand, there are also studies reporting that lycopene has no effect on skin photocarcinogenesis [135, 136]. The reason for these conflicting reports could be the lycopene levels, the UVB radiation dosage, the different experimental conditions and models [132].

4.8 Head and Neck Cancer

Numerous reports have suggested that lycopene and tomato products may have useful properties in the head and neck cancer therapy [13, 33, 137, 138]. For instance, Lodi et al. [139] reported that lycopene significantly reduced multiple forms of HNSCC including laryngeal, oral, and pharyngeal cancer. Lycopene and β-carotene (5–40 μM) dose- and time-dependently reduced the viability of the EC109 human esophageal squamous carcinoma cells. Lycopene and β-carotene treatments upregulated the expression of PPARγ and p21WAF1/CIP1 and downregulated the expression of cyclin D1 and COX-2. These modulatory effects of the carotenoid treatments were suppressed by GW9662, an irreversible PPARγ

antagonist, suggesting that the inhibition of EC109 cell viability by lycopene and β-carotene involves PPARγ signaling pathways and the modulation of p21WAF1/CIP1, cyclin D1, and COX-2 expression [140]. Mayne et al. [138] found that only serum lycopene levels were significantly inversely related with total mortality and mortality in nonsmoking patients. In a clinical trial (754 oral cancer cases and 1775 control), lycopene intake was not significantly linked with oral cancer risk [141]. In another study, high tomato consumption reported that OR was 0.49 for oral cancer [142]. In addition, lycopene inhibited the proliferation of human oral cancer cell line KB-1 by enhanced the expression of the gap junctional protein connexin 43 [33].

In an experimental study, an inverse relationship was detected between lycopene at 2.5 mg/ kg lycopene dose and squamous cell carcinomas with buccal cuts in hamsters. In a study on hamsters, consumption of lycopene 2.5 mg/kg resulted in an inverse relationship between buccal pouch squamous cell carcinomas [143]. El-Rouby [144] found that lycopene treatment at a dose of 2.5 mg/kg BW once a day with intragastric intubation decreased the incidence of laryngeal cancer and increased E-cadherin and β-catenin expression in the lycopene-treated group compared to the control group. Another study showed no carcinomas in lycopene or mixed carotenoid groups [99]. In a study of 228 cases and 491 hospital-based controls, tomato consumption was linked with a decrease in the risk of 0.30, while tomato sauce-rich foods had a protecting effect of 0.57 [145]. The nutrient group consisting of raw and tomato-rich foods presented a strong inverse association with head and neck cancer. Lycopene was also related with a reduced risk of 0.22.

4.9 Prostate Cancer

Prostate cancer is the second most common cancer in men in the world and the fifth most common cancer death in men [146]. There are several ways in which lycopene treatment can protect against prostate cancer, including the prevention of DNA damage by scavenging free radicals [147], modulating gene expression related to prostate cancer [148] and slowing of cancer cell growth [149, 150], inhibiting prostate cancer cell proliferation via the PPARγ-LXRα-ABCA1 pathway, [151], and progression of prostate cancer is hampered by apoptosis induction and angiogenesis suppression [149, 152]. The lycopene intake was significantly linked with decreased PCa risk, and dose-response studies shows a significant linear effect for the dietary lycopene and PCa risk, thus PCa reduced by 1% for every 2 mg of lycopene intake. In addition, for each 10 μg dL-1 circulating lycopene in the linear and nonlinear models, the PCa risk decreased by 3.5% to 3.6% [153]. A substantial inverse association between PC and serum lycopene levels has been found between the highest and lowest quintiles of intake [154–156]. It has been reported that upregulation of miR-let-7f-1 targeted AKT2 and AKT2 in PC3 cells may improve the properties caused by miR-let-7f-1 [157]. Van Hoang et al. [150] reported that the risk of PC reduced by lycopene consumption, tomatoes, tomato products, and carrots. There was no statistically significant correlation for the consumption of α-carotene, β-carotene, β-cryptoxanthin, lutein, zeaxanthin, and other carotenoids.

In a case-control study [158, 159], it was reported that in patients with high-concentration lycopene, the risk of aggressive prostate cancers was reduced. In particular, a significant relationship has been established between high plasma lycopene concentration and a strong reduction in aggressive prostate cancers. Similarly, a meta-analysis found an inverse relationship between lycopene consumption or serum lycopene concentrations and the risk of prostate cancer, with a stronger relationship, detected for the circulating lycopene compared to the highest to the lowest level [109]. However, Morgia et al. [160] reported that Se and lycopene were not related with higher prostate cancer risk.

In a randomized two-arm studies, plasma prostate-specific antigen (PSA) concentration were stated to be reduced by 18% in the intervention group and by 14% in the control group. Eleven of fifteen patients had no extra prostatic tissue involvement with surgical limitations and/or cancer in the intervention group, compared with 2 of the 11 patients in the control group. In the lycopene treatment group, 12 of 15 patients had tumors measured 4 cc or less, 5 of 11 in the control group [161]. In the same study, Cx43 in the malignant part of the prostate gland was higher in the group using lycopene than in the control group. Phase II randomized clinical trial of 15 mg of lycopene intake twice a day for 3 days before radical prostatectomy found a reduction in IGF-I concentration, but no significant change in Bax and Bcl-2 [162]. Another study reported that the median PSA of the tomato group was lower in postoperative-moderate-risk patients than in the control group [163]. Patients with the highest rise in serum lycopene, Se, and C20: 5 n-3 fatty acid had a 1% reduction in median PSA values compared to the lowest increase in lycopene, Se and C20: 5 n-3 fatty acids. Additionally, PSA was reduced in patients with the highest increase in lycopene group. It has also been shown that neither prediagnosis nor post-diagnosis dietary lycopene was associated with PC-specific mortality [164]. Consumption of either low or high dose of lycopene (4 and 16 mg/kg) and a single dose of β-carotene (16 mg/kg) was reported to strongly inhibit tumor growth and decreased prostate tumor volume and tumor weight in nude mice.

Lycopene and β-carotene at high dose levels significantly decreased PCNA expression in tumor tissues and the plasma IGF-binding protein-3 levels. Soares et al. [166] found a significant reduction in primary prostate cancer cell viability upon with lycopene treatment obtained tomato-based food products. Moreover, lycopene, containing tomato extract and tomato sauce, showed a 50-fold increase in the proportion of apoptotic cells by upregulation of TP53 and Bax expression and also downregulation of Bcl-2 compared to the control group [166].

4.10 Renal Cell Carcinoma

It is expected that 63.340 new cases of renal cell carcinoma (RCC) (42.680 in men and 22.660 in women), the most common type of renal cancer in adults, will occur in 2018, and about 14.970 people (10.010 men and 4.960 women) will die from renal cancer. Renal carcinoma is among the 10 most common cancers in both men and women. In general, the risk of developing kidney cancer in men and women is about

1 in 48 and 1 in 83 [167]. Many studies suggest that micronutrients may be used as dietary supplements, including α-carotene, β-carotene, lutein, zeaxanthin, lycopene, vitamin A, vitamin C, and selenium. These agents may inhibit oxidative DNA damage, mutagenesis, and tumor growth [168–170]. Nevertheless, some studies have reported that there is no significant relationship between renal cancer and consumption of antioxidant substances [171], but others have provided evidence that some agents may have a protective effect [169].

Ho et al. (2015) indicated that lycopene intake was inversely linked with the risk of renal cancer; when compared with the lowest quintile of lycopene intake, the highest quartile was related with a 39% lower renal cancer risk. The authors described the potential anticancer effects of lycopene as follows: (i) In contrast to provitamin A carotenoid (α-carotene, β-carotene, and β-cryptoxanthin), it is recommended that lycopene, along with other carotenoids without provitamin A activity (lutein and zeaxanthin), has a different enzymatic affinity. For this reason, absorption and metabolism of lycopene cannot be controlled by vitamin A concentration through intestinal-specific homeobox transcription factors [169, 172]. (ii) Lycopene, one of the most hydrophobic carotenoids, has the ability to affect a variety of transcriptional pathways at the molecular level, unlike other carotenoids. It has also been shown that lycopene has the greatest singlet oxygen quenching activity of any carotenoid [12]. These properties make lycopene a potential anticancer agent. In a study done in the predisposed TSC2 mutant Eker rat model, the incidence of tumor changed from 94% in control rats to 65% in the lycopene-treated rats, but the change was not significant. However, the mean number of tumors was significantly reduced in rats treated with lycopene compared to the controls rats. In the same study, it was also reported that in the lycopene-treated rats, number of tumors reduced and the numbers tended to reduction linearly as lycopene level increased from 0 to 200. Control rats fed only basal diet had a greater length of tumors than rats fed lycopene supplement groups. Furthermore, length of tumor reduced and tumor length inclined to reduction linearly as dietary lycopene level increased from 0 to 200 mg/kg. All tumors presented strong staining with antibodies against mTOR, phospho-S6, and EGFR [173]. However, a clinical trial revealed that RCC risk was inversely associated with β-carotene, α-carotene, β-cryptoxanthin, vitamin A, vitamin C, but not with lycopene or vitamin E [174]. A case-control study also suggested a significant opposite relationship between lycopene and renal in the nonsmoking group, but not in the smoking group [175].

4.11 Ovarian Cancer

Ovarian cancer is the seventh most frequently diagnosed cancer in women and the sixth leading cause of death from cancer among women. Recently, we found significantly decreased tumor incidence and serum MDA levels and increased serum lycopene levels in the hens fed a lycopene-enriched diet compared to control

groups. NF-kB and STAT-3 expression were reduced and Nrf-2, PIAS-3, and HO-1 were improved in the ovarian tissues of lycopene-fed animals [176]. Holzapfel et al. [177] reported that lycopene administration decreased the metastatic load of ovarian cancer-bearing mice, while treatment with lycopene reduced the tumor burden. Lycopene administration also improved the antitumorigenic effects of paclitaxel and carboplatin. Tumor and metastatic tissues for Ki67 revealed that lycopene reduced the number of proliferating cancer cells. They also reported that lycopene reduced the expression of CA125. These effects were complemented by regulation of expression of ITGA5, ITGB1, MMP9, FAK, ILK, and EMT markers, reduced expression of integrin α5.

In a human study, Li and Xu [178] established an insignificant contrary link between lycopene intake and ovarian cancer risk, and subgroup analysis stratified by study design, location, histological type of ovarian cancer, and length of dietary recall presented no significant results. In addition, a case-control study conducted by Cramer et al. [179] indicated a significant inverse relationship between consumption of lycopene and tomato sauce and risk of ovarian cancer mainly in premenopausal women. In another study, it was found that fruit- and vegetable-rich nutrition was related with a reduction in the risk of ovarian cancer, and among the most convincing were tomatoes [180]. Helzlsouer et al. [181] found no correlation between serum lycopene levels and ovarian cancer risk. Nevertheless, Jeong et al. [182] have found an inverse link between serum lycopene levels and ovarian cancer risk. rGO-Ag, a new biomolecule, lycopene, and tricostatin A have been shown to inhibit the viability of the human ovarian cancer cell (SKOV3) in a dose-dependent manner [183].

5 Conclusion

In conclusion, lycopene consumption and higher levels of lycopene in the plasma have been associated with a lower risk of cancer in clinical and experimental studies. Lycopene may lower cancer risk by decreasing oxidative stress through modulation of ROS-producing enzymes including COX-2 and 5-LOX and inducing antioxidant/detoxifying phase II enzymes. These phase II enzymes are also modulated by the Nrf2-ARE system. The NFκB and Nrf2/HO-1 signaling pathway is suggested to be an important primary target for chemoprevention by lycopene. Lycopene can inhibit the proliferation and induce differentiation of cancer cells by modulating the expression of cell cycle regulatory proteins, modulating the IGF- 1/IGFBP-3 system and other mechanisms including the prevention of oxidative DNA damage and modulation of the immune function, as well as the inactivation of growth factors. There is a need for more detailed experimental studies and larger clinical trials investigating the effect of lycopene on cancer prevention and integrative cancer treatment.

Acknowledgments The study was supported in part by Turkish Academy of Sciences (KS).

Contents

Abstract

Bound phenolic compounds are widely distributed among several plants, especially cereals. In most of the cases, covalent bonds are formed with polysaccharides, proteins, or lipids. But additionally, hydrophobic interactions

may affect their release from the food matrix. Many studies have reported their bioactivity after their release from foods, in most of the cases involving acid or basic hydrolysis and further extraction with organic solvents. Besides their antioxidant activity, bound phenolics have important effects on the inhibition of cancer cell growth, key enzymes involved in the metabolism of carbohydrates, as well as in the regulation of inflammatory processes. Food processing and gastrointestinal digestion affect the bound phenolic bioavailability and in consequence the potential benefits to human health. Recent studies have demonstrated that microbiota composition in the gastrointestinal tract affect the release of bound phenolics and their metabolism. Therefore future studies will help us to understand the complex interactions between bound phenolics and gastrointestinal microbiota and produce natural controlled released bioactive phenolic compounds.

1 Introduction

Phenolic compounds (PCs) are plant secondary metabolites necessary for physiology and cellular metabolism. Among the main functions in plants are the protection against insects and animals, structure, growth, and reproduction [1]. PCs come from the phenylpropanoid pathway, and the two main precursors are the amino acid phenylalanine from the shikimate pathway and malonyl-CoA from the acetate pathway [2]. The phenolic acids possess one or more aromatic rings hydroxyl-substituted. Currently, there are 8000 known phenolic structures, which are classified according to the carbon chain (Fig. 1) [3]. Furthermore, the location within the plant and the chemical structure makes possible to categorize phenolic compounds as soluble and insoluble. Soluble phenolics are composed of free simple phenols, glycosides (with single or multiple sugar moieties), and low molecular weight phenolics not bound to the other plant cell major components. Bound phenolic (BP) group is conformed by condensed tannins, phenolic acids, and other compounds of low molecular weight [4]. Particularly in cereals, the insoluble fraction account for the major part of phenolic acids [5].

Phenolic compounds have gained a lot of attention, since these molecules have proved their antioxidant, antimutagenic, antiviral, and antibacterial activities [6–10]. Epidemiological studies have linked the consumption of foods and beverages high in phenolic acids with a reduced risk of development of several diseases [3]. Since bound phenolics are poorly absorbed in the small intestine, their fermentation products generated by the microorganisms in the large intestine generate positive effects on microbiota and inhibit the growth of pathogens.

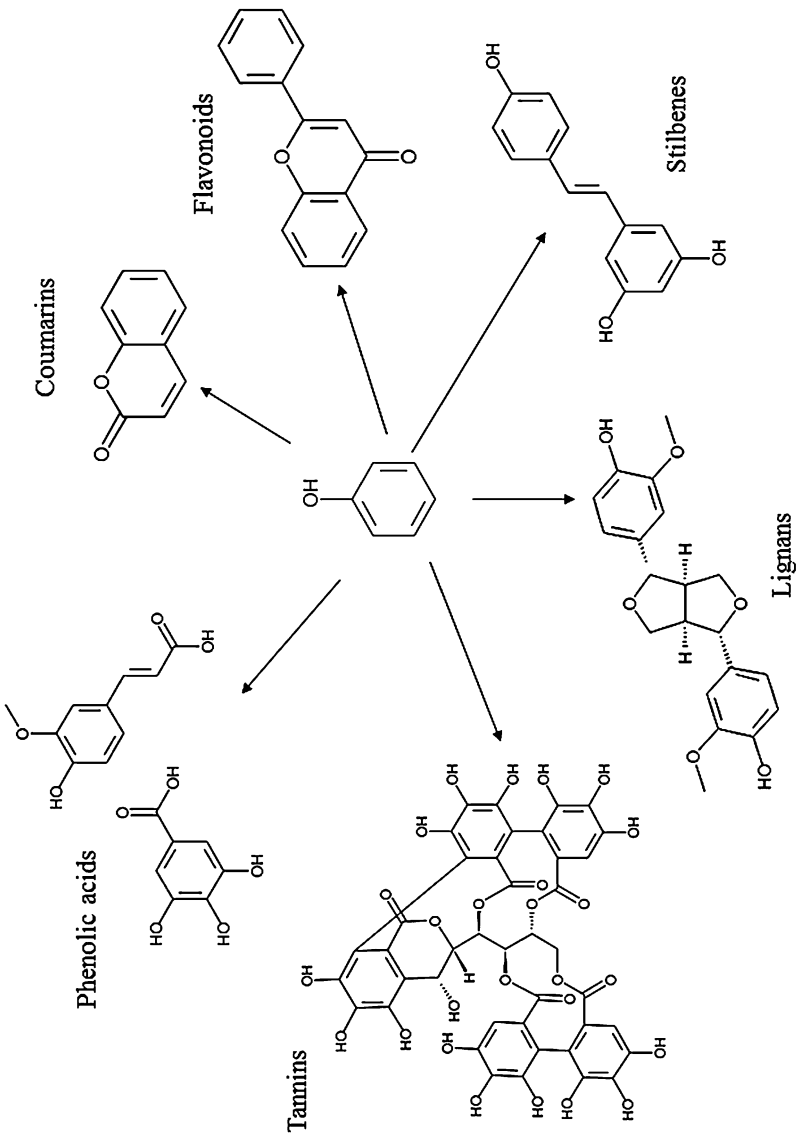

Fig. 1 Diversity of phenolic compound structure

2 Bound Phenolics in Nature

Bound phenolic compounds are widely distributed among several plants, such as cereal grains (>62% of the total phenolic are bound), whereas fruits and vegetables have most of their phytochemicals in the free or soluble form (<24% of the total phenolic are bound) [11]. Phenolics, proteins, and polysaccharides are separated in different compartments in the cell, normally they do not interact until an external stimuli triggers the intracellular contact and then several subsequent reactions can occur and force the interaction (adsorption, oxidation, solubilization, and migration) [12].

PCs are linked to the cell wall structure macromolecules, such as arabinoxylans, pectin, cellulose, lignin, or proteins through ester, ether, and C-C bonds [13]. PCs can interact through hydrogen bonding, covalent bonding, hydrophobic interactions, and ionic bonding with other macromolecules [14]. Some phenolic acids are more abundant in the bound fraction, such as in the case of whole grain oats, where ferulic and p-coumaric acids were found 10- to 100-fold higher in concentration with respect to the free phenolic fraction. However, the profile was less diverse in the bound fraction than in the free phenolics [15].

In the past 20 years, there has been an important increment in research in the field of phenolic interactions with other macromolecules, but there is still limited knowledge about the changes that occur during plant development, postharvest treatments, or interactions produced during food processing and that may affect the release of free phenolics.

2.1 Conjugates with Polysaccharides

Phenolic compounds, mainly phenylpropanoids and simple phenolic acids, can be bound to carbohydrates. Hydrogen bonding and hydrophobic interactions are the driving mechanisms for this type of complexes [14]. The non-covalent complexation between cyclodextrin and phenolic acids is one of the most studied interactions. This complexation is driven by the size of cyclodextrin and its polarity [12].

2.2 Conjugates with Proteins

The molecular weight, affinity of the phenolic acid for water, structural flexibility, and the hydroxyl groups are the main characteristics that dictate the binding of phenolic acids with proteins [16]. In addition, this type of reaction is favored under neutral and basic pH conditions. One of the most studied interactions is the complex with the bovine serum albumin (BSA) [17]. Irreversible interactions involve the oxidation of phenolic compounds and the formation of o-quinones or o-semiquinones or the cleavage of proanthocyanidin interflavanic bonds.

Hydrolysable tannins are conformed by simple phenolic acids (gallotannins) or hexahydroxydiphenic acids (ellagitannins) esterified to polyols (most commonly glucose). Condensed tannins or proanthocyanidins are polymers and oligomers of

flavan-3-ol unit that are distinguished by their degree of polymerization and type of linkage [12]. Tannins can interact with proteins due to hydrophobic interactions between the aromatic ring of the tannin and the hydrophobic region of the protein and the hydrogen bonds. The tannin-protein complexes depend on the size, length, pH, and flexibility of tannins. These molecules are able to precipitate proteins from an aqueous solution. Interaction with PCs can increase the thermal stability of proteins [14, 18, 19]. Protein aggregation is affected by the average size of the condensed tannins rather than the hydroxylation pattern. In special, the procyanidins and *cis*-flavan-3-ol units contributed most to the tannin interactions on the BSA surface [20].

3 Bound Phenolic Extraction and Analysis

For the precise identification and quantification of phenolic compounds, they need to be correctly extracted. Several extraction processes underestimate the total phenolic compounds due to recovery inefficiency [21].

3.1 Traditional Methods

The most common method is the solid-liquid extraction; it involves the extraction of fresh or freeze-dried materials. But a critical step to extract bound phenolic compounds is their release from the insoluble food matrix. Acid or alkaline hydrolysis has been extensively used for this purpose. Alkaline hydrolysis has been proved to be more effective but time, temperature, and base concentration need to be optimized for each crop.

Once the compounds have been released from the matrix and the pH adjusted, extraction with solvents is required to recover bound phenolics. The most used solvents are water, methanol, ethanol, acetone, or several mixes. The parameters in this process are extraction time, temperature, solvent type, solvent to sample ratio, and number of repeated extractions. These parameters must be optimized in order to obtain a substantial recovery of PCs. The main disadvantages of solid-liquid extraction include the need to remove contaminants or other unwanted compounds from the extract, the use of hazardous organic reagents, and the time required for extraction [21].

Traditional food processing releases bound phenolics. Boiling is still the most common cooking method, and it has a negative impact on the total phenolics content of food since bound phenolics are released. After their release, they may form new irreversible covalent bonds with proteins due to the hydrothermal energy [22].

3.2 Emerging Technologies

Several physical methods have been recently used to release bound phenolics from the matrix. They may be used in combination with alkaline hydrolysis. Microwaves, ultrasound, far infrared radiation, pulsed electric field, and pressurized liquids are

examples of emerging technologies for the release of bound phenolics [11]. All these methods increase the extraction yield and reduce the hydrolysis time significantly.

4 Bioactive Potential of Bound Phenolics

Over the years, diverse biological activities from dietary and medicinal plants have been attributed to phenolic compounds, in both free and bound forms. Antioxidant capacity has been the most widely studied effect of phenolics, but effects, such as antiproliferative and apoptotic effect on cancer cells, inhibition of carbohydrate and lipid metabolism enzymes, and anti-inflammatory and vasodilator effects, among others, have been recognized (Table 1). It is important to point out that in these studies, bound phenolics are initially subjected to hydrolysis, as documented in the previous section, to release the phenolic moiety from the carbohydrate or protein moiety and therefore determine their biological effects.

With respect to in vivo potential, bound phenolics are essentially considered non-bioavailable, as they reach the colon still covalently linked. In general, it has been determined that only about 5–10% of insoluble bound phenolics are absorbed in the small intestine and the majority reaches the colon intact [13]. These compounds can be released by pH conditions in the stomach, processed by ß-glycosidase in the intestinal border brush cells, transported as glycosides by sugar transporters, or enzymatically released by fermentation of the colonic microbiota [11, 13]. Additionally, during and after absorption, phenolics undergo conjugation by intestinal and liver enzymes, such as methylation, sulfation, glucuronidation, increasing hydrophilicity, and therefore excretion [23].

4.1 Antioxidant

Antioxidant capacity of bound phenolics, particularly in the case of grains, has been well studied [24]. In most cases only the in vitro or chemical capacity as antioxidants has been analyzed by diverse methods, such as total oxygen scavenging capacity (TOSC), ferric reducing antioxidant power (FRAP), or oxygen radical antioxidant capacity (ORAC) (Table 1). To determine the impact that phenolic compounds can have in a real biological system, models such as LDL cholesterol oxidation, supercoiled DNA fragmentation, and cellular antioxidant activity assays have become more widely used in recent years [46].

4.1.1 Antioxidant Capacity by Chemical Methods

With respect to chemical antioxidant capacity of bound phenolics, Adom and Liu (2002) determined that in the case of whole grains, such as corn, wheat, and oats, this fraction corresponds to over 60% of the total antioxidant capacity evaluated by the TOSC assay, and this activity was highly correlated to total phenolics and ferulic acid content in the grains [24]. In the case of dehulled highland barley, antioxidant capacity evaluated by ORAC showed that around 50–60% of total antioxidant

Table 1 Potential bioactivity of bound phenolic compounds

Source	Phenolics	Bioactivity	Dose/concentration	Reference
Corn, wheat, oats, rice	Ferulic acid and other phenolic acids	Chemical antioxidant capacity evaluated by total oxygen scavenging capacity (TOSC)	50–150 μmol vit C eq/g grain	[24]
Dehulled highland barley	Catechin, phenolic acids	Cellular antioxidant capacity on HepG2 cells	11.3–19.2 μmol QE/mL	[25]
Model system of quercetin-BSA	Quercetin	TEAC antioxidant capacity of BSA-bound quercetin was increased hydrolyzing the protein	2.0–4.6 mM as BSA-quercetin, 3.0–4.0 as peptide-quercetin	[26]
Rice soluble fiber	Ferulic acid bound to arabinoxylans	Antioxidant capacity evaluated by inhibition of ß-carotene oxidation (IC_{50})	1.14–1.24 mg	[27]
White, red, and tannin sorghum bran, corn fiber	Phenolic acids bound to arabinoxylans	Chemical antioxidant capacity evaluated by ORAC	20–100 mM Trolox equivalents (TE)/g	[28]
Cinnamon, oregano, and clove	Phenolic acids, cinnamaldehyde, coumarin, eugenol	Chemical antioxidant capacity evaluated by FRAP and DPPH methods	2.6–34.6 mmol $FeSO_4$/100 g and 2.3–17.7 mmol TE/100 g	[29]
Ginger	Cinnamic and *p*-coumaric acids	Inhibition of lipid peroxidation (IC_{50}), inhibition of DNA fragmentation	5.2 μg GAE/g_{liver}, 2–4 μg GAE	[30]
Blackberry, black raspberry, and blueberry meal seeds	Phenolic acids, catechins, flavonoids, and anthocyanins	Chemical antioxidant capacity, LDL cholesterol oxidation inhibition (48–60% at 22 h), supercoiled DNA strand breakage inhibition (80–98%)	5–68 μmol TE/g, 0.5 mg/mL, 0.10 mg/mL	[6]
Chlorogenic acid-BSA	Model system	Binding of chlorogenic acid to BSA inhibits LDL oxidation in a dose-response way	1–10 μM chlorogenic acid +4% BSA	[31]
Blueberries	Phenolic acids, flavonoids, and anthocyanins	Cellular antioxidant capacity on HepG2 cells	13.5–63.5 μmol QE/100 g	[32]
Litchi pulp	Phenolic acids, (−)-epicathechin, 4-methylcatechol, rutin, quercetin	Cellular antioxidant activity on HepG2 cells, ORAC antioxidant capacity	7.4 ± 1.5 μmol QE/100 g, 286.1 ± 1.5 μmol TE/100 g	[33]
Cancer treatment or prevention				

(*continued*)

Table 1 (continued)

Source	Phenolics	Bioactivity	Dose/concentration	Reference
Maize lime-cooking wastewater (nejayote)	Feruloyl putrescines, ferulic acid	Induction of phase II enzyme quinone reductase	1.28–3.07 μg/mL	[34]
Dehulled highland barley	Catechin, phenolic acids	Antiproliferative activity on hepatic cancer HepG2 cells (IC_{50})	66.4–159.4 mg/mL	[25]
Cactus cladodes (*Opuntia ficus-indica*)	Isorhamnetin glycosides	Apoptotic activity on colon cancer HT-29 (IC_{50}) cells, mediated by caspase 3/7	4.9–34.8 μg/mL	[35]
Tea catechins encapsulated in milk	Epigallocatechin gallate bound to casein micelles	Antiproliferative activity on colon cancer HT-29 cells (IC_{50})	10–20 μg/mL	[36]
Foxtail millet (*Setaria italica*) bran	Phenolics	Apoptotic activity on colon cancer HCT-116 cells, mediated by ROS pathway, and inhibition of NF-κB pathway	0.28–1.43 mg/mL. 0.57–0.88 mg/mL, 0.5–0.7 mg/mL	[37]
Carbohydrate and lipid metabolism				
Citrus fruits	Phenolic acids, hesperidin	Inhibition of α-glucosidase (49.3–80.7%)	Not reported	[38]
Foxtail and little millet	*p*-coumaric, caffeic and ferulic acids, quercetin	Inhibition of α-amylase (IC_{50}) and α-glucosidase (IC_{50})	38.3–54.3 FAE μg/mL, 31.3–35.5 FAE μg/mL	[39]
Whole grain oats and products	Phenolic acids	Modulation of maltose hydrolysis (49–61%)	34–85 GAE μg/mL and 8.5–17 GAE μg/mL	[15]
		Inhibition of intestinal glucose transport (31–67%)		
Shaddock (*Citrus maxima*) peels	Not reported	Inhibition of α-amylase (12.9–64-2%) and α-glucosidase (45.9–95.9%)	80–320 μg/mL	[40]
Soybeans	Not reported	Inhibition of α-amylase (IC_{50}) and α-glucosidase (IC_{50})	320.5 and 458.7 μg/mL	[41]
Black quinoa seeds	Phenolic acids and flavonoids	Mild inhibition of α-glucosidase (IC_{50}) and pancreatic lipase (IC_{50})	37.6–55.6 mg/mL and 9.0–10.5 mg/mL	[42]
Grapefruit peel	Resveratrol, caffeic acid, ellagic acid, and other phenolic acids	HMG-CoA reductase (IC_{50}) inhibition	115.3 μg/mL	[43]
Inflammation and cardiovascular health				
				[44]

(*continued*)

Table 1 (continued)

Source	Phenolics	Bioactivity	Dose/concentration	Reference
Cactus cladodes (*Opuntia ficus-indica*)	Isorhamnetin glycosides	In vivo decrease of cell infiltration (51.8%); inhibition of: NO• (77.2–81.4%), COX-2 (76.3–77.7%), TNF-α (85.2%), and IL-6 (53.0%)	5 mg/kg (rat animal model)	
Antihypertensive and antiulcerative				
Grapefruit peel	Resveratrol, caffeic acid, ellagic acid, and other phenolic acids	Angiotensin converting enzyme (ACE) inhibition (IC_{50})	137.4 μg/L	[43]
Raw and cooked pigmented and nonpigmented rice	Not identified	ACE inhibition (40%) by pigmented rice and (20%) by nonpigmented rice extracts	8 mg FAE/mL. 4 mg FAE/mL	[45]
Ginger	Cinnamic and *p*-coumaric acids	Parietal cell proton pump inhibition (IC_{50}), *Helicobacter pylori* growth inhibition (MIC)	1.5 μg/mL, 38 μg/mL	[30]

capacity corresponded to the bound phenolic fraction [25]. The proportion of bound phenolics with respect to total content may vary among different cultivars or varieties of the same species. In different colored bran rice, it was seen that bound phenolic DPPH radical scavenging capacity represented from 7% to 41% of the total antioxidant capacity of rice, while the ORAC activity varied from 26% to 75% of the total capacity coming from the bound fraction [48]. These results indicated that, in the case of whole grains, evaluating the effect of only free phenolics would underestimate the total antioxidant potential of these particular matrices.

Feruloyl arabinoxylans form an interesting group of bound phenolic compounds with antioxidant potential. The antioxidant capacity of arabinoxylans obtained from rice was found to be a synergy between the phenolic and carbohydrate moieties. Lower IC_{50} values were reported (1.14–1.24 mg) with respect to the predicted amount (54.8–56.9 mg), calculated as the equivalent concentration of ferulic acid bound to the fiber [27]. The authors of this work concluded that ferulic acid is also able to exert antioxidant capacity without needing to be released. Similar results were observed for arabinoxylans extracted from sorghum and maize bran, in which antioxidant capacity in the extracts was attributed to ferulic acid and other bound phenolics to this cell wall component [28]. Since arabinoxylans can be used as ingredients in gluten-free bread formulation, antioxidant capacity of the bound phenolics to the carbohydrates can give added value to such food products [49].

With respect to other non-grain sources, the contribution of bound phenolics to antioxidant capacity is generally lower than 50%, depending on the source. In the case of spices such as cinnamon, oregano, and clove, bound phenolics represented between 3% and 17% of the total antioxidant capacity evaluated by the FRAP method and 3–28% by the DPPH method [29]. In the case of litchi pulp, variation in total antioxidant capacity and the proportion represented by bound phenolics was variable among different cultivars, from 10% to 49% of the antioxidant capacity measured by FRAP assay, and EC_{50} values in DPPH method demonstrated that bound phenolics were three to ten times less effective than free phenolics [50]. Similar results were obtained for litchi pulp when using the ORAC method, where bound antioxidant capacity was reported as 286.1 μmol TE/100 g, while free ORAC values reached up to 3406.8 μmol TE/100 g, representing 7.7% of the total antioxidant capacity [33]. Therefore, in general terms, contribution of bound phenolics to antioxidant capacity of herbs and fruits is lower when compared to cereals and other grains. However, in fruit seeds, a higher amount of antioxidants can be found in the bound fraction. For example, 35–70% of total antioxidant capacity from blackberry, black raspberry, and blueberry seed meals were accounted after hydrolyzing bound phenolics [6].

Binding of PCs to proteins, such as bovine serum albumin (BSA), can affect their antioxidant potential. Such was the case with a quercetin-BSA complex, which had a lower Trolox equivalent antioxidant capacity (TEAC) (2.0–4.6 mM), at concentrations from 7.9 to 17.5 μg of quercetin/mg of protein, with respect to the same amounts of free quercetin (4.4–6.0 mM). Furthermore, a higher antioxidant capacity (3.0–4.0 mM) of the peptide containing 12.2 μg of quercetin/mg of protein obtained after trypsin hydrolysis with respect to the same amount of free quercetin (5.0 mM) [26].

4.1.2 Antioxidant Capacity in Biological Systems

So far, the antioxidant capacity has been discussed in terms of chemical assays; however, the real protective potential of a compound requires evaluation in more complex systems. Antioxidant activity of ginger (*Zingiber officinale*) extracts was analyzed by two methods to determine its protective effect on biomolecules. Results showed that cinnamic acid and *p*-coumaric-rich extract inhibited lipid peroxidation (48–60%) at 5.2 μg gallic acid equivalent/g rat liver homogenate (μg GAE/g_{liver}) and protected against DNA oxidative fragmentation (80–98% inhibition) when adding 2–4 GAE μg [30]. Blackberry, black raspberry, and blueberry seed meal extracts at 0.5 mg/mL inhibited LDL cholesterol oxidation from 46% to 60% after 22 h incubation, and DNA strand breakage was inhibited at levels up to 98% with addition of 0.10 mg/mL of extract [6]. Cellular antioxidant activity is a measurement that takes into account the internalization of the compounds into the cell, therefore, making a more realistic approach to the actual antioxidant activity of a given compound or extract in a living system [51]. This assay has been used to evaluate the antioxidant potential of sources, such as blueberry extracts, where CAA values were found in the range of 13.5–63.5 μmol quercetin equivalents (QE) per 100 g fresh weight of berries, from which 8% to 20% of the total phenolic content

corresponded to the bound fraction [32]. In the case of litchi pulp, bound phenolic fraction exerted a lower antioxidant capacity (7.4 ± 1.5 μmol QE/100 g) than its corresponding free fraction, which reached up to 56.7 μmol QE/100 g, where bound fraction represented 11% of the CAA [33].

As described with respect to chemical antioxidant evaluation, PCs bound to proteins have also exhibited activity in other models. One example is the inhibition of LDL cholesterol oxidation when incubated in the presence of 4% BSA solutions with different doses of chlorogenic acid. It was shown that up to 80% delay in oxidation initiation occurred when 10 μM chlorogenic acid was used in the system, after removing the non-bound phenolic acid from the solution [31]. This study shows promising activity for these complexes, particularly when considering that protein-binding can confer protection during the digestion process but allowing release and increase of bioavailability, as well as stability during storage [16, 52].

In general, these studies have been conducted after hydrolyzing the bound phenolic fraction from the matrix, by any of the methods discussed in Sects. 3.1 and 3.2. This approach allows us to determine whether bound phenolics should be taken into account when evaluating the antioxidant capacity of a given food source. However, when considering bioavailability, bound phenolics are usually not released and absorbed during gastrointestinal digestion [23]. Food processing such as fermentation, malting, extrusion, or cooking allows the release of this fraction, increasing its uptake and making it available to target organs [11].

Therefore, most of the classical assays underestimate the true antioxidant capacity of foods since most of the compounds responsible of this activity are bound to insoluble matrices. Most of the research on the total antioxidant capacity of foods has ignored the interactions that may occur due to the coexistence of multiple antioxidants. In fact, the multiple extraction procedures used as a preliminary step for classical antioxidant determination hinder the generation of a standardized database. "QUENCHER" (Quick, Easy, New, CHEap, Reproducible) is a simple and direct assay for antioxidant capacity measurement that is extraction-independent and may enable interlaboratory comparison [47]. With this method, the functional groups of the soluble and insoluble bound antioxidants in solid samples make contact with free radicals via the liquid-liquid type of reaction and solid-liquid type of reaction, respectively [47].

4.2 Cancer

Antioxidant mechanisms are proposed as one of the primary ways in which PCs exert their bioactive potential [3]. However, there is evidence of additional anticancer mechanisms for preventive and prophylactic effect of PCs against cancer (Table 1).

One of the ways in which BPs can contribute to chemoprevention of cancer is inducing phase II enzymes, such as NADPH-dependent quinone reductase (QR), which work in vivo to inactivate free radicals and electrophiles [53]. Acosta-Estrada et al. (2015) determined that a bound phenolic extract obtained from maize lime-cooking wastewater solids was able to induce QR activity at a concentration of

76 μg/mL and presented a chemopreventive index of 4.58 (cytotoxicity requires a 4.58-fold higher concentration). In this study, QR induction was attributed to coumaroyl-feruloyl and di-feruloyl putrescines that were able to induce QR at 1.28 μg/mL and 3.07 mg/mL, respectively [34].

Antiproliferative effect of BPs released from different sources has been assayed on diverse cell lines. Catechins and phenolic acids from dehulled highland barley showed antiproliferative potential on hepatic cancer HepG2 cells (66.4 μ$\leq$ IC_{50} $\leq$ 159.4 mg/mL), observing variation among four barley varieties [25]. In this study, a lower bioactivity occurred with bound phenolics with respect to free phenolics. Glycosylated flavonoids released by alkaline hydrolysis from *Opuntia ficus-indica* cactus pads and subsequently purified presented a high antiproliferative effect. Alkaline crude extracts were effective on HT-29 (IC_{50}=4.9–9.1 μg/mL) and Caco-2 (IC_{50}=8.2–16.7 μg/mL) colon cancer cell lines. Purified isorhamnetin diglycosides presented IC_{50} values from 8.6 to 15.2 μg/mL on HT-29 and 25.8–36.7 μg/mL Caco-2 [35]. The authors determined that glycosylation pattern of the isorhamnetin derivatives had an important impact, since diglycosides were more effective than triglycosides [35].

Haratifar et al. (2014) demonstrated that PCs capacity to bind to protein could allow encapsulation of compounds, such as epigallocatechin gallate, in casein micelles, while preserving antiproliferative activity on HT-29 cells (16 $\leq$ IC_{50} $\leq$ 20 μg/mL) [36]. This PC-protein complex could be an alternative for delivery of PCs as a food ingredient or dietary supplement, such as fortified breads, dairy products, and processed meats [16, 52].

Besides the evaluation of the antiproliferative effect, some mechanisms related to the anticancer effect of BPs have been explored. In the case of *Opuntia ficus-indica* alkaline extracts, an increase in caspase 3/7 was observed by flow cytometry in HT-29 (33%) and Caco-2 (28–43%) cells treated with the extracts when compared to non-treated cells. Moreover, apoptosis was observed in 32–53% of HT-29 cells treated with isorhamnetin diglycosides and 59% when crude extract was used [35]. On the other hand, bound phenols from foxtail millet induced apoptosis by generation of reactive oxygen species (ROS) in HCT-116 colon cancer cells at concentrations from 0.57 to 0.88 mg/mL. Additionally, apoptotic effect was shown by a decrease in Bcl-2 protein and increase in BAX protein, along with inhibition of the NF-κB pathway [37]. Foxtail millet bran contains BPs such as catechin, myricetin, daidzein, luteolin, quercetin, apigenin, naringenin, and kaempferol, likely accountable for the bioactive effect [39].

4.3 Carbohydrate and Lipid Metabolism

Phenolic compounds, such as phenolic acids and flavonoids, are known inhibitors of starch-hydrolyzing enzymes α-amylase and α-glucosidase, capable of delaying carbohydrate digestion [54, 55] or even absorption by glucose transporters [15]. Bound phenolics also have potential to interfere with the activity of

the fat-digesting enzymes known as lipases, due to PCs affinity with proteins, diminishing the rate of fat absorption [56].

The BP fraction of several citrus fruits showed α-glucosidase inhibitory activity [38]. The main compounds found in these extracts were ferulic acid, *p*-coumaric acid, vanillic acid, and the flavonoid hesperidin. It can be noted that the authors reported in the same study that these extracts activated α-amylase and angiotensin converting enzyme (ACE) instead of inhibiting them [38]. Other authors report a strong inhibitory potential, as observed with BP extracts from foxtail (IC_{50}=35.21–35.26 μg ferulic acid equivalents per mL) (μg FAE/mL) and little millet (IC_{50}=38.27–46.9 μg FAE/mL); in both cases the extracts were obtained from hull and bran [39]. Pradeep and Sreerama (2017) determined that *p*-coumaric, caffeic, and ferulic acids were the major component of the extracts. Additionally, α-glucosidase inhibition was observed for BPs obtained from whole grain oats, with a 49.6–61.3% decrease in maltose hydrolysis at 34–85 μg gallic acid equivalents per gram (GAE μg/g). In this case, ferulic acid represented from 52% to 89.3% of bound phenolics from whole grain oats [15]. The effect of black quinoa seed BPs was weaker, with IC_{50} in the range between 37.6 and 55.6 mg/mL, and the main components of the extract were phenolic acids and flavonoids [42].

With respect to α-amylase, inhibition by PCs has also been reported. Foxtail and little millet showed IC_{50} values of 41.7 and 38.3 FAE μg/mL, respectively, in the hull fraction and 54.3 and 46.9 FAE μg/mL in the bran fraction [39]. Bound phenolics from the citrus shaddock (*Citrus maxima*) fruit peel were able to inhibit α-amylase activity up to 64.2% in a dose-dependent manner, at concentrations from 80 to 320 μg/mL [40]. Soybean BP extracts were found to inhibit 50% of α-amylase activity at 320.5 μg/mL [41]. In general, phenolics are stronger inhibitors of α-glucosidase than of α-amylase, such as in the case of BPs extracted from little millet and shaddock peels, where significant differences were observed [39]. This difference in BPs effect on both enzymes could be important when considering their use as a therapeutic agent for hyperglycemia, since inhibiting α-glucosidase preferentially can prevent side effects from excess inhibition of α-amylase [40, 41]. However, it should be taken into account that in some cases α-amylase was activated by treatment with BPs, as happened with whole grain oat phenolics and citrus fruits [15, 38].

4.4 Interactions with Microbiota

Bound phenolics help to maintain a "healthy" microbiota. For example, cocoa bound flavanols increased the number of *Lactobacilli* and *Bifidobacteria* [57]. Many bound phenolics resist enzymatic digestion (oral, gastric, and small and large intestine phases) and exert their antioxidant activity in the large intestine [58]. But more importantly, their release is slow and continuous [59]. The slow release of bound phenolic compounds could be related to the complexity of the matrix and the diversity of microorganisms required to breakdown the chemical interactions [60].

5 Conclusions

For many years, bound phenolics were considered as poor contributors to improve human health due to their strong interactions with the food matrix and low bioavailability. Particularly in cereals, bound phenolics are major contributors to total phenolic content and antioxidant activity. Most of the studies on bound phenolic compounds involve their extraction after acid or base hydrolysis, and therefore a lot about their chemical structure is known. But when gastrointestinal microbiota is taken into consideration as an important element in the digestibility of dietary fiber, the release of bound phenolics is more complex as well as their potential bioactivity. Microbiota heterogeneity is important to have a vast enzymatic tool to release bound phenolics continuously and slowly to maintain a constant dose of circulating bioactive compounds.

Abstract

A number of epidemiological studies and clinical trials have reported the beneficial effects of both green tea and coffee on human health, including anticancer, anti-obesity, antidiabetic, antihypertensive, and hepatoprotective effects. Furthermore, these findings in humans are supported by cell-based and animal experiments. These effects have been attributed to epigallocatechin gallate (EGCG) in green tea and chlorogenic acid (CGA) in coffee, which have been proposed to function via various mechanisms of action, the most important of which appears to implicate reactive oxygen species (ROS). Both EGCG and CGA can exert conflicting dual actions as an antioxidant and a prooxidant. Their antioxidative action can scavenge ROS, leading to downregulation of nuclear factor-κB to produce various favorable effects such as anti-inflammatory effects and cancer cell apoptosis. The prooxidant actions, however, can promote the generation of ROS leading to the activation of 5'AMP-dependent protein kinase, which modulates various enzymes and factors with beneficial roles. At present, it remains unclear how EGCG and CGA can be directed to act as either a prooxidant or an antioxidant, although their cellular concentrations, the presence of metal cations such as Cu^{+} and Fe^{++}, and the redox state of the cells appear to be important factors. Notably, several human studies did not report the beneficial health effects of green tea and coffee. The inconsistent results may have been caused by various confounding factors including smoking, intestinal microbiota, and genetic factors. This chapter examines the current information on these properties of green tea and coffee with the aim of improving the understanding of a way to enjoy healthy longevity.

Keywords

Green tea · Coffee · Polyphenol · Catechin · EGCG · Chlorogenic acid · Human health · ROS · NF-κB

Abbreviations

ACC	Acetyl-CoA carboxylase
ACE	Angiotensin-converting enzyme
ACF	Aberrant crypt foci
ALT	Alanine aminotransferase
AMPK	5′-AMP-activated protein kinase
ANI	α-Naphthylisothiocyanate
AOM	Azoxymethane
AST	Aspartate aminotransferase

BBN	*N*-Butyl-*N*-(4-hydroxybutyl)-nitrosamine
BMI	Body mass index
C/EBP	CCAAT/enhancer-binding protein
CGA	Chlorogenic acid
CLL	Chronic lymphocytic leukemia
COX	Cyclooxygenase
CPP	Coffee polyphenols
CVD	Cardiovascular disease
DBP	Diastolic blood pressure
EC	(−)-Epicatechin
EGCG	(−)-Epigallocatechin-3-gallate
ERK	Extracellular signal-regulated kinase
FASN	Fatty acid synthase
G6Pase	Glucose-6-phosphatase
GCE	Green coffee extract
GLUT	Glucose transporter
GST	Glutathione S-transferase
GTC	Green tea catechin
GTE	Green tea extract
GTP	Green tea polyphenol
HbA1c	Hemoglobin A1c
HBV	Hepatitis B virus
HCC	Hepatocellular carcinoma
HCV	Hepatitis C virus
HDL	High-density lipoprotein
HFD	High-fat diet
HNF	Hepatocyte nuclear factor
HO	Heme oxygenase
HR	Hazard ratio
HuR	Human antigen R
IFN	Interferon
IGF	Insulin-like growth factor
IL	Interleukin
IRS	Insulin receptor substrate
LDL	Low-density lipoprotein
LPL	Lipoprotein lipase
LXR	Liver X receptor
MAPK	Mitogen-activated protein kinase
MetS	Metabolic syndrome
MMP	Matrix metalloproteinase
mTOR	Mechanistic target of rapamycin kinase
NAFLD	Nonalcoholic fatty liver disease
NF-κB	Nuclear factor-kappa B
NO	Nitric oxide
NOS	Nitric oxide synthase

Nrf2	Nuclear factor, erythroid 2 like 2
OR	Odds ratio
PCa	Prostate cancer
PEPCK	Phosphoenolpyruvate carboxykinase
PKC	Protein kinase C
PPAR	Peroxisome proliferator-activated receptor
PPE	Polyphenon E
QHD	Qushi Huayu Decoction
ROS	Reactive oxygen species
RR	Relative risk
RXR	Retinoid X receptor
SBP	Systolic blood pressure
SHR	Spontaneously hypertensive rats
SREBP	Sterol-responsive element-binding protein
STAT	Signal transducer and activator of transcription
STZ	Streptozotocin
T2DM	Type 2 diabetes mellitus
TNF	Tumor necrosis factor
Treg	Regulatory T
VEGF	Vascular endothelial growth factor

1 Introduction

Green tea is produced by the processing of tea leaves from the plant *Camellia sinensis* (Theaceae) and is popularly consumed worldwide, particularly in Japan and China. Green tea has been shown to have beneficial effects on human health such as anticancer, anti-obesity, antidiabetic, anti-cardiovascular, anti-infectious, and hepatoprotective effects [1–6]. Most of these biological effects are thought to be ascribable to polyphenol catechins, specifically (−)-epigallocatechin-3-gallate (EGCG) (Fig. 1), which is the major catechin. A single 200 mL cup of typically brewed green tea supplies 240–320 mg of catechins, of which EGCG accounts for 60%–65%, together with much lower quantities of other polyphenols including quercetin, myricetin, and kaempferol [7]. Green tea is a rich source of caffeine (Fig. 1), which has strong physiological effects on bodily systems such as the central nervous, respiratory, cardiovascular, urinary, and gastrointestinal systems [8].

Black tea is also produced from *C. sinensis* through enzymic processing (sometimes called fermentation) by intrinsic enzymes and microorganisms during which catechins are polymerized to yield catechin derivatives such as theaflavin (Fig. 1) and theasinensins [9]. It has been shown to have physiological effects similar to those of green tea, albeit with a lesser efficacy than green tea in most cases.

Coffee is also consumed worldwide and, like green tea, exerts various health-related effects. It contains about 2,000 chemicals, including caffeine, and the major polyphenols are chlorogenic acid (CGA) or 5-caffeoylquinic acid (Fig. 1) and its derivatives, which amount to about 3 g per 100 g of roasted coffee powder [8].

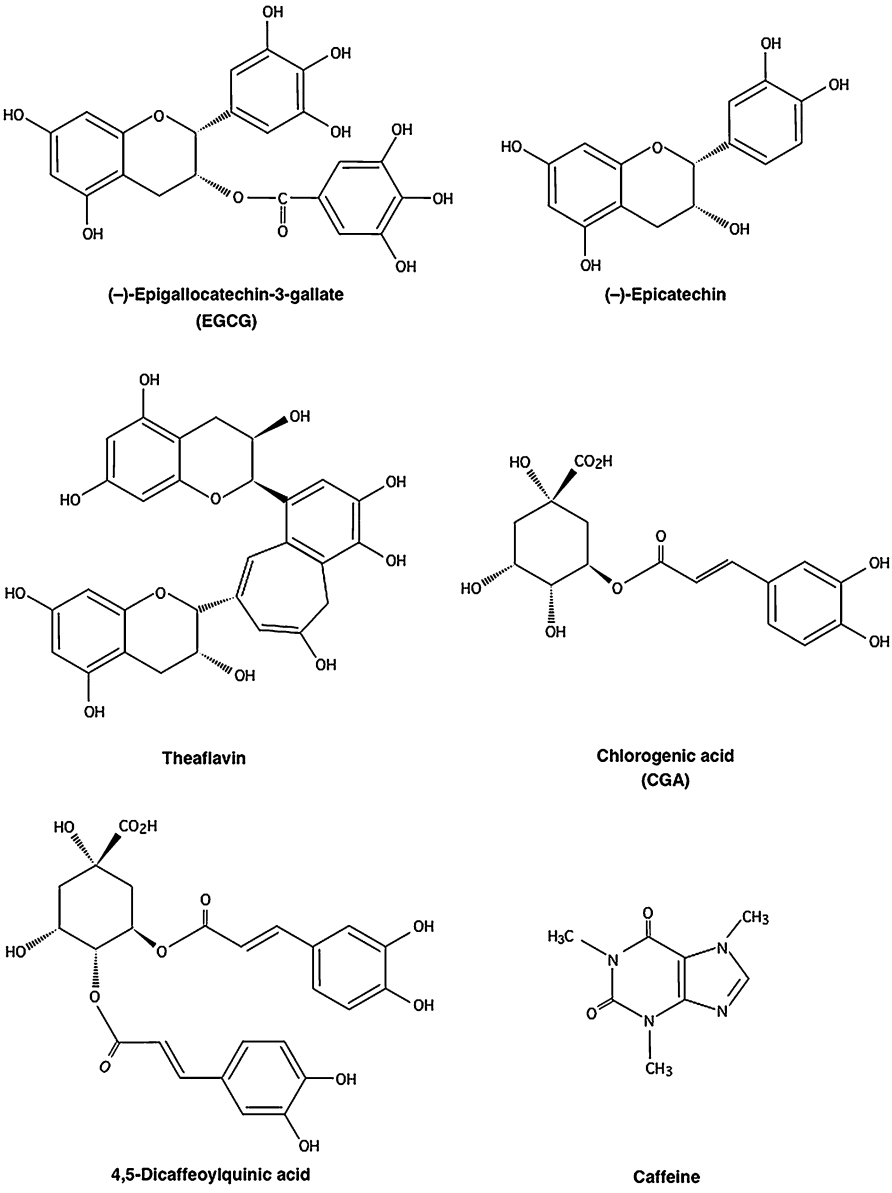

Fig. 1 Chemical structures of compounds pertinent to this chapter

A single serving of coffee provides 20–675 mg of CGAs [10]. It should be noted that a recent analysis using ultrahigh-performance liquid chromatography showed that green tea leaves collected from public markets in Brazil contained 1.1 g of CGAs per 100 g of dried leaves [11].

In this review, we discuss recent evidence that supports the beneficial effects of tea and coffee consumption in relation to the mechanistic aspects of catechins and CGAs by focusing on selected diseases in which we have studied the action of green tea. Caffeine, a highly bioactive constituent contained in both tea and coffee, has been comprehensively reviewed by Temple et al. [12] and is discussed only briefly here. For the sake of readability, 95% confidence interval values and statistical *p*-values, which an original datum contains in statistical evaluation, are not presented here unless otherwise described.

2 Effects on Cancer

2.1 Effects of Tea on Cancer

2.1.1 Human Epidemiological Studies

A number of human epidemiological studies have shown that green tea exerts beneficial effects against various cancers [1–6]. A review article by Yang et al. reported an inverse association between green/black tea consumption and cancer risk for various types of cancer including bladder, breast, colon, gastric, kidney, lung, ovarian, pancreatic, and prostate cancers in 51 of 127 case-control studies and 19 of 90 cohort studies which were carried out from 1965 to 2008 [1]. Yuan and co-workers reviewed the results of 13 studies in which green tea consumption was associated with a significant risk reduction for breast, colorectal, gastric, esophagus, liver, lung, oral cavity, and prostate cancers in 9 studies [13, 14].

Recent studies also demonstrated the beneficial effects of tea, with some examples as follows. The European Prospective Investigation into Cancer and Nutrition study, involving 486,799 men/women for a median follow-up of 11 years, found that increased tea intake was associated with a 59% reduction in the risk of developing hepatocellular carcinoma (HCC) [15]. The analysis of 87 datasets from 57 studies, which included a total of 49,812 subjects, showed that high tea consumption was associated with a reduced risk of oral cancer with a risk ratio (RR) of 0.72, although it had no significant effect on the risk of bladder, breast, colon, gastric, liver, lung, rectal, ovarian, pancreatic, and prostate cancers or gliomas. In a subgroup analysis of individuals in Western countries, the consumption of tea was associated with a reduced risk of bladder cancer, although the consumption of black tea was associated with an increased risk of breast cancer [16].

The results of a hospital-based, case-control study including 160 cases and 320 controls in China showed that the regular consumption of larger amounts of green tea ($\geq$35 g/week) was associated with a lower risk of stomach cancer, with odds ratios (ORs) of 0.72 and 0.53, respectively. Among regular tea drinkers, lower temperature and longer interval between tea being poured and drunk also reduced the risk, suggesting that green tea was inversely associated with risk of stomach cancer [17].

In a study to determine the prostate cancer (PCa) risk associated with green tea and EGCG intake among Hong Kong Chinese men, data from 32 cases and 50 controls showed that habitual green tea drinking had an adjusted OR of 0.60. An

inverse association was also found between intake of EGCG and PCa risk [18]. Similarly, data from the Japan Public Health Center-Based Prospective Study showed that green tea intake may decrease the risk of advanced PCa [19].

A case-control study in Vietnamese men showed that after adjustment for confounding factors, increased tea consumption was associated with a reduced risk of PCa [20]. The adjusted ORs were 0.52 and 0.30 for participants drinking 100–500 mL/day and >500 mL/day, respectively, relative to those drinking <100 mL/day. Significant inverse dose-response relationships were also observed for years of drinking and number of cups consumed daily, showing that habitual tea consumption was associated with a reduced risk of PCa. A meta-analysis of seven epidemiological studies and three randomized controlled clinical trials indicated that green tea consumption reduced the incidence of PCa with a linear dose-response effect and significantly reduced the risk of PCa risk at more than 7 cups/day [21].

A meta-analysis of eight studies comprising 18 independent reports on biliary tract cancer showed that tea intake reduced the risk of cancer by about 34% compared with a no-intake group. This inverse relationship was statistically significant in women but not in men [22]. Chen et al. conducted a meta-analysis to evaluate relationships between tea intake and the risk of biliary tract cancer in 29 qualified studies. The summary OR of developing colorectal cancer for the highest versus the lowest tea consumption was 0.93. A stratified analysis revealed that tea, especially green tea, had a protective effect in female and rectal cancer patients. The dose-response analysis showed that there was a significant inverse association between an increment of 1 cup/day of tea consumption and colorectal cancer risk (OR, 0.68) in women [23].

A meta-analysis performed in April 2016 in a total of 18 (11 case-control and 7 cohort) studies, comprising data for 701,857 female subjects including 8,683 ovarian cancer cases, showed that tea consumption had a significant protective effect against ovarian cancer (relative risk [RR], 0.86). The relationship was confirmed after adjusting for family history of cancer (RR, 0.85), menopause status (RR, 0.85), education (RR, 0.82), body mass index (BMI) (RR, 0.85), and smoking (RR, 0.83) [24].

2.1.2 Clinical Studies

One of the most significant studies may be that of an Italian research group which showed that green tea catechins (GTCs) were safe and highly effective for the treatment of premalignant lesions prior to the development of PCa. Only 1 tumor was detected among a group of 30 men with precancerous lesions who received daily oral administration of 600 mg GTCs, as compared with 9 detected tumors among 30 placebo-treated male patients after 1 year [25]. A later systematic review of 15 studies with 11 reports on the effect of green tea consumption on PCa prevention and 4 reports on the effect of green tea on treatment revealed that green tea appeared to be an effective chemopreventive agent for PCa, particularly in patients with high-grade prostate intraepithelial neoplasia, although evidence of efficacy in the treatment of PCa is currently lacking [26].

To investigate whether erythrocyte oxidative stress was associated with PCa and whether daily consumption of green tea improved the oxidative phenotype, Lassed et al. performed a study on 70 Algerian PCa patients and 120 age-matched healthy subjects. The results at baseline showed reduced glutathione levels and catalase activity and a high level of malondialdehyde in erythrocytes from PCa patients. The consumption of 2–3 cups of green tea per day for 6 months significantly increased glutathione concentration and catalase activity and decreased malondialdehyde concentration. Green tea also significantly decreased oxidative stress in these patients, indicating that regular consumption of green tea for a long period may prevent the development of PCa or at least delay its progression [27].

In a clinical trial in ten patients with stage 0 chronic lymphocytic leukemia (CLL) and ten healthy subjects administered oral green tea extract (GTE) therapy for 6 months, eight out of ten patients showed a reduction in lymphocytosis and absolute number of circulating regulatory T (Treg) cells. Only one nonresponding patient had disease progression at 5 months after the end of GTE administration and chemotherapy. These findings suggest that green tea can control lymphocytosis and prevent disease progression [28].

In a clinical trial in 124 subjects who were recruited and randomly assigned to low-dose GTCs (500 mg), high-dose GTCs (1,000 mg), or placebo for 3 months, urinary fumonisin B_1, a carcinogen, was significantly decreased after 1 month in the high-dose group compared with the placebo group, with reduction rates of 18.95% in the low-dose group and 33.62% in the high-dose group. After a 3-month intervention, urinary levels of fumonisin B_1 were reduced to 40.18% in the low-dose group and 52.6% in the high-dose group compared with both the placebo group and baseline levels. These findings suggest that supplementation with GTCs may represent a useful chemopreventive strategy for reducing co-exposure to aflatoxin B_1 and fumonisin B_1 [29].

In a randomized placebo-controlled trial, 99 women received either Polyphenon E (PPE), a green tea polyphenol formulation primarily consisting of EGCG, or placebo once a day for 4 months. A complete response, defined as negative for high-risk human papilloma virus and normal histopathology, was noted in 17.1% and 14.6% of women in the PPE and placebo arms, respectively, showing a preferable effect of PPE [30].

In a phase II pharmacodynamic prevention trial of PPE, patients with bladder tumors were randomized to receive PPE containing either 800 or 1,200 mg of EGCG or placebo for 14–28 days prior to transurethral resection of the bladder tumor or cystectomy. EGCG levels in plasma and urine increased significantly, and the expression of proliferating cell nuclear antigen and clusterin was downregulated in the bladder tissues. Despite the limitations of this pilot study, the authors pointed out that the observed pharmacodynamics and desirable biological activity warranted further clinical studies of PPE in bladder cancer prevention [31].

In a randomized clinical trial to evaluate GTE for the prevention of metachronous colorectal polyps, 143 patients who underwent the endoscopic removal of colorectal adenomas were divided into a supplementation group (0.9 g GTE/day for 12 months) and a control group without supplementation. Follow-up colonoscopy after conducted

12 months found that the incidence of metachronous adenomas was 42.3% in the control group and 23.6% in the GTE group. The number of relapsed adenomas also decreased in the GTE group compared with that in the control group [32].

Although several studies have demonstrated the anticancer effects of green tea, as described above, conflicting results have also been reported [1, 4]. For example, Je and Park identified five eligible cohort studies comprising 231,870 female participants and 1,831 cases of endometrial cancer [33]. The pooled RR of the three studies conducted in the United States, in which black tea was consumed by most people, was 1.00. These findings do not support an association between tea consumption and endometrial carcinogenesis risk. Furthermore, a meta-analysis of 25 case-control studies (15,643 patients and 30,795 controls) and 7 prospective cohort studies (1,807 cases and 443,076 participants) showed that tea consumption was not significantly associated with bladder cancer risk [34].

In a double-blind randomized controlled trial, subjects with primary multifocal high-grade prostatic intraepithelial neoplasia and/or atypical small acinar proliferation received 35 mg lycopene, 55 μg selenium, and 600 mg GTCs, or placebo, per day for 6 months. The results indicated that the administration of high doses of lycopene, GTCs, and selenium in men was associated with a higher incidence of PCa, suggesting that the use of these supplements should be avoided [35].

In a comprehensive review article, Yang and Wang concluded that the results of human studies on GTCs, mostly from small randomized clinical trials, have been inconsistent [6]. The authors highlighted the following examples. An earlier randomized clinical trial on oral cancer prevention in China showed that a mixed tea product (3 g/day) caused a significant decrease in cancer growth, but a later phase II randomized clinical trial in the United States showed that GTE (500, 750, or 1,000 mg/m^2, twice daily) for 12 weeks resulted in only potentially beneficial effects, which were not significant in reducing oral premalignant lesions. Furthermore, in spite of seemingly promising results reported in the Italian intervention study mentioned previously, a subsequent trial in Florida with a similar design showed that catechin supplementation for 6–12 months did not cause a reduction in the number of PCa cases compared with placebo [6].

Thus, further studies are needed to determine the chemopreventive effects of green tea, but its potentially beneficial effects are supported by Yang and Wang in a phase 2 trial in patients with early CLL where oral doses of PPE (2,000 mg twice/day) caused a sustained decline in absolute lymphocyte count and/or lymphadenopathy in the majority of patients [6]. Furthermore, in a study to assess salivary antioxidant alterations in smokers, participants who consumed 2 cups of green tea per day (2 g of green tea dissolved in 150 mL hot water per cup) had increased levels of salivary antioxidants, suggesting that green tea may reduce the rate of oral cancer, given the likely association between oxidative stress and oral cancer [36].

This optimistic expectation may also be supported by a highly encouraging case report of an EGCG-based ointment (PPE/sinecatechins), approved by the US Food and Drug Administration, which was successfully used to treat anogenital warts. Rob et al. found that after application of the ointment for 10 weeks in an 11-year-old child, the warts disappeared completely without recurrence during a 12-week follow-up [37].

2.1.3 Laboratory Studies and Mechanism of Action

A large number of animal and cell-based experiments have indicated the anticancer effects of green tea [1–6, 38, 39]. For black tea and oolong tea, however, fewer studies are available. Hibasami et al. reported for the first time that catechins, including EGCG, induced apoptosis or programmed cell death in cancer cells [40]. Our research group also observed similar apoptosis-inducing actions of EGCG and has proposed that the binding of EGCG to the cell surface Fas protein is involved in its anticancer activity [41]. Tachibana et al. found that the 67 kDa laminin receptor on the cell surface is an EGCG receptor and mediates various types of EGCG activity, including its anticancer activity [42]. The role of the protein-binding capability of EGCG in its mechanism of action has been reviewed elsewhere by Yang et al. as well as our research group [1, 2].

The number of animal and cell-based experiments showing anticancer effects of EGCG and GTCs continues to increase, as described next. C3H/He mice (8 weeks old; $n = 46$) were treated with 0.05% *N*-butyl-*N*-(4-hydroxybutyl) nitrosamine (BBN) solution for 14–24 weeks. Mice in the BBN + GTP group ($n = 47$) were additionally treated with 0.5% GTP solution over the same period. Cytoplasmic human antigen R (HuR) expression in cancer cells increased at 14 and 24 weeks in the BBN group compared with that in the control group and was associated with increased invasion of tumor cells in muscle. However, these effects were not observed in the BBN + GTP group. GTP was independently associated with cyclooxygenase (COX)-2 and heme oxygenase (HO)-1 expression, while cytoplasmic HuR expression was associated with COX-2 and vascular endothelial growth factor (VEGF)-A levels. Expression of COX-2 and HO-1 was associated with cell proliferation while that of VEGF-A and HO-1 was associated with angiogenesis. Therefore, GTP potentially suppresses tumor cell proliferation and angiogenesis both directly and indirectly via HuR-related pathways in bladder cancer [43].

When the cytotoxic effects of GTPs were examined in human cell lines (MCF-7, A549, Hela, PC3, and HepG2 cells), GTPs were found to inhibit cell growth, particularly in MCF-7 cells. Mechanistic studies showed that the main modes of cell death induced by GTCs were cell cycle arrest at G1/M and G2/M and apoptosis. GTP also caused a reduction in mitochondrial membrane potential, increased the generation of reactive oxygen species (ROS), induced DNA fragmentation, and activated caspase 3 and caspase 9 [44].

The cancer-preventive activity of PPE was demonstrated in an animal model of colorectal cancer induced by azoxymethane (AOM). Dietary PPE increased the plasma and colonic levels of tea polyphenols and decreased tumor multiplicity and size. It also decreased β-catenin nuclear expression, induced apoptosis, and increased the expression of retinoid X receptor (RXR)-α, β, and γ in adenocarcinomas. These results demonstrate the inhibitory effects of orally administered PPE on colon carcinogenesis [45].

Posadino et al. investigated the impact of PPE on PCa cells. PPE treatment at 30 and 100 μg/mL significantly decreased cell viability and proliferation. PPE-induced cell death was associated with mitochondrial dysfunction and the downregulation of Akt activation. Cell exposure to the ROS scavenger *N*-acetylcysteine prevented

PPE-induced ROS increase, Akt activation impairment, and cell death, indicating the causative role of ROS. In cells over-expressing Akt, PPE failed to cause ROS increase, Akt activation impairment, and cell death. Thus, PPE induced apoptotic cell death through a prooxidant rather than an antioxidant mechanism [46].

When estrogen receptor α-positive breast cancer T47D cells were treated with 0–80 μM EGCG, cell viability was decreased, and EGCG at 80 μM increased the gene expression of *PTEN*, caspase 3, and caspase 9 but decreased that of *Akt*. Furthermore, EGCG increased the Bax/Bcl-2 ratio of gene and protein expression and decreased the gene expression of *hTERT*. These findings suggest that EGCG may be a useful adjuvant therapeutic agent for the treatment of breast cancer [47]. Chen et al. found that EGCG inhibited the spheroid formation of colorectal cancer cells as well as the expression of colorectal cancer stem cell markers, suppressed cell proliferation, and induced apoptosis. EGCG downregulated the activation of the Wnt/β-catenin pathway, supporting its potential as an anticancer agent targeting colorectal cancer stem cells through the suppression of this pathway [48]. Aberrant expression of β-catenin is associated with the progression of various cancers, including head and neck cancer. Shin et al. found that EGCG induced apoptosis in KB and FaDu cells via the suppression of β-catenin signaling and promotion of ubiquitin-mediated 26S proteasomal degradation. These effects of EGCG were confirmed in a syngeneic mouse model [49].

Harati et al. found that EGCG suppressed the proliferation and viability of liposarcoma, synovial sarcoma, and fibrosarcoma cells [50]. Cornwall et al. showed that EGCG at concentrations ranging from 25 to 100 μg/mL induced apoptosis in CLL B-cells but did not affect healthy control B-cells. They also showed that, in contrast to healthy controls, T-cells from CLL patients underwent apoptosis in the presence of EGCG. Thus, EGCG differentially induces apoptosis in CLL B- and T-cells but not in healthy B- and T-cells [51].

In an attempt to identify its anticancer activities against cholangiocarcinoma cells, Kwak et al. found that EGCG inhibited the growth of HuCC-T1 cells but not of human embryonic kidney 293 T cells, indicating that EGCG induced apoptosis in cancer cells without adverse effects in normal cells. EGCG inhibited the expression of mutant p53 and induced apoptotic molecular signals such as Bax/Bcl-2, caspases, and cytochrome c. EGCG also inhibited the activity of matrix metalloproteinase (MMP)-2/9, invasion, and migration. In an animal tumor xenograft model using HuCC-T1 cells, EGCG inhibited tumor growth and suppressed carcinogenic molecular signals such as Notch1, MMP-2/9, and proliferating cell nuclear antigen [52].

Similarly, Luo et al. showed that treatment of bladder cancer SW780 cells with EGCG resulted in the significant inhibition of cell proliferation by induction of apoptosis, without obvious toxicity to normal bladder epithelium SV-HUC-1 cells. EGCG also inhibited SW780 cell migration and invasion at 25–100 μM. EGCG induced apoptosis in SW780 cells by the activation of caspases 8, 9, and 3; Bax; Bcl-2; and PARP. Animal studies demonstrated that EGCG decreased tumor volume and weight in mice bearing SW780 tumors and downregulated the expression of nuclear factor-kappa B (NF-κB) and MMP-9 at both the protein and mRNA level in tumor and SW780 cells [53]. As exemplified by this finding and the studies described

above, EGCG exerts stronger apoptosis-inducing effects on cancerous cells than on normal cells. Our research group has also provided evidence that differentiated HL-60 cells are notably less susceptible to apoptosis than undifferentiated cells [54].

Interestingly, Ward et al. reported that different diets may have different effects on the action of GTE. They hypothesized that GTE would have different effects on colon carcinogenesis, body composition, and lipid metabolism in mice fed a basal diet formulated to promote health and growth (AIN93G) compared with total Western diet, which emulates the typical American diet. Mice were fed either AIN93G or the total Western diet for 18 weeks with or without GTE. The quantity of a precancerous marker, aberrant crypt foci (ACF), was nearly three times greater in AOM-treated mice fed the total Western diet than in those fed AIN93G. The consumption of GTE suppressed ACF development only in mice fed the total Western diet. Similarly, supplementation with GTE suppressed weight gain and fasted glucose level only in mice fed the total Western diet, while GTE suppressed fat mass gain in mice fed either diet, suggesting that diet is an important factor for the efficacy of GTCs [55].

In their review of animal and cell experiments, Yang and Wang extensively discussed the molecular mechanisms by which GTCs exert anticancer actions. For example, in tumorigenesis of the small intestine in ApcMin/+ mice, EGCG action was associated with increased levels of E-cadherin on the plasma membrane and decreased levels of nuclear β-catenin, c-Myc, phospho-Akt, and phospho-ERK1/2 in tumors [6]. In a model of AOM-induced precancerous lesions, the inhibitory activity of PPE was associated with decreased levels of nuclear β-catenin and cyclin D1 and increased levels of RXR-α. In male C57BL/KsJ-db/db mice, the inhibition of AOM-induced ACF formation by EGCG was associated with the suppression of insulin-like growth factor 1 (IGF1) signaling. EGCG also increased the levels of IGF1 receptor (IGF1R), phospho-IGF1R, phospho-GSK3, and β-catenin in colonic mucosa. Yang and Wang further described that oral administration of 0.5% PPE or 0.044% caffeine in drinking water to tumor-bearing A/J mice inhibited the progression of lung adenomas to adenocarcinomas by enhancing apoptosis and decreasing the levels of c-Jun and phospho-ERK1/2 in adenocarcinomas.

In a study which examined the cytotoxicity of green, black, and purple tea infusions, green tea inhibited breast cancer 4TI cell proliferation to the greatest extent with an IC_{50}: 13.12 μg/mL. Results also revealed the differential expression of apoptosis-related genes. Caspases 8, 9, 3, and 6 and *8AP2*, *Aifm1*, *Aifm2*, and *Apopt1* genes were significantly upregulated, indicating the process of apoptosis was initiated and executed [56].

In a PCa model, the antitumor action of GTC was associated with the modulation of IGF1 and IGFBP3 levels with reduced levels of phosphatidylinositol 3-kinase (PI3K), phospho-Akt, and phospho-ERK1/2. Furthermore, GTC significantly decreased the levels of angiogenic and metastatic markers such as VEGF-A, MMP-2, and MMP-9 [6].

Tumor metastases are responsible for approximately 90% of all cancer-related deaths [57]. In these events, cancer cells released from the tumor invade surrounding tissues, enter the blood vessels, and extravasate to spread to new organs through

several steps including attachment to and subsequent degradation of the endothelial basement membranes [2]. In 1992, Taniguchi et al. reported that GTCs rich in EGCG inhibited the metastasis of melanoma B16-F10 and BL6 cells in both experimental and spontaneous metastasis systems [58]. Our research group has also observed similar effects of green tea in an animal model of metastasis [59].

In 2001, GTEs were demonstrated to inhibit metastasis in transgenic adenocarcinoma of the mouse prostate (TRAMP) mice, and a later study showed that PPE was an effective chemopreventive agent in preventing metastasis of PCa in this mouse model [60, 61]. A likely molecular basis for the inhibition of metastasis by green tea and GTCs is their ability to inhibit the enzymatic activity and gene expression of MMPs [2]. The results of our research group suggest that EGCG inhibits MMP activity by directly binding to MMPs [62].

Theaflavins have been shown to inhibit the growth and metastasis of HCC in an orthotopic model and a lung metastasis model. Theaflavins induced apoptosis by activating the caspase pathway, suppressing the phosphorylation of constitutive and inducible signal transducer and activator of transcription 3 (STAT3), and down-regulating downstream proteins regulated by STAT3, including antiapoptotic proteins (Bcl-2 and survivin) and invasion-related proteins MMP-2 and MMP-9 [63].

Angiogenesis is required for many physiological processes, including embryogenesis and postnatal growth, but pathological angiogenesis is a hallmark of several diseases including cancer and subsequent metastasis. Rashidi et al. reviewed the ability of green tea constituents to suppress angiogenesis signaling, summarized the mechanism by which EGCG might act on the VEGF family of proteins, and highlighted the microRNAs affected by green tea that are involved in anti-angiogenesis [64].

2.2 Effects of Coffee on Cancer

2.2.1 Epidemiological Studies

Some early epidemiological studies of the health effects of coffee showed that coffee consumption was associated with an increase in cancer risk [65]. For example, Yu et al. reported that daily coffee consumption was a risk factor for renal cell carcinoma in women [66]. However, several later studies have demonstrated the beneficial effects of coffee on cancer. A comprehensive review by Wierzejska showed that coffee consumption reduced cancer risk in 1/4 studies on bladder cancer, 10/17 studies on breast cancer, 6/9 studies on colorectal cancer, 5/5 studies on liver cancer, 2/4 studies on pancreatic cancer, and 3/4 studies on PCa, while 3/3 studies on lung cancer showed an increased risk [65]. Since then, a growing number of studies have sought to further examine these effects, as reviewed here.

In a study of 64,603 participants with a follow-up period of up to 15 years for breast cancer, consumption of $\geq$4 cups/day of boiled coffee was associated with a reduced risk of cancer (hazard ratio (HR): 0.52) as compared with $<$1 cup/day, although no association was found for all cancer sites combined or for prostate and colorectal cancers. An increased risk of premenopausal breast cancer and a reduced

risk of postmenopausal breast cancer were found for both total coffee (HR, 1.69 for premenopausal breast cancer; HR, 0.60 for postmenopausal breast cancer) and filtered coffee (HR, 1.76 for premenopausal breast cancer; HR, 0.52 for postmenopausal breast cancer). Boiled coffee was associated with an increased risk of respiratory tract cancer (HR, 1.81), a finding limited to men. The main results for less common cancer types included reduced risk for renal cell cancer with total coffee (HR, 0.30) and increased risk for pancreatic cancer for boiled coffee (HR, 2.51). These findings demonstrate that coffee has beneficial effects in certain types of cancer and that the effect may be dependent on the brewing method [67].

A population-based prospective cohort study of >215,000 men and women in Hawaii and California with an 18-year follow-up period showed that high levels of coffee consumption were associated with reduced risk of incident HCC and chronic liver disease mortality. Compared with non-coffee drinkers, those who drank 2–3 cups/day had a 38% reduction in risk for HCC (RR, 0.62), while those who drank ≥4 cups/day had a 41% reduction in HCC risk (RR, 0.59). Compared with non-coffee drinkers, participants who consumed 2–3 cups of coffee/day had a 46% reduction in risk of death from chronic liver disease (RR, 0.54), and those who drank ≥4 cups/day had a 71% reduction (RR, 0.29). These findings suggested that coffee consumption reduces the risk of HCC and chronic liver disease in multiethnic US populations [68].

A study of 738 middle-aged Japanese patients with adenoma and 697 controls showed that high coffee consumption was associated with a reduced risk of adenoma. A multivariate-adjusted OR for the highest versus lowest quartile of coffee intake was 0.67, suggesting a protective effect of coffee drinking on colon adenoma, a precursor of colon cancer [69].

Results from a Danish case-control study from 1995 through 1999 showed that both coffee (OR, 0.90 per cup/day) and total caffeine consumption from coffee and tea combined (OR, 0.93 per 100 mg/day) decreased the risk of ovarian cancer [70].

The results of the European Prospective Investigation into Cancer and Nutrition study in a total of 335,060 women from 1992 to 2000 indicated that higher caffeinated coffee intake may be associated with a lower risk of postmenopausal breast cancer, with a null association in the case of decaffeinated coffee [71].

A prospective study of breast cancer in the Swedish Women's Lifestyle and Health study of 42,099 female participants suggested that coffee consumption and caffeine intake were inversely associated with the overall risk of breast cancer and of estrogen receptor-positive/prolactin-negative breast cancer [72].

In a case-control study, during and 6 months after adjuvant chemotherapy, 953 patients with stage III colon cancer prospectively answered questionnaires which included the dietary intake of caffeinated coffee, decaffeinated coffee, and non-herbal tea. The results showed that patients who consumed ≥4 cups/day of total coffee had an adjusted HR of 0.58 for colon cancer recurrence or mortality, compared with nondrinkers. The daily consumption of ≥4 cups of caffeinated coffee resulted in reduced cancer recurrence or mortality risk (HR, 0.48), while decaffeinated coffee was not associated with cancer outcome [73].

In a prospective cohort study in 307 patients over 4 years, the risk of colorectal tumor recurrence was significantly lower (OR, 0.21) in patients who consumed >3 cups of coffee/day compared with those who did not consume coffee. In a sub-analysis of tumor location, OR of colorectal tumor recurrence in the proximal colon showed a tendency toward reduction as coffee consumption increased; however, increased coffee consumption significantly increased colorectal tumor recurrence in the distal colon [74].

A meta-analysis with a total of 1,534,039 participants from 13 published studies showed that the RR of total coffee consumption and endometrial cancer was 0.80. A stronger inverse association between coffee intake and cancer incidence was found in patients who had never received hormone therapy (RR, 0.60) and subjects with a BMI $\geq$25 kg/m^2 (RR, 0.57). The overall RR for caffeinated and decaffeinated coffee was 0.66 and 0.77, respectively. Endometrial cancer risk decreased by 5% for every 1 cup of daily coffee intake, 7% for every 1 cup of daily caffeinated coffee intake, 4% for every 1 cup of daily decaffeinated coffee intake, and 4% for every 100 mg of daily caffeine intake. These findings suggest that coffee and caffeine may reduce the incidence of endometrial cancer and that these effects may be modified by BMI and history of hormone therapy [75].

A systematic review and meta-analysis of nine observational studies with a total of 927,173 study participants showed that the pooled RR for melanoma among regular coffee drinkers was 0.75 compared with controls. The pooled RR for melanoma among decaffeinated coffee drinkers was, however, not statistically significant [76].

A systematic review and meta-analysis of prospective cohort studies including 12 studies on HCC (3,414 cases) and 6 studies on chronic liver disease (1,463 cases) found that the summary RRs for HCC were 0.66 for regular, 0.78 for low, and 0.50 for high coffee consumption, respectively. The summary RRs for chronic liver disease were 0.62 for regular, 0.72 for low, and 0.35 for high consumption and 0.74 for an increment of 1 cup/day. These findings indicate an inverse relation between coffee consumption and the risk of HCC and chronic liver disease [77].

In a meta-analysis of observational studies published until February 2016, the intake of caffeinated coffee was inversely associated with nonmelanoma skin cancer risk (summary RR, 0.82 for those in the highest versus lowest category of intake), as was the intake of caffeine (summary RR, 0.86). In a subgroup analysis, these associations were limited to the basal cell cancer histotype. There was no association between decaffeinated coffee intake and summary RR, suggesting that caffeine may contribute to the risk reduction [78].

A meta-analysis of 9 cohort and 13 case-control studies involving 7,631 cases and 1,019,693 controls reported a summary RR for gastric cancer of 0.94 for the highest category of coffee consumption compared with the lowest category and 0.93 for coffee drinkers compared with nondrinkers. The pooled RRs for the population consuming <1 cup/day, 1–2 cups/day, and 3–4 cups/day compared with that of nondrinkers were 0.95, 0.92, and 0.88, respectively, indicating that an increase in coffee consumption was associated with a decreased risk of gastric cancer [79].

Another meta-analysis of the cohort and case-control studies reported a summary RR for nonmelanoma skin cancer of 0.96 for 1 cup of coffee, 0.92 for 1–2 cups, 0.89 for 2–3 cups, and 0.81 for >3 cups/day, respectively. The results suggest that caffeinated coffee might have dose-dependent chemopreventive effects against basal cell carcinoma [80].

The results of a study of 18 cohorts, involving 2,272,642 participants and 2,905 cases, and of 8 case-control studies, involving 1,825 cases and 4,652 controls, showed that increased consumption of caffeinated coffee and, to a lesser extent, decaffeinated coffee was associated with reduced risk of HCC, including in patients with preexisting liver disease. An extra intake of 2 cups/day of coffee was associated with a 35% reduction in the risk of HCC [81].

However, several studies have failed to demonstrate the beneficial effects of coffee, as exemplified by the following studies. A cohort study with 560,356 participants in the UK Million Women Study found no significant association between endometrial cancer risk and consumption of coffee [82]. In a systematic meta-analysis of 2,803 cases and 503,234 controls in ten independent studies, Chen et al. found that coffee consumption was significantly associated with the increased risk of laryngeal carcinoma (RR:1.47) [83].

A meta-analysis of 9 prospective cohort studies involving 1,250,825 participants and 3,027 gastric cancer cases demonstrated that coffee consumption was not associated with overall gastric cancer risk and that it may even be a risk factor for gastric cardia cancer [84].

A meta-analysis of 17 studies (5 cohort and 12 case-control studies) involving 12,276 cases and 102,516 controls showed that coffee intake was associated with an increased risk of lung cancer. Particularly over the past 5 years, studies have consistently indicated that lung cancer risk is significantly increased by 47% in the population with the highest category intake of coffee compared to that with the lowest category intake [85].

In a large population-based case-control study in Italy, no association was observed between regular coffee consumption and any type of leukemia [86]. A meta-analysis of 12 case-control studies, comprising a total of 3,649 cases and 5,705 controls, showed that high maternal coffee consumption was associated with increased risk of acute lymphoblastic leukemia (OR, 1.43) and acute myeloid leukemia (OR, 2.52) in children. The finding indicates a detrimental association between maternal coffee consumption and childhood leukemia risk [87].

A multicentric case-control study on 690 bladder cancer cases and 665 hospital controls conducted in Italy between 2003 and 2014 showed that decaffeinated coffee, tea, cola, and energy drinks were not related to bladder cancer risk [88]. A meta-analysis of 13 prospective cohort studies with 20 independent reports involving 3,368 patients with gastric cancer and 1,372,811 participants during a follow-up period ranging from 4.3 to 8 years did not support the hypothesis that coffee consumption was associated with the reduced risk of gastric cancer and even indicated an increased risk of gastric cancer for participants in the United States [89].

The results of a population-based prospective cohort study in Japan on 89,555 people aged 45–74 years showed no clear association between coffee consumption

and biliary tract, gallbladder, or extrahepatic bile duct cancer [90]. Furthermore, based on the meta-analysis of five cohort studies and nine case-control studies, Akter et al. concluded that the evidence was insufficient to support that coffee drinking increased or decreased the risk of colorectal cancer [91].

These conflicting results may have been caused by several confounding factors, including the methods of quantifying coffee consumption, coffee temperature, cigarette smoking, alcohol consumption, and differences in genetic and environmental factors such as race, sex, age, intestinal microbiota, and lifestyle as in the case of tea consumption [1, 2, 92].

2.2.2 Clinical Studies

A total of 31 men and 33 women were randomly assigned to two groups with two intervention periods of 2 weeks separated by a washout period of 8 weeks, and they consumed 1,000 mL of cafetière (French press) coffee daily or no coffee [93]. The results showed that unfiltered coffee significantly increased the glutathione content in the colorectal mucosa by 8% and in plasma by 15%. Unfiltered coffee did not influence the colorectal mucosal proliferation rate, but appeared to cause an increase in detoxification capacity and antimutagenic properties in the colorectal mucosa by increasing the glutathione concentration. Thus, the findings suggest a possible reduction of colon cancer risk by coffee consumption.

A controlled intervention trial with a crossover design in which 38 participants consumed 800 mL coffee or water daily over 5 days demonstrated that the proportion of DNA migration attributable to the formation of oxidized purines was decreased by 12.3% after coffee intake. However, other biochemical parameters including the total antioxidant levels in plasma, glutathione concentrations in blood, and superoxide dismutase and glutathione peroxidase activity in lymphocytes were not markedly altered. These results indicate that coffee consumption prevents the endogenous formation of oxidative DNA damage in humans [94].

A clinical trial in which ten participants consumed 1 L of unfiltered coffee/day over 5 days showed a weak induction of glutathione S-transferase (GST) and a threefold increase in the induction of placental-type GST in blood, whereas the level of GST-α was not altered [95]. Although serum cholesterol levels were increased without statistical significance, other clinical parameters (creatinine, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase), which are markers for organ damage, were not altered. In a similar trial with seven participants who consumed 1 L coffee/day over 3 days, a significant threefold induction of placental-type GST was observed. The effects were identical between filtered and unfiltered coffee, indicating that caffeine concentration was not responsible for this result. In a further trial, the consumption of unfiltered coffee (1 L/day for 5 days) resulted in a 45% reduction effect. These findings show that coffee induces placental-type GST, which may confer protection against chemical carcinogenesis [95].

However, a placebo-controlled intervention trial on 160 healthy human subjects who consumed 3 or 5 cups of coffee per day for 8 weeks showed that blood pressure, oxidation of DNA and lipids, blood glucose level, insulin, cholesterol, triglycerides,

and inflammatory markers were unchanged, although a slight elevation of serum creatinine level and a significant elevation of serum γ-glutamyl transaminase level were observed in the 5 cups/day group. These findings indicated that there was no detectable effect, either beneficial or harmful, of coffee consumption on human health [96]. Given the conflicting results of these clinical studies, further studies are warranted to understand the relationship between coffee and cancer.

2.2.3 Laboratory Studies and Mechanism of Action

Numerous cell-based and animal experiments have demonstrated the anticancer effects of CGAs, the most common polyphenols found in coffee.

A cell-based experiment found that CGA inhibited the viability of colon cancer HCT116 and HT29 cells. CGA induced ROS production and cell cycle arrest at the S phase and suppressed the activation of ERK. These events may lead to a reduction in viability of cancer cells and suggest that CGA is a potential treatment for colorectal cancer. Deka et al. found that CGA killed MDAMB-231 and MCF-7 breast cancer cells with an IC_{50} of about 76 and 53 μg/mL, respectively. CGA bound to protein kinase C (PKC) with a dissociation constant of about 29 μM and caused the translocation of PKC from the cytosol to the plasma membrane, leading to cell cycle arrest at the G1 phase. CGA induced apoptosis through a mitochondrial pathway which involves a reduction in mitochondrial potential and the release of cytochrome c into the cytosol [97].

Salomone et al. reviewed the effects of coffee and its components in experimental models of liver cancer. Coffee exerted beneficial effects, including a reduction in preneoplastic lesions in an aflatoxin-induced liver cancer model, a reduction in tumor growth and metastasis in hepatoma-bearing rats, and a reduction in the incidence of liver tumors in an aminopyrine-sodium nitrite-induced cancer model. Regarding the mechanism of action of coffee and CGA, the authors highlighted the antioxidant effects associated with nuclear factor, erythroid 2 like 2 (Nrf2) signaling, the activation of which leads to (1) the induction of enzymes involved in xenobiotic detoxification processes and cellular antioxidant defenses; (2) the induction of gene expression of hepatic and intestinal NAD(P)H/quinone oxidoreductase 1, GST class α1, intestinal uridine-5′-diphosphoglucose-glucuronosyl transferase 1A6, and the glutamate cysteine ligase catalytic subunit; (3) the induction of the transcription of several UDP-glucuronosyltransferases in hepatoma cells; and (4) an increase in hepatic superoxide dismutase, catalase, and glutathione peroxidase activity [98].

When G422 glioma cells were injected subcutaneously into the right flank of ICR mice in a xenograft model experiment and the mice were intraperitoneally administered either CGA or vehicle daily for 2 weeks, CGA inhibited glioblastoma growth. Moreover, CGA increased the population of CD11c-positive M1 macrophages and decreased the distribution of CD206-positive M2 macrophages in tumor tissue via the promotion of STAT1 activation and inhibition of STAT6 activation, respectively, suggesting its therapeutic potential for the reduction of glioma growth [99].

CGA was also shown to have therapeutic effects in breast cancer, brain tumors, lung cancer, colon cancer, and chronic myelogenous leukemia. Suggested mechanisms of action of CGA include (1) the induction of *GSK-3 β* and *APC* genes; (2) the

inhibition of the *β-catenin* gene; (3) the inhibition of activator protein-1, NF-κB, and MAPKs; and (4) the induction of phase 2 detoxifying enzyme activity [100].

The bark of *Odina wodier* is one of the Indian tribes for treating inflammatory disorders, and its major constituent is CGA. Ojha et al. demonstrated that both the methanol extract of bark and CGA exerted significant anti-inflammatory activity, inhibiting the expression of tumor necrosis factor (TNF-α), interleukin (IL)-1β, IL-6, and IL-12. The expression of murine TLR4, NF-κBp65, MyD88, iNOS, and COX-2 molecules was also reduced in CGA-treated groups. These findings suggest that CGA can inhibit inflammation by downregulating the TLR4/MyD88/NF-κB signaling pathway. Through these activities, CGA may be beneficial for the prevention of chronic inflammatory diseases including cardiovascular diseases, diabetes, and cancer [101].

In contrast, Choi et al. found that neither caffeine, caffeic acid, nor CGA showed any cytotoxicity against colon adenocarcinoma HT-29 cells, while a coffee diterpene, kahweol, did [102].

Cancer metastasis may be prevented by coffee polyphenols. Weng and Yen reviewed several studies to show anti-invasive and anti-metastasis activities of dietary phenolic compounds including CGA and caffeic acid in various cancer cells such as hepatoma Hep3B and SKHep1 cells, glioma U-87 cells, prostate cancer PC3 cells, fibrosarcoma HT1080 cells, and colon adenocarcinoma CT26 cells [103]. The authors concluded that the daily consumption of natural dietary components that are rich in phenolics could be beneficial for the prevention of cancer metastasis.

2.3 Simultaneous Evaluation of the Anticancer Effects of Tea and Coffee

Several epidemiological studies have simultaneously evaluated the anticancer effects of tea and coffee. These results are briefly summarized in Table 1. In the European Prospective Investigation into Cancer and Nutrition study in 486,799 subjects, the results from a median follow-up of 11 years showed that increased coffee and tea intake was associated with lower HCC risk. Coffee and tea consumers in the highest quintile had a lower HCC risk by 72% and 59%, respectively, compared with the lowest quintile [15].

The results of a Danish case-control study indicated that both coffee and total caffeine consumption from coffee and tea combined decreased the risk of ovarian cancer, while no relationship was observed between tea consumption and ovarian cancer risk [70].

In a middle-aged Japanese population, Budhathoki et al. found that high coffee consumption was associated with a reduced risk of colorectal adenoma, with a multivariate-adjusted OR of 0.67 for the highest versus the lowest quartile of coffee intake, indicating a protective effect of coffee drinking against colon adenoma, a precursor of colon cancer. Green tea intake was not found to be associated with colorectal adenoma risk [69].

Table 1 Examples of the simultaneous evaluation of the effects of tea and coffee on human cancer risk[a]

Cancer type	Tea	Coffee	Reference
Liver cancer	—	↓	[106]
Hepatocellular carcinoma	↓	↓	[15]
Colorectal adenoma	—	↓	[69]
Colorectal tumors	—	↓	[74]
Laryngeal carcinoma	—	↑	[83]
Breast cancer	—	↓	[71]
Breast cancer	↑	↓	[72]
Ovarian cancer	—	↓	[70]
Endometrial cancer	—	—	[82]
Endometrial cancer	—	↓	[104]
Bladder cancer	—	—	[88]
Biliary tract cancer	↓	—	[90]
Nonmelanoma skin cancer	—	↓	[78]
Brain tumor	—	↓	[105]
Leukemia	↓	—	[86]
All cancers combined	↓	—	[104]

[a]Cancer risk is reduced (↓), increased (↑), or not affected/evaluated (—)

A systematic meta-analysis of 2,803 cases and 503,234 controls in ten independent studies, including case-control and cohort studies, showed that tea drinking was not associated with laryngeal carcinoma. However, coffee consumption was positively associated with laryngeal carcinoma (RR, 1.47) [83].

A cohort study with 560,356 participants in the UK Million Women Study found no significant association between endometrial cancer risk and the consumption of either tea or coffee [82].

The prospective study of breast cancer in the Swedish Women's Lifestyle and Health study among 42,099 female participants suggested that coffee consumption and caffeine intake reduced the risk of both overall and estrogen receptor-positive/prolactin-negative breast cancer, while tea consumption increased the risk [72].

A multicenter case-control study on 690 bladder cancer cases and 665 hospital controls conducted in Italy between 2003 and 2014 showed that consumption of decaffeinated coffee, tea, cola, and energy drinks was not related to bladder cancer risk [88].

In a meta-analysis of observational studies reported up to February 2016, intake of both caffeinated coffee and caffeine was inversely associated with nonmelanoma skin cancer risk (summary RR, 0.82). In a subgroup analysis, these associations were limited to the basal cell cancer histotype. There was no association between intake of decaffeinated coffee and green tea and nonmelanoma skin cancer risk [78].

A meta-analysis of 12 case-control studies, comprising a total of 3,649 cases and 5,705 controls, showed that high maternal coffee consumption was associated with increased risk of acute lymphoblastic leukemia (OR, 1.43) and acute myeloid leukemia (OR, 2.52). On the contrary, low-to-moderate tea consumption was inversely associated with overall leukemia (OR, 0.85), although the trend was not significant. These findings

indicate the detrimental association between maternal coffee consumption and childhood leukemia risk. In contrast, an inverse association was found with tea, implying that other micronutrients contained in this beverage could potentially counterbalance the deleterious effects of caffeine [87].

The results of a population-based prospective cohort study in Japan on 89,555 people aged 45–74 years showed no clear association between coffee consumption and biliary tract, gallbladder, or extrahepatic bile duct cancer. However, the findings suggested that high green tea consumption might lower the risk of biliary tract cancer [90].

In a large population-based case-control study in Italy, no association was observed between regular coffee consumption and any type of leukemia. A small protective effect of tea intake was found among myeloid malignancies, which was more evident among acute myeloid leukemia (OR, 0.68) [86].

In a study of 97,334 eligible individuals, 10,399 developed cancers including 145 head and neck, 99 esophageal, 136 stomach, 1137 lung, 1703 breast, 257 endometrial, 162 ovarian, 3037 prostate, 318 kidney, 398 bladder, 103 glioma, and 106 thyroid cancers. Coffee intake was not associated with the risk of all cancers combined, whereas tea drinking was associated with an overall decreased risk of cancer (RR, 0.95 for 1 cup-increment/day versus <1 cup/day). For endometrial cancer, a decreased risk was observed for coffee intake (RR, 0.69) of ≥ 2 cups/day [104].

A Japanese cohort study with 106,324 subjects (50,438 men and 55,886 women) found a significant inverse association between coffee consumption and brain tumor risk in both total subjects (≥ 3 cups/day; HR: 0.47) and in women (≥ 3 cups/day; HR: 0.24) [105]. No association was observed between green tea and brain tumor risk. A prospective cohort study with 18,815 subjects aged 40–69 years showed that coffee consumption may reduce the risk of liver cancer regardless of hepatitis C virus (HCV) or hepatitis B virus (HBV) infection status, whereas green tea may not [106].

Thus, there are conflicting results related to the effects of both tea and coffee in a variety of human cancers. These differences may have arisen from several confounding factors, including the method of quantifying tea consumption, tea temperature, cigarette smoking, alcohol consumption, and differences in genetic and environmental factors such as race, sex, age, and lifestyle [1, 2, 6, 92]. In addition, caffeine consumption is an important factor to be adjusted for. Intestinal microbiota and genetic polymorphisms may also have influenced the effects of coffee in these studies [107]. The differences in results between human and animal experiments may have been due to different doses of tea and coffee [3].

3 Effects on Metabolic Syndrome and Related Disorders

3.1 Effects of Green Tea on Metabolic Syndrome

3.1.1 Epidemiological Studies

Metabolic syndrome (MetS) is diagnosed based on variables related to the five components of obesity, blood triglycerides, high-density lipoprotein (HDL) cholesterol, systemic hypertension, and fasting glucose. Any agent that exerts beneficial

effects on these components may potentially prevent MetS [108]. Several human studies have suggested that tea is one such agent.

Grosso et al. conducted a cross-sectional survey among 1,889 inhabitants in Sicily, southern Italy, and found that tea consumption was inversely associated with MetS (OR, 0.51) after adjusting for all covariates. Although no direct association between caffeine intake and MetS or its components was observed, tea and coffee were significantly related to reduced OR of MetS. Similarly, results from a cross-sectional population-based survey including 8,821 adults of the Polish arm of the Health, Alcohol and Psychosocial Factors in Eastern Europe cohort study showed that a high consumption of tea was inversely related to MetS, and the analysis stratified by gender revealed a significant association for men but not for women. After adjusting for potential confounding factors, tea consumption was inversely associated with MetS (OR, 0.79) [109].

In a comprehensive review, Yang et al. provided several examples of reports, including two epidemiological studies to demonstrate the mitigating effects of tea on MetS [7]. One example is the study by Vernarelli and Lambert in 6,472 US adults. Hot tea consumption was inversely associated with obesity, mean waist circumference, and BMI and also increased HDL cholesterol and reduced blood triglyceride levels in women [7, 92]. It should be noted that these associations were not observed with iced tea consumption.

In contrast, some studies did not show a beneficial effect of tea on MetS [7, 92]. For example, a cross-sectional study by Tsubono and Tsugane found no association between green tea intake and serum lipid levels [110]. An epidemiological study on 1,902 Japanese men and women showed no correlation between green tea intake and MetS, since green tea consumption did not influence blood pressure, abdominal circumference, fasting plasma glucose, or lipid levels [111]. The results of a cross-sectional study that enrolled 554 adults in Tokushima, Japan, showed that green tea consumption was not associated with the prevalence of MetS. Thus, epidemiological studies have provided conflicting results, which may have resulted from various factors as discussed above. Further studies are therefore required to determine whether there is an association between tea consumption and MetS [112].

3.1.2 Clinical Studies

Legeay et al. reviewed six human intervention studies and found that EGCG was associated with decreased BMI (three cases), body weight (four cases), low-density lipoprotein (LDL) cholesterol (five cases), blood pressure (three cases), triglycerides (two cases), and blood glucose (two cases) [113]. In one of these studies, a randomized, double-blind trial in 115 women with central obesity, significant weight loss, from 76.8 kg to 75.7 kg, was observed as well as decreased BMI and waist circumference after 12 weeks of high-dose EGCG treatment, with a consistent trend of reduced total cholesterol and decreased LDL plasma levels [114].

Amiot et al. conducted a systematic review of dietary polyphenols on subjects with MetS and summarized the effects of green tea and pu-erh tea extracts in ten studies [115]. These studies showed significant improvements in BMI (eight cases), weight circumference (seven cases), blood pressure (one case), LDL cholesterol

(five cases), triglycerides (four cases), and blood glucose (two cases) in subjects with MetS. One example showed that in older adults with MetS, the consumption of 3 cups of green tea per day for 60 days was effective in inducing weight loss and reducing both BMI and waist circumference [116].

3.1.3 Laboratory Studies and Mechanism of Action

A number of experiments using animal models and cultured cells have demonstrated the beneficial effects of tea consumption on MetS and its components and underlying molecular mechanism. For example, a study to evaluate the effect of GTE on drug-induced weight gain and metabolic abnormalities in rats found that GTE exerted protective effects against obesity, partially due to its lowering effect on leptin [117]. In this study, GTE significantly decreased body weight gain and average food and water intake, improved the lipid profile and fasting blood glucose levels, and decreased hyperleptinemia and hypertension in this animal model.

A study using a rat model of benign prostatic hyperplasia accompanied with MetS induced by a high-fat diet (HFD) combined with testosterone injection demonstrated that orally administered EGCG decreased the levels of glucose, total cholesterol, triglycerides, insulin-like growth factors, and inflammatory cytokines, normalized the activities of antioxidant enzymes, and increased the prostatic expression of insulin-like growth factor-binding protein-3 and peroxisome proliferator-activated receptors (PPARs) [118].

Yang et al. have described two major mechanisms of action for tea: one is the action of tea constituents in the gastrointestinal tract in decreasing the digestion and absorption of macronutrients or by altering the gut microbiota, and the other is that produced by tea constituents following systemic absorption, namely, the inhibition of anabolism and stimulation of catabolism in liver, muscle, adipose, and other tissues [7]. GTCs may decrease the digestion and absorption of nutrients through the inhibition of pancreatic lipase, phospholipases, and lipid transporters to reduce body weight gain. Furthermore, green tea consumption can increase the proportion of favorable intestinal bacteria such as *Bifidobacterium* species [7].

Yang et al. have proposed the "AMPK hypothesis," in which the activation of 5'AMP-activated protein kinase (AMPK) is the main mechanism by which EGCG and other catechins influence energy metabolism to alleviate MetS [7]. AMPK activated by phosphorylation can decrease the expression of enzymes involved in gluconeogenesis, such as phosphoenolpyruvate carboxykinase (PEPCK); lipogenesis, such as fatty acid synthase (FASN); adipogenesis; and protein synthesis, such as homolog of target of rapamycin (mTOR), and increase the expression of those involved in lipolysis, such as acyl-CoA dehydrogenase (ACAD). Activated AMPK can also modulate the expression of transcription factors such as HNF, SREBP, PPAR-α, and PPAR-γ [7]. Through the activation of AMPK, GTCs can activate the ERK1/2-PPAR-γ-adiponectin pathway, leading to a reduction in fat deposits in HFD-fed rats [119].

Thus, the AMPK hypothesis can explain many of the beneficial actions of tea/GTCs on MetS and other diseases (Fig. 2). However, it is not clear how GTCs activate AMPK. One possible explanation is the GTC-mediated generation of ROS,

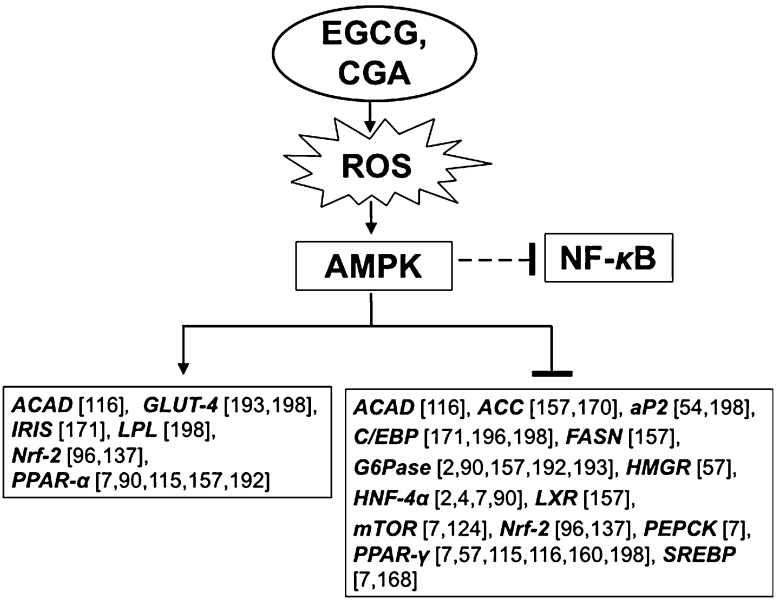

Fig. 2 EGCG and CGA as a prooxidant can modulate gene expressions via promoting ROS production. Related genes to those described in the text are shown. AMPK may possibly suppress NF-κB activity [224, 225], leading to modulation shown in Fig. 2.

which may activate AMPK (Fig. 2) [120]. On the other hand, the scavenging ROS activity of GTCs is well established (Fig. 3) [4, 107]. The factor which directs GTCs to act as either an antioxidant or a prooxidant agent thus remains to be determined.

3.2 Effects of Green Tea on Obesity

3.2.1 Epidemiological Studies

A limited number of epidemiological studies on obesity are available to date. Some of these studies have indicated a beneficial effect of tea on obesity [107]. For example, Vernarelli and Lambert found an inverse association between hot tea consumption and obesity as a component of MetS, as described above [121].

3.2.2 Clinical Studies

Several clinical studies have demonstrated a beneficial effect of tea on obesity [92, 115]. For example, in a meta-analysis of 11 studies which met the inclusion criteria, Hursel et al. found that GTCs significantly decreased body weight and also significantly maintained body weight after a period of weight loss [122].

A clinical trial in which 240 Japanese subjects with visceral fat-type obesity ingested green tea containing 583 mg of catechins (catechin group) or 96 mg of catechins (control) per day for 12 weeks found that decreases in body weight, BMI,

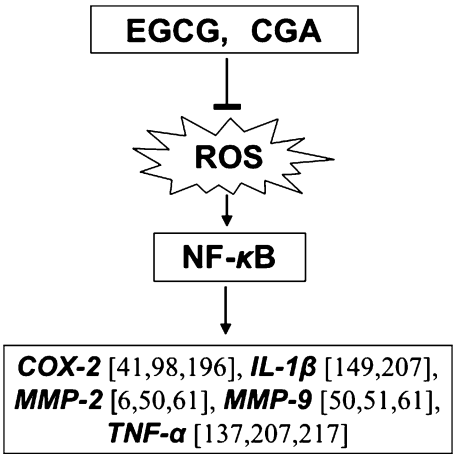

Fig. 3 EGCG and CGA as an antioxidant can modulate gene expressions via elimination of ROS. Related genes to those described in the text are shown.

body fat ratio, body fat mass, waist circumference, hip circumference, visceral fat area, and subcutaneous fat area were greater in the catechin group than in the control group [123].

As mentioned previously, Yang et al. provided several examples of studies that indicated the preventive effect of tea on MetS through the mitigation of obesity [7]. Similarly, a systematic review by Amiot et al. reported the beneficial effects of green tea on BMI [115]. In a literature search, Ferreira et al. found that six out of eight randomized intervention studies showed a beneficial effect of green tea on obesity, such as a reduction in body weight and body fat, while two studies did not [124].

Green tea may also be useful in the treatment of obesity, as suggested by Sulibursk a et al. [125]. In their randomized, double-blind, placebo-controlled study, 46 obese patients were randomly assigned to receive either 379 mg of green tea extract or placebo daily for 3 months. They found that 3 months of GTE supplementation decreased BMI, waist circumference, and the levels of total cholesterol, LDL cholesterol, and triglycerides.

By contrast, a randomized controlled trial showed that two kinds of Japanese brand green tea did not affect body weight, although they did show an LDL cholesterol-lowering effect [126].

3.2.3 Laboratory Studies

The molecular mechanisms for the anti-obesity effects of green tea have been presented in many studies, as described in above section. A comprehensive article published by Huang et al. in 2014 reviewed the anti-obesity effects of green tea in human and laboratory studies and summarized the mechanisms of action of GTC. These included (1) interference with energy absorption and metabolism to inhibit the proliferation of preadipocytes and induce apoptosis in the preadipocyte and matured adipocyte; (2) inhibition of preadipocyte differentiation and the adipogenesis of

maturing adipocytes; (3) inhibition of the activity of gastrointestinal digestive enzymes, luminal emulsification, and micellar solubilization of lipids; (4) interference with the uptake and intracellular processing of lipids and secretion of chylomicrons in enterocytes; (5) enhancement of fecal excretion; (6) downregulation of hepatic gene expression of lipogenic enzymes and related transcription factors; (7) upregulation of hepatic mRNA levels of β-oxidation genes; (8) stimulation of fatty acid oxidation and glucose uptake in skeletal muscle; (9) stimulation of the gene expression of lipolysis and fatty acid oxidation-related genes in adipose tissue; and (10) suppression of glucose intake and gene expression of lipogenesis-related genes in adipose tissue [127]. Many of these actions may be explained by the "AMPK hypothesis" of Yang et al. [7, 107] (see Fig. 2).

A recent cell-based experiment also provided one possible mechanism. In adipocytes differentiated from $C_3H_{10}T1/2$ cells and immortalized preadipocytes in vitro, EGCG reduced the triglyceride content. While EGCG did not affect protein kinase A signaling or brown adipocyte marker expression in adipocytes, it did increase autophagy and reduce mitochondrial membrane potential and intracellular ATP levels. Although mTOR signaling was not upregulated by EGCG treatment, AMPK phosphorylation was induced and lipophagy was activated. These results indicated that EGCG upregulated autophagic lipolysis in adipocytes, supporting the therapeutic potential of EGCG as a caloric restriction mimetic to prevent obesity and obesity-related metabolic diseases [128]. AMPK activation by EGCG was also demonstrated in the brown adipose tissue of diet-induced obese mice [129].

For black tea, detailed information is available in the review article by Pan et al. [130].

3.3 Effects of Green Tea on Hypertension

3.3.1 Epidemiological Studies

As compared with clinical studies, less information is available for epidemiological cohort studies on the antihypertensive effect of tea/green tea. In a cross-sectional epidemiological study of Singaporean Chinese residents aged ≥40 years, consumption of green tea at least 150 mL per week was associated inversely with hypertension risk (OR, 0.63). Drinking combination of green tea and British tea was associated with higher reduction in the risk of hypertension (OR, 0.58), suggesting that consumption of tea lowers the risk of hypertension [131]. By contrast, a study of the population-based prospective cohort that recruited 63,257 Chinese aged 45–74 years and residing in Singapore found that daily drinkers of green tea/black tea had slight increase in the hypertension risk, but these risk estimates were attenuated and became nonsignificant after adjustment for caffeine [132].

3.3.2 Clinical Studies

Several studies have demonstrated the beneficial effects of tea on blood pressure. For example, a meta-analysis of 10 studies (834 participants) published from 1946 to September 27, 2013, showed statistically significant reductions in systolic blood

pressure (SBP, mean differences −2.36 mmHg) and diastolic blood pressure (DBP, mean differences −1.77 mmHg) with tea consumption in individuals within the prehypertensive and hypertensive blood pressure ranges [133]. Similarly, a meta-analysis of 14 randomized controlled trials in 971 participants found that green tea or GTE supplementation caused a small but significant reduction in blood pressure [134].

A crossover, randomized, double-blind, placebo-controlled clinical trial in 20 middle-aged women found that GTE supplementation for 4 weeks resulted in a significant decrease in SBP compared with placebo, but not in DBP [135].

In contrast to reports describing the favorable effect of green tea on hypertension, several studies did not show such an effect. For example, Suliburska et al. found that daily supplementation of 379 mg of GTE for 3 months had no effect on blood pressure in a randomized, double-blind, placebo-controlled study in 46 obese patients, although the supplementation decreased BMI, waist circumference, and the levels of total cholesterol, LDL cholesterol, and triglycerides [125].

3.3.3 Laboratory Studies

Several laboratory studies have shown the favorable effects of green tea on hypertension and cardiovascular disease (CVD). For example, Yi et al. found that EGCG delayed the progression of hypertension in spontaneously hypertensive rats (SHR). SHR have higher mean arterial pressure, plasma pro-inflammatory cytokines, and circulating norepinephrine levels compared with normotensive control rats and also manifest increased NF-κB activity and higher levels of the subunit of NAD(P)H oxidase, ROS, and pro-inflammatory cytokines and lower levels of IL-10 in the hypothalamic paraventricular nucleus. The bilateral hypothalamic paraventricular nucleus infusion of EGCG (20 μg/hour) for 4 weeks improved these parameters in SHR, and the involvement of ROS and NF-κB activity in the mechanism of action of EGCG was suggested [136] (see Fig. 3).

In another experiment in rats fed a high-NaCl diet, supplementation with GTE was shown to reduce blood pressure, concentration of TNF-α, and antioxidant status compared with a control group that did not receive GTE [137].

Kluknavsky et al. found that subchronic (−)-epicatechin (EC) (Fig. 1) significantly prevented the development of hypertension, increased the total antioxidant capacity of blood, and decreased blood nitrotyrosine concentration in young SHR. In the aorta, EC significantly increased nitric oxide (NO) synthase (NOS) activity and elevated NO-dependent vasorelaxation [138]. These findings suggest that a pathway involving ROS and NF-κB is associated with the antihypertensive activity of EGCG.

In addition, the direct action of EGCG on angiotensin I-converting enzyme (ACE) may also mediate its antihypertensive effect. Takagaki and Nanjo demonstrated that EGCG and its metabolites produced by intestinal bacteria showed inhibitory activity against ACE and that a single oral intake of metabolites decreased SBP in SHR [139]. A molecular docking mechanism may explain the potential of EGCG as a new class of ACE inhibitors. Further chemical modification via fragment modification guided by structure and ligand-based computational methodologies may lead to the discovery of better inhibitors as clinical candidates [140].

3.4 Effects of Green Tea on Diabetes

3.4.1 Epidemiological Studies

Many epidemiological studies have reported the antidiabetic effects of tea and GTE [92]. For example, Panagiotakos et al. reported that long-term tea intake reduced levels of fasting blood glucose and was associated with a lower prevalence of diabetes. In a cohort of 937 older adults living on Mediterranean islands, the consumption of 1–2 cups/day of green tea and/or black tea was associated with 70% lower odds of developing type 2 diabetes mellitus (T2DM), irrespective of age, sex, body mass, smoking, physical activity status, dietary habits, and other clinical characteristics [141]. In a literature review of the antidiabetic effects of tea, Fu et al. identified six, ten, and one epidemiological studies published from 2006 to 2016 showing the beneficial effects of green tea, black tea, and oolong tea, respectively [142].

However, several epidemiological studies failed to demonstrate antidiabetic effects [92, 142]. For example, Pham et al. found a rather positive association between green tea consumption and insulin resistance in 1,440 participants aged 18–69 years [143]. Thus, further studies are necessary to confirm the antidiabetic effects of tea in human subjects.

3.4.2 Clinical Studies

A number of intervention studies have reported the antidiabetic effect of green tea [92]. For example, a randomized controlled trial conducted in 66 Japanese T2DM patients found that daily ingestion of GTE containing 544 mg catechins for 2 months caused significant reductions in hemoglobin A1c (HbA1c) levels and DBP [144]. Similarly, a 2-month intervention study in 60 patients with mild hyperglycemia showed that the daily ingestion of GTE decreased the HbA1c level, although other biomarkers were unaffected [145].

In a randomized, double-blind, placebo-controlled trial performed in 92 Taiwanese subjects, the ingestion of 500 mg GTE three times a day for 16 weeks ameliorated the expression levels of an insulin resistance marker and the secretion of glucagon-like peptide-1 in T2DM patients [146]. In a double-blind randomized intervention study in nondiabetic overweight or obese male subjects in the United Kingdom, Brown et al. found that twice-daily ingestion of 400 mg EGCG for 8 weeks resulted in reduced DBP, although no significant effects on glucose tolerance, insulin sensitivity, or insulin secretion were observed [147].

In a randomized, double-blind study in 42 diabetic subjects with a urinary albumin-creatinine ratio >30 mg/g, patients were randomly assigned to two groups to receive either GTP containing 800 mg of EGCG (17 patients with T2DM and 4 with type 1 diabetes) or placebo (21 patients with T2DM) for 12 weeks. The results indicated that GTP reduced the urinary albumin-creatinine ratio by 41%, while the placebo group had a 2% increase, suggesting that GTP may reduce the risk of diabetic nephropathy [148].

In contrast, several intervention studies found no beneficial effects of green tea on diabetes. For example, a double-blind, placebo-controlled, randomized multiple-dose (0, 350, or 750 mg catechins and theaflavins for 3 months) study

conducted in the United States showed no effect on the level of HbA1c in patients with a medical history of diabetes of more than 6 months [149]. A crossover randomized controlled trial in southern Sweden showed that no glucose or insulin-lowering effects were demonstrated by the consumption of 300 mL of green tea or water [150].

Furthermore, a meta-analysis of randomized controlled trials found that the consumption of green tea did not decrease the levels of fasting plasma glucose, fasting serum insulin, hemoglobin HbA1c, or the insulin resistance index in populations at risk of T2DM [151]. Thus, clinical trials in humans on the effects of green tea in diabetes have demonstrated conflicting results. The discrepancy may be explained as discussed in the previous section.

3.4.3 Laboratory Studies and Mechanism of Action

Multiple studies using cultured cells and laboratory animals have demonstrated the antidiabetic effects of green tea and GTCs [92, 152].The underlined mechanisms include (1) inhibition of α-amylase and α-glucosidase activity, (2) inhibition of glucose absorption in the small intestine, (3) protection of pancreatic β-cells, (4) improvement of insulin sensitivity in peripheral organs, and (5) inhibition of glucose production from noncarbohydrates such as amino acids in the liver, known as gluconeogenesis.

Inhibition of α-amylase and α-glucosidase results in reduced glucose production leading to the prevention and suppression of diabetes by impeding the rise in blood sugar levels [92, 152]. Similarly, the inhibition of glucose absorption in the small intestine suppresses the increase in blood sugar levels [92, 152]. Improvements in insulin sensitivity would result in the rapid suppression of blood glucose levels by promoting glucose uptake by peripheral tissues. Green tea ingredients such as EGCG have exhibited insulin-like activity in terms of increased glucose uptake [153]. EGCG may also protect insulin-secreting pancreatic β-cells from injury since EGCG protected IL-1β and interferon (IFN)-γ-mediated cytotoxicity in an insulinoma cell line, presumably through the inhibition of NF-κB activation [154] (see Fig. 3).

Several studies have reported inhibitory effects of EGCG on gluconeogenesis. EGCG exhibited insulin-like activity by suppressing the gene expression of gluconeogenic enzymes, glucose-6-phosphatase (*G6Pase*), and phosphoenolpyruvate carboxykinase [155]. One of the proposed mechanisms is the suppression of transcription factor, hepatocyte nuclear factor-4α (HNF4α) expression by EGCG, leading to a decrease in expression of these gluconeogenic enzymes and resulting in diminished glucose production [2, 92]. The suppressive action of EGCG on HNF4α expression may be explained by its prooxidative activity to generate ROS, leading to the activation of AMPK which is known to inhibit HNF4α expression [2, 4] (see Fig. 2). Collins et al. postulated that ROS was involved in the activation of AMPK by EGCG and the suppression of hepatic gluconeogenesis [120].

In addition, several other mechanisms have been proposed for the antidiabetic activity of tea. These include (1) improvement of endothelial dysfunction, (2) modulation of cytokine expression, and (3) amelioration of insulin resistance,

as reviewed by Fu et al. [142]. These authors pointed out the involvement of GTCs in the modulation of gene expression under its antidiabetic effects [142]. GTE may increase the mRNA levels of glucose transporter family proteins. EGCG can also attenuate the formation of advanced glycation end products; activate Nrf2, which regulates the expression of antioxidant proteins protecting against oxidative damage; and inhibit the expression of the AGE receptor. Green tea decreases the expression of receptor activator of NF-κB and pro-inflammatory cytokine TNF-α in a rat model of diabetes and increases anti-inflammatory cytokine IL-10. EGCG may also suppress the expression of genes related to inflammation such as *IL-1β*, *TNF-α*, *IL-6*, *CD11s*, *CD18*, and *MCP-1* in adipose tissues in another animal model [142] (see Fig. 3).

3.5 Effects of Coffee on Metabolic Syndrome and Related Disorders

3.5.1 Epidemiological Studies

Hino et al. conducted a population-based health check in 1999 and found that all components of MetS (blood pressure, waist circumference, fasting plasma glucose, and lipid profiles) except for HDL cholesterol were inversely related to the consumption of coffee but not of green tea after adjusting for confounding factors [111].

Using the PubMed, Embase, Scopus, and Science Direct databases, Yesil et al. found that four out of six human studies showed an inverse association between coffee consumption and the risk of MetS, although two studies showed no such association in a cohort consisting of young persons with a low prevalence of MetS [156].

In addition, the following studies reported beneficial effects of coffee. From May 2009 to December 2010, a cross-sectional survey was conducted on 1,889 inhabitants living in Sicily, southern Italy. As a result, coffee consumption (OR, 0.43) was found to be associated inversely with MetS after adjusting for all covariates. No association was observed between caffeine intake and MetS. Triglycerides were inversely associated with the consumption of espresso coffee. Thus, coffee consumption was demonstrated to have a reduced OR for MetS [108].

Results from a cross-sectional population-based survey including 8,821 adults showed that high coffee drinkers had lower BMI, waist circumference, SBP and DBP, and triglycerides and higher HDL cholesterol than those drinking < 1 cup/day. After adjusting for potential confounding factors, higher coffee consumption was demonstrated to be inversely associated with MetS (OR, 0.75) [109].

A Mendelian randomization study with 93,179 individuals from two large general population cohorts found that in a cross-sectional analysis, there was a lower risk of MetS with higher coffee intake. Compared with individuals with no coffee intake, ORs for MetS were 0.91, 0.89, 0.88, 0.83, 0.84, and 0.89 for 0.1–1, 1.1–2, 2.1–3, 3.1–4, 4.1–5, and >5 cups/day, respectively [157].

Shang et al. conducted a meta-analysis of 11 studies published between January 1999 and May 2015 with a total of 159,805 participants to determine the association between coffee intake and MetS risk. The aggregated result for the highest versus

lowest category of coffee consumption was 0.872, suggesting that coffee consumption was associated with a reduced risk of MetS [158]. A cross-sectional study of a random sample of 5,146 participants aged ≥20 years found that moderate drinkers had 17% lower odds of developing MetS compared with nondrinkers. Tea consumption was related to some components, but not to MetS in general [159].

Although these findings appear to show beneficial effects of coffee on MetS, caution should be taken as coffee, particularly instant coffee mix, may have a potentially harmful effect arising from the excessive intake of sugar and powdered creamer [160].

3.5.2 Clinical Studies

Several clinical studies on the effect of coffee and CGAs have been reported. Patti et al. evaluated the impact of a natural supplement, Kepar, which contains several plant extracts such as curcuma longa, silymarin, guggul, CGAs, and inulin, in 78 patients with MetS. Although Kepar exerted beneficial effects on body weight, BMI, and waist circumference, fasting glucose and total cholesterol levels, further studies are required to verify whether CGAs indeed contribute to these effects [161].

Santana-Gálvez et al. reviewed several clinical trials to evaluate the effects of CGA on the prevention and treatment of obesity and hypertension, which are the component disorders of MetS. These studies are discussed in the Sects. 3.6.2 and 3.7.2 [162].

3.5.3 Laboratory Studies and Mechanism of Action

Many studies have evaluated the effect of CGA on MetS or associated disorders, including obesity, dyslipidemia, diabetes, and hypertension. Santana-Galvez et al. reviewed the literature and found the beneficial effects of CGA on MetS and its components [162].

Similarly, Yesil and Yilmaz identified three animal studies on the effects of coffee on MetS and five on the risk of fatty liver infiltration. All showed a protective effect of coffee against the development of MetS and nonalcoholic fatty liver disease (NAFLD) [156].

In a study investigating the effects of Colombian coffee extract in an animal model of MetS, rats were fed a corn starch-rich diet, whereas two other groups were given a high-carbohydrate, HFD with 25% fructose in drinking water for 16 weeks. The high-carbohydrate, HFD group showed the symptoms of MetS leading to cardiovascular remodeling and NAFLD. Colombian coffee extract supplementation attenuated the impaired glucose tolerance, hypertension, cardiovascular remodeling, and NAFLD without affecting abdominal obesity and dyslipidemia. This study suggests that Colombian coffee extract can attenuate diet-induced changes in the structure and function of the heart and the liver without changing abdominal fat deposition [163].

Tsumura-Suzuki obese diabetic mice are a newly developed MetS model which spontaneously exhibits obesity, diabetes, hyperlipidemia, and nonalcoholic steatohepatitis with liver nodules. When animals were divided into two coffee intake groups (with and without caffeine), coffee intake did not affect obesity and

hyperlipidemia. However, coffee intake caused various degrees of improvement in pancreatic β-cell damage and steatohepatitis with liver carcinogenesis. Most of the effects were likely caused by a synergistic effect of caffeine with other components such as polyphenols, and the anti-fibrotic effects of coffee appeared to be attributable to the polyphenols rather than the caffeine [164].

Ma et al. conducted two sets of experiments. In one experiment, 6-week-old C57BL/6 mice were fed regular chow or HFD for 15 weeks with twice-weekly intraperitoneal injection of CGA (100 mg/kg) or vehicle. In another experiment, obese mice (average weight of 50 g) received intraperitoneal injection of CGA (100 mg/kg, twice a week) or vehicle for 6 weeks. CGA significantly inhibited the development of diet-induced obesity but did not affect body weight in the obese mice. CGA treatment also curbed HFD-induced hepatic steatosis and insulin resistance; suppressed the hepatic expression of *PPAR-γ*, *Cd36*, *Fabp4*, and *Mgat1* genes; and attenuated inflammation in the liver and white adipose tissue accompanied by a decrease in mRNA levels of macrophage marker genes including *F4/80*, *Cd68*, *Cd11b*, *Cd11c*, and *TNF-α*, *Mcp-1*, and *Ccr-2* encoding inflammatory proteins. These results suggest that CGA is a potent compound for preventing diet-induced obesity and obesity-related MetS [165].

Santana-Galvez et al. proposed a possible mechanism of action for CGA, whereby it may act as an antioxidant to reduce ROS, which stimulate inflammation leading to fat accumulation, weight gain, and insulin resistance (see Fig. 3). The antioxidative activity of CGA may also stimulate NO production, leading to an improvement in endothelial function and blood pressure. CGA may also improve lipid metabolism by downregulating transcriptional factors such as LXRα and PPAR and the gene expression of enzymes such as FASN, acetyl-CoA carboxylase (ACC), and HMGCR and by upregulating PPAR-α, adiponectin, and AMPK phosphorylation [162] (see Fig. 2).

Although these studies support a beneficial effect of CGA in MetS, others failed to show such effects. For example, in a controlled dietary intervention of over 12 weeks in which male C57BL/6 mice were divided into three groups: (i) normal diet, (ii) HFD, and (iii) HFD plus CGA (1 g/kg of diet), Mubarak et al. found that CGA supplementation in mice fed HFD did not reduce body weight compared with mice fed HFD alone. CGA caused increased insulin resistance compared with mice fed HFD and led to reduced phosphorylation of AMPK and ACC-β, a downstream target of AMPK in the liver. The livers of mice fed an HFD supplemented with CGA had a higher lipid content and more steatosis relative to mice fed an HFD, indicating impaired fatty acid oxidation. This study suggests that CGA supplementation in HFD does not protect against the characteristics of MetS in diet-induced obese mice [166].

3.6 Effects of Coffee on Obesity

3.6.1 Epidemiological Studies

Few studies have been published on the effect of coffee on obesity. The result of cross-sectional analyses in a Mendelian randomization study showed that higher

coffee intake of up to 4 cups/day was associated with a lower risk of obesity. Compared with individuals with no coffee intake, ORs were 0.82, 0.86, 0.86, 0.83, 0.95, and 1.02 for 0.1–1, 1.1–2, 2.1–3, 3.1–4, 4.1–5, and >5 cups/day, respectively [157]. A study on 137 patients with NAFLD and 108 controls found that coffee consumption was inversely associated with insulin resistance and obesity [167].

3.6.2 Clinical Studies

Several clinical studies have reported the effects of coffee or CGAs on obesity. In a meta-analysis of randomized clinical trials, Onakpoya et al. found a significant reduction (−2.47 kg) in body weight in a green coffee extract-treated group compared with placebo. The magnitude of the effect was moderate, and there was significant heterogeneity among the studies. The authors summarized that the results from these trials were promising but that the studies were of poor methodological quality. More rigorous trials are thus required to assess the usefulness of green coffee extract as a weight-loss tool [168].

In a randomized controlled trial, overweight men with a mild-to-moderate elevation of fasting plasma glucose were randomly allocated to a 16-week intervention of the consumption of 5 cups of caffeinated ($n = 17$) or decaffeinated ($n = 15$) instant coffee per day or no coffee ($n = 13$). The results indicated that waist circumference decreased by 1.5 cm in the caffeinated coffee group, increased by 1.3 cm in the decaffeinated coffee group and decreased by 0.6 cm in the non-coffee group. Body weight at 16 weeks showed a similar pattern; the corresponding changes from baseline were −1.1 kg, 0.5 kg, and −0.6 kg, respectively. The authors proposed that the decreases in the caffeinated coffee group were attributable to caffeine, which increases thermogenesis and fat oxidation [169].

In a review article, Santana-Gálvez et al. listed two clinical studies showing the effect of CGA on obesity [162]. One study was a randomized, double-blind, 12-week study in 30 overweight people. The result indicated that the average loss in body weight among subjects who consumed CGA-enriched coffee was 5.4 kg, while that in the normal instant coffee groups was 1.7 kg, suggesting a beneficial effect of CGA on body weight reduction [170]. Another study was a placebo-controlled, double-blind, crossover intervention study in 18 healthy male subjects in which those who consumed 185 mL of a test beverage with or without CGAs (329 mg) per day for 4 weeks showed no effects on body weight, BMI, or body fat, although a significantly higher postprandial energy expenditure was observed in the CGA group compared with the control group [171]. Thus, further studies are required to determine the effects of coffee and CGAs on obesity.

3.6.3 Laboratory Studies and Mechanism of Action

A number of laboratory studies have provided evidence for the anti-obesity effect of coffee and its mechanism of action. Hsu et al. found that the addition of coffee phenols to culture medium decreased the cell growth of 3T3-L1 preadipocytes. The IC_{50} values of CGA, gallic acid, *o*-coumaric acid, and *m*-coumaric acid on the preadipocytes were 72.3, 43.3, 48.2, and 49.2 μM, respectively. A relationship analysis indicated that there was a linear correlation between the influence of

phenolic acids on cell growth and their antioxidant activity. The treatment of preadipocytes with CGA, *o*-coumaric acid, and *m*-coumaric acid caused cell cycle arrest in the G1 phase. These results suggest that coffee phenols have anti-obesity effects [172].

When C57BL/6 J mice were fed a control diet, HFD, or HFD supplemented with 0.5–1.0% coffee polyphenols (CPP) for 2–15 weeks, CPP supplementation reduced body weight gain, abdominal and liver fat accumulation, and infiltration of macrophages into adipose tissues. The mRNA levels of sterol regulatory element-binding protein (SREBP)-1c, ACC-1 and -2, stearoyl-CoA desaturase-1, and pyruvate dehydrogenase kinase-4 in the liver were also significantly lower in CPP-fed mice than in HFD and control mice (see Fig. 2). Similarly, CPP suppressed the expression of these molecules in Hepa 1-6 cells, concomitant with an increase in microRNA-122. Structure-activity relationship studies of nine quinic acid derivatives isolated from CPP suggested that CGA and di-caffeoylquinic acids were active substances in the beneficial effects of CPP in these cells. Furthermore, CPP and 5-CQA decreased the nuclear active form of SREBP-1, ACC activity, and cellular malonyl-CoA levels. These findings indicate that CPP enhances energy metabolism and reduces lipogenesis by downregulating SREBP-1c and related molecules, leading to the suppression of body fat accumulation [173].

When a commercially available supplement composed of cocoa, coffee, green tea, and garcinia which contains 196 mg/g of total polyphenols and 4.0 mg/g of EGCG was given to high-energy diet (HED)-induced obese rats, a reduction was observed in the levels of free fatty acids, triglycerides, total cholesterol, LDL-C, and LDL-C/HDL-C, AST, ALT, and ketone bodies in serum as well as hepatic triglycerides and total cholesterol content, while the levels of HDL-C in serum and lipase activity in fat tissues increased compared with the HED group. These results suggest that the supplement stimulated lipid metabolism in HED-induced obese rats through fat mobilization from adipose tissue [174].

When hyperlipidemia was induced in Wistar rats using HFD, the animals given CGA complex from green coffee bean, CGA7 (50, 100, and 150 mg/kg body weight), showed decreased triglycerides and free fatty acid levels in plasma and the liver compared with the control group. CGA7 administration led to the activation of AMPK and a subsequent increase in the levels of carnitine palmitoyltransferase 1 and a decrease in ACC acetyl-CoA carboxylase (ACC) activity (see Fig. 2). These results suggest that CGA7 complex may be suitable as an active ingredient in nutrition for obesity management [175].

Maki et al. found that coffee intake significantly suppressed HFD-induced metabolic changes such as increased body weight and the accumulation of adipose tissue and the upregulation of glucose, free fatty acid, total cholesterol, and insulin levels in the blood. In the early phase of adipogenesis, 3T3-L1 cells treated with coffee extract displayed delayed cell cycle entry into the G2/M phase, termed as mitotic clonal expansion. Coffee extract also inhibited the activation of CCAAT/enhancer-binding protein β (C/EBP-β) by preventing its phosphorylation by ERK and suppressed adipogenesis-related events such as mitotic clonal expansion and C/EBP-β activation through the downregulation of insulin receptor substrate 1 (IRS1). The stability of the IRS1 protein was markedly

decreased by treatment with coffee extract, due to proteasomal degradation. These results showed an anti-adipogenic function for coffee intake and identified IRS1 as a novel target for coffee extract in adipogenesis [176].

Although these results indicate the favorable effects of coffee and/or its extract in obesity, several other studies do not support these findings. For example, Cheong et al. carried out a study in which C57BL6 mice were randomly divided into the following experimental groups: (i) normal diet, (ii) HFD, or (iii) HFD supplemented with 0.5% w/w GCE rich in CGA. The results showed that groups (ii) and (iii) displayed MetS symptoms more profoundly than group (i) and that GCE did not attenuate HFD-induced obesity, glucose intolerance, insulin resistance, or systemic oxidative stress [177].

3.7 Effects of Coffee on Hypertension

3.7.1 Epidemiological Studies

A meta-analysis of 7 cohorts including 205,349 individuals showed a 9% significant decreased risk of hypertension per 7 cups of coffee per day in a nonlinear analysis, while in a linear dose-response association, there was a 1% decreased risk of hypertension for each additional cup of coffee per day. The analysis also suggested smoking as an important confounder [178].

In contrast, a large prospective study during 112,935 person-years of follow-up in 5,566 cases of incident hypertension showed that neither caffeinated coffee nor caffeine intake was associated with mean SBP or DBP but that decaffeinated coffee intake was associated with a small but clinically irrelevant decrease in mean DBP. Decaffeinated coffee intake was not associated with mean SBP. Thus, no anti-hypertension effects were demonstrated, but caffeinated coffee, decaffeinated coffee, and caffeine appeared not to be risk factors for hypertension in postmenopausal women [179].

A cross-sectional study conducted in 2012 among 1,164 individuals aged $\geq$63 years showed that among the 715 hypertensive participants, those consuming $\geq$3 cups of coffee per day showed higher 24-hour SBP and DBP than non-coffee drinkers. Compared with non-coffee drinkers, ORs for uncontrolled BP among those consuming 1, 2, and $\geq$3 cups of coffee/day were 1.95, 1.41, and 2.55, respectively [180].

3.7.2 Clinical Studies

Santana-Gálvez et al. reviewed human studies on the effects of CGA on blood pressure and found that CGA or coffee extracts reduced SBP and DBP in three out of four human intervention studies [162]. In a similar approach, Tajik et al. found that five out of six human intervention studies showed favorable effects on blood pressure [181]. One example is the report by Revuelta-Iniesta and Al-Dujaili, who conducted a randomized pilot crossover study in healthy subjects. The results indicated that green coffee consumption reduced SBP, arterial elasticity, BMI, and abdominal fat [182].

3.7.3 Laboratory Studies and Mechanism of Action

Several studies have demonstrated the beneficial effects of CGA on blood pressure and suggested the underlying molecular mechanisms. Suzuki et al. demonstrated that a single ingestion of CGA (30–600 mg/kg) reduced blood pressure in SHR, an effect that was blocked by the administration of an NOS inhibitor, *N(G)*-nitro-L-arginine methyl ester. When SHR were fed diets containing 0.5% CGA for 8 weeks (approximately 300 mg/kg per day), the development of hypertension was inhibited. The authors proposed, as the underlying mechanism, that dietary CGA reduces oxidative stress and improves NO bioavailability by inhibiting the excessive production of ROS in the vasculature, leading to the attenuation of endothelial dysfunction, vascular hypertrophy, and hypertension in this animal model [183].

Zhao et al. summarized that CGA may exert an antihypertension effect through (1) inhibition of NAD(P)H oxidase expression and activity, leading to reduction in free radical production; (2) direct free radical scavenging; (3) stimulation of NO production by the endothelial-dependent pathway; and (4) inhibition of ACE in the plasma and possibly also in the organs and tissues. The anti-inflammatory effects of CGA may also contribute to the effect [184].

3.8 Effects of Coffee on Diabetes

3.8.1 Epidemiological Studies

Ding et al. conducted a systematic review and meta-analysis of 28 prospective studies with 1,109,272 participants and 45,335 cases of T2DM for coffee consumption and disease risk. The results showed that compared with no or rare coffee consumption, RR for diabetes was 0.92, 0.85, 0.79, 0.75, 0.71, and 0.67 for 1–6 cups/day, respectively. Thus, the decreases in RRs for every 1 cup/day were 9% for caffeinated coffee consumption and 6% for decaffeinated coffee consumption, indicating that the consumption of both types of coffee is inversely associated with the risk of T2DM [185].

Based on three large cohort studies of men and women in the United States, Bhupathiraju et al. found that coffee consumption was associated with a lower risk of T2DM. During 1,663,319 person-years of follow-up, participants who increased their coffee consumption by >1 cup/day over a 4-year period had an 11% lower risk of T2DM in the subsequent 4 years compared with those who made no changes in consumption. Participants who decreased their coffee intake by >1 cup/day had a 17% higher risk for T2DM [186].

In another study in 90,317 US adults, where 8,718 deaths occurred during 805,644 person-years of follow-up from 1998 through 2009, coffee drinkers had a lower HR for several diseases, including diabetes, compared with nondrinkers [187].

Nordestgaard et al. conducted a Mendelian randomization study among 93,179 individuals from two large general population cohorts. The results indicated that higher coffee intake was associated with a lower risk of obesity, MetS, and T2DM. However, per-allele meta-analyzed ORs for T2DM were in the range of 0.98–1.01,

indicating that there was no genetic evidence to support corresponding causal relationships [157].

In 2001–2002, a random sample of 1,514 men and 1,528 women was selected to participate in a study in the Athens metropolitan area in Greece. This 10-year follow-up study showed that individuals who consumed ≥250 mL of coffee had 54% lower odds of developing diabetes compared with abstainers, indicating the significance of long-term habitual coffee drinking in the onset of diabetes. The inverse association between habitual coffee drinking and diabetes was suggested to be mediated by serum amyloid-A levels [188].

A cross-sectional study in a large Brazilian cohort of 12,586 middle-aged and older individuals provided evidence of a protective effect of coffee on the risk of adult-onset diabetes. The results showed 23% and 26% lower odds of diabetes among those consuming coffee 2–3 and >3 times per day, respectively, compared with those reporting no or almost no consumption of coffee. An inverse association was also found for 2-hour post-load glucose but not for fasting glucose concentrations, suggesting the action of coffee on postprandial glucose homeostasis [189].

A population-based cohort study over a follow-up period of 4 years was conducted to examine the association between habitual coffee intake and the risk of T2DM and to determine whether this association varied by genetic polymorphisms related to T2DM. The results on 4,077 Korean adults aged 40–69 years with a normal glucose level at baseline showed an inverse association between coffee intake and the combined risk of T2DM and prediabetes. This inverse association was found among individuals with the GT/TT of IGF2BP2 rs4402960, GG/GC of CDKAL1 rs7754840, or CC of KCNJ11 rs5215 polymorphisms, which are known to be related to T2DM in East Asians [190].

The European Prospective Investigation into Cancer and Nutrition-Potsdam study involving 27,548 middle-aged participants found that coffee consumption was inversely associated with diacyl-phosphatidylcholine and liver injury markers in both sexes and positively associated with certain acyl-alkyl-phosphatidylcholines in women. Coffee consumption showed an inverse relationship with C-reactive protein in women and with triglycerides and phenylalanine in men. These findings may partly explain the inverse association between long-term coffee consumption and T2DM risk [191].

A population-based cohort study on first-trimester coffee and tea intake and risk of gestational diabetes among 71,239 nondiabetic women with singleton pregnancies showed that moderate first-trimester coffee and tea intake was not associated with the risk of gestational diabetes and possibly may have a protective effect [192].

A recent review article based on review papers from in vivo, ex vivo, and in vitro experimental studies in animals and human tissues as well as epidemiological studies reported a reduced risk of developing T2DM in regular coffee drinkers of 3–4 cups a day. The effects were proposed as attributable to CGAs and caffeine [193].

In a cross-sectional epidemiological study aimed to investigate the mechanism of the association of coffee with liver injury, caffeinated coffee showed a significant inverse association with ALT, AST, and NAFLD liver fat score but not with fetuin-A, another liver injury marker. However, there was no significant association

between decaffeinated coffee intake and markers of liver injury. These results indicate a beneficial impact of caffeinated coffee on liver morphology and/or function and suggest that this relationship may mediate the inverse association of coffee with risk of T2DM [194].

By reviewing the literature, Chrysant concluded that coffee consumption has either neutral or beneficial effects on blood pressure, CVD, heart failure, cardiac arrhythmias, and diabetes, and that the established concept that coffee consumption is a risk factor for hypertension, heart disease, or diabetes is no longer warranted, although some caution should be exercised in vulnerable populations [195].

3.8.2 Clinical Studies

Santana-Gálvez et al. reviewed clinical trials to evaluate the effects of CGA on MetS-related diseases and found that five studies showed beneficial effects on diabetes [162]. One such study was a randomized crossover trial for the effects of 12 g decaffeinated coffee, 1 g CGA, and placebo (1 g mannitol) on glucose and insulin concentrations during a 2-hour oral glucose tolerance test in 15 overweight men. The results indicated that CGA ingestion significantly reduced blood glucose and insulin concentrations [196].

3.8.3 Laboratory Studies and Mechanism of Action

Evidence has been accumulating to support the beneficial effects of CGA on diabetes in cell-based and animal experiments. A comprehensive review by Meng et al. indicated that CGA stimulated glucose uptake in murine adipocytes and L6 muscle cells and inhibited G6Pase in hepatic cells [197]. It also reported that more than ten animal experiments found favorable effects of CGA such as improvement in blood glucose levels, glucose tolerance, and insulin resistance and inhibition of α-glucosidase, together with AMPK activation and the upregulation of hepatic PPAR-α [197] (see Fig. 2).

Similarly, a recent review of five animal studies found that CGA had beneficial effects in diabetes through a reduction in the levels of blood glucose and HbA1c, prevention of the development of sugar cataracts, acceleration of wound healing, and inhibition of hepatic G6Pase levels [162].

In an experiment in which female db/db mice were administered 80 mg/kg/day CGA by lavage for 12 weeks, the percentage of body fat and the fasting plasma HbA1c level decreased compared with that in the control group; transforming growth factor-β1 protein expression and aldose reductase activity in the kidney also decreased, while the adiponectin level in visceral adipose increased. CGA significantly upregulated phospho-AMPK in the liver and skeletal muscle and downregulated G6Pase in the liver, while upregulating GLUT4 (see Fig. 2). Thus, CGA lowered the levels of fasting plasma glucose and HbA1c during late diabetes and improved kidney fibrosis through the modulation of adiponectin receptor signaling pathways in db/db mice [198].

Several other investigations also demonstrated the beneficial effects of CGA in diabetes. For example, in a study aimed to investigate whether short-term treatment with plant polyphenols, including CGA, could improve endothelial dysfunction related to diabetes, streptozotocin-induced diabetic mice received CGA (0.03 mmol/kg/day) by injection for 5 days. This treatment improved the NO components of relaxation without the normalization of acetylcholine-stimulated NO production. In addition, CGA treatment suppressed the acetylcholine-stimulated level of thromboxane B2 in aortas from streptozotocin-induced diabetic mice. Thus, the treatment caused basal NO production and a prompt improvement in endothelial function in diabetic mice, which may involve the normalization of thromboxane B2 levels but not NO production under acetylcholine stimulation [199].

In an animal experiment to evaluate the effects of CGA on diabetic auditory pathway impairment, CGA was shown to prevent the progression of auditory pathway dysfunction caused by diabetes. The study also found that CGA may aid in the recovery from outer hair cell and otic hair cell damage. Thus, CGA appears to have beneficial effects in the management of diabetic sensorineural auditory dysfunction [200].

There is a possibility that CGA can protect kidney function against oxidative stress in diabetic nephropathy. Ye et al. showed that CGA decreased the levels of blood glucose, blood urea nitrogen, and serum creatinine in a rat model of diabetic nephropathy. CGA increased the activity of superoxide dismutase, glutathione peroxidase, and catalase and decreased the level of lipid peroxidation. Immunohistochemical analysis showed that CGA downregulated COX-2 protein expression in renal tissues. In addition, CGA blocked the expression of activating transcription factor-6 and C/EBP homology protein as well as the phosphorylation of eukaryotic initiation factor 2α and double-stranded RNA-activated protein kinase-like endoplasmic reticulum kinase. These findings suggest that CGA attenuates oxidative stress in diabetic nephropathy, leading to modulation of the endoplasmic reticulum signaling pathway [201].

In alloxan-induced diabetic rats, oral administration of aqueous infusions of *Artemisia herba-alba Asso* and *Ajuga iva Schreber*, used in folk medicine, was shown to reduce blood glucose levels. Since *A. herba-alba* infusion contains CGA as the main compound, CGA may contribute to this effect [202].

On the other hand, some studies did not show the beneficial effects of CGA in diabetes. For example, in a study using 3T3-L1 cells, coffee was shown to reduce the accumulation of lipids during adipocytic differentiation of these cells, which may explain the antidiabetic action of coffee. Coffee also inhibited expression of PPAR-γ, a transcription factor which upregulates the differentiation of adipocytes. However, CGA showed no effect on *PPAR-γ* gene expression, suggesting that CGA does not contribute to the antidiabetic activity of coffee [203].

In a study aimed to determine whether bioactive substances in coffee increase insulin secretion from β-cells and improve insulin sensitivity in skeletal muscle cells, cafestol and caffeic acid but not CGA were found to increase insulin secretion, both acutely and chronically [204].

3.9 Comparison of the Effects of Tea and Coffee in Simultaneous Studies on Metabolic Syndrome and Related Disorders

A cross-sectional epidemiological study among Singaporean Chinese residents aged ≥40 years reported that drinking at least 150 mL green tea per week was associated with lower hypertension risk (OR, 0.63). Drinking a combination of green tea and British tea was associated with a higher reduction in the risk of hypertension (OR, 0.58). In contrast, consumption of coffee (OR, 1.44–1.46) was found to be a potential risk factor for hypertension [131].

A population-based prospective cohort study among 63,257 Singapore Chinese aged 45–74 years found that, compared to those who drank 1 cup of coffee/day, the HRs were 0.87 for <1 cup/week drinkers and 0.93 for ≥3 cups/day drinkers. Compared to <1 cup/week drinkers, daily drinkers of black or green tea had a slight nonsignificant increase in risk, after adjustment for caffeine. Compared with the lowest caffeine intake (<50 mg/day) group, the highest caffeine intake (≥300 mg/day) group had a 16% increase in risk [132].

In a study of the effects of tea and coffee consumption in cardiovascular diseases and risk factors such as hypertension, hyperglycemia, and hyperlipidemia, Di Lorenzo et al. concluded that data from the clinical literature showed that tea consumption reduced some risk factors, especially in overweight people and obese subjects. For coffee, the results were controversial and did not allow conclusions to be drawn [205].

4 Effects on Liver Disease

4.1 Effects of Green Tea on Liver Disease

4.1.1 Epidemiological Studies

Several human studies have indicated that GTC has beneficial effects in liver diseases such as hepatitis, hepatoma, and liver fibrosis [92]. In a meta-analysis of studies published from 1995 to 2014, Yin et al. found that there was a significant reduction in the risk of liver disease with GTC intake. RRs were 0.74, 0.65, 0.57, 0.56, and 0.49 for hepatocellular carcinoma, liver steatosis, hepatitis, liver cirrhosis, and chronic liver disease, respectively [206].

A retrospective cross-sectional study on 1,018 patients with NAFLD, HCV, and HBV infection found that patients who drank ≥2 cups of coffee per day had a lower liver stiffness, which is indicative of less fibrosis and inflammation, but that tea consumption had no effect [207].

4.1.2 Clinical Studies

Only a few studies have examined the effects of green tea in liver disease. In a clinical experiment on nine cases of intractable chronic hepatitis C with a high viral load of >850 kIU/mL, Sameshima et al. found that combination therapy of 6 g of green tea powder/day and interferon/ribavirin showed 3.5-fold efficacy compared

with interferon/ribavirin therapy alone [208]. This result and that of another clinical trial in which a single 400 mg oral dose of EGCG was safe and well tolerated by all 11 patients with hepatitis C and detectable viremia strongly encourage further studies [209].

4.1.3 Laboratory Studies and Mechanism of Action

Several cell-based and animal experiments demonstrated the hepatoprotective effects of EGCG [5]. For example, our research group showed that consumption of an EGCG-rich green tea beverage reduced liver damage in rats with galactosamine-induced hepatitis [210]. Administration of the beverage restored the plasma levels of inflammatory factors TNF-α and IL-1β and their hepatic expression upregulated by galactosamine. Similarly, in concanavalin A-induced hepatitis mice, oral administration of EGCG (10 or 30 mg/kg) twice daily for 10 days prior to concanavalin A injection was associated with decreased immunoreaction and pathological damage by reducing inflammatory factors, such as TNF-α, IL-6, IFN-γ, and IL-1β (see Fig. 3). EGCG also exhibited antiapoptotic and anti-autophagic effects by inhibiting the expression of proapoptotic protein BNIP3 through the IL-6/JAKs/STAT3 pathway [211].

Steinmann et al. reviewed the antiviral and antibacterial activities of EGCG against human pathogens including HBV, HCV, human immunodeficiency virus, and influenza A virus. In most of the studies, EGCG exhibited antiviral properties within physiological concentrations in vitro [212]. The actions of EGCG were suggested as being mediated through (1) the inhibition of viral entry by interference with binding to target cells, (2) the inhibition of integrase and reverse transcriptase, (3) the destruction of virions by binding to CD4 and interference with gp120 binding, (4) the inactivation of virus particles, (5) the inhibition of intracellular virus growth and viral protease, (6) the alteration of physical integrity of virus particles, and (7) the suppression of viral replication via modulation of cellular redox milieu [212]. One of the studies reviewed by the authors showed that HCV infection was suppressed by EGCG in Huh7.5.1 cells infected with the JFH1-GFP chimeric virus when monitored for HCV RNA and protein expression levels. The inhibitory mechanism was proposed to involve the suppressive effects of EGCG on both the HCV entry and RNA replication steps. In addition, 50 and 25 μM EGCG was shown to eliminate HCV from cell cultures after two and five passages, respectively [213].

Xu et al. demonstrated that EGCG inhibited transcription of the HBV promoter in HEK293 cells co-transfected with expression plasmids of farnesoid X-activated receptor-α and RXR-α, suggesting that EGCG, as an antagonist of farnesoid X-activated receptor-α in liver cells, has the potential to be employed as an effective anti-HBV agent [214].

4.1.4 Hepatotoxicity

Green tea is generally considered to be safe for human health. However, a considerable number of reports have described hepatotoxicity related to GTE. For example, Navarro et al. found that since 2006, there have been more than 50 reports of

clinically apparent acute liver injury with jaundice attributed to GTE [215]. The illness was generally self-limiting, but fatal instances have been reported in up to 10% of cases, typically among those who presented with acute hepatocellular injury and jaundice. These authors pointed out that in most reports of GTE hepatotoxicity, the human dose of EGCG (generally less than 12 mg/kg daily) did not appear to be excessive or in the range that might have direct toxicity (estimated for humans to be 30–90 mg/kg), suggesting that liver injury associated with GTE is an idiosyncratic reaction, typical of conventional drug-induced liver injury. Naturally, the excessive consumption of catechin supplements should be avoided.

A recent investigation by Wang et al. suggested that melatonin may be useful for preventing the potential adverse effects of EGCG in its application for MetS alleviation and body weight reduction [216]. Future studies may explore effective ways to prevent or reduce the possible adverse effects of tea constituents.

4.2 Effects of Coffee on Liver Disease

4.2.1 Epidemiological Studies

Coffee intake may exert beneficial effects in the liver. In population studies among persons with an unknown diagnosis of liver disease, greater coffee intake was associated with lower risk of cirrhosis, chronic liver disease, and HCC [217]. In a large prospective study of patients with chronic hepatitis C and advanced liver disease who had failed to achieve a sustained virological response with peginterferon plus ribavirin treatment, Freedman et al. found an inverse association between coffee intake and liver disease progression. Drinkers of $\geq$3 cups of coffee/day had a 53% lower risk of liver disease progression than non-coffee drinkers. In contrast, no association was observed for the consumption of black or green tea [217].

Yesil et al. identified two cross-sectional studies and three case-control studies investigating the association between coffee consumption and the risk of NAFLD. All of these studies suggest a reduced risk of NAFLD associated with coffee drinking [156].

4.2.2 Clinical Studies

Wadhawan and Anand reviewed the literature for an association between coffee and liver disease and provided clinical evidence of the benefit of coffee consumption in hepatitis B and C, as well as in NAFLD [218]. Coffee consumption was associated with an improvement in liver enzymes such as ALT and AST, especially in individuals at risk for liver disease. Coffee intake of $\geq$2 cups/day in patients with pre-existing liver disease was shown to be associated with lower incidence of fibrosis and cirrhosis, lower HCC rates, and decreased mortality [218]. Similarly, Wijarnpreecha et al. found a significantly decreased risk of NAFLD among coffee drinkers and significantly decreased risk of liver fibrosis among patients with NAFLD who drank coffee on a regular basis [219].

A study to examine whether or not coffee consumption was associated with lower serum aminotransferases in the general Korean population and in those at high risk

for hepatic disease showed that the proportions of individuals with elevated AST were 32.5%, 33.1%, and 26.7% in subjects who drank coffee <1, 1, and ≥2 times/day, respectively. The ORs for elevated ALT and AST were significantly lower in subjects who drank ≥2 cups of coffee/day than in those who drank <1 cup/day. Thus, higher coffee consumption may be associated with lower risk of liver disease [220].

4.2.3 Laboratory Studies and Mechanism of Action

Twenty-five male 129/Sv mice were administered CGA, and an α-naphthylisothiocyanate (ANI) challenge was performed at 75 mg/kg on day 4 after treatment. CGA almost totally attenuated the resulting drug-induced liver damage and cholestasis compared with the untreated group. A dose of 50 mg/kg of CGA significantly prevented drug-induced changes in serum levels of ALT, alkaline phosphatases, total bile acid, direct bilirubin, indirect bilirubin (5.3-, 6.3-, 18.8-, 158-, 41.4-fold, respectively), and AST (4.6-fold). Expression of the altered bile acid metabolism and transport-related genes was normalized by treatment with CGA. The expression of *IL-6*, *TNF-α*, and suppressor of cytokine signaling 3 was found to be significantly decreased (1.2-fold, 11.0-fold, and 4.4-fold, respectively) in the CGA/ANI group. Western blotting revealed that CGA inhibited the activation and expression of signal transducer and activator of transcription 3 and NF-κB. These data suggest that CGA inhibits both ANI-induced intrahepatic cholestasis and liver injury by down-regulating STAT3 and NF-κB signaling [221] (see Fig. 3).

Feng et al. examined the impact of the Chinese herbal medicine Qushi Huayu Decoction (QHD) and its active components (geniposide and CGA) on the NAFLD liver transcriptome and gut microbiota using NAFLD rats. Increased expression of genes required for glutathione production and decreased expression of genes required for lipid synthesis were observed in NAFLD livers treated with QHD and CGA. CGA treatment decreased serum lipopolysaccharide, which could be explained by reduced mucosal damage in the colon of CGA-treated rats. In addition, the results suggested an increased abundance of Treg cell-inducing bacteria, which stimulated Treg cell activity in the CGA-treated colon, which in turn downregulated inflammatory signals, improved gut barrier function, and consequently reduced hepatic exposure to microbial products. These findings suggested that QHD simultaneously enhanced the hepatic antioxidative mechanism, decreased hepatic lipid synthesis, and promoted Treg cell-inducing microbiota in the gut [222].

Watanebe et al. found that coffee intake did not affect obesity or hyperlipidemia in TSOD mice, but that it did cause various degrees of improvement in pancreatic β-cell damage and steatohepatitis with liver carcinogenesis. Most of the effects appeared to be caused by a synergistic effect between caffeine and other components such as polyphenols. The anti-fibrotic effects of coffee were likely attributable to the polyphenols rather than to caffeine [164].

Arauz et al. examined the hepatoprotective properties of coffee and caffeine in a model of chronic bile duct ligation in Wistar rats. Western blot assays showed decreased protein expression levels of transforming growth factor-β1, connective tissue growth factor, α-smooth muscle actin, and collagen 1 in the coffee- and

caffeine-treated ligation groups compared with untreated rats. Similarly, coffee decreased the mRNA levels of these proteins. The results indicated that coffee prevented bile duct ligation-induced liver cirrhosis by attenuating the oxidant processes, blocking hepatic stellate cell activation, and downregulating the main profibrotic molecules involved in extracellular matrix deposition [223].

The beneficial effects of coffee in liver disease have also been supported by a recent review by Salomone et al. [98]. The authors described that in experimental models of fibrosis, caffeine inhibited hepatic stellate cell activation by blocking adenosine receptors and may favorably impact angiogenesis and hepatic hemodynamics, while CGA suppressed liver fibrogenesis and carcinogenesis by reducing oxidative stress and counteracting steatogenesis through the modulation of glucose and lipid homeostasis in the liver.

In contrast, Aoyagi et al. reported that CGA did not contribute to the coffee's suppressive effect on *PPAR-γ* gene expression. They observed that coffee reduced the accumulation of lipids during the adipocytic differentiation of 3T3-L1 cells and that 5% coffee decreased the accumulation of lipids by about 50% compared with control. Coffee inhibited the expression of PPAR-γ, a transcription factor that controls the differentiation of adipocytes, and reduced the expression of other differentiation marker genes *aP2*, adiponectin, *C/EBP-α*, *GLUT-4*, and lipoprotein lipase (*LPL*) during adipocyte differentiation (see Fig. 2). Major bioactive constituents of coffee extracts such as CGA, caffeine, trigonelline, and caffeic acid showed no effect on *PPAR-γ* gene expression. The inhibitory activity of coffee was found to be produced by the roasting of coffee beans [203].

5 Conclusions

Multiple human studies have shown that both green tea and coffee exert beneficial effects in human diseases, and most animal and cell-based experiments support these outcomes. Clearly, GTCs and coffee CGAs are implicated in these activities. Several mechanisms of action have been proposed, among which the involvement of ROS appears to be the most prominent. Two conflicting actions have been proposed: GTCs and CGAs can either scavenge ROS or promote its generation. The scavenging of ROS results in the inhibition of NF-κB activity, leading to the modulation of cytokines and apoptosis-related factors to yield various favorable outcomes such as anti-inflammatory effects and the induction of apoptosis in cancer cells (Fig. 3) [4, 5]. It is also possible that the generation of ROS results in the activation of AMPK, leading to the modulation of various enzymes and factors with roles in health promotion (Fig. 2) [4, 107]. In addition, AMPK activation has been suggested to downregulate NF-κB (Fig. 2), leading to modulation shown in Fig. 3 [224, 225].

At present, no explanation is available for these dual actions of GTCs and CGAs, although some conditions may direct them to act as either prooxidant or antioxidant agents. These conditions include their concentrations, the presence of cations such as Cu^{+} and Fe^{++}, cellular concentrations of antioxidants and oxidoreductive enzymes, and the cellular redox state [4, 107]. These issues remain to be resolved in future studies.

Furthermore, conflicting results in human studies have also been reported. The reasons for these inconsistencies include incomplete adjustment for confounding factors and lack of necessary questions in questionnaires, such as the temperature of tea or coffee, intestinal microbiota, and genetic factors. Nevertheless, we may expect the overall favorable effects of green tea and coffee consumption to promote healthy longevity in view of the growing of evidence presented in this chapter.

Theobroma cacao and *Theobroma grandiflorum*: Bioactive Compounds and Associated Health Benefits

36

Maria Inés Genovese and Helena Rudge de Moraes Barros

Contents

Abstract

The genus Theobroma comprises about 20 species, among them cocoa (*Theobroma cacao* L.), with the highest economic importance, and cupuassu (*T. grandiflorum*), of growing interest. Chemical compositions of cocoa and cupuassu unprocessed fresh seeds, pulps, and products (chocolate and cupulate) are presented, and the effects of processing in profile and quantity of the bioactive compounds, namely polyphenols and methylxanthines, are discussed. Dietary consumption of cocoa and dark chocolate has been associated to beneficial effects on health, mainly related to polyphenols and their antioxidant and anti-inflammatory activities affecting important signaling pathways and also modulating intestinal microbiota. Vasodilation and cardioprotective effects of cocoa polyphenols are related to release of nitric oxide (NO) through activation of

endothelial NO synthase. Significant improvement of insulin resistance and flow-mediated dilatation (FMD) and reductions in diastolic blood pressure and mean arterial pressure were reported. In particular, the effects of cocoa and cupuassu polyphenols on obesity and glucose metabolism are reviewed.

Keywords
Cocoa · Cupuassu · Polyphenols · Obesity · Glucose metabolism

Abbreviations

AA	Arachidonic acid
ALT	Alanine aminotransferase
AMPK	AMP-activated protein kinase
AST	Aspartate aminotransferase
BMI	Body mass index
DW	Dry weight
FA	Fatty acid
FFA	Free fatty acids
FMD	Flow-mediated dilatation
FW	Fresh weight
GK	Glucokinase
GLP	Glucagon-like peptide
GLUT	Glucose transporter
GPx	Glutathione peroxidase
GR	Glutathione reductase
GS	Glycogen synthase
GSK3	Glycogen synthase kinase 3
HDLc	High-density lipoprotein
HF	High fat
HO-1	Heme oxygenase-1
HOMA-B	Homeostatic model assessment of cell function
IRS	Insulin receptor substrate
JNK	Jun N-terminal kinase
LDLc	Low-density lipoprotein
MDA	Malondialdehyde
MES-WAT	Mesenteric white adipose tissue
NF-κB	Nuclear factor kappa B
NO	Nitric oxide
Nrf2	Nuclear factor erythroid 2-related factor
PEPCK	Phosphoenolpyruvate carboxykinase
ROS	Reactive oxygen species
SOD	Superoxide dismutase
T2D	Type 2 diabetes
Tb/Cf ratio	Theobromine/caffeine ratio
TBARS	Thiobarbituric acid reactive substances
TC	Total cholesterol

TG	Triacylglycerol
TLR4	Toll-like receptor 4
UCP	Uncoupling protein
VLDLc	Very low-density lipoprotein

1 Introduction

The genus *Theobroma* comprises about 20 species, and several of them produce edible seeds, notably cacao and cupuaçu. The highest economic importance is of the cultivars (varieties) "Criollo," "Forastero" and "Trinitario," a hybrid of Criollo and Forastero, of the species *Theobroma cacao* L., which are used for chocolate production [1]. On the other side, the species *T. grandiflorum* (cupuassu or cupuaçu) is getting more relevance for the South American market where the fruit pulp is highly appreciated and seeds are used for the manufacture of chocolate-like products. Cupuassu pulp can be consumed as juices, mousses, drinks, ice-creams, jellies and candies, although not usually consumed directly due to its strong acidity. The seeds contain high amounts of fat and may be used in food products and in a variety of cosmetics. The seeds can also be processed in a similar way as cocoa to yield a chocolate-like product called "cupulate®," firstly described and patented by the Brazilian Research Institute Embrapa (Empresa Brasileira de Pesquisa Agropecuária) [2].

Processing of raw cocoa involves several stages and starts with a fermentation step, crucial for the development of the desirable flavor of cocoa products. After drying/roasting and separation of shells, the grinding of beans results in cocoa nibs, which are then milled to a liquid paste known as cocoa liquor. Pressing of cocoa liquor removes cocoa butter and leaves a solid cake which is pulverized into cocoa powder. Chocolate is produced adding more cocoa butter and other ingredients such as sugar, milk, and emulsifying agents to cocoa liquor, in different proportions depending on the type of chocolate desired. All these processing steps result in changes in composition and quantity of the bioactive compounds present in cocoa, mainly a sharp decrease in concentration after fermentation and drying [3].

2 Chemical Composition of Cocoa and Cupuassu

Cocoa butter is the major nutrient in cocoa beans. Differences in chemical composition of cocoa beans are due to different geographic origin, genetic variability and post-harvesting processing. Cocoa beans from five regions of Cameroon, the fourth largest producer of cocoa in the world, variety Trinitario, showed fat contents ranging from 24.6% to 43.1%, moisture from 3.1% to 4.2%, carbohydrates from 24.4% to 43.4%, and proteins from 11.7% to 13.4% [4]. Ecuadorian unroasted cocoa beans showed higher moisture (5.95%), fibre (19.5%) and total fat (43.4%) content than Ghanaian beans, lower carbohydrates (33.8%), and similar contents of protein (12.8%) and ash (~4%) [5].

Table 1 Chemical compositions of cocoa and cupuassu fresh seeds and products (%)

Sample	Moisture	Ashes	Lipids	Proteins	Carbohydrates
Cupuassu					
Fresh seeds	53 ± 1^{a}	1.46 ± 0.06^{a}	22 ± 1^{a}	4.3 ± 0.1^{a}	16 ± 1^{a}
Fermented and dried seeds	8.6 ± 0.1^{b}	2.76 ± 0.01^{b}	45 ± 3^{b}	10.0 ± 0.4^{b}	31 ± 1^{b}
Fermented and roasted seeds	3.2 ± 0.1^{c}	3.02 ± 0.02^{c}	48 ± 2^{b}	10.0 ± 0.2^{b}	31 ± 2^{b}
Liquor	2.64 ± 0.03^{d}	3.0 ± 0.2^{c}	54 ± 2^{c}	10.5 ± 0.3^{b}	27 ± 1^{c}
Cupulate	1.12 ± 0.01^{e}	1.78 ± 0.05^{d}	37 ± 2^{d}	7.0 ± 0.2^{c}	52 ± 3^{d}
Cocoa					
Fresh seeds	46 ± 2^{f}	2.09 ± 0.05^{e}	20 ± 1^{a}	9.1 ± 0.2^{b}	19 ± 1^{a}
Chocolate	1.5 ± 0.1^{g}	1.55 ± 0.04^{a}	35 ± 2^{d}	7.8 ± 0.6^{c}	53 ± 4^{d}

Values in the same column with different letters are statistically different ($p < 0.05$). Data from Pugliese [7]

Fresh seeds of cupuassu, from three different harvest seasons, presented ca 53% moisture, 1.5% ashes, 22% lipids, 3.8–4.2% proteins, and 14–18% carbohydrates. Fresh pulps presented higher moisture (90%), as expected, and lower ashes (0.5%), lipids (1%), proteins (0.7%) and carbohydrates contents (5–6%) [6]. For comparison, cocoa fresh pulp from the same origin (Bahia, Brazil) presented 85% moisture, 0.43% ashes, 0.22% lipids, 0.77% proteins, and 12% carbohydrates [7].

Chemical compositions of cocoa and cupuassu unprocessed fresh seeds and products prepared by CEPLAC (Comissão Executiva do Plano da Lavoura Cacaueira, Cocoa Processing Unit, Fazenda Riachuelo, Bahia, Brazil) are presented in Table 1. Although with similar lipid content, protein content of cocoa fresh seeds was more than double that of cupuassu fresh seeds. Cupulate and chocolate, on the other side, presented a similar composition.

Similar to what happens to cocoa, processing results in alteration of the chemical composition of cupuassu seeds. Fermentation and sun-drying reduce drastically moisture content of seeds, leading to a proportional increase of the other constituents. After the elimination of shells from roasted seeds, there is a reduction in carbohydrate content (fiber) and an increase in lipid content of the resulting nibs, which are then ground to produce the liquor (Table 1). Finally, cupuassu liquor (52%) is mixed with cupuassu butter (8%), milk powder (6%), lecithin (0.5%) and sugar (33.5%), resulting in an increase in carbohydrates content in the final product, cupulate [7].

Quantitatively C16:0 (hexadecanoic acid or palmitic acid) (>25%), C18:0 (octadecanoic acid or stearic acid) (>33%) and C18:1 (octadecenoic acid or oleic acid) (>34%) are the most important fatty acids in unroasted cocoa beans of both origins Ecuadorian and Ghanaian [5]. Among the fatty acids detected in cocoa beans from five different regions of Cameroon, stearic acid was the most abundant (37.6–39.5%) followed by oleic acid (30.4–33.2%) and palmitic acid (24.8–28.2%), and saturated fatty acids were most abundant (63.9–66.8%), followed by monounsaturated (30.4–33.2%) and finally by polyunsaturated fatty acids (2.7–3.2%) [4].

Table 2 Fatty acid composition of cupuassu fresh seeds and cupuassu liquor (% total lipids)

Formula	Fatty acid	Fresh seeds %	Liquor %
16:0	Palmitic	7.54 ± 0.08[a]	6.86 ± 0.05[b]
17:0	Margaric	0.19 ± 0.01[a]	0.18 ± 0.01[a]
18:0	Stearic	32.6 ± 0.1[a]	31.4 ± 0.2[b]
18:1 (n-9)	Oleic	41.31 ± 0.06[a]	43.5 ± 0.1[b]
18:1 (n-7)	Vaccenic	0.47 ± 0.02[a]	0.46 ± 0.01[a]
18:2 (n-6)	Linoleic	4.9 ± 0.1[a]	5.04 ± 0.01[a]
18:3 (n-3)	α-linolenic	0.20 ± 0.01[a]	0.13 ± 0.00[b]
20:0	Eicosanoic	10.51 ± 0.04[a]	10.23 ± 0.09[b]
20:1 (n-9)	Eicosenoic	0.34 ± 0.01[a]	0.37 ± 0.01[b]
22:0	Docosanoic	1.72 ± 0.01[a]	1.70 ± 0.05[a]
24:0	Tetracosanoic	0.19 ± 0.00[a]	0.17 ± 0.01[a]
Total	Saturated	52.81 ± 0.07[a]	50.5 ± 0.4[b]
	Monounsaturated	42.12 ± 0.04[a]	44.4 ± 0.1[b]
	Polyunsaturated	5.07 ± 0.11[a]	5.17 ± 0.01[a]

Values in the same row with different letters are statistically different ($p < 0.05$). Data from Pugliese [7]

Fatty acid composition of cupuassu fresh seeds and liquor is shown in Table 2. Although the fatty acid composition is very similar to cocoa, as it can be seen, cupuassu fat stands out for the prevalence of oleic acid (18:1, 41%), followed by stearic acid (18:0, 33%), and much lower amounts of palmitic acid (16:0, 7.5%) than cocoa fat (~26%). Cupuassu fat also presents ten times more arachidic acid (20:0) than cocoa fat [8]. The fatty acid composition of cupuassu fat provides softness and enables its use in chocolates, replacing cocoa butter [9]. According to Lucas [10], in spite of the higher melting point of cupuassu butter (33.9 °C) compared to cocoa butter (31 °C), the high content of monounsaturated fatty acids, mainly oleic acid, of cupuassu fat turns it softer than cocoa fat.

Bezerra et al. [11] also found that the primary fatty acids in cupuassu fat are oleic (41.6%) and stearic (31.6%) acids, and that the fat has low atherogenicity and thrombogenicity indexes, melting point of 38.1 °C, and can be combined in blends with suitable physicochemical properties for many applications.

Among by-products, cupuassu peel flour stands out for presenting an elevated dietary fiber content (~80%), mainly insoluble fiber (~78%), higher than that of cocoa peel (~64%, 52% insoluble fiber), and for being able to be incorporated in whole-bread at 6% level without affecting color, aroma, texture and flavor attributes [12].

3 Bioactive Compounds of Cocoa and Cupuassu

Cocoa is rich in polyphenols and methylxanthines, and the higher the amount of cocoa solids, the higher the content of methylxanthines and polyphenols in cocoa products such as cocoa liquor, cocoa powder, dark, milk, and powdered chocolate [13].

Besides, processed cocoa beans and cocoa-based products may present other substances and chemical compounds of microbial and fungal origin which can be also related to human health benefits. Bacteria and fungi which drive spontaneous postharvest fermentation of cocoa beans immediately after bean harvesting produce various primary and secondary metabolites with antifungal, antineoplastic, anti-infective and cholesterol-lowering activities [14].

The physiological effects of methylxanthines are mainly mediated by adenosine receptors blockage and include central nervous system stimulation, diuresis, cardiovascular and metabolic effects, bronchial relaxation and increased secretion of gastric acids [15]. The main methylxanthines of cocoa are theobromine (0.8–2% on a dry weight basis, DW) and caffeine (about 0.2%) and concentrations vary depending on bean type, plant species, and degree of fermentation [16]. As expected, concentrations of theobromine and caffeine decrease in cocoa products, following the order cocoa > baking chocolate > dark chocolate > milk chocolate > cocoa butter, and theophylline is normally below limit of detection. The benefits of chocolate on mood seem to be mainly exerted by caffeine whereas theobromine may be related to other effects [15].

Methylxanthine contents of fresh cocoa beans from different cocoa varieties grown in Peru were in the range of 1.09–1.45%, for theobromine, and 0.20–0.41% DW, for caffeine, decreasing during fermentation and drying. Liquor from these samples presented theobromine contents from 0.84 to 1.14, and caffeine contents from 0.08 to .165% DW [17]. The average contents of total methylxanthines decreased from 15.05 mg/g dry matter in non-fermented to 12.94 mg/g dry matter in fermented cocoa samples from Nicaragua [18]. Although methylxanthines do not undergo chemical degradation during fermentation, about 30% of alkaloids are lost due to diffusion out of the bean cotyledons [19].

The theobromine/caffeine (Tb/Cf) ratio is considered an important parameter for cocoa, and lower ratios (<3) are typical of Criollo cocoa (less bitter), as it presents lower concentration of theobromine and higher levels of caffeine relative to other genetic groups, Trinitario (< 9 Tb/Cf >3) and Forastero (Tb/Cf >9) cocoas [16–18].

Caffeic acid was reported to be present in a concentration range of 1.1–2.1 mg/g dried extract, theobromine in a concentration range of 4.7–11.6 mg/g dried extract and (−)-epicatechin in a concentration range of 1.1–142.9 mg/g dried extract in cocoa beans from five different regions of Cameroon [4].

Cupuassu presents a high amount of phenolics, especially on seeds, and of ascorbic acid on pulp. However, a much lower content of theobromine (1 mg/g) and caffeine (0.5 mg/g) was reported for ground seeds (both raw and roasted) of cupuassu in comparison to cacao seeds (33–36 mg/g theobromine, 3.3–5.6 mg/g caffeine) [20]. Fresh pulp of cupuassu showed a high content of ascorbic acid (ca 102 mg/100 g DW sample, or 17 mg/100 g FW) but commercial frozen pulps seem to suffer a drastic loss during processing, presenting a ten times lower ascorbic acid content (9–13 mg/100 g DW), probably as a result of oxidative reactions during pulp separation and thermal processing [6].

Cocoa by-products are also important sources of bioactive compounds. Cocoa husks are part of the cocoa bean and are separated from the cotyledons after the

roasting process. They have a high content of total dietary fibre, mainly insoluble fibre, and represent a secondary source of theobromine, caffeine, and phenolics (these last in the range 2.6–4.1 mg/g DW) [21].

4 Cocoa Polyphenolic Composition

Polyphenols in cocoa beans can be classified into three main groups: flavan-3-ols or catechins (37%), anthocyanins (4%) and proanthocyanidins (58%), and the main catechin is (−)-epicatechin with up to 35% of polyphenol content [3]. Polyphenols represent about 10% of the whole bean's dry weight, with epicatechin concentrations among freshly harvested beans ranging from 21.9 to 43.3 mg/g of dry defatted sample [1].

Besides these major compounds (catechin, epicatechin and their dimers procyanidin B1 and procyanidin B2), other polyphenols have been reported in cocoa beans or cocoa products: procyanidin B3 = catechin-(4α → 8)-catechin, procyanidin B4 = catechin-(4α → 8)-epicatechin, procyanidin B5 = epicatechin-(4 β → 6)-epicatechin, procyanidin C1 = epicatechin-(4β → 8)-epicatechin-(4β → 8)-epicatechin, procyanidin D = epicatechin-(4 β → 8)-epicatechin-(4 β → 8)-epicatechin-(4 β → 8)-epicatechin, higher oligo- and polymers, mostly homologues of epicatechin with 2–18 monomeric units, as well the flavanols quercetin, quercetin-3-O-glucoside (isoquercitin), quercetin-3-O-galactoside (hyperoside), quercetin-3-O-arabinoside, the flavones apigenin, apigenin-8-C-glucoside (vitexin), apigenin-6-C-glucoside (isovitexin), luteolin and luteolin-7-O-glucoside, dihydroquercetin, dihydroxykaempferol, kaempferolrutinoside, naringenin, naringenin-glucoside, myricetin-glucoside, and also caffeic acid, chlorogenic acid, coumaric acid, ferulic acid, phenylacetic acid, phloretic acid, protocatechuic acid, syringic acid, vanillic acid, clovamide and dideoxyclovamide [1].

5 Cupuassu Polyphenolic Composition

Nine known flavonoids were found in cupuassu seeds: (+)-catechin, (−)-epicatechin, isoscutellarein 8-*O*-*β*-D-glucuronide, hypolaetin 8-*O*-*β* glucuronide, quercetin 3-*O*-*β*-D-glucuronide, quercetin 3-*O*-*β*-D-glucuronide 6″-methyl ester, quercetin, kaempferol, and isoscutellarein 8-*O*-*β*-D-glucuronide 6″-methyl ester. Two new sulphated flavonoid glycosides, theograndins I and II, were also described [22].

Pugliese et al. [6] reported that the main flavonoids both in seeds and pulp of cupuassu were the glycosyl flavones, mainly the glucuronide and glucuronide-sulfates: Hypolaetin-8-O-β-D-glucuronide, Hypolaetin-8-O-β-D-glucuronide-3″-O-sulfate (Theograndin II); Isoscutellarein-8-O-β-D-glucuronide; Hypolaetin-3′-methyl ether-8-O-β-D-glucuronide; Isoscutellarein-8-O-β-D-glucuronide-3″-O-sulfate (Theograndin I); Hypolaetin-3′-methyl ether −8-O-β-D-glucuronide- 3″-O-sulfate, with a total flavone concentration above 31 mg/g of unfermented cupuassu

seeds. Similar flavonoid profiles were observed for fresh and commercial frozen pulps, but commercial frozen pulps presented lower contents than did fresh pulps, on average 0.5 and 2.2 mg/g, respectively.

Cupuassu did not show any anthocyanidins, which are common in cocoa seeds. The total proanthocyanidin content of unfermented cupuassu seeds was 23 mg/g. Cupuassu pulp has a phenolic content similar to that found in other tropical fruits, like passion fruit [23].

6 Effect of Processing on Polyphenols

Polyphenols in the cocoa beans are stored in the cotyledons. Processing of cocoa seeds for chocolate manufacture is responsible for a significant decrease in polyphenol content, mainly during fermentation and drying. Polyphenols diffusion from storage cells results in exposition to other bean constituents and oxidation reactions to produce insoluble high molecular weight tannins, both nonenzymatic and catalyzed by polyphenol-oxidase. Fermentation of cocoa beans is crucial for the development of precursors for chocolate flavour. Anthocyanins that represent ca. 4% of the total polyphenol content are hydrolyzed during the fermentation process of cocoa bean. During drying, additional loss of polyphenol occurs, mainly due to nonenzymatic browning reactions. After fermentation and drying, the nibs obtained are roasted and ground, resulting in the cocoa liquor. Removal of part of the cocoa butter from the liquor results in cocoa powder, and these products can be further alkalinized (*Dutching*), a process that also leads to significant losses of cocoa polyphenols [3, 24, 25].

A total of 11 different cocoa powder products available in the Spanish market presented a mean content of total flavonoids equivalent to 2.65 mg/g, with a high prevalence of (−)-epicatechin. The alkalinization process of cocoa powder resulted in 60% loss of the flavonoid content. Among flavanols, (−)-epicatechin presented a larger decline (67%) than (+)-catechin (38%), probably because of its epimerization into (−)-catechin, a less bioavailable form of catechin. Among flavonols, quercetin suffered the highest loss (86%), whereas quercetin-3-glucuronide, quercetin-3-arabinoside, and isoquercitrin showed a similar decrease (58, 62, and 61%, respectively). Di-, tri-, and tetrameric procyanidins also declined, 69% for dimer B2, 67% for trimer C1, and 31% for tetramer D [26]. Todorovic et al. [27] also reported a 1.8 times lower polyphenol content in alkalized cocoa samples than in natural ones with a decrease in epicatechin/catechin ratio (2.21 in natural and 1.45 in alkalized cocoa powders).

Processing also affects the bioavailability of cocoa polyphenols. The comparison of an unfermented, nonroasted, and blanch-treated cocoa powder with a conventional one showed four times more procyanidins, and eight times more epicatechin and procyanidin B2. A crossover intervention with healthy volunteers consuming cocoa milk drinks prepared with these powders showed that the content of epicatechin glucuronide, the main metabolite detected in plasma, was five-fold higher upon consumption of the low-processed as compared with the conventionally processed cocoa powder [28].

7 Health Benefits Associated to Cocoa and Cupuassu Ingestion

Dietary consumption of cocoa and dark chocolate has been associated to beneficial effects on health, mainly related to polyphenols and their antioxidant and anti-inflammatory activities affecting some important signaling pathways, such as Toll-like receptor 4 (TLR4)/nuclear factor kappa B (NF-κB) /signal transducer and activator of transcription. Vasodilation and cardioprotective effects of cocoa polyphenols are related to inducing release of nitric oxide (NO) through activation of endothelial NO synthase. The effects of chocolate, cocoa, and flavan-3-ols on major cardiovascular risk factors were systematically reviewed by Hooper et al. [29] who observed significant improvement of insulin resistance and flow-mediated dilatation (FMD) and reductions in diastolic blood pressure and mean arterial pressure. Also, cocoa polyphenols also modulate intestinal microbiota, leading to the growth of bacteria that trigger a tolerogenic anti-inflammatory pathway in the host [30].

However, commercial cocoa and chocolate products present a high variability in polyphenols content [26], and as a consequence, it is very difficult to generalize any associated health benefits of their consumption and/or deriving from cocoa polyphenols. Below we examine specifically the reported effects of cocoa and cupuassu polyphenols on obesity and glucose metabolism.

8 Effects of Cocoa and Cupuassu on Obesity

Although the scientific research on the beneficial properties of cocoa or dark chocolate has increased, clinical studies determining their effects on weight regulation have rarely been conducted. Many studies were related to cardiovascular diseases and body fat is only assessed as part of routine measurement of the research [31–33]. So far, there are no studies with humans evaluating the effects of *Theobroma grandiflorum* (cupuassu) consumption on weight control.

Interventional and observational studies that relate cocoa consumption with antiobesity effects have presented many controversial results until now. Some studies found an inverse correlation between body mass index (BMI) and regular cocoa consumption at small portions [31, 34, 35, 36]. However, other studies did not detect significant changes in weight following the regular consumption of dark chocolate [37–41], even when offered along with a restrictive diet [42]. In contrast, Desch et al. [43] found a slight increase in body weight of patients with hypertension that consumed 25 g of dark chocolate daily for 3 months. Greemberg et al. [44] found that there was an increase in body weight with chocolate consumption by healthy individuals in a dose-response manner, concluding that the hypothesis that chocolate intake was associated with lower body weight did not apply to participants without preexisting illness.

Therefore, this led to more focused animal studies on the effects of cocoa on weight control. Some studies have been conducted to examine whether cocoa may reduce weight gain, hyperlipidemia and inflammation and, thus, improve weight

control and other outcomes related to obesity [33, 45–49]. Some animal studies have also reported the effects of cupuassu on weight control [50, 51]. These studies are summarized in Table 3 and potential mechanisms by which cocoa could exert antiobesity effects are discussed below.

Almost all studies listed in Table 3 demonstrated reduced weight gain in high fat mice induced obesity by cocoa ingestion, while cupuassu demonstrated no changes or only attenuated weight gain. However, supplementation with both fruits promoted improvements in lipid-related outcomes as dyslipidemia and hepatic steatosis, glucose-related outcomes as hyperinsulinemia and hyperglycemia, inflammation and oxidative stress. Different outcomes may be explained by the wide range of doses used, as well as the variety of intervention methods (gavage, in diet), different types of products utilized (powder, extract, liquor, pure compounds) and the role of intervention (preventive or treatment).

Among treatments for obesity, one of the most promising strategies to decrease energy intake without altering central mechanisms is the development of nutrients digestion inhibitors [52]. Thus, interactions of polyphenols with digestive enzymes altering their activity may represent a significant caloric restriction and contribute to improve the energy metabolism regulation [53]. Cocoa extracts and mainly procyanidins with higher degree of polymerization have demonstrated inhibition of pancreatic lipase and secreted phospholipase A2 activities in a dose-dependent manner in vitro [54]. In this sense, a lower weight gain and adipogenesis observed in mice fed a high-fat diet supplemented with cocoa was suggested to be in part due to cocoa's inhibitory effect on pancreatic lipase activity [46, 47, 55]. Cocoa supplementation resulted in reduced fat absorption from the gut as indicated by the presence of a high fecal fat content in mice fed a high fat diet [47]. Cupuassu phenolic extract also showed inhibition of pancreatic lipase in vitro and increased lipid fecal excretion in mice fed high-fat high-sucrose diet, followed by reduction of liver triacylglycerol contents and cholesterol levels in plasma [50]. However, cocoa flavanols and cupuassu polyphenols have not been evaluated for inhibition of lipid digestion and absorption in humans yet.

In addition to the reduction of fat absorption, several studies have shown that cocoa decreases diet induced lipogenesis and hyperlipidemia by enhancing fat oxidation and inhibiting the syntheses of fatty acids in liver and adipose tissue of mice fed a high-fat diet [49, 56, 57]. Ali et al. [56] demonstrated that cocoa polyphenols treatment down-regulated the expression of PPAR-γ, SREBP-1c, Acaca and Mcat genes in white adipose tissue and Fasn and Scd1 genes in the liver, the key enzymes of fatty acid synthesis. Conversely, the expression of genes involved in fatty acid oxidation PPAR-α, CPT1, and Prkaa1 was significantly higher in liver and in adipose tissue of mice treated with cocoa [56, 58]. In accordance with these results, Matsui et al. [48] found that cocoa ingestion decreased the expression of genes for fatty acid synthesis in the liver, however without activating the expression of genes for fatty acid oxidation in this tissue. In adipose tissue, cocoa ingestion decreased the expression of genes for fatty acid transport molecules and their transcription factor PPAR-γ with concurrent activation of thermogenesis. In contrast, other study [33] showed that cocoa and their polyphenolic derivatives were

associated with the upregulation of the expression of genes involved in fatty acid uptake (PPAR-γ and FAT/CD36) suggesting an improvement in adipose tissue function with a better capacity to store nutritional overload and reduce ectopic lipid deposition in other tissues and lipoproteins levels. However, fat oxidation in adipose tissue was also enhanced by the upregulation and activation of PPARα, PGC1α and SIRT1. In addition, some studies also related the antiobesity effect of cocoa with the increase of the gene and protein expressions of the UCPs in the adipose tissues and skeletal muscle, which are involved in the reduction of weight, lipid contents in tissues and lipoprotein levels [33, 48, 49]. Although the intake of cupuassu polyphenols did not demonstrate an effective reduction in weight gain, improvements related to lipotoxicity could be observed. Supplementation with cupuassu phenolic extract significantly reduced the plasma concentrations of VLDL and LDL cholesterol, and the accumulation of triglycerides in the liver [50, 51]. This suggests that the presence of flavones, which are not found in cocoa, in combination with flavanols, may also help to alleviate the metabolic changes triggered by a diet rich in fats and sugars. However, further studies are needed to elucidate the mechanisms associated with these effects.

Evermore, obesity chronic inflammation seems to be a key mediator of other pathologies including insulin resistances and fatty liver disease. Cocoa has been found to ameliorate obesity related inflammation, insulin resistance, and fatty liver disease in HF-fed mice, possibly by reducing pro-inflammatory gene expression and adipokines in white adipose tissue and modulating eicosanoid metabolism, gut barrier function and metabolic endotoxemia [46, 47, 59]. Cocoa supplementation also significantly increased plasmatic adiponectin levels in mice compared to HF-fed controls, which may contribute to the decreased triglyceride accumulation in liver and protect from inflammation and fibrosis [33, 49, 59].

In fact, adiponectin has been associated with maintaining glucose homeostasis through activation of AMPK. Cocoa has the potential to prevent insulin resistance and obesity by activating the adiponectin–AMPK pathway. Interestingly, cocoa also reduced insulin plasmatic level without having effect on fasting glycaemia in high-fat fed induced obesity studies. However, cupuassu improved fasting glycaemia and glucose tolerance, which was associated with reduced lipotoxicity and oxidative stress [50, 51]. The effects of *Theobroma* on glucose metabolism will be discussed in the next section.

Until now, these antiobesity effects of cocoa can be explained by the activation of AMPK and PPARα signaling, molecules responsible for suppressing lipogenesis (fatty acid synthesis) and promoting lipolysis (fatty acid oxidation). These effects also appear to be due in part to the modulation of dietary fat absorption, modulation of gut microbiota and the down-regulation of NF-κB target gene expression, reducing inflammation. However, other genes and/or transcription factors may play a role in beneficial effects. Although research to date has not specifically addressed the mechanisms that *Theobroma* can act on obesity, there is reason to believe that consumption of cocoa and cupuassu may induce beneficial metabolic changes through the effects described above.

9 Effects of Cocoa and Cupuassu on Glucose Metabolism

As antidiabetic, cocoa polyphenols have been found to attenuate postprandial glycemic responses while improving acute insulin secretion and insulin sensitivity in animal models and in a limited number of human studies [46, 60–64]. In fact, cocoa ingestion has been shown to protect β-cells by reducing oxidative stress and decreasing levels of blood glucose, limiting the risk factors for diabetes and other chronic diseases [63, 65, 66].

Currently, animal studies continue to evaluate the physiological effects of *Theobroma*'s intake on different diabetic models. These studies are summarized in Table 4 and potential mechanisms by which cocoa could exert antidiabetic effects are discussed below.

The possible mechanisms of *Theobroma*'s action include inhibition of carbohydrate digestion and glucose absorption in the intestine, stimulation of insulin secretion from the pancreatic *β*-cells, modulation of glucose release from the liver, activation of insulin receptors and glucose uptake in the insulin-sensitive tissues, and modulation of intracellular signaling pathways and gene expression. These positive effects on glucose homeostasis are also supported by epidemiological evidence on polyphenol-rich diets [67–69].

Experimental data from in vitro studies have suggested that cocoa and its main phenolic compounds can act as potential antidiabetic agents by inhibition of carbohydrate digestion [54, 70] and glucose absorption in the intestinal lumen [71, 72]. Cocoa extract demonstrated an in vitro inhibition of α-amylase activity in a dose-dependent manner, which was enhanced by the degree of polymerization of cocoa procyanidins [54, 70]. Cupuassu extract rich in flavonoids also demonstrated a potent inhibition in vitro of α-amylase activity when compared to other Brazilian fruit extracts [73]. However, these results were not related to procyanidins contents because the extracts were obtained through a solid phase extraction in a polyamide SC6 column, which eliminates procyanidins, sugars, vitamins and minerals. In addition, in this study, flavanol contents of other fruit extracts seemed to be related to inhibitory activity of α-amylase. Interestedly, in contrast with other studies [6, 50, 51], flavanol contents were not detected in cupuassu in this study, what suggests that flavones may also exert effects on α-amylase activity. In another study [50], cupuassu phenolic extract also inhibited α-glucosidase activity in a dose-dependent manner and was more effective than acarbose in inhibiting α-glucosidase in vitro.

Chronic hyperglycemia and hyperlipidemia exposure increases intracellular reactive oxygen species (ROS) generation, disturbs mitochondrial function and can exert deleterious effects on β-cell function impairing insulin secretion [69, 74, 75]. Cocoa polyphenols have been suggested to protect pancreatic β-cells from oxidative stress and improve insulin secretion, thus alleviating hallmarks of T2D [63, 65, 66].

Studies in vitro demonstrated that cocoa polyphenols could protect INS-1 cells against oxidative stress and modulate insulin secretion [65, 66]. Supporting these findings, a study using diabetic fatty rats showed that cacao rich diet ingestion increased β-cell mass and function by preventing beta cell apoptosis and improving antioxidant defenses in pancreas [66]. In accordance with these data, ob/ob rats fed

Table 4 Animal studies related to the effects of dietary cocoa and cupuassu polyphenols on glucose metabolism[a]

Vehicule	Dose	Duration	Model	Animals	Outcomes	References
Cocoa powder	Cocoa rich diet (10%)	9 weeks	Type 2 diabetes (pre-diabetic stage)	Male Zucker diabetic fatty rats (mutation in the leptin receptor)	↓ body weight gain and liver weight ↓ glucose and insulin plasmatic levels Improved glucose tolerance and insulin resistance Liver: ↓ p-(Ser)-IRS-1, p-GS and PEPCK ↑ p-GSK3, GK and GLUT-2 ↓ p-JNK and p-p38	[60]

[a]The arrow indicates an increase (↑) or decrease (↓) in the levels or activity of the different parameters analyzed. *FFA* free fatty acids, *GK* glucokinase, *GLUT* glucose transporter, *GS* glycogen synthase, *GSK3* glycogen synthase kinase 3, *GPx* glutathione peroxidase, *GR* glutathione reductase, *HDLc* high-density lipoprotein, *HO-1* heme oxygenase-1, *HOMA-B* homeostatic model assessment of cell function, *IRS* insulin receptor substrate, *JNK* Jun N-terminal kinase, *NFkB* nuclear factor-kappa B, *Nrf2* nuclear factor erythroid 2-related factor, *PEPCK* phosphoenolpyruvate carboxykinase, *ROS* reactive oxygen species, *SOD* superoxide dismutase, *TBARS* thiobarbituric acid reactive substances, *TG* triacylglycerol

cocoa extracts demonstrated decreased oxidative stress and enhanced glucose-stimulated insulin secretion, thereby enhancing functional β-cell mass [76].

In addition, cocoa might improve insulin secretion by inhibiting lipid accumulation in the cells. Considering this hypothesis, the supplementation of cupuassu polyphenols in mice fed a diet high fat high sucrose diet reestablished the phosphorylation of AKT and therefore insulin signaling in liver. These results were associated with a reduction of triacylglycerol and oxidative stress in liver, as evidenced by the reduction of MDA production and plasma transaminase activities [50]. However, further studies are needed to identify the exact mechanisms by which these effects are induced.

Liver is a key organ in the maintenance of blood glucose levels in tight cooperation with peripheral tissues. In this sense, Cordero-Herrera et al. [60] demonstrated that cocoa ameliorates hyperglycemia through its ability to preserve the hepatic functionality by preserving the levels of GLUT-2 and glycogen content and to

modulate gluconeogenic and glycolytic enzymes, as it decreases hepatic PEPCK and enhances hepatic GK. Although enzymes involved in hepatic production have not been evaluated in the cupuassu study, the increase of AKT phosphorylation suggests inhibition of hepatic glucose production through the improved insulin signaling in this tissue and reduced glucose plasmatic levels [50].

Cocoa polyphenols may also exert important antidiabetic effects by improving glucose uptake in muscles and adipocytes, through the action of GLUT4 [77]. Since cupuassu administration did not demonstrate a significant reduction in adipose tissue and body weight in mice fed a high fat high sucrose diet, the decrease in glycolipotoxicity demonstrated could be explained by an increase in GLUT4 activity in adipose tissue. However, this hypothesis was not evaluated for cupuassu yet.

10 Conclusions

Considering the evidences presented, cocoa may be useful in ameliorating insulin resistance, body weight gain and lipid alterations, thus reducing metabolic damage associated to diabetes and obesity. Numerous studies on the effect of cocoa on endothelial function also point to a possible effect on insulin sensitivity. However, additional studies to confirm these effects in humans are needed, mainly establishing a dose-response relationship between cocoa polyphenols and their overall effect. Cupuassu, another *Theobroma*, but little studied, also deserves attention as a potential polyphenolic source to act against metabolic alterations caused by diabetes and obesity.

of poultry, fish, eggs, milk and dairy products, as well as a regular but moderate ethanol consumption (generally in the form of wine during meals); and (3) a low intake of red and processed meat and industrial confectionary. Olive oil (OO) is the main fat used in all preparations of the MD. The health benefits of consuming OO have been known since antiquity and were traditionally attributed to its high MUFA content, mainly oleic acid. A large number of epidemiological and laboratory studies suggest beneficial and protective effects of OO in reduced risk of suffering cardiovascular disease (CVD) and cerebrovascular diseases, diabetes mellitus, metabolic syndrome, certain cancers, and neurodegenerative diseases. Potential effects of OO on various diseases-related parameters are discussed in relation to OO and its phenolics.

Keywords
Olive oil · Mediterranean diet · Phenolic compounds · Virgin olive oil · PUFA · MUFA

Abbreviations

CRP	C-reactive protein
EFSA	European Food Safety Agency
GcMAF	Gc protein-derived macrophage activating factor
HDL	High-density lipoprotein
ICAM-1	Intercellular adhesion molecule-1
IL	Interleukin
LDL	Low-density lipoprotein
MD	Mediterranean diet
MUFA	Monounsaturated fatty acid
OO	Olive oil
OOPC	Olive oil phenolic compound
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid
VCAM-1	Vascular cell adhesion molecule-1
VOO	Virgin olive oil

1 Introduction

In a number of studies, the Mediterranean diet (MD) has been connected with longevity and a reduced risk of morbidity and mortality. Life-style factors, such as regular physical activity, a healthy diet, and the existing social cohesion in southern European countries have been recognized as candidate protective elements which may explain the Mediterranean paradox. The term MD was coined in the 1960s by Ancel Keys within the framework of the Seven Countries Study. This epidemiological study with more than 12,000 individuals reported that Italian and Greek populations had lower mortality rates, and a reduced incidence of cancer and cardiovascular disease (CVD), compared to those from other European countries,

America, and Asia [1]. Such findings led to an exponential increase from 1999 of original articles regarding the MD [2]. High adherence to this diet pattern has been associated with a reduction in the risk of suffering CVD and cerebrovascular diseases, diabetes mellitus, metabolic syndrome, certain cancers, and neurodegenerative diseases [3]. The link between adherence to the MD and a reduction in total mortality has also been confirmed [4, 5].

In general, the MD is characterized by (1) a high intake of cereals, vegetables including leafy greens, legumes, nuts, and fruit; (2) a moderate intake of poultry, fish, eggs, milk and dairy products, as well as a regular but moderate ethanol consumption (generally in the form of wine during meals); and (3) a low intake of red and processed meat and industrial confectionary [4–7]. Along with some other traits of the Mediterranean diet, the use of olive oil (OO), as the main source of fat (especially dressings), is common in southern European countries. A relatively high fat consumption (up to 40% of total energy intake), mostly from monounsaturated fatty acids (MUFAs) (up to 20% of total energy consumption) is characteristic of this diet [8]. In the Mediterranean area, it is estimated that subjects consume between 25 and 50 mL of OO per day (raw and that used for cooking). Nevertheless, its consumption varies around the Mediterranean countries.

The health benefits of consuming OO have been known since antiquity and were traditionally attributed to its high MUFA content, mainly oleic acid. In this regard, a recent meta-analysis of 32 cohort studies with the aim of studying MUFA (of both plant and animal origin), oleic acid, MUFA/saturated fatty acid (SFA) ratio, and OO intake, indicated that, when comparing the upper to the lower tertile of consumption, OO, but not MUFA, was associated with a reduced risk of all-cause mortality, CVD events, and stroke [9]. Thus, the extra constituents of OO may also have a protective potential [10–12].

2 Cancer

Cancer is a multifactorial disease in which several aberrant processes are involved (deregulation of cell cycle, abnormal expression of pro-oncogenes, deregulated angiogenesis, excessive oxidative stress, chronic inflammatory responses, etc.). Several lifestyle factors such as smoking, unhealthy eating, and sedentary habit can increase the predisposition to develop cancer. Thirty to 40% of all cancers could be prevented by appropriate diets, physical activity practice, and maintenance of appropriate body weight [13]. Traditionally, a high consumption of fruit and vegetables has been inversely related to chronic degenerative diseases such as cancer [13, 14]. In the EPIC study, fiber intake from cereals, fruit, and vegetables showed a protective effect on colorectal cancer, and fruit consumption was also associated with lower rates of lung cancer [15]. Among the Mediterranean countries, meta-analyses of ecological and cohort studies found that cancer morbidity and mortality are lower than in other ones [16]. A high adherence to the MD, in which OO is the main source of fat, has been associated with reduced mortality for all type of cancers in prospective studies [5]. Around 25% of colorectal cancer incidence, 15% of breast

cancer, and 10% of prostate, pancreas, and endometrial cancer could be prevented by a TMD in the Western countries [17]. Recently, a 4.8-year adherence to a traditional MD (supplemented with virgin olive oil (VOO) or nuts) was found to protect against breast cancer development in an elderly women [18]. In contrast, in Mediterranean cohorts within the framework of the EPIC Study, OO consumption was not linked to lower breast cancer risk in postmenopausal women. Nevertheless, an inverse association between OO intake and the levels of estrogens and progesterone receptor-negative tumors was suggested [19]. Also within the EPIC Study, the adherence to an MD was associated with a decrease in the incidence of gastric adenocarcinoma [20]. In this respect, the antimicrobial activity conferred by OO against *Helicobacter pylori* (a microorganism related to gastric ulcers and subsequent carcinomas) could play a role in such an observation [21]. Finally, in Caucasian populations in the Mediterranean basin, prostate cancer incidence is lower than that in Caucasian males from other areas. The richness of MUFAs versus SFAs in the MD pattern has been postulated as a possible explanation [22].

With reference to OO, an inverse association between its intake and the appearance of different types of cancers has been described mainly from case-control studies [23]. In this respect, a meta-analysis of case-control studies assessing the effects of OO and MUFA intake was performed ($N = 19$, 13,800 cancer patients and 23,340 controls). Subjects in the group with the highest OO consumption presented lower odds of suffering any type of cancer (logOR $= -0.41$; CI: $[-0.53, -0.29]$). Considering different cancer origins, the meta-analysis showed that high OO intake is linked to a lesser probability of having cancer of the digestive tract (logOR $= -0.36$; CI: $[-0.50, -0.21]$) and breast cancer (logOR $= -0.45$; CI: $[-0.78, -0.12]$) [24].

In a clinical trial, patients with advanced cancer received a dietary intervention rich in oleic acid and Gc protein-derived macrophage activating factor (GcMAF) which can inhibit cancer cell proliferation. The diet, which was low in carbohydrates, rich in proteins, fermented milk products (which contains naturally-produced GcMAF), Vitamin D3, and omega-3 fatty acids, enhanced the immune system, and a 25% reduction in tumor volume was observed [25].

3 Neurodegenerative Diseases

Chronic inflammatory status, together with oxidative stress, affects neuron functionality. Oxidation and inflammation processes promote the deposition of a number of proteins inside neurons, consequently, the correct function of the mitochondria becomes impaired. When these processes are perpetuated over a long period of time, the development of several neurodegenerative diseases can occur. In particular, Alzheimer's disease, which is one of the greatest challenges of any national health system, given the population aging. As there is no curative treatment to date, preventive strategies based on a healthy aging are being promoted. A number of epidemiological studies suggests that several nutrients (such as antioxidants, E and B-vitamins, and polyunsaturated fatty acids) [26], and foods (such as fish,

vegetables, fruit, and wine) [27] may decline cognitive impairment, including Alzheimer's disease [28]. As oxidative stress can play a role in the development of neurodegenerative diseases [29], the intake of phenolic compounds (PCs), with a considerable spectra of bioactivities in vitro and in vivo, has been proposed for their management [30].

Given the association between cardiovascular risk factors and neurodegenerative ones, the cardiovascular health benefits of the MD can also confer protection against neurodegenerative disorders [31]. While diets rich in saturated fats and simple carbohydrates are linked to neurodegenerative diseases [32], the MD is able to enhance cognitive function. An association between MD adherence and delay in cognitive decline was observed in elderly subjects in a prospective cohort study in France [6]. Moreover, in elderly individuals at high cardiovascular risk following the MD, better cognitive efficiency [28] and performance were reported [33]. The majority of these studies have been performed in the Mediterranean areas; nevertheless, other projects have been conducted in non-Mediterranean countries which suggest that the healthy benefits of an MD can be transferred to other populations. In this respect, greater adherence to the MD pattern was linked to a reduced risk of Alzheimer's disease with approximately 2000 subjects in New York [7].

The reduced vascular comorbidities observed with an MD, together with its richness in compounds with antioxidant and anti-inflammatory effects, can play a role in central nervous system benefits [34–36]. In this regard, VOO, one of the key foods of the MD pattern, has been linked to improved cognitive function due to its relevant bioactive compounds [28]. Hydroxytyrosol, oleuropein, and especially oleuropein aglycon have been shown to inhibit Tau aggregation in vitro [37].

4 Diabetes Mellitus

4.1 Type-II Diabetes and Impaired Glucose Tolerance

Impaired glucose tolerance is defined as high blood glucose levels after eating, whereas impaired fasting glucose is defined as high blood glucose after a period of fasting. People with impaired glucose tolerance are at high risk of developing DM2. Unsurprisingly, impaired glucose tolerance shares many characteristics with DM2 and is associated with obesity, advancing age, and the inability of the body to use the insulin it produces. Not everyone with impaired glucose tolerance goes on to develop DM2 [38]. DM2 is a chronic disease that occurs either when the pancreas does not produce enough insulin or when the body cannot effectively use the insulin it produces. Hyperglycemia is a common effect of uncontrolled diabetes and over time leads to serious damage to many of the body's systems, especially the nerves and blood vessels [39]. Some 382 million people worldwide, or 8.3% of adults, are estimated to have diabetes. According to International Diabetes Federation, the causes are still unclear but people with overweight, poor diet, lack of physical activity, and family story of diabetes are at high risk of DM2 [38].

Several studies have found a link between MD and glucose metabolism. The ATTICA study observed that adherence to MD was related to better homoeostasis factors related to fasting glucose (fasting plasma glucose, insulin levels and the insulin resistance index: HOMA) in normoglycemic people [40]. Moreover, PREDIMED study found that a long-term intervention with a high-quality dietary pattern based on traditional MD and rich in EVOO could reduce the incidence of DM2 in older people at high cardiovascular risk. This beneficial effect was mainly due to the overall composition of the dietary pattern and not to calorie restriction, increased physical activity, or weight loss [41]. A couple of meta-analysis [42, 43] also found a significant association between adherence to dietary patterns and decreased risk of DM2. One of the previous meta-analysis specifically concluded that adherence to a MD is associated with a decreased risk of becoming diabetic at a reasonable magnitude (19%) [43]. Other systematic review of eight meta-analyses and five randomized controlled trials studied the effect of MD on the treatment of DM2 and prediabetic states. This review indicated that in DM2 patients, the adherence to MD was associated with lower glycated hemoglobin (HbA1c) levels and improved cardiovascular risk factors, as compared with control diets, mainly lower fat diets [44]. Thus, it is suggested that the Mediterranean diet is not only suitable for prevention but it is also an appropriate dietary pattern for the management of DM2.

Another meta-analysis of prospective cohort studies to assess the association between different diets and prevention of DM2 found that although the diets associated with prevention of DM2 may vary in their composition, nonetheless they shared several common components, including whole grains, fruit, vegetables, nuts, legumes, protein sources such as white meat and seafood, little or moderate alcohol, and reduced intake of red and processed meats and sugar-sweetened beverages, and noteworthy healthy table oils (i.e., olive oil) [45]. MD covers all of the above being one of its emblematic characteristics is the use of olive oil.

One of olive oil's characteristics is its high content in monounsaturated fatty acids (MUFA). Evidence suggests that diets enriched in MUFAS from OO have a positive effect in glycemic control. A study examining intakes of MUFA through the increased consumption of olive oil found an association with lower fasting plasma glucose concentration [46, 47]. Another cohort study of women found a similar result after a 22 years follow-up. The published results showed that higher olive oil intake was associated with modestly lower risk of DM2 and that hypothetically substituting other types of fats and salad dressings (stick margarine, butter, and mayonnaise) with olive oil was inversely associated with the onset of DM2 [48]. In another cross-sectional study in Spain (Pizarra study), it was found that insulin resistance was significantly lower in people who consumed OO than in those who consumed sunflower oil or a mixture [167].

Furthermore, a randomized trial with two groups of DM2 patients, following a MD using OO or a control low-fat diet presented that the MD with OO can improve endothelial dysfunction, inflammation, and oxidative in DM2 patients compared to a control diet [49]. The PREDIMED trial also provides strong evidence that long-term adherence to a MD supplemented with EVOO, which is high in MUFAS and

bioactive polyphenols, results in a substantial reduction in the risk for DM2 among older people with high cardiovascular risk [41].

Oleic acid (cis C18:1 n-9), the predominant MUFA on OO, has been related to a lower insulin resistance as well. A study addressing [50] the relationship between changes in membrane fatty acid composition and glucose transport as an index of insulin sensitivity found a reduction in insulin resistance when a polyunsaturated (linoleic acid; C18:2 n-6) rich diet was changed to an oleic acid (C18:1 n-9) rich diet. This improvement was related to the change in membrane fluidity, as an oleic acid-rich membrane would be less fluid to its linoleic acid-rich equivalent [46]. Similar results were found in another study [51] where changes in membrane fatty acids and signaling proteins induced by VOO consumption in elderly persons with DM2 compared to a control group were analyzed. The long-term consumption of VOO induced changes in the fatty acid content of erythrocyte membranes from elderly DM2 participants. These changes were due to an increase amount of oleic acid in the membranes and in consequence biochemical changes in the amount of signaling proteins (G proteins and protein kinase C). The above could explain the mechanisms of glycemic homeostasis after consumption of olive oil.

In addition to MUFA, extra virgin olive oil contains also other bioactive components, some of them are called the phenolic compounds such as oleuropein and hydroxytyrosol, flavonoids, specially flavones, and lignans. Apart from PREDIMED, other clinical trials have evaluated the effect of EVOO rich in polyphenols on glycemic biomarkers [52]. Daily consumption of polyphenol-rich EVOO (25 mL/day, 577 mg of phenolic compounds/kg) for 8 weeks significantly reduced fasting plasma glucose and HbA1c, as well as other circulating inflammatory adipokines (visfatin), in overweight patients with DM2 [53], in a crossover randomized trial.

Mediterranean-type dietary patterns are known to improve several parameters of the postprandial state with high atherogenic potential, such as the glycemic load and the secretion and clearance of chylomicrons [54]. The consumption of OOPCs has been able to decrease oxidative stress (as observed in several biomarkers related to oxidative modifications of plasma lipids, proteins, and DNA) in healthy volunteers after meals [10] and in long-term interventions [11]. Concretely, a single dose of 25 mL of OO does not promote postprandial oxidative stress whereas doses equal or superior to 40 mL do [10, 55]. In addition, phenolic compounds from OO have been able to modulate postprandial oxidative stress in healthy volunteers [10]. The glycemic load of a meal can depend on the bioavailability of carbohydrates and food preparation. In this regard, in a study with 12 women with obesity and insulin resistance, food fried in VOO improved both insulin and C peptide responses after a meal [56]. VOO may additionally contribute, within the context of a traditional MD, to the long-term improvement of the glycemic load and the dietary glycemic index [57].

In conclusion, there is already widespread experience of the benefits of olive oil in glucose metabolism, both in a medium- and long-term period and in the postprandial phase, in the context of dietary patterns, of olive oil by itself, and the bioactive compounds of olive oil.

5 Cardiovascular Diseases

The development of an atherosclerotic plaque in the endothelium of blood vessels is common to CVDs. The plaque is formed by the accumulation of cholesterol inside the macrophages and other cells, such as the smooth muscle ones, located in the intima media. This generates an inflammatory chronic response that eventually can trigger acute thrombotic vascular disease, including myocardial infarction, stroke, and sudden cardiac death [58]. Atherosclerotic plaques are linked to the coexistence of several processes related to inflammation, lipid oxidation, dysfunction of the vascular endothelium, exacerbated activation of immune cells, and migration of vascular smooth muscle cells, among others [59].

Since Ancel Keys presented the MD as a health protecting one [1], there have been many studies supporting this link [5, 7, 16, 60]. The most impressive benefits of this diet, however, have been related to reductions in cardiovascular morbidity and mortality [61]. In general, countries from southern Europe present the lowest values of accumulated incidence and mortality rate of coronary heart disease [62, 63]. The paradox of the Mediterranean countries with a low incidence rate of cardiovascular disease [64–66], in spite of a marked prevalence of classical cardiovascular risk factors [67, 68], is attributed in part to a high degree of adherence to the MD. Nevertheless, most studies were observational so that any causal inference was hindered by residual confounding among other biases. Thus, large-scale randomized trials using dietary patterns, and assessing clinical end-points, are needed to provide a high level of scientific evidence. In this regard, very few randomized trials have been performed. On one hand, the Lyon Diet Heart Study, a secondary prevention trial, showed a large reduction in rates of coronary heart disease events with a modified MD enriched with alpha-linolenic acid [69]. On the other hand, the PREDIMED study, a multicenter, randomization, intervention trial with the MD, reported the protection of the traditional Mediterranean Diet (TMD) on incident CVD in high cardiovascular risk individuals, in primary prevention [70]. In addition, the PREDIMED Study has also provided evidence of the efficacy of the TMD on primary prevention for stroke [70], atrial fibrillation [71], type-2 diabetes (DM2) [72], and peripheral vascular disease [73].

Nowadays, the relevance of overall high-quality diet patterns, rather than focusing on single nutrients and foods, has highlighted the need to address the complexity of dietary exposures. Nevertheless, it is well-known that OO plays a pivotal role in this diet pattern. Data from EPIC cohorts showed an inverse relationship between OO consumption and coronary heart disease mortality and incidence [74–76]. Also, results from the Three-City Study reported an inverse relationship between OO consumption and stroke risk in women [77]. Finally, results of the PREDIMED Study showed that consumption of OO, specifically the extra-virgin variety, within the framework of the Mediterranean diet, reduces the risk of CVD and mortality in elderly high cardiovascular risk individuals [78].

It is increasingly accepted that chronic degenerative diseases, such as CVD, cancer, and neurodegenerative ones, share common risk factors. Besides the classical

cardiovascular risk factors (diabetes, hypertension, lipid profile, tobacco, and obesity), perpetuated molecular dysregulation with respect to oxidation, low-grade inflammation, LDL atherogenicity, HDL function, and endothelial dysfunction, among others, may be behind their onset.

5.1 Arterial Hypertension and Endothelial Dysfunction

OO has also been linked to an improvement of endothelial dysfunction and blood pressure state. In a meta-analysis of randomized controlled assays ($N = 12$, with a duration of 6 months or longer) high- versus low-MUFA intake (low MUFA intake was considered a MUFA consumption below 12% of total daily energy consumption) was compared, and MUFA-rich diets decreased systolic (mean effect: −2.26 mmHg; CI: [−4.28, −0.25]; $p = 0.03$) and diastolic blood pressure (mean effect: −1.15 mmHg; CI: [−1.96, −0.34]; $p = 0.005$]. In addition, an improvement of the fat mass −1.94 kg, CI: [−3.72, −0.17], p = 0.03] was additionally reported [79]. MUFA intake also has effects on doses of antihypertensive drugs prescribed to patients. A MUFA-rich diet (17.2% of total daily energy intake by MUFAs, 3.8% by PUFAs) was able to decrease blood pressure relative to a polyunsaturated fatty acid (PUFA)-rich one (10.5% of total daily energy intake, 10.5% by PUFAs) and, moreover, decreased the daily dosage of hypertensive agents [80]. A decrease of diastolic blood pressure in hypertensive women was observed after an MD intervention, enriched with VOO or nuts, within the context of the PREDIMED Study [81]. Nitric oxide and endothelin-1 levels, together with endothelin-1 receptor gene expression, could play a role in blood pressure improvement [82].

Regarding OOPCs, in a meta-analysis with 13 studies concerning the effects of high phenolic OO oil on cardiovascular risk factors, medium effects for lowering systolic blood pressure (n = 69; mean effect: −0.52; CI: [−0.77, −0.27]; $p<0.01$) were described; however, no effects for improving diastolic blood pressure were reported (mean effect: −0.20; CI: [−1.01, 0.62]; $p = 0.64$) [83].

Endothelial function improved in hypercholesterolemic patients at postprandial state with phenol-rich OOs and OOPC-enriched functional OO intake [84, 85], after a 4-month intervention of a daily intake of VOO in patients with incipient atherosclerosis [86], and after 2 months in women with high-normal blood pressure or stage-1 essential hypertension [87].

Endothelial homeostasis can be disturbed by oxidative stress and chronic inflammatory processes and finally lead to endothelial dysfunction [58]. An increase in nitric oxide metabolites was observed after a phenol-rich OO postprandial intake versus a low-phenolic OO [84]. Also, a decrease in systolic blood pressure after the intake of VOO was described, with a decrease in lipid oxidation markers, in hypertensive stable patients [88]. Finally, in two randomized crossover studies, a 50 mL intake of phenol-rich OO decreased the postprandial leukotriene B4 (a pro-inflammatory eicosanoid) and thromboxane B2 (a vasoconstrictor eicosanoid) levels in comparison to refined OO in healthy [169] and mildly dyslipidemic subjects [89].

5.2 Haemostasis and Platelet Aggregation

Olive oil has been shown to improve the production of coagulation factors and biomarkers linked to platelet aggregation, thus improving the thrombogenetic profile [90].

With regard to monounsaturated fats, a MUFA-rich diet such as the MD decreases postprandial levels of coagulation factor VIIc [91]. In addition, oleic acid (75% of OO fatty acids) attenuates the prothrombotic state in the postprandial phase [91–93].

Regarding OOPCs, the consumption of phenol-rich OOs improved the postprandial prothrombotic state (activated coagulation factor VII, tissue factor, tissue plasminogen activator, plasminogen activator inhibitor type-1, and fibrinogen) in a number of randomized controlled trials in both healthy [94] and hypercholesterolemic subjects [90]. In long-term interventions, a decrease in plasma fibrinogen in women with high baseline fibrinogen concentrations has been reported after OO consumption, in a randomized crossover trial [95].

5.3 Lipid Profile

Improved dietary fat quality, achieved through a replacement of SFA by unsaturated fat, enhances the lipid profile by reducing low density lipoprotein (LDL) cholesterol and increasing high-density lipoprotein (HDL) cholesterol [96]. Olive oil intake assures an increase of MUFA, without a significant rise of SFA, and guarantees an appropriate intake of (PUFA). As a consequence, the MUFA/SFA ratio is much higher in areas where an MD is followed [97]. An updated review suggested a small, but potentially relevant, reduction in cardiovascular risk with low saturated fat intake [98]. The replacement of energy from saturated fat with polyunsaturated fat provides more healthy benefits than with carbohydrate. Regarding the substitution of SFAs for MUFAs, although the benefits are more modest, some positive effects on lipid profile have been observed. The reduction of dietary saturated fat, and partial replacement by unsaturated fats, has been proposed to achieve maximum health benefits although the ideal type of unsaturated fat is still unclear [98].

Schwingshackl et al. published a meta-analysis including 32 studies with overweight and obese patients. On one hand, decreases in total cholesterol (weighted mean difference −0.12 mmol/L, 95% CI: [−0.28 to −0.03]; P = 0.01) and LDL cholesterol (−0.08 mmol/L, 95% CI: [−0.12 to −0.04]; P<0.0001) were more marked after low-fat diets. On the other hand, a rise in HDL cholesterol (0.06 mmol/L, 95% CI: [0.03, 0.09]; P<0.0001) and a reduction in triglyceride (−0.095 mmol/L, 95% CI: [−0.15, −0.04]; P = 0.001) were more pronounced after the high-fat diet groups [99].

Regarding OO, in a recent meta-analysis about the effects of PC-rich OO on cardiovascular risk factors, no significant effects in improving lipid profile were observed (total cholesterol $N = 400$; mean effect: −0.05; CI: [−0.16, 0.05]; $p = 0.33$); HDL cholesterol ($N = 400$; mean effect: −0.03; CI: [−0.14, 0.08]; $p = 0.62$); LDL cholesterol ($N = 400$; mean effect: −0.03; CI: [−0.15, 0.09]; $p = 0.61$); and triglycerides ($N = 360$; mean effect: 0.02; CI: [−0.22, 0.25];

$p = 0.90$). Nevertheless, the small number of studies ($N = 8$) is a limitation [83]. Specifically, the beneficial effects of OO polyphenols on blood HDL cholesterol concentrations were evaluated by the European Food Safety Authority (EFSA) and they concluded that evidence was insufficient to establish a cause-effect relationship [100]. A recent review indicated that the intake of PC-rich OO induced no significant increases in HDL cholesterol levels [83], while several high-quality randomized controlled trials have pointed to a dose-dependent increment in HDL cholesterol after the consumption of OOPCs [11, 12, 101].

5.4 Lipid Oxidation

In November 2004, the USA Federal Drug Administration [102] permitted a claim on OO labels regarding "the benefits on the risk of coronary heart disease of taking 2 tablespoons (23 grams) of OO daily, due to monounsaturated fat." However, if the effect of OO is only attributed to its MUFA content, any type of MUFA-rich food (such as rapeseed oil, canola oil, or MUFA-enriched fats) would provide the same beneficial effects for health. The minor components of OO (1–2% of the total content) are classified in two groups: (1) the unsaponifiable: squalene and other triterpenes, sterols, tocopherol, carotenoids, and pigments and (2) the soluble fraction which includes the PCs [168]. In this respect, the EFSA released a health claim concerning the protection of OOPC (5 mg/day) against LDL oxidation [103]. Based on well-designed intervention trials, a cause-effect relationship was established by the EFSA between the consumption of VOO and the protection of LDL particles from oxidative damage [103].

Not only changes in LDL cholesterol are involved in cardiovascular risk, oxidation modifications of the LDL particle may play a major role in atherosclerosis [58, 104, 105]. Several OO components contribute to decreasing LDL oxidizability. On the one hand, MUFAs are less prone to becoming oxidized when compared to other unsaturated fats [106]. On the other hand, OO antioxidants (vitamin E, carotenoids, and OOPCs) can bind to the LDL particle and protect it from oxidative modifications.

A recent meta-analysis ($N = 13$) reported that oxidized LDL levels decrease significantly after the consumption of high-phenolic OO ($N = 300$; mean effect: -0.25; CI: $[-0.50, 0.00]$; $p = 0.05$) [83]. In the EUROLIVE Study, 200 volunteers were given 25 mL/day of raw OO with high (366 mg/kg), medium (164 mg/kg), and low (3 mg/kg) phenolic content in a randomized, crossover, and controlled trial [11]. Covas et al. reported a decrease of the in vivo lipid oxidative damage (concretely in oxidized LDL, uninduced conjugated dienes, and hydroxy fatty acids) in a linear manner with the phenolic content of the OO administered [11]. As potential mechanisms to explain this benefit, we could consider an increase in the content of vitamin E and OOPC in LDL that may counteract locally oxidative modifications [107, 108]. In addition, the reductive effect of the OOPC on oxidized LDL could be due to the generation of antibodies [109]. Vázquez-Velasco et al. observed, in healthy volunteers, a decrease in the concentration of oxidized LDL when

hydroxytyrosol-enriched sunflower oil (45–50 mg/d) was administered during 3 weeks [110]. In 40 males suffering from stable coronary heart disease, VOO was able to decrease the oxidized LDL in plasma compared with another olive oil with a smaller amount of PC in a randomized crossover trial [88]. Finally, LDL oxidizability has also been evaluated in vitro, and it decreased after the consumption of MUFAs [111, 112] and phenol-rich OOs [11, 101, 113, 114].

Finally, Fitó et al. reported an improvement of circulating oxidized LDL after a 3-month MD intervention in high cardiovascular risk patients [115].

5.5 HDL Functionality

Although low levels of HDL cholesterol are considered an independent cardiovascular risk factor [116], it has been recently observed that presenting high HDL cholesterol levels does not always lead to a decrease in cardiovascular risk [117–119]. An increase in HDL cholesterol is one of the goals of clinical management of cardiovascular diseases [117]. In this regard, recent studies have shown that the functionality of HDL can be of greater relevance than its amount [120]. Decreased values of the most relevant HDL function have been reported to be related to a high incidence of subclinical atherosclerosis [121] and coronary events [122].

The functionality of the HDL particle involves the promotion of cholesterol efflux from macrophages and peripheral cells, which constitutes part of the so-called "reverse cholesterol transport" [123]. Furthermore, HDLs play a crucial role in inhibiting the oxidation of plasma lipids (mainly, the ones in LDLs) and also present anti-inflammatory and vasoprotective capacities [124]. Oxidative modifications of the HDL can additionally affect the lipid and/or protein of the lipoprotein and alter its physiological properties [120, 124–126] and, in this regard, antioxidants linked to the particle could be able, direct or indirectly, to counteract such oxidation. An increment in HDL fluidity, enhanced HDL composition, and better HDL size distribution could also mediate improvements in HDL function [127–129].

Regarding OO, the consumption of a MUFA-rich diet improved the cholesterol efflux capacity of HDLs in a linear trial [130]. This functional improvement could be due to a lower degree of oxidative modifications of the lipoprotein after increasing its MUFA content [131]. Regarding OOPCs, Hernáez et al. reported for the first time an increase in cholesterol efflux after the daily intake of 25 mL of VOO (366 mg/kg) in healthy volunteers within the framework of the EUROLIVE Study [132]. In parallel, biological metabolites of OOPC bound to the HDLs (hydroxytyrosol sulfate, and homovanillic acid sulfate, and glucuronate) were determined. The improvement of HDL fluidity and a triglyceride-poor core can also result in a more functional HDL particle [132]. In this respect, functional VOO supplemented with olive and thyme phenols versus a VOO intervention produced an increase in the lecithin-cholesterol acyltransferase concentration which esterifies free cholesterol and mediates its migration into the particle core [133]. The consumption of OOPCs has also been shown to be able to increase the levels of the main HDL antioxidant enzyme, paraoxonase-1, as well as HDL anti-inflammatory ability, in a noncontrolled trial [134]. Besides the direct

antioxidant effect of OOPCs on HDL particles, these compounds have also been observed to be able to improve the gene expression related to HDL function [135].

Finally, a TMD, especially when supplemented with real-life doses VOO, was able to improve HDL functionality [136]. Concretely, a 1-year intervention with an MD increased cholesterol efflux capacity and, in particular, the VOO-rich MD enhanced nitric oxide synthesis by endothelial cells promoted by HDLs, decreased cholesteryl ester transfer protein activity, and increased HDL ability to esterify cholesterol and paraoxonase-1 arylesterase activity [136].

5.6 Inflammatory Processes and Systemic Oxidative Status

Oxidation and inflammation are intertwined processes which, when sustained for a long period, may induce the onset of a number of chronic degenerative diseases, such as CVD, diabetes, neurodegenerative diseases, and cancer. The increased circulating concentrations of pro-inflammatory analytes (tumor necrosis factor-α, monocyte chemotactic protein-1, soluble vascular cell adhesion molecule 1, and soluble intercellular adhesion molecule-1) perpetuate the inflammatory response in the subendothelial space and establish endothelial dysfunction.

Traditionally, the health benefits of the MD have been attributed to its richness in antioxidants. Among the approximately 230 chemical compounds of OO, the main antioxidants are carotenes and phenolic compounds, including lipophilic and hydrophilic phenols [137]. Current evidence points to oxidative damage as a promoter of pathophysiological processes in oxidative stress-related diseases such as coronary heart disease, cancer, neurodegenerative pathologies, and, in addition, aging [138–140]. Although phenolic compounds are good antioxidants in vitro, their in vivo effects can be indirectly mediated through the activation of several nutrigenomic pathways and not only by their intrinsic antioxidant activity [141, 170]. Benefits of olive oil on lipid oxidation have been extensively explained in the Sect. 5.4 apart.

Several benefits on the levels of pro-inflammatory biomarkers have been proven in human trials with OO or MUFA-rich diets. A daily intake of real-life doses of OO has been shown to produce a decrease of the C-reactive protein (mean effect: −0.64 mg/L; CI: [−0.96, −0.31]; $p<0.0001$) and IL-6 (mean effect: −0.29; CI: [−0.70, −0.02]; $p<0.04$) in a recent systematic review [43]. Nevertheless, the heterogeneity of design among studies makes further research necessary. With regard to other MUFA-rich diets, a randomized controlled trial with 28 hypertriglyceridemic and 14 healthy males who followed a diet rich in refined OO (high-oleic acid diet) or a diet rich in high-palmitic sunflower oil, revealed a postprandial decrease of the soluble adhesion molecules (VCAM-1, ICAM-1) after the high-oleic intervention [142]. And in another randomized controlled trial, a 2-month MUFA-rich diet decreased the expression by peripheral blood mononuclear cells of ICAM-1 in healthy males [143]. In contrast, a randomized crossover trial in healthy subjects regarding the effect of three Malaysian diets: palm olein, coconut oil, and OO (the fat source providing approximately 20% of total energy intake in

each case), the postprandial and 2-week fasting circulating concentrations of a number of inflammatory biomarkers (tumor necrosis factor-α, IL-1β, IL-6, IL-8, CRP, and interferon-γ) were not affected [144].

The consumption of OO, which provides oleic acid as the main fatty acid, also yields a moderate intake of PUFA (mainly omega-6 linoleic acid and omega-3 alpha-linolenic acid) without a noticeable increase in the intake of SFA. Omega-6 fatty acids, in which PUFAs are predominant (especially in the Western diets), are precursors of pro-inflammatory eicosanoids (2-prostaglandins, tromboxanes, and 4-leukotrienes) [145]. In this regard, omega-3 fatty acids in OO may play a role in the inhibition of the inflammatory process boosted by omega-6 fatty acids [146]. It has been reported that a low incidence of coronary heart disease is related to a diet rich in omega-3 fatty acids [147].

The OOPCs have also shown effects on pro-inflammatory biomarkers. Surprisingly, Beauchamp et al. described oleocanthal anti-inflammatory properties that were similar to those of ibuprofen (cyclooxygenase-2 inhibition and nuclear factor kappa beta counteract) [148]. Moreover, the intake of phenol-enriched OO (50 mL/day) decreased C-reactive protein (CRP) levels at postprandial state relative to refined olive or corn oils in healthy individuals, in a randomized controlled trial. In this regard, a regular intake of OO at long term can contribute to controlling the postprandial inflammatory burden [149]. Also, a combined consumption of white wine (2–3 glasses/daily) and extra VOO (*ad libitum*) for a 2-week period decreased the levels of CRP and IL-6 in both patients with chronic kidney disease and healthy subjects [150]. Finally, a raw real-life daily dose of 50 mL of VOO for 3 weeks decreased the IL-6 and CRP concentrations (versus refined OO) in a randomized controlled trial with stable coronary heart disease patients [151].

Within the context of a traditional MD, supplementation with VOO or nuts decreased the systemic levels of CRP, IL-6, sVCAM1, and sICAM1 in high cardiovascular risk volunteers within the framework of the PREDIMED Study [81]. In addition, the traditional MD (supplemented with VOO or nuts) was able after 3 months of intervention to decrease the expression of CD49d (an adhesion molecule) and CD40 (a pro-inflammatory ligand) in monocytes isolated from the blood of high cardiovascular risk volunteers [152].

The MD participants had lower plasma concentrations of atherosclerosis-related inflammatory markers (IL-6, IL-8, MCP-1, and MIP-1β) after 3 and 5 years of an MD intervention versus a low-fat diet control group. In addition, IL-1β, IL-5, IL-7, IL-12p70, IL-18, TNF-α, IFN-γ, GCSF, GMCSF, and ENA78 decreased especially after an MD supplemented with VOO [153]. Finally, the reduction in CD49d and CD40 expressions in T lymphocytes and monocytes at 3 years were greater in the MD group than in the low-fat diet control one [154].

5.7 Immune System

Regarding MUFAs, they have been reported to modulate a number of biological pathways of immune competent cells [155]. In this regard, in a randomized

controlled trial with healthy males, there was a significant decrease in the expression of intercellular adhesion molecule 1 by peripheral blood mononuclear cells after MUFA-rich 2 month-diet. Nevertheless, natural killer cell activity and the proliferation of mitogen-stimulated leukocytes were not affected [143].

The consumption of a functional VOO showed an increase in the proportion of IgA-coated bacteria, which indicates a local stimulation of the intestinal mucosal immunity [156]. Based on the effects of OO intake on the immune system, it has been suggested that OO consumption may have benefits on rheumatoid arthritis [155]. In contrast, other authors have published that OO-rich diets do not alter host resistance to infection [157, 158]. Given that data are scarce, more studies are required to establish the possible immunostimulation of OO in vivo.

5.8 Microbiome

Gut microbiota, a complex and dynamic ecosystem, is an emergent factor of a number of diseases including obesity and type-II diabetes [159]. PCs can selectively stimulate growth bacteria, such as Lactobacillus [160], which can play a role in lowering cholesterol levels [161]. Intestinal lactobacilli produce bile-salt hydrolase, which deconjugates bile acids, prevents their reabsorption, and therefore promotes their fecal excretion [162]. This can be one of the mechanisms involved in the decrease of systemic cholesterol after PC consumption [163]. PCs may also be related to the growth of other bacterial populations (such as Bifidobacterium) which might be linked to a lesser development of the atherosclerotic plaque [164].

Since most PCs are not fully absorbed into the upper gastrointestinal tract and reach the large intestine, they can be metabolized by gut microflora [165]. A 3-week intake of a phenol-enriched VOO (with OO and thyme PCs) increased populations of Bifidobacteria and the levels of microbial metabolites of antioxidant PCs, such as protocatechuic acid and hydroxytyrosol, in hypercholesterolemic individuals [166].

6 Conclusion

In summary, current evidence indicates the potential benefits of olive oil, within the framework of a healthy diet such as the Mediterranean one, on the prevention of chronic degenerative diseases including cardiovascular and degenerative ones. To date, the majority of these effects have been demonstrated from the perspectives of atherosclerosis and cardiovascular risk research. Nevertheless, there is increasing evidence that such beneficial properties also display a protection towards other diseases including neurodegenerative ones and cancer.

The daily diet represents the consumption of a mixture of foods in which the type of cooking plays an indisputable role in the availability and properties of nutrients. Furthermore, synergism among nutrients and foods, and their cumulative effects, must also be taken into consideration. With respect to the

Mediterranean diet, olive oil as the main source of fat is determinant with respect to the properties attributed to this dietary pattern.

Olive oil intake facilitates more vegetable consumption and thus benefits on health can be maximized. Nutrient-specific biases and type of olive oil should be considered in order to disentangle the benefits of MUFA and/or other minor components. Further well-designed, large-scale cohort studies in Mediterranean and non-Mediterranean areas are needed to reaffirm the therapeutic properties of olive oil and establish in which subjects and under which conditions benefits can be more easily achieved.

Abstract

After consumption of anthocyanin-rich foods, there is a long journey before these bioactives may exert a health-promoting property. They must pass through the oral cavity, the gastrointestinal tract, undergo metabolism events, pass cellular barriers, and eventually trigger a biological event.

Hence, before looking at the health effects of anthocyanins, some topics related to their food bioaccessibility, interaction with biomolecules (proteins, biomembranes, and DNA), and bioavailability/metabolism will be described as possible interferers to their bioactive effects.

There are several reports on the health preventing properties of anthocyanins on several diseases like cardiovascular diseases, some types of cancers, diseases, diabetes, allergies and osteoporosis. In this chapter some of the less revisited ones giving emphasis to obesity/metabolic syndrome, microbiota modulation, neurodegenerative diseases and skin health will be reviewed.

1 Introduction

1.1 Chemistry, Occurrence, and Stability

Anthocyanins constitute the largest group of water-soluble pigments widespread in the plant kingdom arising from plant secondary metabolism, being responsible for the colors displayed by many flowers, fruits, and leaves of angiosperms (Fig. 1). Chemically, anthocyanins are flavonoids, hence based on a C15 skeleton with a chromane ring bearing a second aromatic ring B in position 2 (C6–C3–C6). In nature, anthocyanidins are usually glycosylated in one or more positions of the basic flavanic nucleus by different sugars (Fig. 2). According to the literature,

Table 1 Anthocyanidins found in nature [3]

Name	Position of substitution
Substituted with a hydroxyl group	
Apigeninidin	5,7,4′
Aurantinidin	3,5,6,7,4′
Cyanidin	3,5,7,3′,4′
Delphinidin	3,5,7,3′,4′,5′
6-Hydroxycyanidin	3,5,6,7,3′,4′
Luteolinidin	5,7,3′,4′
Pelargonidin	3,5,7,4′
Triacetidin	5,7,3′,4′,5′
Substituted with a methyl ether group	
Apensinidin	5,3′,5′
Europenidin	5,3′
Hirsutidin	7,3′,5′
Malvidin	3,5′
5-Methylcyanidin	5
Poenidin	3′
Petunidin	3′
Pulchellidin	5
Rosinidin	7,3′

there are 17 anthocyanidins with differences in the number and position of hydroxyl groups and/or methyl ether groups, but six of them are the most common anthocyanidin in the plant kingdom (Table 1, in bold). From these 17 structures, the ones with at least one sugar molecule give origin to anthocyanin compounds. The range of anthocyanin is greatly increased by the sugar diversity and all the possible structural positions of glycosylation (glucose, rhamnose, xylose, galactose, arabinose, and fructose). Additionally, many acylated anthocyanins show in their

structures ester bonds between sugars and organic acids such as coumaric, caffeic, ferulic, *p*-hydroxybenzoic, synaptic, malonic, acetic, succinic, oxalic, and malic.

While acylated anthocyanins in general have increased stability due to co-pigmentation effects, this effect may also decrease the absorption of these compounds during digestion [1]. In fact, in human studies have found that non-acylated anthocyanins are more bioavailable than acylated anthocyanins [2].

The degree of complexity of those structures in aqueous solution increase because they are in different equilibrium forms depending on the pH [4].

In very acidic aqueous solution (pH $<$ 1), these pigments are present as red flavylium cations. The increase of pH leads to a reduction of the intensity of the color due to a decrease of the concentration of the flavylium cation that is converted into its colorless hemiketal form through nucleophilic attack of water. The hemiketal further undergoes a tautomerization reaction to give the pale yellow *cis*-chalcone (Cc), which isomerizes to *trans*-chalcone (Ct). At low acidic, neutral, and basic pH values, deprotonation of the flavylium cation also occurs, giving rise to the violet/blue quinoidal forms (Fig. 3) [4]. Indeed, anthocyanins GI absorption is highly affect by this pH dependence (Fig. 3).

Anthocyanins are responsible for many attractive colors, from scarlet to blue, of flowers, fruits, leaves, and storage organs. Anthocyanins display several functions in plants: antioxidant, photoprotection, defense mechanism, as well as other reproductive functions such as pollination and seed dispersal. The type of anthocyanins in plants is so variable that some plants present only one type of anthocyanin, whereas others have mixtures. In the same trend, some fruits are a source of one anthocyanin: cyanidin in apple, cherry, fig, and peach and delphinidin in eggplant and pomegranate; some fruits have two main anthocyanins such as cherry sweet and cranberry (cyanidin and peonidin), while others have several anthocyanins (grape, myrtillus). In general, the anthocyanin concentration in most of the fruits and vegetables goes from 0.1 up to 1% dry weight [3].

Other anthocyanin derivatives may be found in processed foodstuff and in fermented and unfermented fruit juices including pyranoanthocyanins and polymeric anthocyanins (Fig. 4) derived from these common anthocyanins by the reaction with a reaction partner that may include hydroxycinnamic acids, vinylphenols, vinylflavanols, pyruvic acid, acetaldehyde, acetone, or the genuine pigment [4].

Since anthocyanins are the most important coloring compounds between flavonoids, they provide characteristic colors to fruits, vegetables, and food beverages having a huge impact on this key quality parameter that influences consumer acceptance.

From a nutritional perspective, anthocyanins are consumed not only in fresh fruits and vegetables but also in many foodstuffs that are thermally processed prior to consumption, and this process can greatly influence anthocyanin content in the final product. Heating at lower temperatures (~40 °C) for up to 3 days may not be detrimental, but heating at higher temperatures (60–125 °C) for more than 8 h results in considerable loss of anthocyanins [6]. Bleaching by the effect of heat occurs because the anthocyanin equilibrium is moved toward the uncolored forms, as shown in Fig. 3. The flavonoid structure opens to form a chalcone, which is

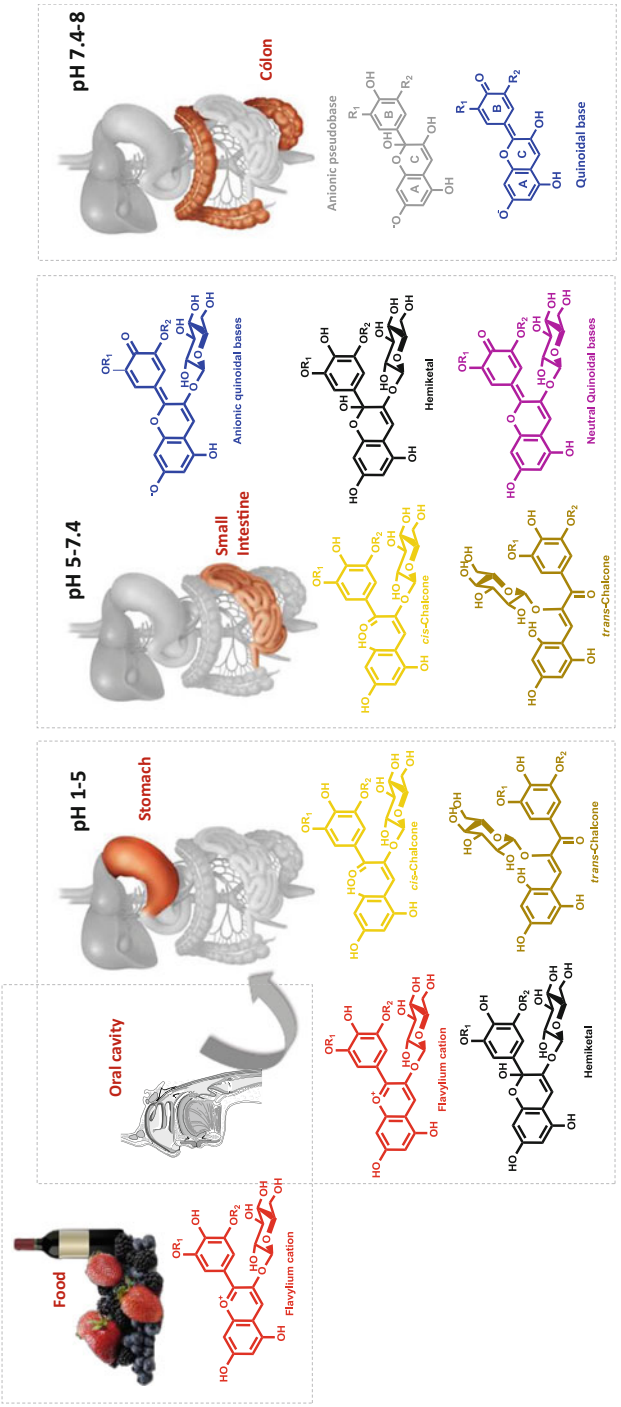

Fig. 3 Anthocyanin equilibrium forms according to the GI tract pH. (Adapted from [5])

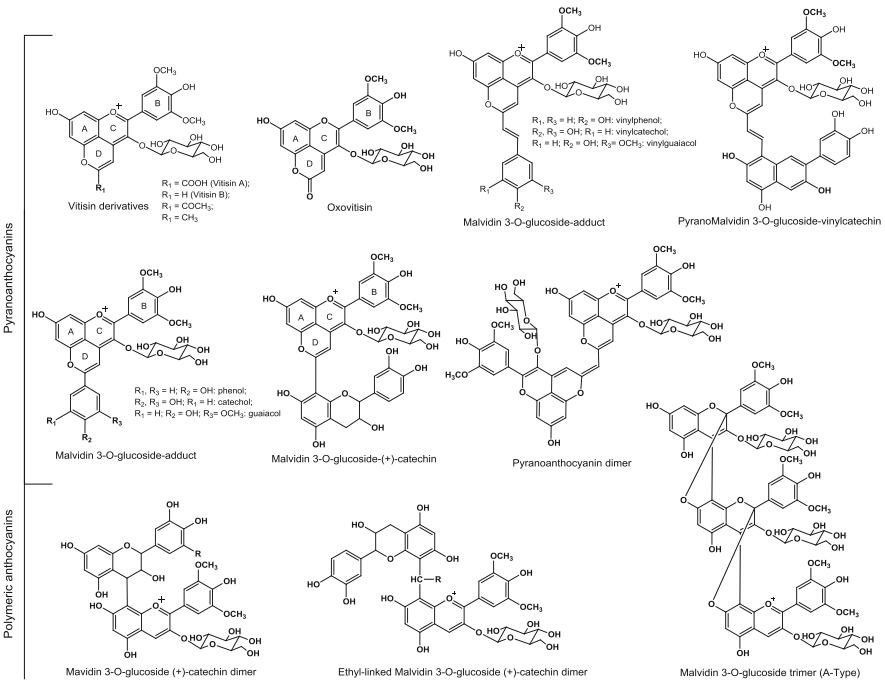

Fig. 4 Pyranoanthocyanins and polymeric anthocyanins identified in processed foodstuffs and in fermented and unfermented fruit juices

further degraded to brown products. In slightly alkaline solutions (pH 8 to 10), highly colored ionized bases are formed [7].

This thermal degradation can have a dramatic impact on color and may also affect nutritional properties. Still, the thermal degradation of anthocyanins could be accompanied by the formation of products which may also possess antioxidant properties. Therefore, it is not clear whether the formation of these components results in an overall reduction in antioxidant activity, besides affecting other food features [8].

Besides, anthocyanin stability is not merely dependent on the final processing temperature but is in turn influenced by the intrinsic properties of the product and the process such as pH, storage temperature, chemical structure and concentration of anthocyanins, light, oxygen, the presence of enzymes, proteins, metallic ions, and carbohydrates.

1.2 Anthocyanin Food Bioaccessibility

The structural diversity and physical-chemical properties of anthocyanins greatly interferes with their absorption and digestion and also with their final excretion during metabolic processes [1]. Before the endogenous factors such as pH, the presence of food, digestive enzymes, bile acids, microbiota, and the motility and permeability of the gastrointestinal (GI) tract may exert their actions, food bioaccessibility is one major impairment of anthocyanins absorption.

In order for anthocyanins in fruits and vegetables to become available for absorption within the human GI tract, these compounds must be released from the vacuole of plant cells [9]. When cells are ruptured during processing or oral mastication, anthocyanin and plant cell wall component (cellulose and pectin) complexes come into contact for the first time with other in vivo components [9, 10]. In processed foodstuffs, interactions between different anthocyanins and the food matrix (carbohydrates, proteins, fibers, other polyphenols) are likely to affect their bioaccessibility (i.e., the amount of anthocyanins released from the food matrix prior to absorption) of anthocyanins. This could potentially have an impact on the nutritional content and functional potential of diets [11]. Besides the initial mechanic and enzymatic action in the oral cavity (further discussed), foodstuffs are ingested as small pieces, so these types of interaction may be kept until the gastric environment.

In a recent work, it was shown that the flavylium cation (at pH 1) and hemiketal forms (at pH 3–5) of two anthocyanins (cyanidin-3-glucoside and delphinidin-3-glucoside) interact with ionic carbohydrates (pectin) [12]. This is indicative that this type of complexes may be stable at the gastric environment and prevent absorption and metabolization. In addition, the more polar anthocyanins revealed a stronger binding to pectin [13].

Anthocyanin uptake in the small intestine appears to be very likely considering the increase in their plasmatic levels [14], but their release from complexes may not be easily achieved, and their maintenance in the intestine/gut in that form may resemble a prebiotic effect.

The co-ingestion of anthocyanins with other meal components is also detrimental for the absorption of anthocyanins [15, 16]. Normally, to reduce the biological samples complexity, animal and human studies are performed with purified anthocyanins or extracts dissolved in water or even red fruit consumed after overnight fasting, thereby not taking into account possible interactions of anthocyanins with other dietary constituents. These are highly reactive pigments, and their possible reaction with other polyphenols and interaction with carbohydrates or proteins may greatly alter their pharmacokinetics.

Likewise, Xiao and coworkers concluded that milk did not influence the oral relative bioavailability of pelargonidin anthocyanins under meal conditions; however, the oral relative bioavailability of pelargonidin anthocyanins was reduced by ~50% by milk under meal conditions ($p < 0.05$) [15]. The simultaneous intake of a food source reduces anthocyanins absorption and urinary excretion [16]. However, the additional food matrix does not appear to have an effect on anthocyanin metabolism [16].

2 Interactions of Anthocyanins with Biomolecules

2.1 Proteins

During oral consumption, a variety of molecular interactions can occur, namely, interaction with food proteins resulting from the mastication processes or with salivary proteins, and later in the digestive process, the released anthocyanins may exert their effect in the modulation of the activity of digestive enzymes [17].

Only some local effects in the oral epithelium may be considered. Anthocyanins are not usually directly linked to astringency sensation, although they may contribute to the bitterness of some fruits and drinks [18]. The bitter taste perceived after the ingestion of some foodstuffs, for example, red or port wine, may be attributed to the activation of some bitter receptors [19], or anthocyanins could form complexes with saliva proteins [18].

Moreover, anthocyanins may display inhibitory effects on carbohydrate digestion and glucose absorption. Suppression of the activity of pancreatic lipase, α-glucosidase, and α-amylase is positively associated with the reduction of fat and sugar absorption from the gastrointestinal tract [20]. This ability may be explored as part of a strategy to reduce postprandial hyperglycemia by optimizing the functionality of foods with anthocyanin extracts that would strengthen efforts to reduce the risk of T2D.

Inhibition of pancreatic α-amylase and α-glucosidase activity was correlated with anthocyanin ingestion resulting in a reduction of blood glucose levels after starch-rich meals [20, 21]. A range of berry polyphenols (e.g., flavonols, anthocyanidins, ellagitannins, and proanthocyanidins) can inhibit protease activities at levels which could affect protein digestion in the gastrointestinal tract [21, 22].

In addition, anthocyanidins with vicinal hydroxyl groups in ring B (cyanidin and delphinidin) were found to inhibit glycogen phosphorylase activity being able to affect glucose/glycogen homeostasis [23].

This in vitro data is supported by several human trials reporting the regular consumption of berries in association with a reduction in the risk of T2D. Growing evidence from randomized controlled trials suggests that berry extracts, purees, and nectars acutely inhibit postprandial glycemia and insulinemia following oral carbohydrate loads [24]. Consumption of black currant extract in amounts roughly equivalent to 100 g black currants reduced postprandial glycemia, insulinemia, and incretin secretion, which suggests that inclusion of black currant polyphenols in foods may provide cardio-metabolic health benefits [24, 25].

Berry extracts and anthocyanins inhibit the activities of pancreatic α-amylase and α-glucosidase in the gut lumen and interact with intestinal sugar transporters, sodium-dependent glucose transporter 1, and GLUT2, hence reducing the rate of glucose uptake into the circulation. This topic is further explored in the bioavailability section.

In a fundamental work, the affinity of Cy3glc for human serum albumin (HSA) was studied showing to be stronger at pH 7, thereby underlining its potential in the transport and distribution of anthocyanins in the organism [26]. Hydroxyl substituents and glycosylation of anthocyanins decreased the affinity for binding to HSA at lower pH (especially pH 4) but increased the strength of binding at pH 7.4. Conversely, methylation of a hydroxyl group enhanced the binding at acidic pH, while this substitution reduced the strength of binding at pH 7.4. According to these findings, binding of anthocyanins to HSA is influenced not only by their structure but also by the pH of the medium [27].

Some questions still remain as to how far such interactions may improve the stability of anthocyanins and how far such interactions may influence their bioavailability.

2.2 Biomembranes

In a recent work of Trouillas and collaborators, the capacity of various anthocyanin derivatives to insert lipid bilayer membrane was evaluated [28]. Malvidin-3-O-glucoside was studied in its different charge forms (flavylium cation, neutral and anionic quinonoidal bases) as well as its deglycosylated, hydrated, and conjugated derivatives. Most of the derivatives were theoretically predicted to insert rather deep in the membrane, i.e., embedded in between lipid chains, therefore being prone to scavenge both the initiation and propagation stages of lipid peroxidation.

Besides this protective antioxidant effect, in a recent in vitro study, the effect of anthocyanins (pelargonidin-3-O-glucoside chloride and cyanidin-3-O-galactoside chloride) on erythrocytes morphology showed that their incorporation into the outer region of the erythrocyte membrane affects its shape and lipid packing order, which is reflected in the increasing number of echinocytes (abnormal red blood cell membrane) [29].

This involvement of anthocyanins in cellular morphologic alterations through membrane interactions may be associated with the antiproliferative effect of anthocyanins present in several foodstuffs [30]. Similar to what was observed by other authors, anthocyanidins were shown to interact with the deeper regions of the lipid bilayers in a structure-dependent manner and to decrease their fluidity. Greater membrane interacting potency was associated with a 3-hydroxyl group, 3′,4′-dihydroxyl groups of ring B, and 5,7-dihydroxyl groups of ring a, and anthocyanidins meet these structural requirements.

The amphiphilic properties of flavonoids allow them to interact not only hydrophobically with phospholipid acyl chains but also electrostatically with phospholipid polar heads. In addition to hydrophobic interaction and hydrogen bonding, steric configuration also participates in the interaction between anthocyanins and membranes. The presence of polyhydroxyl groups, the heterocyclic ring C (pyran or pyrone), and structural hydrophobicity are important for flavonoids to interact with biomimetic membranes. The lower membrane interactivities are attributable to the more hydrophobic anthocyanins, like delphinidin.

2.3 DNA

Nucleic acids such as DNA and RNA have also been proved to act as highly reactive ligands for anthocyanins. The interaction of anthocyanins with calf thymus DNA (ctDNA) was reported [31]. The anthocyanin-DNA complexes might be a possible defense mechanism against oxidative damage to DNA and might have normal physiological functions in vivo. This interaction is thought to occur between the positively charged flavylium cation and the PO_2 group; the ctDNA complex led to phosphate charge neutralization and helix stabilization [31]. In vivo, this type of interaction is not likely to occur since the nuclear pH is around 7.4, and at this value, the positively charged fraction of the anthocyanin equilibrium forms is almost absent.

On the other hand, the DNA triplex stabilization property of seven natural anthocyanins (five monoglucosides and two diglucosides) has been determined by triplex denaturation experiments [32]. It was assumed that the difference between the diglucosides and monoglucosides could be due to the supplementary sugar moiety at position 5 for the diglucosylated compounds, which would make anthocyanins too crowded and close together to allow their interactions with the triplex. Furthermore, the most active compounds among the monoglucoside series were the only anthocyanins that bear a catechol B-ring in their structure, which could be important for such an interaction.

This ability of anthocyanins may be a possible mechanism for the antiproliferative against cancer cell lines described for this class of pigments.

3 Bioavailability and Metabolism of Anthocyanins

Considering the wide distribution of anthocyanins in the diet, it is reasonable to assume that humans are very likely to consume these compounds in large amounts. In a survey with Italian subjects, anthocyanin daily intake was in the range 25–215 mg/person, depending on gender and age, and this intake is largely enough to induce pharmacological effects [3]. Nonetheless, among all polyphenol classes, anthocyanins are the ones considered to have the lowest bioavailability. However, recent reports suggest an underevaluation of the real bioavailability of these compounds.

The early appearance of anthocyanins in stated blood and urine after consumption of anthocyanin-rich foods is not compatible with an exclusive absorption at the intestinal level, as initially accepted [33]. Furthermore, when considering the metabolites of anthocyanins resulting from the action of gastrointestinal enzymes and flora, their bioavailability increases substantially [33].

3.1 Oral Cavity

The oral cavity is the first environment for the absorption and digestion of anthocyanins in humans. In chokeberry juice, among the several anthocyanins present in the original juice, Cy3glc was the one preferentially accumulated in epithelium cells [17]. This result suggests that anthocyanin structure affects oral cell uptake and therefore the potential anthocyanin type and concentration available for further absorption. Due to the short residence time of food in this compartment and the transient passage of drinks, its contribution to the oral uptake of anthocyanins is still in discussion, although their possible adhesion to the surface of the oral cavity cells should be explored, together with the effect of chronic exposure (dairy intake). This adhesion could be prompted by interaction of anthocyanins with membrane proteins.

Besides the physiological conditions (pH and temperature) impact, the dental plaque and saliva oral microorganisms may contribute to anthocyanin degradation during oral intake [17, 34]. Some reports point for the oral degradation of

anthocyanins after 5–60 min of residence in in vitro or ex vivo simulations or even in human intervention studies [17, 34]. These may be attributed to enzymatic action of oral microbiota, high oral temperatures, and pH and to binding of anthocyanin to salivary proteins [18, 35]. In fact, in the oral cavity (pH ~6.8), the chalcone form of cyanidin 3-O-glucoside may account for as much as 30% of the original amount of standard cyanidin 3-O-glucoside incubated with ex vivo saliva [35].

Besides pH interconversion, deglycosylation of anthocyanins due to oral native or microbiota-related glycosidases is one of the main products identified in the oral cavity [35, 36]. In this latter study, Cy3glc microbiota metabolite, protocatechuic acid, was also detected in saliva. The enzymatic machinery for phase II metabolism and enteric recycling of anthocyanin was identified in the oral cavity of humans [36]. Furthermore, saliva samples (collected at 5, 60, 120, and 240 min) contain glucuronidated anthocyanin conjugates and glucuronidated metabolites, consistent with intracellular uptake and phase II conversion of anthocyanins [36]. Besides, as subtracts of phase II enzymes, anthocyanins seem also to contribute to their activation [36].

3.2 Stomach

Based on the short residence time of anthocyanins in the oral cavity, their bulk portion should reach the stomach in their ingested native form.

Within the stomach and due to its quite acidic pH, anthocyanins are in their most stable medium. Besides being the main breakdown site in the digestion system of the human body for other food ingredients, in the case of anthocyanins, it may also have an important role in their absorption and metabolism. In fact, previous studies indicated that significant amounts of anthocyanins could be absorbed quickly and efficiently in the stomach in their native forms [37, 38]. In vitro studies using the human MKN-28 and NCI-N87 as gastric barrier models also indicated that the stomach could be an important site for anthocyanin absorption [39, 40].

By using in vitro cell barrier models, the gastric absorption mechanism was described, and the influence of different parameters was determined. The transport efficiency of anthocyanins is dependent on incubation time, pH, and anthocyanin polarity and size and independent of the presence of ethanol [39, 41].

The presence of D-(+)-glucose was found to decrease anthocyanins gastric uptake suggesting the involvement of glucose transporters [39]. In addition, gastric cells pretreated with anthocyanins were found to increase anthocyanin transport, possibly by inducing the expression of glucose transporters.

Using gene silencing technology in the same in vitro gastric model, it was possible to attribute to glucose transporters the partial implication on the transport of anthocyanins independent on the position of the glucose residue in the anthocyanin moiety. The fact that these compounds can reach an equilibrium in different structural forms at a specific pH value (Fig. 3) suggests that anthocyanin transport in vivo is dependent on the molar fraction of each equilibrium form. This highlights for the fact that this particular class of polyphenols can be absorbed in different forms by

different transporters that contribute to the net transport efficiency determined. This ability of anthocyanins to share the transport mechanism with glucose may give to these compounds the capacity to modulate glucose absorption, which could be important for several pathologies.

In addition, anthocyanins can be absorbed in fermented drinks like red wine in the form of derivative pigments like carboxy-pyranoanthocyanins (type A vitisins) and methyl-pyranoanthocyanins [42]. The gastric absorption of pyranoanthocyanin derivatives is slightly reduced in comparison with the parental anthocyanins possibly due to some steric interferences resulting from the higher size of these molecules. The slightly higher gastric absorption value observed for oxovitisin among other pyranoanthocyanins may be related to the absence of charge on this molecule [42]. The importance of pH on the anthocyanin transport efficiency that may be related not only with the main anthocyanin forms present but also with the influence on the possible transporters involved in their transport was already reported [39]. Besides the proven gastric absorption of these pigments, also the intestinal compartment may contribute to the circulatory appearance of anthocyanin derivative pigments [43]. Few in vivo studies have already proven the rapid detection of anthocyanin derivatives in rat plasma after oral administration of malvidin-3-glucoside-pyruvic acid adduct [44].

Considering studies with human volunteers, additional information may be obtained from the pharmacokinetic parameters and from the chromatographic profiles of the biological samples. Moreover, besides extracts or purified anthocyanins, different foods are consumed as anthocyanin sources, which will give a more realistic scenario of the matrix effect, especially in the crossover studies.

Previous studies evaluating the bioavailability of red wine anthocyanins have only looked for the main native anthocyanin (Mv3glc) in plasma and urine, underestimating the total anthocyanin content in biological samples [45, 46]. Increases in plasma of malvidin-3-*O*-glucoside (Mv3glc) concentrations were not significantly different after the consumption of either red wine or dealcoholized red wine [45]. In the work of Garcia-Alonso et al. where volunteers consumed 180 mg of a grape anthocyanin extract in a sugar-sweetened yogurt, the main pigment detected in plasma was native Mv3glc followed by peonidin-3-*O*-glucoside (Pn3glc), but the authors were already able to identify some anthocyanin metabolites in plasma including glucuronyl conjugates of malvidin and peonidin [47]. Similarly, after anthocyanin-rich grape juice consumption, the most abundant native anthocyanins found in plasma and urine were malvidin and peonidin and glucuronidated metabolites [48].

In another work, several anthocyanin conjugates (methylated, glucuronidated, and sulfated) were detected both in plasma and urine after ingestion of blackberry purees, with or without ethanol, by two groups of volunteers with different body mass indexes [14]. Altogether these works highlight for the possible implication of the gastric epithelium on the metabolization of these pigments. In fact, previous in vitro works had already detected methylated anthocyanins after incubation with total protein extract of gastric cells [33]. The majority of these compounds may be produced in the liver and kidneys since the plasma concentration of total

anthocyanin conjugates continues to increase after 60 min [14]. Moreover, this study indicated for the first time that ethanol enhances cyanidin-3-*O*-glucoside (Cy3glc) metabolism potentiating its conversion into methylated and glucuronidated derivatives (Me-Cy-Glucr and 3′-Me-Cy3glc). This effect was more pronounced in overweight and obese individuals. These results should prompt the attention of the scientific community to the fact that the kinetics of these compounds is influenced by ethanol and body mass index.

Recently, a crossover trial with healthy volunteers was performed using table and Port red wine in order to compare the pharmacokinetics of anthocyanins in these two red wines [49]. In this study, red wine anthocyanins were detected in their intact forms in both plasma and urine samples, but MvGlucr and PnGlucr were the two main derivatives detected after both red wines consumption. For the first time, and supported by the synthesis of Mv3Glucr, the main pathway followed by Mv3glc after absorption was described and involve the anthocyanidin conjugation with glucuronic acid after glucose removal.

According to these and other works performed with radiolabel anthocyanins [50], this class of pigments seem to be more bioavailable than previously reported. Nevertheless, the high impact of phase II conjugates detected in human plasma and urine, anthocyanin catabolites, seem also to be produced in huge amounts. The most important catabolites corresponded to products of anthocyanin degradation (i.e., benzoic, phenylacetic, and phenylpropanoic acids, phenolic aldehydes, and hippuric acid) and their corresponding phase II conjugates, which were found at 60- and 45-fold higher concentrations than their parent compounds in urine and plasma, respectively [50] (Fig. 5).

All in all, this data suggests that anthocyanins would be as bioavailable as other flavonoid subclasses, such as flavan-3-ols and flavones, which have relative bioavailabilities between 2.5% and 18.5% [51].

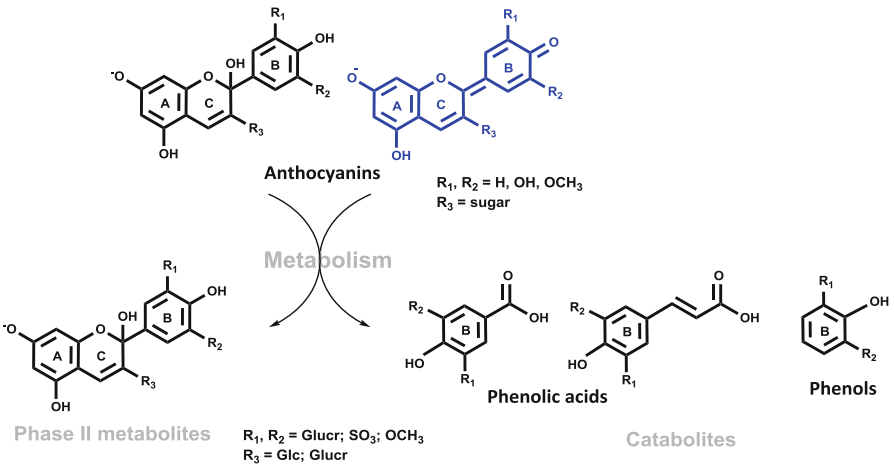

Fig. 5 Schematic representation of anthocyanins phase II metabolites and catabolites

3.3 Intestinal Tract

During the absorption process, anthocyanins can efficiently cross the intestinal wall [38]. To describe the intestinal transport mechanism, in vitro studies with Caco-2 cell line as an intestinal barrier model have been done. This cell line has an enterocyte phenotype after differentiation, and it expresses hexose transporters, ATP-binding cassette (ABC) gene family, and H^+-dependent monocarboxylic acid transporter in a similar way as small intestinal cells [52–55].

The pretreatment of caco-2 cells with red grape anthocyanin extract seems to increase (glucose transporter 2) GLUT2 expression, and this effect was positively correlated with anthocyanin and glucose transport [55]. In addition, cyanidin 3-O-glucoside absorption is dependent not only on the activity of GLUT2 but also on the activity of SGLT1 (sodium-dependent glucose transporter 1) although no implication of P-gp and MRP2 was observed [53]. Anthocyanins and anthocyanidins have moderate to high affinities for the human efflux transporter BCRP and moderate to low affinities for MDR1, so they may be actively transported out of intestinal tissues and endothelia, limiting their bioavailability [56]. Anthocyanidins may alter pharmacokinetics of drugs that act as BCRP and MDR1 substrates [56].

By using a phenolic berry extract containing 60% of anthocyanins, an opposite effect was observed as GLUT2 and SGLT1 mRNA expression was reduced by acute or longer pretreatments [52]. This contradictory results may once more highlight for the importance of matrix effect. Since the standards for metabolites detected in in vivo samples are not commercially available, no evidence for the transport mechanism has ever been described.

Besides the obvious implication of the small intestine in the absorption of anthocyanins, the huge impact of colon was also recently described. Using ileostomy subjects, a high proportion of anthocyanins from blueberry (up to 85%, depending on the attached sugar moiety) were found in the ileostomy bags unchanged; this amount would therefore reach the colon under physiological conditions and be subjected to microbial degradation [57]. Comparison of the bioavailability of anthocyanins in healthy subjects versus ileostomists revealed substantially higher amounts of anthocyanins and degradants in the plasma/urine of subjects with an intact gut [58]. The results suggested that the colon is an important site for absorption of bioactive components such as anthocyanins and their degradation products.

4 Obesity/Metabolic Syndrome

Epidemiological studies have established an association between unhealthy dietary behaviors and chronic diseases such as cardiovascular diseases (CVD) and type 2 diabetes, which are leading causes of death in high-income countries. In this context, the interest on functional food ingredients that might confer health benefits to the populations has increased.

Several reviews have been published concerning the effects of anthocyanins on obesity and metabolic syndrome, a set of interrelated risks factors for cardiovascular

disease and diabetes [59–62]. However, the number of robust and well-designed clinical trials about the effects of anthocyanins on obesity and metabolic syndrome is still limited to sustain health claims. Without solid scientific evidence, governmental authorities do not allow health claims on foods.

A search at the http://ClinicalTrials.gov database, a service of the US National Institutes of Health, for "anthocyanins" retrieved a total of 87 studies (last update February 9, 2018). From those addressing some of the metabolic syndrome features, three important randomized, double-blind placebo-controlled studies are highlighted.

One study was conducted on hypercholesterolemic participants, assigned either to the anthocyanin group ($n = 75$; 31 males and 44 females) or to the placebo group ($n = 75$; 32 males and 43 females), for 12 weeks. The anthocyanin capsules used (80 mg anthocyanins per capsule, 4 per day) provided a total daily intake of 320 mg anthocyanins. Compared with the control group, the authors observed significant increases in HDL cholesterol and a significant reduction in the LDL cholesterol concentrations [63].

In the second study conducted on a total of 58 diabetic patients, 160 mg of anthocyanins (80 mg anthocyanins per capsule) or placebo were provided twice daily ($n = 29$ in each group). Here, the authors found that anthocyanin supplementation significantly decreased serum LDL cholesterol (by 7.9%; $p < 0.05$) and triglycerides (by 23.0%; $p < 0.01$) and increased HDL cholesterol (by 19.4%; $p < 0.05$), compared with placebo, after the 24-week intervention period [64]. Anthocyanin supplementation exerted beneficial metabolic effects in subjects with type 2 diabetes by improving dyslipidemia, enhancing antioxidant capacity, and preventing insulin resistance [64].

Lastly, in the most recent study, a total of 160 eligible participants with either prediabetes or early untreated diabetes were recruited and randomly assigned to two intervention arms to receive either purified anthocyanins (320 mg/day) or placebo ($n = 80$ in each group). Compared with placebo, purified anthocyanins moderately reduced HbA1c (-0.14%; $p < 0.05$) and LDL cholesterol (-0.2 mmol/L; $p < 0.05$) after the 12-week intervention period [65].

These trials provided solid evidence on the effects of anthocyanins in the treatment of hypercholesteremia and diabetes by using commercialized capsules of purified anthocyanins extracted from bilberries and black currants (Medox®). The effects observed in these studies can be attributed exclusively to anthocyanins rather than other compounds (e.g., fibers) often present in anthocyanin-rich foods (e.g., berries).

Several mechanisms may explain the effects of anthocyanins on these metabolic syndrome features. Anthocyanins are antioxidant and anti-inflammatory, but only a few studies have considered their modulatory effects on the gut microbiota composition [66]. The effects of anthocyanins on gut microbiota are discussed in the next sections; nevertheless, it is important to bear in mind that the gut microbiota might compromise itself the effects of anthocyanins on obesity and metabolic syndrome.

The gut microbiota plays an important role in the bioavailability of anthocyanins. Anthocyanins are absorbed mainly in the intestine. However, those that are not

absorbed in the upper part of the gastrointestinal tract, in the colon might be metabolized by the existing bacteria, originating low molecular weight metabolites [67]. Given the enterohepatic recirculation, these compounds may prevail in the human body for several days [67]. This reveals the importance of the gut microbiota in anthocyanins metabolism. Since the gut microbiota differs between obese and lean individuals, this factor might be taken into account when evaluating the effects of anthocyanins in obese individuals [68]. In fact, two studies have shown that there are differences between normal weight and obese individuals regarding anthocyanins' metabolism [14, 69]. The disrupted gut microbiota as well as the generalized metabolic dysfunction unveiled by obese individuals may be behind the variability observed between these two groups. Obesity may comprise the metabolism of these compounds which deserves special consideration since obese individuals might be the ones who would benefit the most from anthocyanins intervention. It is important to note that anthocyanins are extensively metabolized in the organism (either by host or bacterial enzymes), and therefore, their metabolites are probably responsible for the health benefits of anthocyanins rather than the parent compounds that naturally exist in plants. Thus, future clinical trials should address this issue to achieve the optimal dose of anthocyanins according to the body mass index of the individuals.

5 Gut Microbiota Modulation

The human body harbors a collection of trillions of microorganisms. Bacteria, archaea, virus, fungi, and other eukaryotes live inside different organs establishing a symbiotic relationship with the host [70–72]. The microbes that collectively inhabit the gut – the gut microbiota – constitute the largest and most diverse community in the body [73]. Most of them are bacteria belonging to the *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, *Proteobacteria*, or *Verrucomicrobia* phylum [74].

Supported by the technological advances, the scientific community have been exploring the dynamics of such complex ecosystem. The role these microorganisms play in our health is still a mystery, but emerging evidence suggest that gut microbiota dysbiosis is implicated in a number of diseases ranging from localized gastrointestinal disorders to autoimmune, hepatic, respiratory, cardiovascular, oncologic, metabolic, neurologic, and psychiatric diseases [75].

The expansion of pathobionts (commensal microorganisms that can cause pathology under uncontrolled proliferation), the loss of beneficial bacteria, and the loss of diversity (microbial richness) are common characteristics of a dysbiotic state [76, 77]. These features have detrimental consequences for the host (may initiate obesity and metabolic diseases as well as neurologic disorders) and can be caused by environmental factors such as dietary modifications that encompass high contents of fat.

Diet is one of the most important factors that can modulate the gut microbiome and rapidly induce alterations in its composition [23]. High-fat and high-sucrose diets (HF diets) cause profound alterations in the gut microbial ecology, reducing bacterial diversity [24, 25]. In addition to HF diets, antibiotics, environmental

pollutants [28, 29], and food additives such as dietary emulsifiers [30–32] and noncaloric artificial sweeteners [33] have been shown to disrupt the gut microbiota (causing dysbiosis) in a similar way to what is observed in HF diet-induced obesity models. On the other hand, modulation of the gut microbiota composition by prebiotics might be a dietary strategy to prevent or counteract gut microbiota dysbiosis.

To fulfill the criteria of a previous prebiotic definition, the most studied prebiotics are nondigestible carbohydrates [78]. However, the definition of prebiotics has been modified to "a substrate that is selectively utilized by host microorganisms conferring a health benefit" [79]. Other substances, besides carbohydrates, might fit the updated definition if convincing evidence demonstrates their health benefits. Compounds such as polyphenols, namely, anthocyanins, may be considered prebiotics, according to this new definition.

Anthocyanins turn out to be particularly relevant since their bioavailability is considered to be low. Therefore, after consumption of anthocyanin-rich foods, it is expected that high amounts of anthocyanins reach the intestine to modulate bacterial growth at the same time they are metabolized by the existing bacteria.

Table 2 summarizes the studies evaluating the effects of anthocyanins on gut microbiota composition. There are substantial differences in the results since the type and the amount of anthocyanins used vary widely among the studies. Furthermore, the methodology used to characterize the gut microbiota composition is focused only on specific microbial groups which may not be sufficient to have a complete picture of the gut microbiota modifications that anthocyanins might bring about. For this reason, the gut microbiota composition of rats fed either a standard or a HF diet and supplemented with an anthocyanin-rich blackberry extract (BE) was recently evaluated, using next-generation sequencing (NGS) technology, the gold standard method. The dose chosen was 25 mg/kg body weight/day, easily achievable with 100 g of blackberries for a 60 kg man [14, 88]. Interestingly, BE was able to counteract some of the features of HF diet-induced dysbiosis by decreasing *Ruminococcus* and increasing *Sporobacter*, and, in the context of a standard diet, BE increased bacteria belonging to *Pseudoflavonifractor* genus [89].

6 Gut-Brain Axis

The gut-brain axis encompasses the strong bidirectional communication between the gut microbiota and the central nervous system (CNS) [90]. Multiple mechanisms may be involved in this bilateral communication: e.g., the gut microbiota has the capacity to produce many neurotransmitters and neuromodulators such as gamma-Aminobutyric acid (GABA), noradrenaline, serotonin, and acetylcholine [91, 92] and has the ability to control host tryptophan metabolism, regulating the fraction of tryptophan available for serotonin synthesis and, on the other hand, the production of neuroactive and neurotoxic metabolites along the kynurenine pathway [93–95]. As a result, modulation of the gut microbiota might be a tractable strategy to the development of novel therapeutics for complex CNS disorders.

Table 2 Studies reporting the effects of anthocyanins or anthocyanin-rich food sources on gut microbiota

Study design	Dose/duration	Methods	Changes in gut microbiota composition	Ref.
Fecal batch culture fermentation ($n = 3$)	Red wine extract (0.6 mg/ml) • 5, 10, 24, 30 and 48 h	FISH	= Bacteria (EUB mix) = Bifidobacterium spp. (Bif 164) = *Lactobacillus*/*Enterococcus* spp. (lab 158) = *Bacteroides* spp. (bac 303) = *C. histolyticum* (chis 150)	[80]
Fecal batch culture fermentation ($n = 3$)	Malvidin-3-glucoside (200 mg/l) • 5, 10, 24 h	FISH	↑ *Bifidobacterium* spp. (Bif 164) ↑ *Lactobacillus*/*Enterococcus* spp. (lab 158) = *Atopobium* spp. (Ato 291) = *Bacteroides* spp. (bac 303) ↓ *C. histolyticum* (chis 150) ↑ *Eubacterium rectale* – *Clostridium coccoides* (Erec 482) ↑ Total bacteria (EUB338)	[81]

Anthocyanins have emerged as anti-inflammatory agents and are promising candidates for the prevention of neuroinflammation, a common hallmark of obesity-associated neuropsychiatry disorders and neurodegenerative diseases [60, 61, 96, 97]. The mechanisms underlying these effects might be related to the interaction of anthocyanins with neuron and microglia biology. Recent studies suggest that anthocyanins may protect neurons against neuroinflammatory injury by stimulating the production of proteins involved in synaptic plasticity [96, 98].

Anthocyanins and their metabolites are able to cross the blood-brain barrier [99]. Nonetheless, to be neuroprotective, anthocyanins do not necessarily need to reach the brain. By changing the gut microbiota and acting on the gut-brain axis, anthocyanins may exert a biological activity even without being absorbed. Alterations in gut microbial composition afforded by anthocyanins were shown to result in changes in the levels of tryptophan and kynurenic acid which has been implicated in CNS inflammation, excitation, and behavior (Fig. 6) [89]. Besides, the tryptophan/kynurenine ratio has been implicated in neuropsychiatry conditions such as depression and anxiety [95]. Therefore, by decreasing this ratio, anthocyanins might constitute a new promising strategy for the treatment of neuropshychiatry disorders.

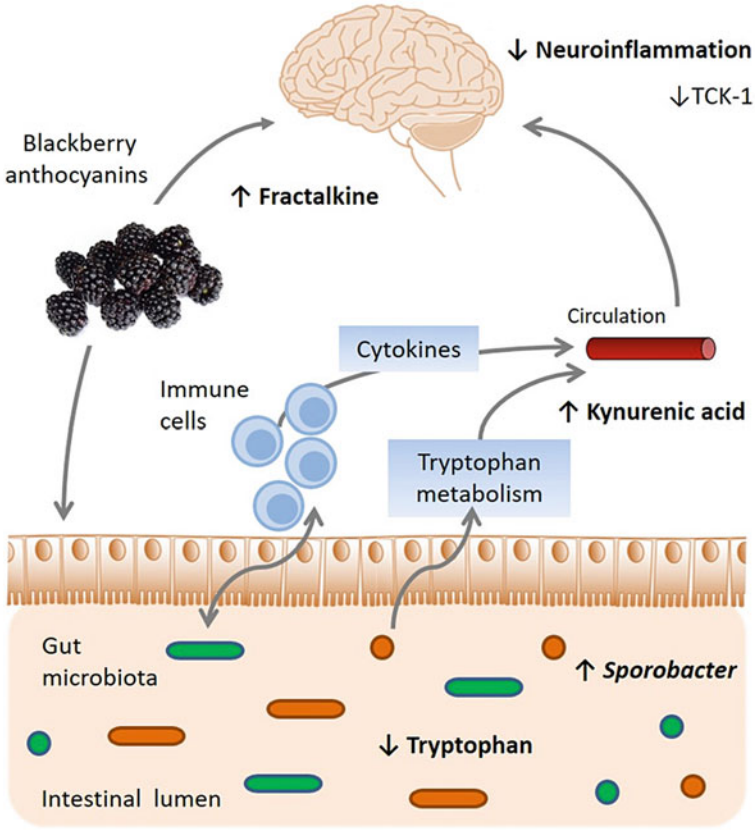

Fig. 6 Mechanisms behind the neuroprotective effects of anthocyanins, in the context of HF diet-induced obesity. Anthocyanins act directly in the brain increasing the expression of fractalkine, a chemokine extremely important in the crosstalk between neurons and microglia during synaptic plasticity [96]. On the other hand, anthocyanins modulate the gut microbiota composition, increasing the bacterial genus *Sporobacter* and alter host tryptophan metabolism. The amount of tryptophan available is decreased by anthocyanins to undergo the kynurenine pathway and originate kynurenic acid, a metabolite whose neuroprotective actions were recently identified [100, 101]. Through these routes, anthocyanins counteract the HF diet-induced neuroinflammation and may attenuate the neurological complications of obesity as well as neurodegenerative diseases. Anthocyanins might constitute, therefore, a new class of psychobiotics

7 Skin Health

Consumers have grown eager for natural solutions toward daily problems, paying more and more attention to natural sources of botanical products as bioactives in the products they consume. The cosmetic and skin health industry is no exception, and companies start to worry more about this issue, creating organic lines of products

and natural solutions to treat a variety of problems and diseases of the skin. At the same time, general concern from the population is rising toward the visible changes in skin structure and functionality associated with chronological aging that are aggravated by sun exposure. Consumers look up for innovation that englobes natural compounds when treating skin aging manifestations, as wrinkles and hyperpigmentation. On the other hand, while one out of three diagnosed cancers is a skin type cancer (nonmelanoma and melanoma), as revealed by the World Health Organization, WHO, there are not many products with natural bioactives to prevent these diseases.

Although cosmetic products with natural compounds and extracts usually claim a large variety of effects and benefits related to skin aging attenuation, truth is that there is a lack of scientific evidence to support those claims in terms of the role, stability, and absorption of such actives in cosmetic formulations. Despite this, fundamental knowledge regarding botanical compound bioactivity, particularly polyphenols and, most recently, anthocyanins, toward skin conditions is rising, and several works are now published about their role in skin aging, cancer, and other skin diseases. This section reviews the scientific literature existing on the potential of anthocyanins as skin actives to be used in preventing skin aging and skin diseases.

7.1 Skin Aging and UV Protection

The sun emits a wide spectrum of electromagnetic waves of which UV is the most cytotoxic, namely, UVB (295–315 nm) and UVA (325–400 nm), responsible for many skin diseases [102]. UV damage happens via two different mechanisms: the production of reactive oxygen species through the interaction of UVA with endogenous photosensitizers, which leads to the formation of oxidized products, such as lipid hydroperoxides and protein carbonyls, or the absorption of UVB by the heterocyclic bases of the DNA, causing damage to the genetic material. Hence, even if UV radiation possesses some health benefits, such as the stimulation of cholecalciferol (vitamin D) production, it is also responsible for some photosensitive diseases such as sunburn, immunosuppression, photocarcinogenesis, and premature skin aging (also called photoaging) [103].

Photoaging affects all layers of the skin, particularly epidermis and dermis [104]. The epidermis is the most external layer of the skin, and it is manly composed of keratinocytes. The dermis, located bellow the epidermis, is rich in connective tissue (collagen and elastic fibers), and it is the tissue responsible for the strength, extensibility, and elasticity of the skin. In physical and anatomical terms, skin aging is manifested by the appearance of skin wrinkles, dryness, thinning of the skin, loss of subcutaneous fat, and uneven pigmentation [105].

These visible changes of the skin depend on many molecular alterations which happen under UV irradiation. One of the key phenomena is the overexpression of metalloproteinases (MMPs), which are a family of zinc-dependent endopeptidases capable of degrading proteins of the ECM (the extracellular matrix), i.e., collagen

and elastin, which are important processes happening during skin regeneration and cell migration. When overexpressed, matrix maintenance is impaired, which leads to the loss of skin elasticity and resilience, leading to the appearance of wrinkles. At the same time, UV radiation triggers the increase in redox-sensitive transcription factors such as the nuclear factor-kappa B (NF-kB) and activator protein-1 (AP-1). On the other hand, as skin ages, cellular regeneration slows, making the recovery from mechanical injuries harder. This has led to an increasing research for compounds capable of blocking UV radiation or stopping its consequences, by a number of strategies, namely, by suppressing the oxidative damage, inhibiting MMP overexpression, modulating NF-kB/AP-1 pathways, and acting as wound-healing agents.

The harmful effects of UV radiation on the skin are usually fought using sunscreens. These are topically applied and can absorb or reflect UV radiation, preventing the damage to cellular material and diminishing the risk of skin diseases. There is a growing interest from the consumers' part toward the implementation of compounds from natural sources in general consumables, which is leading the markets toward natural alternatives. Botanical supplements with antioxidant activity have been proposed as sunscreen actives, usually in combination with well commonly used compounds [106]. Polyphenols [107–109] and particularly anthocyanins [110–112] have been described as potential agents in skin aging prevention, firstly because they absorb strongly in the visible and UV spectrums, with maximum absorbances in the ranges of 500–550 and 280–320 nm. This characteristic varies depending on their specific aglycone, sugar conjugation, and acylation patterns. An in vitro study with a cosmetic formulation containing anthocyanins from purple sweet potato (TNG73) investigated the potential of their absorbance patterns for dermatological purposes. Researchers found that, at a concentration of 0.61 mg/100 g of cream, anthocyanins could act as solar protectors, once they were shown to absorb 46% of the incident UV radiation [113], hence preventing damages to the dermal tissue.

The effects of anthocyanins in preventing skin damage have been studied using a different set of cellular and animal models, exploring which molecular pathways these compounds could be modulating (Fig. 7). Anthocyanins from blueberry could reduce UVA-stimulated ROS formation and lipid peroxidation in keratinocyte cells [114], and an extract from bog blueberry rich in cy3glc, petunidin-3-glucoside (Pt3glc), malvidin-3-glucoside (Mv3glc), and delphinidin-3-glucoside (Dp3glc) also prevented UVB-induced overexpression of MMPs and reduced the inflammatory response, modulating NF-kB- and MAPK-dependent pathways [115]. Another report showed that Cy3glc inhibited UV-induced translocation of the transcription factors NF-kB and AP-1, as well as the overexpression of IL-8, caspase-3 activation, and DNA fragmentation in human keratinocytes [116]. Blackberry anthocyanin-enriched fractions could reduce UV-mediated oxidative injury toward skin keratinocytes, by reducing reactive oxygen species and superoxide ion [117]. Skin photoprotection by anthocyanins has also been studied by Pornpimpa Phetpornpaisan et al., 2013, reporting that a black rice bran extract with high content of cyanidin-3-glucoside has a high antioxidative effect. This extract was able to inhibit MMP-2 and MMP-9 and possessed wound-healing effects by the

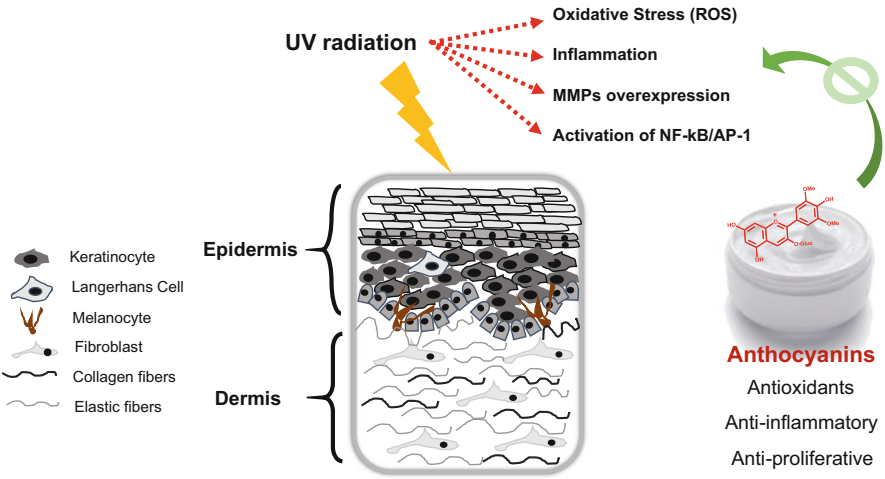

Fig. 7 Schematic representation of the skin layers and the main skin damages resulting from UV irradiation and potential actions of anthocyanins in pharmaceutical and cosmetic formulations

enhancement of collagen production and fibroblast proliferation [118]. A study using an anthocyanin-rich red orange extract showed that these compounds could reduce the translocation of NF-kB factor and AP-1 upon irradiation of cultured keratinocytes with UV light, as well as to reduce inflammation [119]. Green tea polyphenols were shown to be capable of preventing UV-induced immunosuppression [120], and cyanidin-3-glucopyranoside could prevent UVA-induced damage to keratinocytes [121]. At the same time, malvidin and cyanidin derivatives from açai fruit were able to counteract UVA-induced oxidative stress in fibroblasts, keeping the glutathione and lipid peroxidation levels close to the normal cellular values [122].

According to Tsoyi et al. (2008), anthocyanins from black soybean coats offer protection against UV radiation, not only to cultured keratinocytes but also in vivo to hairless mice skin, by reduction of cyclooxygenase-2 (COX-2) and prostaglandin E2 (PGE(2)) through NF-kB-dependent pathways and by the prevention of the apoptotic cell death, inhibiting caspase-3 activation and reducing the levels of proapoptotic Bax protein [112]. In a different study, cyanidin-3-glucoside, the main anthocyanin in black soybean coats, was reported to inhibit the ROS/COX-2 pathway in HaCat cells (human normal keratinocytes cell line), scavenging reactive oxygen species by decreasing COX-2 expression [123].

Delphinidin, the most abundant anthocyanidin found in pomegranate fruit extract, has also shown a protective effect against oxidative stress and apoptosis in HaCat cells and in mouse skin in an in vivo experiment [124]. In another in vitro study, this anthocyanidin was capable of restoring the elastic modulus of irradiated keratinocytes, regenerating the mechanical properties of these cells [125], and of reducing the UV-induced MMP-1 expression in human dermal fibroblasts [126].

Using a reconstituted human skin – EpiD5erm™ FT-200, Afaq et al., 2009, explored the bioactives of pomegranate anthocyanin-enriched extracts. The extracts

were applied 1 h prior to a 12-h UVB irradiation period (60 mJ/cm^2), and it was noted that they could prevent UVB-induced damage to the dermal tissue [110]. These anthocyanins were able to significantly inhibit protein oxidation and to reduce the presence of cyclobutane pyrimidine dimers and 8-dihydro-2′-deoxyguanoside. On the other hand, anthocyanins showed some bioactive properties against the extracellular matrix of the skin, decreasing the UVB-induced overexpression of various MMPs, such as collagenase (MMP-1), gelatinase (MMP-2 and MMP-9), and elastase (MMP-12) [110].

Another group investigated the effect of encapsulated anthocyanins from *H. sabdariffa* on melanogenesis process using A375 melanocytes. It was found that these flavonoids, besides their potent antioxidant activity, could inhibit tyrosinase activity and suppress its expression alongside with the microphthalmia-associated transcription factor (MITF), involved in melanin production [127].

Another important feature of an aged skin is the slowing down of the cell cycle and the difficulty in regenerating injured skin. This leads to the investigation of compounds that, on one hand, may induce the production of collagen by fibroblasts on the dermis and, on the other hand, may accelerate recovery from injury. A few studies have tried to understand the role of anthocyanins in helping skin recover from wounding. Cell migration assays using HaCat and fibroblast cells were performed with black soybean anthocyanins (Cy3glc, Dp3glc and Pt3glc) in which the positive effect of anthocyanins in cellular migration was observed. At the same time, this study explored the production of VEGF (angiogenic factor) which was increased in both cell lines in the presence of anthocyanins. The authors also found that anthocyanins prevented TNF-α-mediated inflammatory responses, including ROS accumulation, NF-kB activation, and monocyte adhesion in endothelial cells [128].

Another model has been employed to study wound healing in a more reproducible way than with traditional assays such as the scratch assay, using a biophysical system – the electrical cell-substrate impedance sensing (ECIS). This system correlates impedance readings with biological behaviors of cells in culture. In one study, a model was developed to study the wound healing of skin cell monolayers such as keratinocytes (HaCat cell line) and fibroblasts [129]. Wound was electrically triggered with a higher voltage, and cells on top of the working electrode died. The healing was followed up by impedance readings, as the cells migrated and proliferated on top of the electrode, recovering from the damage. The time of recovery was analyzed in the absence or presence of red wine and blackberry anthocyanins, particularly mv3glc and cy3glc. It was shown that anthocyanins could reduce the time of recovery by more than half [130]. Although there are not many studies exploring the effects of anthocyanins in this phenomenon, the few existing suggest that anthocyanins may accelerate wound healing, promoting regeneration of the skin. This requires further studies with different anthocyanins and in a more reliable model of skin.

Even though these in vitro studies suggest the potential roles of anthocyanins in fighting photoaging, there is a huge gap in terms of dermatological preclinical and clinical studies performed with formulations containing anthocyanins. A study by

Leonel E. Rojo et al. (2013) showed that anthocyanins could be bound to protein-rich matrices and be stabilized without losing their pharmacological properties up to 50 weeks [131]. Anthocyanin-rich protein matrices were tested toward their inhibition ability of MMP-9, and it was observed that cranberry-rich protein matrix could abolish enzyme activity, followed by maqui berry and blueberry anthocyanins, inhibiting 85 and 80% of the enzyme activity, respectively. Another group recently performed an assay with a strawberry-based cosmetic formulation to test its efficacy against UV-induced damage to dermal fibroblasts [132]. They proposed the use of a strawberry/reduced CoQ10-based formulations as sunscreens, because it was observed that the conjugation of strawberry extract and CoQ10 could reduce ROS and pro-inflammatory markers, as well as to improve the mitochondrial function and the expression of antioxidant enzymes. Even though the class of polyphenols present in the extract was not identified, this kind of studies opens doors to the investigation of new ways to stabilize anthocyanins in formulations and to study their effect in vitro and in vivo in respect to aging conditions.

7.2 Anthocyanins and Skin Diseases

Anthocyanins have a variety of physiological functions, such as antioxidant activity and playing a protecting role in some chronic and age-related diseases that include some skin diseases and conditions.

A study performed using a three-dimensional reconstituted human skin model investigated the role of delphinidin in psoriasis. Psoriasis is an autoimmune, chronic, and inflammatory disease that affects 2–3% of the population [133]. The histologic marks reveal marked epidermal hyperproliferation and thickening, and the clinical features include skin inflammation with demarcated erythematous papules and scaly dermatological plaques [133]. Delphinidin has been reported to suppress proliferation and inflammation as well as to induce epidermal differentiation markers; thus this anthocyanidin is said to possess pro-differentiation effects [134]. In addition to this, delphinidin significantly decreased the thickness of the viable normal and hyperplastic epidermis, consolidating the differentiating and cornified layers of the skin equivalent [134]. Another study identified delphinidin as a novel potent dual PI3K/mTOR inhibitor, which possesses antipsoriatic activity in vitro in cell-free and cell culture, as well as in vivo in preclinical IMQ-induced psoriasis-like disease in Balb/c mice [135]. Another research group explored the effects of the topical application of delphinidin to flaky skin of mice and noted that it reduced the pathological markers of psoriasis lesions, by inducing the differentiation and reducing the proliferation and inflammation [136]. On the other hand, delphinidin also modulated the expression of tight junction proteins and increased the expression of protein JunB [136]. When using a three-dimensional reconstituted human skin model of psoriasis, researchers found that this anthocyanidin could significantly decrease the thickness of the viable normal and hyperplastic epidermis and consolidate the differentiating and cornified layers of the skin equivalent. This differentiation is correlated with an increase in expression of both caspase-14 and profilaggrin.

These set of studies indicate that delphinidin could be an important agent in ameliorating psoriasis lesions and suggest that preclinical and clinical studies should be performed to understand the efficacy of this anthocyanidin on the management of psoriasis. Heather R. Austin et al. (2014) investigated the potential role of cyanidin as an agent in psoriasis therapy by exploring its effect on the expression of late cornified envelope (LCE) genes as their deletion is a risk factor for psoriasis. In this study they show that this cyanidin upregulates the five LCE genes in cultures of differentiating primary human keratinocytes [137].

The effect of anthocyanins and other polyphenols from blueberry in atopic dermatitis has also been studied. This is a chronic and relapsing inflammatory skin disease with a prevalence of 10–20% and is more common among children [138]. Cyanidin-3-glucoside and quercetin fraction could inhibit inflammation of the lesion skin, correcting the Th1/Th2 balance and reducing IL-17. Anthocyanin-rich but not anthocyanidin-rich bilberry extract were shown to alleviate chronic pruritus of experimental dermatitis, probably by inhibition of mast cell degranulation [139].

Skin cancer is one of the most common of cancers in pale skin individuals, and it is directly related to sun exposure, namely, because of UV radiation. There are some studies regarding the use of anthocyanins as chemopreventive agents, particularly with pomegranate fruit extract (PFE), juice, and seed oil. Tests have been performed in cell culture, reconstituted human skin models and animal models of skin cancer and pomegranate was reported to exhibit immense potential for preventing UVB-induced skin cancer. PFE contains several polyphenols (such as catechins, gallic and ellagic acids) and anthocyanins. Pretreatment of human normal keratinocytes with PFE resulted in a dose- and time-dependent inhibition of UVB-induced phosphorylation of ERK1/2, JNK1/2, and p38 proteins and inhibition of the activation of nuclear factor-KB (NF-kB) pathway [140]. PFE treatment also resulted in a significant inhibition of UVA-induced expression of Ki-67 and PCNA and led to an enhanced expression of pro-apoptotic Bas and Bad with downregulation of anti-apoptotic Bcl-xL protein [141]. The chemopreventive properties of PFE were further evaluated in mice exposed to UVB radiation. Oral administration of PFE inhibited UVB-induced epidermal hyperplasia, leukocyte infiltration, and protein oxidation and also attenuate the activation of key inflammatory and cell proliferative pathways such as NF-kB and MAPK [142]. Oral administration of PFE in drinking water also reduced UVB-induced skin tumor incidence and tumor multiplicity in SKH-1 hairless mice [143]. In a study using delphinidin, it was also shown to inhibit UVB-induced COX-2 expression in JB6 P+ cells (a skin mouse cell line) by blocking the MAPKK4 and PI-3 K pathways and suppressing AP-1 and NF-kB activities, indicating that delphinidin may suppress UV-mediated skin carcinogenesis [144]. Diaconeasa Z. et al. (2017) performed a study on the effect of anthocyanins in melanoma inhibition. Different anthocyanin sources, namely, red grapes and chokeberries, were applied to melanoma cells and were able to reduce proliferation, to diminish mitochondrial membrane potential, and to induce oxidative damage, without showing these negative effects on normal skin cells [145].

A clinical study was performed to evaluate the effects of anthocyanins toward a skin condition. A formulation containing anthocyanins and glutathione was tested in

patients with erythema resulted from radiation therapy of breast cancer. This report does not present statistical significance or information on doses and types of anthocyanins used, but a trend was still observed toward improvement from the erythema in the group with the tested formulation. The theory behind this formulation is that while the breast is being irradiated, glutathione may clean up oxygen and carbon radicals formed, and anthocyanins may then help on the recycling of the glutathione so it can keep working.

Skin is the most superficial organ and the most exposed to environmental aggressions, UV radiation being one of the most important aggressors and the cause of skin photoaging and some skin diseases such as melanoma cancer. Oxidative damage, inflammation, apoptotic cell death, and overexpression of MMPs are some of the consequences of UV irradiation of the skin. In here it is suggested by accumulating scientific evidence that anthocyanins may play a role in delaying and fighting skin aging, as well as in protecting this organ against cancerous lesions. Even though the evidence obtained from different in vitro and in vivo studies shows the potential of these polyphenols, this might be insufficient to guarantee that the skin-protective effects are solely from anthocyanins, because in most studies, extracts are used and there is always the possibility that other compounds may be present. Furthermore, there is a gap in technology for the development of chemically stable and clinically effective anthocyanin-rich formulations for dermatological applications that must be addressed in the future.

8 Functional Foods and Cosmeceuticals

The concept of functional foods appeared first in Japan in the 1980s and mentioned foods that were developed specifically to promote health or to reduce the risk of disease. In Europe, the European Commission's Concerted Action on Functional Food Science, coordinated by the International Life Science Institute, defined functional foods as "a food that, together with the basic nutritional impact, has beneficial effects on one or more functions of the human organism thus either improving the general and physical conditions or/and decreasing the risk of the evolution of diseases" [146]. The amount of intake and form of the functional food should be as it is normally expected for dietary purposes. Consequently, it could not be in the form of pill or capsule just as normal food [147]. Therefore, they are usually considered to be those foods which are intended to be consumed as part of the normal diet and that contain bioactive components with potential health benefits such as vitamins, fatty acids, or dietary fiber or foods that include phytochemicals and other antioxidants or probiotics. These types of foods are being integrated into the corporate mainstream and being increasingly accepted by the public.

Anthocyanins are widely distributed in the human diet, and their chemical and biological functions have been extensively studied. These natural pigments are broadly used in the food industry as natural colorants, and their use is not only valuable for improving the overall appearance but also because anthocyanins have beneficial properties to our health. Anthocyanin extracts have been demonstrated to

play a role in several diseases and conditions, displaying antioxidative and radical-scavenging properties [148, 149], acting as chemopreventive agents [150], but also playing a role in diabetes [151–154]. Because of their coloring and biological properties, anthocyanins are now being considered as potential functional food ingredients and dietary supplements. This section will discuss the possibility of using anthocyanins in functional foods.

Anthocyanins are widely spread in fruits and vegetables, as well as in red wines which results in high ingestion and a daily intake ranging from several milligrams to hundreds of milligrams per person [155]. These flavonoids are now extensively studied and commonly used as food colorants especially in acidic foods that favor their chemistry, by stabilizing the flavylium cation form. Some vegetable sources like black carrot, red-fleshed and purple sweet potato, as well as red cabbage have been shown to provide high amount of acylated anthocyanins [156–158] that are more stable to pH than non-acylated [159]. An example of anthocyanins used as colorants is red rice, which was approved by the Chinese Ministry of Health as a modern food additive to increase the color and delicacy of meat, fish, and soybean products [160]. Besides this, red rice is also used as a functional food to treat abdominal pain and cardiovascular disease [161]. Even so and to this day, there are not many works performed on the manufacture of products that include anthocyanins as functional ingredients, but as the consumers interest on the incorporation of bioactives into popular foods is growing, innovative work is rising. An example of a product that can incorporate anthocyanins as functional ingredients is bread. This can be used by the production of anthocyanin-enriched flours as explored by Donatella Ficco et al. in 2017 [162]. They performed the micronization followed by air classification to select anthocyanin-rich fractions of durum and soft wheats and noted that the pigmented durum wheat showed the greatest acceptability in terms of aroma and taste of the bread obtained.

Anthocyanins have a variety of biological properties and may be used as potential functional foods against some metabolic syndromes such as obesity and type 2 diabetes [24]. Some anti-obesity strategies include the increase of physical activity and the consumption of non-starch polysaccharides and fiber, accompanied by the reduction of micronutrient-poor diets [163]. Another strategy that may be employed to fight obesity is related to the use of inhibitors of some digestive enzymes, such as α-glucosidase and α-amylase. Inhibitors may help retarding the increase of sugar in the bloodstream after a meal, and anthocyanins and other polyphenols, such as tannins, may be employed to this end [164]. On the other hand, cyanidin-3-glucoside (cy3glc) has been shown to reduce blood glucose and to enhance insulin sensitivity by downregulating retinol binding protein-4 expression in type 2 diabetic mice [165]. In two other studies, the effect of anthocyanins in diabetes was explored, and it was found that, even though black raspberry anthocyanins do not alter the development of obesity in mice that were fed an obesogenic high-fat diet [166], purified anthocyanins from blueberry as well as blueberry juice could prevent dyslipidemia and obesity in the same animal model [167]. Another study revealed that blueberry anthocyanins could reduce glucose production in hepatocytes and body weight gain [168]. Another source of anthocyanins, maqui berry rich in

delphinidin-3-sambubioside-4-glucoside, also decreased the glucose production and downregulated glucose-6-phosphatase in liver cells, which is a gluconeogenic enzyme [169]. Edirisinghe et al. (2011) also found that the strawberry anthocyanin pelargonidin-3-O-glucoside could reduce inflammation and increase insulin sensitivity in overweight adults [170]. These studies suggest the potential of anthocyanins to be used as functional foods to fight obesity and type 2 diabetes and to lead the way to the conception of new products enriched in these flavonoids to be consumed as supplement in patients with these conditions or as a fundamental tool to convert our diet in a functional one, preventing food-related diseases. Because anthocyanins are usually unstable outside their environment, work has been done toward the stabilization of anthocyanins for their use in the food industry which may be of importance when conceiving new functional foods [171–173]. Anthocyanin-loaded chitosan nanoparticles, for example, were found to slow the breakdown of anthocyanins in simulated gastrointestinal fluid and improved the stability of these compounds in a beverage [172].

Anthocyanins are now known as bioactives with potential health benefits extensively studied in several field such as at metabolic syndromes but also play a role in cardiovascular disease and possess anti-inflammatory, chemopreventive, and antioxidant activities, among others. The development of functional foods and supplements incorporating these compounds is now being promoted as the information on the biological properties of these flavonoids arises. Soon, it might be possible to purchase enriched beverages to aid in the treatment of diabetes or purple bread to incorporate in a more functional diet as well as other products usually consumed but improved not only in its nutritional value but also in health promoting and functional role in our diet.

Wine Polyphenols and Health

39

Giovanna Giovinazzo, Maria A. Carluccio, and Francesco Grieco

Contents

Abstract

The various polyphenol families present in wine are important for a number of technological properties of wine such as clarity, hue, and palatal taste. Dietary polyphenols are associated with a wide range of health benefits, protecting against chronic diseases and promoting healthy aging. However, basic and clinical science is showing that the reality is much more complex than this and that several issues, notably daily intake, bioavailability, or in vivo antioxidant activity, are yet to be resolved. The concentration of phenolic compounds in wine is determined by viticulture and vinification practices, peculiar of different countries. Interesting are the effects of different yeast strains on the final concentration of polyphenols in red wine. We here summarize the recent findings concerning

1 Introduction

Wine contains a large and diverse class of phenolic compounds known variously as "polyphenols" or "biophenols." These compounds contribute to the characteristic colors and flavors of wine and act as natural wine preservatives that allows a long aging process [1]. Polyphenols are extracted during crushing and fermentation when the juice is in contact with the grape skins and seeds. The amount of phenolic compounds in red wine is about six times higher than that in white wine because red juice has longer contact time with the grape skins and seeds. The concentration of polyphenolic compounds in red wine is approximately 1800–3000 mg/L [2].

There is emerging evidence that a functional diet can help in modulating the immune system responses to the inflammation processes through a variety of mechanisms based on the absorption and utilization by the human metabolism of specific compounds.

Polyphenols are the principal compounds related to the wine consumption benefits due to their antioxidant and free radical scavenging properties. This class of compounds has been proven to exert important health effects, acting against cancer pathologies [3] as well as reactive oxygen species (ROS) which are considered the main cause of different cardiovascular and neurodegenerative diseases.

Grapevine (*Vitis* spp) is the most cultivated fruit crop in the world, with an area dedicated to viticulture. The berries are harvested primarily for winemaking but also to provide fresh table grapes, raisins, and other minor products. Phenolic composition of grape is genetically driven and greatly affected by environmental factors. A major challenge for breeding of grapevine cultivars adapted to climate change and with high potential for winemaking is to dissect the complex plant metabolic response involved in adaptation mechanisms. Among plant products are the polyphenols, a large family of secondary metabolites, which are involved in plant responses to biotic and abiotic stresses. The most represented polyphenols in plants are the flavonoids, the cinnamic and benzoic acids, and the stilbenes. They derive from the phenylpropanoid metabolism, but flavonoids are ubiquitous in plants, whereas stilbenes are specific to certain plant families.

Other polyphenols, as the phytoalexins, are antimicrobial compounds synthesized in response to pathogen or herbivore attack. However, other roles have been described for stress-induced polyphenols, including the defense signaling of responses and protection against ultraviolet (UV) light damage [4, 5].

Phenolic compounds are secondary metabolites synthesized [4] during normal development of the berry grape in response to stress conditions.

A large-scale experiment involving cultivation of an association panel of a large number (more than 200) *V. vinifera* cultivars designed to represent the genetic and phenotypic variation encountered in cultivated grapevine and metabolomics analysis targeted to a large number of polyphenolic compounds (polyphenomics) was performed. Chemometrics analysis of the data showed large differences in polyphenol composition related to genetic factors, environmental factors (i.e., water stress), and genetic-environment interactions. Correlation networks shed light on the relationships between the different polyphenol metabolites and related biosynthetic pathways. In addition, detailed polyphenomics analysis confirmed that polyphenol reactions described in wine take place in the berries.

Finally, was reported a large-scale study demonstrating an influence of environmental influence (water stress) on the different classes of polyphenols but also cultivar differences in the types and extents of drought responses, with different molecules affected either positively or negatively and different impacts on grape and wine quality [6].

Grape phenolic compounds comprise several families, divided between non-flavonoids (hydroxybenzoic acids, hydroxycinnamic acids, and stilbenes) and flavonoids, based on the same C6-C3-C6 skeleton (flavonols, dihydroflavonols, flavan-3-ols, and anthocyanins). Each family is represented by several compounds differing by their hydroxylation level and by substitution of the hydroxy groups (methylation, glycosylation, acylation). For example, anthocyanins, the red grape pigments, are based on six aglycones, which can be mono- or di-glucosylated and further acylated with acetic, p-coumaric, and caffeic acid, giving rise to a large number of compounds [6]. Grape flavan-3-ols also show high diversity. They include several monomers (catechin, epicatechin, gallocatechin, epigallocatechin, and epicatechin 3-gallate) that are the constitutive units of oligomers and polymers (proanthocyanidins or condensed tannins), with degrees of polymerization ranging from 2 to over 100 in grape skin [6].

The flavonoid family includes the flavonols, such as myricetin, quercetin, and kaempferol, which exist both as aglycones and sugar conjugates. The non-flavonoids encompass hydroxybenzoic acids such as gallic acid, hydroxycinnamic acids, including p-coumaric, caffeic, and caftaric acids, and the stilbenes, such as *trans*-resveratrol and *cis*-resveratrol [5]. The synthesis of stilbenes in grape berry tissues is activated in response to fungal attack, to berry injury, and to ultraviolet irradiation [5].

The healthy physiological effects are especially associated to flavonoids and stilbenes [7], namely, quercetin, (+)-catechin, gallic acid, and trans-resveratrol [8]. The stilbene trans-resveratrol has gained great attention, and a number of scientific papers have appeared related to the moderate consumption of red wine for its ability to inhibit platelet aggregation and LDL oxidation and its beneficial effects in health. Since *trans*-resveratrol is postulated to be involved in the health benefits associated with a moderate consumption of red wine, it is one of the most extensively studied natural products.

The various polyphenol families present in wine [7, 9] are important for a number of technological properties of wine [7]. The knowledge about their qualitative and

quantitative profile in grapes is very important to predict wine aging attitude and can help to solve problems related to color stability, especially in the case of red wines that are destined to long aging periods [10]. The wine aging also changes the phenolic composition, as these compounds can suffer diverse transformations, like oxidation processes, condensation and polymerization reactions, and extraction from wood, usually associated to the changes in color and colloidal stability [11], flavor, bitterness, and astringency [12, 13]. The polyphenolic fingerprint can be useful for the classification of wines, since it can give us information about the variety, the geographic and winery origin, and even the applied winemaking technology [14].

During winemaking, only a fraction of the grape flavonoids is selectively transferred to the wine and a final yield strongly depending on the management of the contact of the liquid must, containing berry skin and seeds, with the solid parts of the grape bunches and on the grape variety [10].

The data concerning the extractable phenolics of the grape cannot be simply generalized to predict the wine composition, since a high variability in the extraction yield from grape to wine is introduced by the technological factors governing the winemaking process (such as temperature, duration and intensity of the liquid-solid contact, final ethanol concentration).

Many conditions (i.e., genetic, agronomic, technological, storage, etc.) linked to each other by complex and multifactorial phenomena affect both profiles and concentrations of bioactive compounds, either in grape or in wine [15].

2 Soluble Acids, Flavonols, and Stilbenes: Bioactive Compounds in Wine

Wine is a complex mixture of hundreds of molecules, some of them showing important biological properties, while others are mainly associated with its organoleptic characteristics. In particular, we describe specific classes of polyphenols such as phenolic acids (hydroxybenzoic and hydroxycinnamic acids), flavonols, and stilbenes (Fig. 1).

2.1 Phenolic Acids

In wine, there are two groups of phenolic acids: hydroxybenzoic acids and hydroxycinnamic acids [16]. Hydroxybenzoic acids, including gallic acid, protocatechuic acid, gentisic acid, p-hydroxybenzoic acid, vanillic acid, and syringic acid, derive from benzoic acid. Chlorogenic acid, as the main constituent of the hydroxycinnamic acid derivative group, increased with harvest time delay, and the same occurred with sinapic acid. The converse was true of caffeic acid and ferulic acid, which were also esterified with tartaric acid as the known compounds caftaric acid and fertaric acid, respectively [16, 17]. Hydroxycinnamic acids have gained an increasing interest in health because they are known to be potent antioxidants.

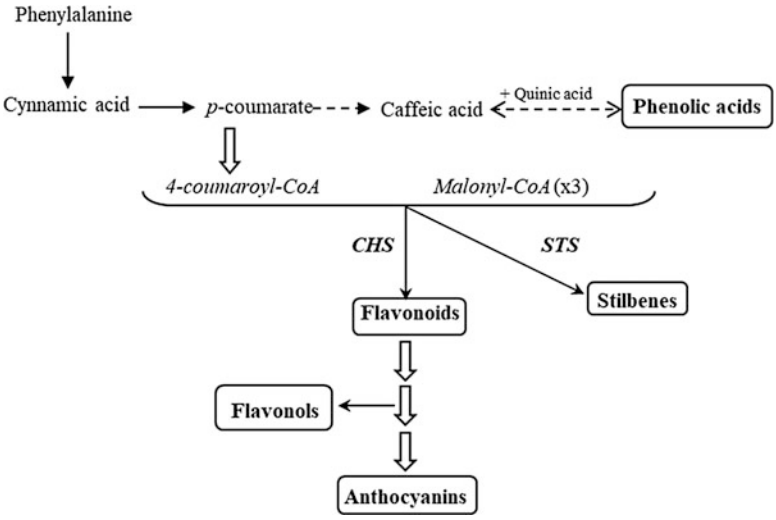

Fig. 1 Polyphenol biosynthesis pathway in grape tissues. *CHS* chalcone synthase, *STS* stilbene synthase

These compounds have been described as chain-breaking antioxidants acting through radical scavenging activity that is related to their hydrogen or electron donating capacity and to the ability to delocalize/stabilize the resulting phenoxyl radical within their structure. The free radical scavenger ability of antioxidants can be predicted from standard one-electron potentials.

Phenolic acids represent important fraction of wine phenolics, but their biological effects have been scarcely investigated. The interrelationship between antioxidative capacity and vasodilatory activity, two potentially beneficial biological effects, of phenolic acids from wine was examined. Antioxidative and vasodilatory effects of phenolic acids relate to the number of hydroxyl groups in the phenyl ring, degree of compactness and branching of molecules, and three-dimensional distributions of atomic polarizability of the tested molecules [18]. Caffeic acid has been shown to have neuroprotective effects against injury induced by 5-S-cysteinyl-dopamine, against Aβ-induced neurotoxicity and by inhibiting peroxynitrite-induced neuronal injury [19, 20]. Ferulic acid has been cited as an antidiabetic effect by lowering blood glucose and by increasing plasma insulin [21].

2.2 Flavonols

Four aglycones belong to the flavonols class: myricetin, quercetin, kaempferol, and isorhamnetin. The diversity in the flavonols structure is due to changes in the basic skeleton introduced by enzymes such as glycosyl transferase, methyl transferase, and rhamnosyl-transferase. In one plant species, dozens of different flavonoids may be present, and many of these are conjugated to various types of sugars. Both the basic

structure and the level of glycosylation determine the biological function and bioavailability of polyphenols in the human and animal intestines. Depending on their structure, these molecules have diversified activities.

Flavonols are found throughout the plant foods. The best-known flavonols are quercetin and kaempferol. Quercetin, kaempferol, myricetin, and isorhamnetin are flavonols presents in grape skins and stems as several different glycosides. Quercetin accumulates in grape skins to protect against damage from ultraviolet (UV) light. There are high concentrations of quercetin in wine made from sun-exposed grapes. Quercetin is readily extracted from grape skins during fermentation. Stems may contribute additional flavonols in whole cluster fermentations.

Quercetin glycosides may be hydrolyzed in wine to form quercetin aglycone. This process is similar to the hydrolysis that can occur with anthocyanins. Unlike anthocyanins, flavonol aglycones are stable in wine and can be used to monitor hydrolysis reactions. Quercetin may cause problems as a precipitate in bottled wines. Flavonols can interact with anthocyanins, enhancing their red color in a process known as co-pigmentation. This process may also help anthocyanin color stability.

Dietary flavonols inhibit LDL oxidation and so reduce the primary risk factor for atherosclerosis and related diseases. The animal studies are supported by human epidemiological studies, which show inverse correlations between the occurrence of CVD, certain cancers, and age-related degenerative diseases and the consumption of flavonol-rich diets [22–25]. Flavonols have been linked to protective effects against several specific cancers, including leukemia and pancreatic, breast, cervical, prostate, uterine, and urinary tract cancers. Subjects with regular flavonol intake have a 10–60% lower incidence of these types of cancer compared with subjects with low flavonol intake.

This protective activity results from both the action of flavonols as stimulators of antioxidant defenses and their direct inhibitory effects on cellular proliferation. Quercetin consumption has been reported to be inversely associated with breast cancer incidence [26].

2.3 Stilbenes

Stilbenes are a class of compounds with multiple pharmaceutically relevant properties. The stilbenes production in grape berry tissues is considered to be a part of the general defense mechanism since they display strong antifungal and antimicrobial activities [27].They are a group of plant phytoalexin polyphenols found in high concentrations in grapes, berries, nuts, and teas. In plants, their main function is to protect the plants against pathogens and fungi; therefore, their content is highly variable and increases with stress exposure. UV radiation, heavy metal exposure, and fungal infection may thus be utilized to enrich grapes with stilbenoids [28, 29].

Resveratrol (3,4_,5-trihydroxystilbene) may be found especially in red wine, grapes, and berries, at a concentration ranging from 0.1 to 15 mg/L. Nowadays, the primary source of resveratrol is the roots of perennial plant *Polygonum cuspidatum* (Japanese knotweed) [29]. Due to the positive health effects attributed

to resveratrol through so-called French paradox, its biological activity has been extensively studied. Most biological effects are assigned to trans-resveratrol, the more stable of the two isoforms. However, also cis-resveratrol, which is formed from trans-resveratrol upon UV light exposure, exhibits certain anti-inflammatory activity. Unless otherwise stated, the activities mentioned here apply to trans-resveratrol. Stilbenes are non-nitrogen polyphenols with acidic and amphiphilic character which causes their enrichment in biomembranes, where many of their targets occur (COX, 5-LOX, protein kinase B) [30]. Structurally, stilbenoids possess two aromatic rings connected by an ethylene or ethene bridge with a variety of substituents. Even though the presence of double bond suggests that stilbenoids exist in cis- as well as trans-form, the trans-form is more stable and the biologically relevant form. In nature, stilbenoids are synthesized from phenylalanine through multiple enzymatic reactions [31]. Stilbenoids are heterogeneously spread throughout the plant kingdom. They are especially abundant in *Gnetaceae*, *Pinaceae*, *Cyperaceae*, *Fabaceae*, *Dipterocarpaceae*, and *Vitaceae* families [32]. Resveratrol has a function of phytoalexin produced by specific plant species in response to biotic and abiotic challenges. It is thought to be one of the principal agents in the health-promoting effects of red wine [33]. Results of clinical studies show that the most important source of resveratrol and piceid are wines (98.4%) and grape and grape juices (1.6%), whereas peanuts, pistachios, and berries contribute to less than 0.01% [34]. Wine is the major source of resveratrol and piceid to the diet, ranging from 95% and 98.7% for *trans*-resveratrol and *trans*-piceid to 99.9% and 99.7% for *cis*-resveratrol and *cis*-piceid, respectively. Other food items such as grapes contribute by amount of 3.8% of total trans-resveratrol, whereas other contributors such as pistachios or berries provide less than 1% of the dietary total amount of trans-resveratrol and trans-piceid.

Resveratrol possesses numerous important bioactivities, including anti-inflammatory, antioxidant, anti-aggregatory functions, and modulation of lipoprotein metabolism [35–37]. It has also been shown to detain chemo preventive properties against certain forms of cancer and cardiovascular disorders and to have positive effects on longevity [38–42].

Anticancer activity of this compound is mainly due to induction of apoptosis via several pathways, as well as alteration of gene expressions, leading to a decrease in tumor initiation, promotion, and progression [43]. Resveratrol blocks the growth of lymphoma cells and increases their rate of cell death [44]. Resveratrol sensitizes chemotherapy-resistant lymphoma cells to treatment with paclitaxel-based chemotherapy [45], also reduces the production of growth factors, such as vascular endothelial growth factor and interleukin [33], and may reduce the ability of lymphoma cells to spread to other organs [46]. Finally, it was demonstrated that in vitro administration of resveratrol favorably altered gene expression in the androgen axis and in cell cycle regulators, providing potential anticancer benefit for prostate cancer [47]. Moreover, *trans*-resveratrol appears to protect against diabetes [48] and neurodegenerative disorders [49], due to induction of sirtuin 1 genes [50]. *Trans*-resveratrol might also contribute to increasing the life span of metazoans and mice by miming the effect of caloric restriction and thus decreasing age-related signs [51, 52]. Experimental studies have shown that resveratrol exhibits

both an anti-inflammatory and cardioprotective potential by inhibiting the expression of inflammatory mediators and the monocyte adhesion to vascular endothelial cells [53, 54]. Although resveratrol exhibits potent anticancer activities against transformed cells, its effectiveness is limited by its poor bioavailability, and as a dietary phytonutrients, it is most effective against tumors with which it comes in direct contact, such as skin cancers and tumors of the gastrointestinal tract. Furthermore, inhibition of sirtuin 1 by both pharmacological and genetic means abolished protein de-acetylation and autophagy as stimulated by resveratrol, but not by piceatannol, indicating that these compounds act through distinct molecular pathways. In support of this notion, resveratrol and piceatannol synergized in inducing autophagy as well as in promoting cytoplasmic protein de-acetylation [55].

3 Technological Approaches to Enhance Polyphenol Content and Antioxidant Activity in Wine

The winemaking steps determine the phenolic content of red wines that able the extraction of phenolic compounds from the grape berries. Numerous winemaking procedures have been developed to enhance the extraction of phenolic molecules, by preventing the several motives that affect the release of polyphenols from the berry tissues [56, 57]. Several investigations have studied the effect of the fermentation temperature during the winemaking process on the extraction of polyphenols, thus demonstrating that their concentration increased when wines were produced at higher fermentation temperatures [58, 59]. Moreover, it has recently shown the efficacy of thermo-vinification to improve a number of factors, such as the antioxidant potential and the polyphenolic and resveratrol content, in Pinot noir, Prokupac, Merlot, and Cabernet Sauvignon wines [60].

The impact of maceration time and of the utilization of enological additives (enzymes, sulfur dioxide) on the polyphenol content has been studied [57]. Gambuti and coworkers [61] have examined the effects of those factors during vinification of Aglianico grape must. The authors indicated that the simultaneous addition, during the pre-fermentation stage, of pectolytic enzymes and SO_2 increased the release of these molecules from grape tissues, thus resulting in a higher concentration of polyphenols in the produced wine. Comparable evidences were recently obtained by investigating experimental vinification of grape must from the Vranec cultivar [62, 63]. Also in this case, both increased maceration time and SO_2 addition augmented the final concentration of total polyphenols, anthocyanins, flavonoids, and flavan-3-ols in the final product, this effect action not dependent by the wine aging.

The action of diverse winemaking approaches in determining polyphenolic profile of red wines obtained from the Italian red cultivar “Negroamaro” has been recently studied. Were compared three different pre-fermentative steps: the traditional (7 days of maceration at 25 °C), the cryomaceration, (24 h at 0 °C using dry ice), and ultrasound (37 kHz, 150 W, 15 min at 30 °C) [64]. The authors demonstrated that the ultrasound action enhanced the release of all polyphenol classes,

whereas the cryomaceration only improved the anthocyanin content in the produced wine.

This evidence has been recently supported by a recent study of Ferraretto and Celotti [65]. They evaluated the effect of high-power ultrasound (20 kHz) on the phenolic structure of red wines and demonstrated that this physical treatment promote the polymerization of the phenolic compounds as the wine matures and consequently speed up the aging course of wines.

Another investigation [66] has evaluated the consequence of different technological approaches on the polyphenolic profile and the antioxidant activity of wine produced from grape of the Italian cultivar Primitivo. The addition of tannins was more efficient in enhancing the concentration of phenolic molecule when compared in musts to the other considered technologies and the aging to get better wine antioxidant activity. Furthermore, a recent report indicated that protracted post-fermentation maceration up to 50 days increased the polyphenol concentration and, consequently, the potential healthy effect of the obtained wine [67]. However, a number of reports do not agree with this hypothesis.

However in contrast with the above findings, Mulero and coworkers [68] did not detect variation in the concentrations of the different types of phenolic compounds in three wines from Monastrell grapes, produced by separately adopting the protracted maceration, must fermentation by adding enzymes, or the traditional procedure above three technological approaches.

The pulsed electric field (PEF) technology represents a very promising approach because of its ability to enhance the extraction of polyphenolic compounds throughout the vinification process. The PEF pretreatments on Cabernet Sauvignon must gave substantial differences in the produced wines, since the same PEF-treated must showed an increase of 97% in the content of total flavonols of 32% in the content of total phenolics and of 62%, in the color, when compared to the untreated control [59]. The above findings were confirmed by similar investigations that analyzed the vinification of Cabernet [69], Merlot [70], and Syrah [71] grape musts after the application of the PEF step. Moreover, PEF treatment allowed the acceleration and enhancement in the extraction of phenolic compounds throughout the maceration step of winemaking process [72].

An interesting research have recently assessed the effects of a novel fermentation technologies based on the "Ganimede" that is able to trap the carbon dioxide (CO2) generated during the alcoholic fermentation on the phenolic contents of Cabernet Sauvignon wines [73] indicating that this device was able to increase the concentration of anthocyanins superior in the wines produced.

The mechanisms through which yeast influences the color and content of polyphenolic compounds of wine are currently being researched, but three modes of interaction between the yeasts and the polyphenolic component have been already identified. Some strains of yeast adsorb polyphenols on the cell wall. However, although it has been shown that yeast is one of the factors able of inducing the reduction of the polyphenol concentration in wines, it is unknown whether their adsorption on the cell walls is the only mechanism responsible of this behavior. The amount of biomass produced during the alcoholic fermentation is capable to adsorb

on the cell walls a significant amount of polyphenols. This capacity is likely to be strain-specific, since different yeast strains have a different composition of the cell wall. In fact, it could be hypothesized that specific yeast strains could perform a "differentiated" adsorption of the diverse polyphenol classes. The second type of interaction between yeast strains and the wine polyphenol is related to the microbial β-glucosidase enzymatic activity. In fact, the greatest part of anthocyanins is found in the wine as glucosidase derivatives (linked to a sugar); thus, in this state they are much less sensitive to chemical or enzymatic oxidation; therefore the β-glucosidase activity decreases color and stability, since it produces free anthocyanins in wine. The third mechanism regards the strain-specific secretion throughout the alcoholic fermentation, by some wine yeast, of polysaccharides capable to combine with the polyphenols and to form with them stabile complexes.

It has been shown that different yeast metabolites, including pyruvic acid, can react with the anthocyanins of the grapes giving rise to stable pigments during the maturation and aging of red wines [74]. Taken together, the above considerations highlight the pivotal role played by yeasts in modifying the polyphenolic profile of wines.

Indeed, several investigations have highlighted the ability of different wine yeast strains and of enological additives of microbial origin to improve the phenolic profile of red wines. The addition of β-glucanases or other yeast-derived enzyme preparations as enological additives increased the antioxidant potential of sparkling wines [75]. On the opposite, yeast lees have been demonstrated to lower the amounts of polyphenolic compounds [76] and anthocyanins [74] in wines, because they formed stabile complexes with the mannoproteins released by yeasts after their yeast.

Even though previous studies did not show any effect of yeast starters on the polyphenolic profile of Pinot noir [77], Cabernet Franc, and Merlot [78] wines, several recent reports indicated a correlation between the utilized yeast strain and the antioxidant capacity of the produced wine.

Brandolini and coworkers [79] carried out an investigation by evaluating the properties of wines produced by the separate inoculation of 19 strains of *Saccharomyces cerevisiae* in the same grape must. The antioxidant capacity and the polyphenol profile detected in the different wines were extremely different, thus showing the strain-specific yeast feature to differentially adsorb polyphenols during the vinification process. Kostadinović and coworkers [62] showed analogous evidence on Vranec and Merlot wines in Macedonia. The authors used different starter cultures to carry out vinification tests, where the strains demonstrated that they were capable to affect specifically the *trans*-resveratrol concentration and antioxidant activities in the final wines.

The employment of different yeast starter strains allowed the production of Pinot noir wines with a dissimilar polyphenolic content [80]. This study has analyzed how yeast selection can modify phenolic content in Pinot noir wine. In fact, five different yeast starters were tested in multiple vinifications, where the *Saccharomyces cerevisiae* strain RC212 was able to raise conspicuously the concentrations of total pigment, anthocyanin, and tannins. Recently, Carrascosa and collaborators [81] have recently shown that different yeast strains were able to produce Albariño wines

denoted with a specific polyphenol composition. The above findings were further confirmed by a recent report [82], where an unambiguous correlation between the yeast starter utilized to promote the fermentation process and chemical profile of wine was recognized, thus underlining the strain-specific yeast property to modify the color and the polyphenolic composition of the final product.

Moreover, a recent study has produced the identification of yeast starter cultures able to enhance the quality of the wine produced from the Italian red cultivar "Gaglioppo" a cultivar with reduced synthesis of anthocyanins [83]. The obtained evidences further evidenced the strain-specific capacity of wine yeast to modify the final amounts of total anthocyanins, total polyphenols, and total tannins.

Recently, Giovinazzo and coworkers (manuscript in preparation) highlighted a positive role of autochthonous yeast starter cultures for the enhancement of polyphenol content throughout the industrial production of Negroamaro wine. The statistical assessment of the experiment showed that the use of autochthonous strains increased the concentrations of several classes of polyphenols in the produced wines when compared to wines produced from the Sama grape must with commercial starter strain.

Taken together, the above-described scientific outcomes emphasize the relevance of the development and the industrial application of innovative biotechnological approaches in order to exalt the presence of healthy molecules in wine, thus improving "functional parameters" with the consequential enhancement of the final wine quality.

4 Wine Polyphenol Mechanism of Action Against Cardiovascular Diseases

Wine polyphenols have garnered much attention, especially with regard to their potential role in the protection against cardiovascular diseases. Indeed, red wine is thought to be responsible for the "French paradox" [84], a term used to describe the low incidence of cardiovascular disease in the French population despite their high intake of saturated fats.

Many preclinical and some clinical studies have identified a number of mechanisms and targets by which specific wine polyphenols could exert benefits against cardiovascular diseases. Wine polyphenols, including flavonols and resveratrol, have been shown to modulate the expression of inflammation-related genes involved in the atherosclerotic process as well as in chronic degenerative diseases.

Flavonols (quercetin, kaempferol, and myricetin) significantly downregulate the coordinated expression of the endothelial adhesion molecules, E-selectin, vascular cell adhesion molecule (VCAM)-1, and intercellular adhesion molecule (ICAM)-1, in human cultured endothelial cells activated by inflammatory triggers [85], thus decreasing the adhesion and subsequent trans-endothelial migration of monocytes into the intima of the vascular wall, i.e., processes that constitute the initial steps in the development of atherosclerosis. Flavonols have also been reported to significantly downregulate the expression of monocyte chemoattractant protein (MCP)-1

and macrophage colony-stimulating factor (M-CSF); both pro-inflammatory endothelial proteins guide monocytes into the subendothelial space, during inflammatory state [85]. The anti-inflammatory flavonol effects were mediated by the reduced activation of NF-κB and AP-1, whose binding sites are present in the promoter region of the pro-inflammatory genes including VCAM-1, ICAM-1, E-selectin, as well as MCP-1 and M-CSF [86]. Furthermore, flavonols also affected the inflammatory response by downregulating the expression of inflammation-related genes, like interleukin (IL)-6, IL-4, and tumor necrosis factor (TNF)-α. In human vascular endothelial cells, our research group reported that quercetin reduced inflammatory angiogenesis, a key pathogenic process contributing to atherosclerotic lesion formation, progression, and vulnerability, through inhibition of the pro-inflammatory enzyme cyclooxygenase (COX)-2 and gelatinases, the matrix metalloproteinase (MMP)-9 [87].

A limitation of the anti-inflammatory effect by flavonols in these in vitro studies is the use of flavonols at supraphysiological concentrations and as aglycone forms. It has been proven that after oral absorption, flavonols are rapidly converted to circulating conjugates through glucuronidation, sulfidation, or methylation. This accounts for the very low aglycone concentrations in human plasma (in the nanomolar range).

Few studies have investigated the effects of flavonol metabolites on vascular cell function. It has been shown that human quercetin plasma metabolites at physiologically significant concentrations were able to inhibit COX-2 expression in human lymphocytes. Furthermore, Tribolo et al. showed that quercetin and its phase II metabolites affected the expression of VCAM-1, ICAM-1, and MCP-1 in inflamed endothelial cells [88]. However, at 10 μM, quercetin metabolites showed a reduced ability to decrease the stimulated expression of these genes when compared with quercetin. This suggested that the chemical transformation of quercetin during phase II metabolism resulted in a reduction of bioactivity, at least with respect to regulation of inflammatory gene expression. However, at a vascular level, quercetin glucuronides can be freed of their sugar moiety by a deconjugation process performed by β-glucuronidases, and the free aglycone is delivered to tissues, particularly under inflammatory conditions [89]. In a vascular co-culture model represented by human arterial smooth muscle cells and endothelial cells, quercetin and its phase II metabolites at physiologically relevant concentration significantly decreased the stimulated expression of the vasoconstrictor endothelin-1 [90], involved in the endothelial regulation of vascular tone.

Many results obtained in cell culture studies have been replicated in animal model but not in human trials. However, several human studies have shown that quercetin can reduce blood pressure in hypertensive patients [91], although the precise mechanisms have not been elucidated.

In addition to flavonols, the anti-inflammatory action of wine polyphenols is exerted by resveratrol.

Resveratrol, like quercetin, has been reported to modulate the expression of inflammation-related genes involved in the cellular processes that control adhesion and migration of monocytes to vascular endothelium [92, 93]. We reported that

(**a**) Polyphenol content PWPE and NWPE (10 µg/mL). (**b**) Chemical structures of polyphenol groups identified in red wine extracts: hydroxycinnamic acids (*CFF* caffeic acid, *CMR* p-coumaric acid, *CFT* caftaric acid), flavonols (*KMP* kaempferol, *QRC* quercetin, *MYR* myricetin), and stilbenes (*RSV* trans-resveratrol, *PCD* trans-piceid)

resveratrol decreased monocytoid cell adhesion to human endothelial cells via reduction of VCAM-1 gene expression and by suppressing VCAM-1 promoter activity (see Figs. 2 and 3) [15]. In addition to VCAM-1, resveratrol also inhibited ICAM-1 and E-selectin, as well as MCP-1 and M-CSF [85, 93]. In human endothelial cells, monocytes, and smooth muscle cells, resveratrol strongly inhibited the expression of MMPs [85, 93, 94], responsible for the degradation of extracellular matrix, an essential event in atherosclerotic process, thus preventing plaque development, progression, and vulnerability. Furthermore, in endothelial and mononuclear cells, resveratrol inhibited, in a dose-dependent manner, the stimulated expression of tissue factor [96], a key regulator in the extrinsic pathway of blood coagulation. These anti-inflammatory and anti-thrombotic effects of resveratrol were at least in part mediated by lowered levels of intracellular ROS and the reduced activation of redox-sensitive transcription factors, NF-κB and AP-1 [85, 93, 96]. Part

of the beneficial effects of resveratrol was also mediated by the upregulation of endothelial nitric oxide synthase (eNOS), involved in the regulation of vascular homeostasis. Most of the studies about the cardiovascular beneficial effect of resveratrol were performed by using its aglycone form; however it has been shown that piceid, a glycosidic form of resveratrol, also preserved the vascular anti-inflammatory properties, although at a lesser extent [85, 94].

As a critical point of in vitro studies, the cardio-vasculo-protective effects of resveratrol have been shown to occur at supraphysiological (10 μM) concentrations, which cannot be achievable through dietary intake. However, some beneficial properties of resveratrol have been also observed at dietary doses. In human endothelial cells, resveratrol at physiological concentrations decreased the stimulated expression of VCAM-1, ICAM-1, and MCP-1 [54], as well as the cytokines, IL-6 and CCXL2. A significant increase in eNOS expression in HUVEC has been reported also at lower concentration of resveratrol (1 μM), following repeated

stimulation for 6 days [97]. Physiological concentrations (0.1–1 μM) of resveratrol have also been reported to modulate the expression of genes involved in cell proliferation, blood pressure regulation, oxidative stress response, and autophagy in endothelial cells [98].

Another critical point for resveratrol efficacy is its low bioavailability. It is rapidly absorbed, metabolized, and excreted; however, in spite of its low bioavailability, evidence that beneficial activities occur in humans is beginning to emerge, and this phenomenon has been described as the "resveratrol paradox." This paradox could thus be related to a possible action of resveratrol metabolites [99] and/or to a synergistic effect of resveratrol with other polyphenols or micronutrients. Accordingly, resveratrol as a blend of polyphenols from grape extracts exhibited a greater inhibitory effects on the expression of inflammatory markers in vascular cell than resveratrol alone [85, 95], suggesting the occurrence of a synergism among resveratrol and other polyphenols.

Though resveratrol's potential utility in preventive medicine has been demonstrated using in vitro models, few clinical trials have also evaluated the effects of resveratrol on clinically relevant biomarkers. In healthy individuals, Agarwal and collaborators evaluated the effects of 1-month resveratrol treatment on endothelial response and plasma biomarkers [100]. Exposing cultured human coronary artery endothelial cells to plasma drawn post-resveratrol supplement resulted in significantly lower mRNA expression of VCAM-1, ICAM-1, and IL-8 than plasma drawn from the same subjects at baseline. This clinical trial highlighted for improved gene expression in vascular endothelium by resveratrol. A triple-blind, randomized, placebo-controlled, 1-year treatment with a resveratrol-containing grape supplement on stable patients with coronary artery disease [101] showed dose-dependently an increase of the anti-inflammatory serum adiponectin and a decrease of plasminogen activator inhibitor-1. Moreover, the transcriptional profiling showed a down-regulation of pro-inflammatory genes and a modulation of inflammatory transcription factors, confirming previous in vitro findings [102].

Moreover, in peripheral blood mononuclear cells of type 2 diabetes and hypertensive patients with coronary artery disease [102], the supplementation with resveratrol-containing grape supplement significantly reduced the expression of the pro-inflammatory cytokines CCL3, IL-1, and TNF-α and modulated inflammatory-related microRNAs. These clinical studies support the conclusion of beneficial anti-inflammatory and immunomodulatory effects of grape extract enriched in resveratrol for secondary prevention of patients with coronary artery diseases.

5 Conclusion

The precise nature of the role played by polyphenols in human health has been largely highlighted in these last years. A better knowledge concerning the composition and dynamics of polyphenol profile in red grape will help vinedresser and winemakers in producing grape-derived products and wines with high content of

phenolic antioxidants and considerable antioxidant activity, maintaining optimal organoleptic properties and a significant link with the original terroir.

Even though, a better understanding is still requested about the several different cellular mechanisms and complex pathways involved in wine polyphenol metabolism, the present findings suggest that the contribution of antioxidant phenols through a reasonable daily drinking of red wines may offer additional protection against in vivo oxidation and other damages of human cell components.

Natural Estrogenic Substances, Origins, and Effects

40

Catherine Bennetau-Pelissero

Contents

Abstract

Some natural substances have been scientifically identified as estrogenic since the late 1930s when they were found to be deleterious at high doses for cattle

reproduction. Several compounds belonging to different chemical families are considered here: isoflavonoids, coumestans, lignans, and resorcylic acid lactones. This list is not exhaustive. The vegetable sources of these compounds are probably not all identified yet, but all the compounds presented here were shown to act as endocrine disruptors, i.e., modifying the hormonal natural balance, at dietary doses either in human, in cattle, or in other vertebrates.

Estrogenic compounds mimic estradiol activities and can interact nearly with all biological functions in lower and higher vertebrates. Some mollusks are also sensitive to estrogens. The effective dose is crucial to consider since as other endocrine disruptors the natural substances may have opposite effects at low, dietary, and pharmacological concentrations. Different cell pathways are triggered by the natural estrogenic substances, including some that are not influenced by estradiol itself, and this explains why their effect is not a monotonic dose–response line. This questions the classical toxicological approach which considers acute exposure (short and high concentrations) as the key of the toxicity evaluation. The history of human exposure to isoflavones was recently casted on doubt, reinforcing the need for careful study of these compounds' occurrence and effects on humans. It is clear now that the traditional soy food makings were able to remove isoflavones from foodstuffs. This is no longer the case in modern processing, and this means that the exposure to this estrogenic substances has increased markedly in recent times. Estrogens in mammals can have both beneficial and harmful effects which are evoked here.

1 Introduction

Nowadays, as the concern on endocrine disruptors is back to front stage, scientists realize that natural estrogenic compounds which were ignored for ages have to be included in the panel of active and potentially deleterious compounds [1]. This is mainly due to the recent discovery that humans were not traditionally exposed to natural estrogenic compounds [1] and that this recent exposure is synchronized with that to other anthropoid endocrine disruptors such as pesticides or wrapping agents [2]. Humans were not traditionally exposed to natural estrogenic compounds because they used to prepare all grain legumes, which are the major sources of estrogenic substances in human diet, by prolonged soaking, cooking, or simmering in water. The water was then discarded, and because natural estrogenic compounds are mainly under a glycosidic form in plants, they leaked into the water during the cooking steps and were then eliminated with water [3]. Reproductive problems were recently reported in multigenerational toxicological studies in animal models [4] and

in humans [5]. They occur at actual dietary exposure levels, although the acute toxicity studies performed classically on short-term durations and with pharmacological concentrations do not show major adverse effects [6]. Since endocrine disruptors were discovered, the toxicology studies dealing with reproductive issues were moved to multigenerational exposure and to low doses. Following this guidance, studies can show hormonal disruption of reproduction including epigenetic effects visible even in generations not exposed per se but issued from exposed genitors [7]. For the compounds studied here, the toxicity studies all converge in claiming an estrogenic activity. The present chapter is therefore focusing on the so-called phytoestrogens taken in their large definition since it included the mycotoxins zearalenone (ZEN) and zearalenol (ZOL) produced on grains by fungi. They also focus on natural estrogenic substances produced by plants or by the human gut after plant-substance absorption, i.e., coumestans, isoflavones, isoflavans, and enterolignans. Flavonoids can also have estrogenic effects, but at nutritional exposure, their effects remain low enough to be neglected here. However, if tomorrow a synergy with other anthropological endocrine disruptors taken at environmental doses is demonstrated, they will also have to be considered. Sources and concentrations, roles in plants, and effects in plant consumers are exposed together with the questions remaining on their beneficial and deleterious effects in human and domestic animal consumers.

2 The Natural Estrogenic Substances and Their Sources

2.1 Estrogenic Effects

The estrogenicity of a substance being anthropogenic or natural relies on two major pillars: its efficiency on estrogen-dependent gene transcription which is approached by its efficient dosage in in vivo and in vitro systems and its bioavailability at the target cell. The estrogenic effects of natural substances are based on their chemical structures which share some similarities with that of the 17β-estradiol (17β-E_2) molecule, which is the most potent estrogen in vertebrate animals. 17β-E_2 is an aromatized C18 steroid with hydroxyl groups at 3- and 17-β-position (Fig. 1a). In humans, it is produced primarily by the cyclic ovaries and the placenta. It is also produced by the brain, the adrenal cortex, and the adipose tissue of men and postmenopausal women. It is also crucial for male tract development [8] and adequate sperm production [9]. As seen in Fig. 1, 17β-E_2 is a three-dimensional molecule with its two hydroxyl groups at a distance of 10 angstroms (Å). 17β-E_2 bears a phenolic ring called cycle A.

The hydroxyl groups form an angle allowing the best interaction with the specific estradiol receptors (ERs) [10]. These receptors are proteins with specific quaternary structures allowing estradiol binding via a ligand-binding domain (LBD) and a subsequent activation of gene transcription via phosphorylation processes and activation of transcription factors. This transcription phenomenon can either follow the canonical route or be induced via cell phosphorylation pathways. The canonical

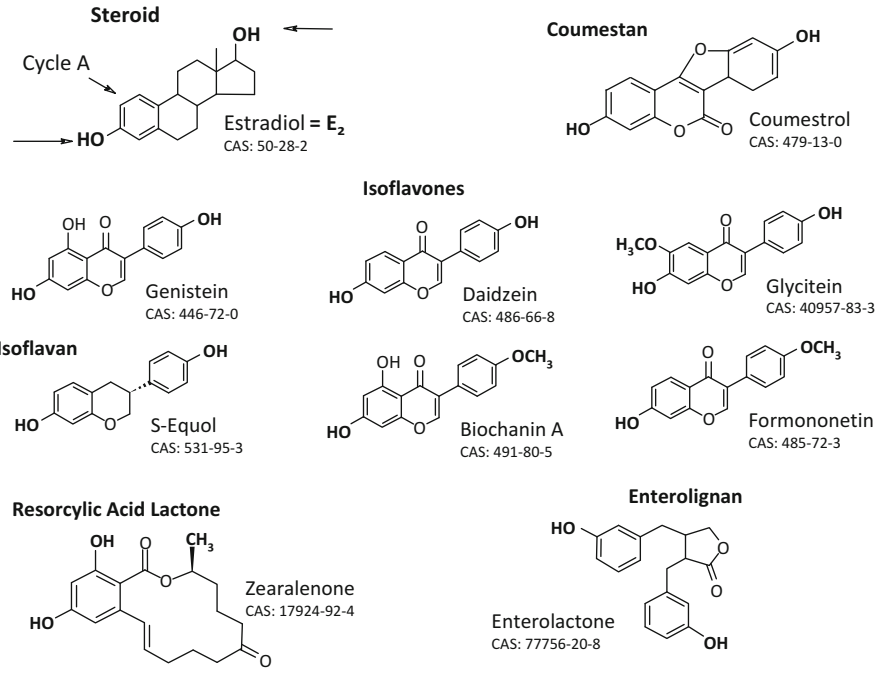

Fig. 1 17β-Estradiol structure together with the structures of the main phytoestrogen families: isoflavones, coumestans lignans, and resorcylic acid lactones

route involves a direct DNA receptor interaction, and it is known to rely on both ERα and ERβ estradiol receptor subtypes. These two estradiol receptors derive from two different genes: ESR1 located in humans on chromosome 6 and ESR2 located on chromosome 14, respectively [11]. The two receptors derive from a common ancestor but evolved differently, and nowadays they do not exhibit the same primary structure, and their activation by various ligands can be rather different.

These receptors present a LBD with a hydrophobic pocket constituted by the E/F domain (C-terminal domain) of the protein and a part of the A/B domain (N-terminal domain) folded in its vicinity [11]. The E/F domain is constituted of several helix structures, and the spatial position of the H12 helix depends on the chemical structure of the ligand. Estradiol taken as reference is a full agonist of its ERs. Other estrogens can exhibit selective modulating effects depending on the way they fit into the ligand-binding pocket of the ERs. If their structure induces a structural conformation of the H12 helix which does not allow the recruitment of all transcription factors, then the estrogenic effect can be partial. Because the transcription factors are not the same in all cell types, referring to their differentiating history, then some compounds can induce the transcription of estrogen-dependent genes in certain cell types only. This situation refers to the SERM (selective estrogen receptor modulators) concept [12]. The 17β-E_2 spatial structure

is so relevant for the ligand–receptor interaction that the natural 17-α-isomer of estradiol binds only weakly to the ERs and exhibits little estrogenic–genomic activity, considering its natural concentrations, in estrogen-responsive tissues [13]. 17β-E_2 physiological plasma concentrations in women usually vary from 10 to 20 pg/mL (i.e., from 36 to 72 pM) in the metestrous phase of the female cycle to 500–600 pg/mL (i.e., 2 to 4 nM) in the estrous phase of the female cycle. During pregnancy these 17β-E_2 levels can reach values over 30 ng/mL (i.e., over 110 nM). In the meantime, 17β-E_2 levels in men are below 50 pg/mL and below 40 pg/mL in postmenopausal women (i.e., below 200 pM in both cases). Estradiol receptors coded by ESR1 and ESR2 are also present in cell membranes. This is due to the palmitoylation of the ERs at the AA corresponding to the 451 DNA base [14] since a mutation at this point prevents membrane location. The physiological roles of the membrane forms of the ER subtypes are currently under investigation [15]. A role of the membrane ERs as transmembrane channels for steroid hormones is evoked by some authors [16].

Other estradiol receptors were found in cell endoplasmic reticulum and mitochondria membranes, the so-called GPER or GPR-30. This is a completely different molecule belonging to the seven transmembrane G-protein-coupled receptors of the rhodopsin receptor family. These receptors were shown to react with estradiol and with several estrogens, including phytoestrogens [17, 18], and to induce cell signaling pathways and growth factor receptor cross talk [19]. Finally and although these last receptors do not transmit estrogenic effects, the orphan estrogen-related receptors, i.e., ERRα, ERRβ, and ERRγ, were found to bind with different affinities several categories of phytoestrogens [20]. In some cases, the ERRs are involved in physiological processes known to be influenced by estrogens. The ERRs' function is currently under investigation, but they seem to be involved in the cell energy balance and considering an integrative view in metabolic syndrome in humans.

Because of a partial similarity (Fig. 1), the affinities of isoflavones for the ERs are lower than that of 17β-E_2. They range from 1/1000 to 1/10,000 for ERα when genistein (GEN) and kievitone are considered (with the following order of magnitude decrease: GEN > daidzein (DAID) > glycitein > biochanin A > formononetin > phaseolin > kievitone) [11, 21]. For ERβ the affinity of isoflavones is known to be higher, 1/60 and 1/150 for GEN and DAID, respectively. Other compounds like glyceolin were also found to exhibit estrogenic activity. However, these activities are not fully characterized yet [22] even though they are expressed at nutritional doses. Although the affinities of the natural estrogens for the ERs can be low, natural estrogenic substances can be present at mg level in edible plants, and some of them can reach plasma concentrations 10,000 to 100,000 times higher than those of 17β-E_2. Namely, isoflavones which present the highest bioavailability can reach micromolar concentrations in plasma, whereas 17β-E_2 is currently found at picomolar to nanomolar (pregnancy) concentrations in those same plasmas. Cell bioavailability specifically controlled by phase III enzymes (ABC transporters) acting after phase I (CYP) and II (Glut and Sult) enzymes can also play a role in the tissue-specific activities of the natural substances. See [11] for more details.

2.2 Isoflavones

The estrogenic isoflavonoids studied here include GEN, DAID, glycitein, and the DAID metabolite *S*-equol produced by the gut flora and which is an isoflavan (Fig. 1). Two other isoflavones are methylated precursors of estrogenic compounds, the so-called formononetin and biochanin A (Fig. 1). All these compounds are secondary metabolites from legumes and mainly present in Fabaceae. Some of them contain high amounts of isoflavones with estrogenic properties (i.e., up to several hundred mg/100 g of dry matter [23]). The most concentrated Leguminosae are, namely, black beans (a variety of soybean) [21], soy (*Glycine max*) [24], kudzu (*Pueraria lobata* or *tuberosa*) [25], alfalfa (*Medicago* sp.) [23], and clover (*Trifolium* sp.) [26]. Estrogenic isoflavones are also found in a smaller quantity in pulses traditionally edible in Western countries like beans, lentils, broad beans, and chick-peas, but in these vegetable sources, the concentrations are about 500 times lower than in the plants previously cited [27, 28] (Table 1). These compounds were also found in more than 300 different plants, including many species of Leguminosae like *Baptisia*, *Cytisus*, *Dalbergia*, *Genista*, *Lupinus*, *Medicago*, *Phaseolus*, *Teline*, *Trifolium*, and *Ulex* and in several species of Rosaceae like *Prunus* [29, 30]. In Western countries, these plants were traditionally used as sources of antifertility agents [29, 30].

2.3 Coumestans

The main estrogenic substance in the coumestan family is coumestrol (COUM) although it also exists as methylated substances (4′-*O*-methyl and 7-*O*-methyl derivatives) which were found in alfalfa (*Medicago sativa*) [39]. When they reach the liver, the methylated forms can be demethylated in COUM by phase I enzymes. Coumestrol estrogenic potency is by far the highest in vitro especially through ERα [40]. However, its bioavailability appears to be lower than that of isoflavones in rat [41]. No data were found in humans since this compound is considered as toxic, and therefore, pharmacokinetic studies have not been published yet in humans. In addition, this compound is present in significant amounts in alfalfa especially after fungi's attacks (*Pseudopeziza medicaginis*) [42] or in clover sprouts [43]. However, if these pulses can be used for animal feeding, they are only anecdotally used in humans, and in that case, it is essentially as dietary supplements. According to [44], clover sprouts, raw, contain 14.079 mg COUM/100 g; kala chana, mature seeds, raw, contain 6.130 mg COUM/100 g; and pinto beans, mature seeds, raw, contain 1.805 mg COUM/100 g. In addition, alfalfa seeds, sprouted, raw, contain 1.596 mg COUM/100 g; mung beans, mature seeds, sprouted, raw, contain 0.932 mg COUM/100 g; and split peas, mature seeds, raw, contain 0.812 mg/100 g. Still according to [44], soymilk, original and with vanilla, unfortified, can contain 0.807 mg COUM/100 g, and soybeans, mature seeds, sprouted, raw, can contain 0.341 mg COUM/100 g. However, soybean does not seem to be a constant source of COUM. It is likely that COUM synthesis depends on the plant culture conditions and its contamination by fungi.

2.4 Lignans

Lignans are not estrogenic substances per se, but some compounds in the lignan family (Fig. 2) can be transformed into enterolignans exhibiting low or partial estrogenic effects [45]. As far as it is known, the classical precursors of the estrogenic metabolites enterolactone (ENL) and enterodiol (END) are lariciresinol, matairesinol, medioresinol, pinoresinol, secoisolariciresinol, sesamin, sesamolin, and syringaresinol [46, 47]. Figure 2 gives their chemical formula.

However, in rats it was shown that lignin could be metabolized into enterolignans via its hydrolysis into lignans [48]. The current sources of enterolignan precursors are given in Table 2. However, this list is most likely not exhaustive.

Therefore, the exposure to enterolignan precursors is far to be precise, and in some populations, data are missing. As a consequence, the exposure is more reliably evaluated based on blood or urine measurements of enterolignans. This is particularly true since the ability to form enterolignans varies largely between human subjects [11].

2.5 Resorcylic Acid Lactones

The estrogenic resorcylic acid lactones are the mycotoxins ZEN and ZOL types α and β. All are produced by fungi of the *Fusarium* family developing on maturing corn, wheat, barley, rye oats, soybeans, sorghum, peanuts, and other food and feed

crops in the field and in grain during transportation or storage. Zearalenone and ZOL (Fig. 1) are mainly produced by *F. graminearum* and *F. semitectum* [50]. Due to its structural similarity to the naturally occurring estrogens, ZEN is an estrogenic mycotoxin that induces obvious estrogenic effects in animals [51]. Zearalenone and ZOL productions are favored by high-humidity and low-temperature conditions. They can occur simultaneously with other mycotoxins such as deoxynivalenol (DON) and less frequently with aflatoxins [52]. Zearalenone is stable in food under regular cooking temperatures but can be partially eliminated under deep heating [53]. In the human diet, the main sources are grain milling products, for human consumption, e.g., breakfast cereals, breads, and rolls. Cooked pastas only contain small amounts of ZEN, and meat and meat products are always below the detection limits (Table 3).

3 Human Exposure

3.1 Isoflavones

Isoflavones nowadays are present in almost all domestic animal food except when an alternative breeding practice is adopted, namely, if grass or other human residues are used instead of the conventional diet. In most animal breeds, the protein input is brought by pulses. The most nutritionally interesting are soy, alfalfa, or clover. All three can contain natural estrogenic compounds at high concentrations as previously mentioned. However, estrogenic isoflavones, although having a good bioavailability, have a low distribution volume and are usually eliminated for the most part during the 24 h coming after intake. Because animals are currently fasting for at least 12 h before slaughtering, the amount of isoflavones remaining in their flesh is generally low [55]. Meat or fish, even though they have been fed pulses during their life, are not good isoflavone vectors in human diet.

In human, the exposure is mainly due to soy intake, although clover, alfalfa, and kudzu extracts can be used in food supplements. Until recently, this exposure was thought to be safe assuming that isoflavones had always been part and parcel of the human diet in Asia. However, it was recently shown that all traditional Asian recipes, which were elaborated sometimes over several centuries, included prolonged cooking, simmering, or soaking in water. These steps empirically removed the glycosylated isoflavones which are soluble in water but heat resistant. As an example, for traditional tofu, a rough soy meal is simmered and soaked in water for a total of 2–3 h before curdling. Then, water is squeezed out by pressing to make the soy cheese. In the same way, kudzu, which contains high levels of isoflavones with inverse proportions of GEN and DAID compared to soy, is directly powdered to prepare medicines. It is also boiled in water to be eaten as we could do with potatoes. The boiling step can last over 2 h and removes isoflavones. In 2004, looking at isoflavone intakes in rural Chinese women who are more likely to have kept their traditional tofu making, Liu and co-workers [56] found that 65% of them had an isoflavone intake below 15 mg/day, the majority being below 5 mg/day. Nowadays,

Table 3 Occurrence of ZEN in unprocessed grains from EFSA [54]

[a]If $N < 60$, then the calculated P95 should be considered only as an indicative value [54]

in Western countries as in the developed countries of Asia, soy is essentially produced using industrial techniques. In all cases, cooking steps were reduced in time to reduce energy costs, and water is used either in small proportion (steaming) or not used at all. As a consequence, the amounts of isoflavones can be very high. Therefore, the amount of isoflavones in modern products can be high when a portion is considered (Table 4). Soy is also incorporated in processed food as soy flakes (Table 4) which can contain from 90 to 182 mg of isoflavones for 100 g [1]. Therefore, isoflavones can be present in significant amounts in processed food containing soy flakes (Table 4).

Why is there such amount of isoflavones in modern soy preparation? This is because when the industrial processes were set up, in the 1930s, hardly anything was known about isoflavones, and the processes were designed essentially to prevent protein degradation. As an example, defatted soy flakes are treated with hexane which removes fat and concentrates isoflavones in the protein matrix. The matrix is then extruded. Extrusion destroys most of the anti-nutritional factors but not isoflavones. Generally speaking, in the industry, the cooking steps were shortened to save energy and costs. When it was possible to assay isoflavones accurately, in the early 1980s, the assays were performed in several popular areas essentially eating industrial soy-based products produced in mass for city populations. The study by Liu [56] is one of the very few dealing with exposure in remote Chinese areas still consuming soy food traditionally cooked. It showed that the largest proportion of rural women was exposed to low doses of isoflavones. Therefore, nowadays and

Figures are mean ± SD of three measures performed on three different microtitration plates
[a]The traditional tofu is an industrial product

especially in developed Asian countries where soy is traditionally eaten but where the processing has been industrialized, the isoflavone intakes have risen dramatically, sometimes over the 45 mg/day which shown to have an effect on premenopausal menstrual cycle [57]. According to recent studies, the mean human exposure in Japan lies between 45 and 60 mg/day [58], in Korea the highest value recorded was 33.6 mg/day for adults [59], and in China it tends to increase nowadays [60] with 16.2 mg/day for adults and 27 mg/day for adolescents and a large interindividual variation. In Western countries, the exposure to isoflavones also rose recently although it is most likely underestimated. Usually, in Western countries, the isoflavone intake is based on the evaluation of pulse consumption and essentially based on soy which is the major provider [61]. Therefore, many countries consider the intake below 2 mg/day especially because they tend to calculate a mean intake over the total population and taking only soy food intake into account. In the USA, the exposure was estimated to be less than 2.7 mg/day in 2001 [31] and confirmed later by subsequent studies [62, 63]. However, the amount of isoflavones in modern soy-based food is higher than that found in the past in traditional foodstuffs (Table 4). Hence, soy juices which are very popular in the West, together with their side products (yogurts and creams), can be good vectors of isoflavones, since in this case, isoflavones are concentrated at the juice filtration step [1]. Soy is also prepared as flakes containing large amount of isoflavones. As already

Table 5 Isoflavone intakes by infants fed with soy-based infant formula in different countries

Countries	Isoflavones mg/liter	Daily isoflavone intake (mg/kg bw)	Reference
USA	20.9–47	2.3 to 9.3	[68]
UK	18–46.7	1.7 to 4.4	[68, 69]
Australia	17.2–21.9		[68]
New Zealand	17.1–33	2.9 to 3.8	[68, 70]
Brazil	10–47.4	0.8–1.6 to 6.6	[68, 71, 72]
France	19.4–42.3	2.3 to 6.04	[73]

mentioned, flakes are incorporated into many recipes marketed as traditional but made by the food industry. Soy is then incorporated as an ingredient for its nutritional and technological properties or for economic reasons. Most studies have underestimated this exposure, but it is so significant that in recent studies no urine samples were found to be devoid of isoflavones in American men [5]. Isoflavones were also detected in 88% of the urine of American pregnant women [64], in all Israeli adults [65], and in all German adolescents [66] of a study cohort. Finally, it must be pointed out here that the human populations most exposed nowadays are infants or children on soy-based infant formula [67]. These formulas were advised to children with lactose intolerance mainly in the 2000s. In the USA and according to authors, 17–30% of infants received these formulas in the last past years. Table 5 shows data recorded in different countries by several authors.

In their paper [67], Badger and co-workers also showed that infant exposure to soy isoflavones is a modern practice. They explained the exposure to estrogens of infants fed with soy-based infant formula is dramatically different from that of Asian children enjoying traditional Asian soy intake. Traditional soy consumption in Asia was based on solid foodstuffs (tofu, natto, miso, tempeh), which were not suitable for babies. Traditionally, these foodstuffs were prepared following recipes including prolonged cooking, simmering, or soaking in water and most probably contained much less isoflavones than the modern industrial products. Therefore, the isoflavone exposure calculated in [67] was nearly nil before 12 months in Asian children but rose progressively thereafter. By comparison, in Western babies fed with soy-based infant formulas, the exposure rate is high as soon as soy formula intake begins, which rises and continues to rise progressively until food diversification. Exposure levels are currently 10–20 times higher than those inducing an estrogenic effect in women, as shown on breast reactivity [74–76], menstrual cycle lengthening [57, 77], and impaired sperm production [78–80]. The plausible consequences of such exposures will be discussed later.

3.2 Coumestans

Coumestrol as a phytoalexin is essentially produced by pulses following fungal attacks. Therefore, and because human foodstuffs are usually better controlled, this substance is more likely to be present in animal food rather than in human diet.

Although, it is not excluded that it could be present in food supplements such as those based on alfalfa. In England the study of Clarke and co-workers [81] failed to detect any COUM in the samples analyzed. In France, in 2011, according to the EAT2 study [82], the consumer exposure was considered to be at least 1,891 ng/day. However, the authors tend to think that this exposure is underestimated since all the contributors could not be analyzed in the EAT2 study. Recently a protein supplement based on alfalfa was authorized by EFSA although the supplier was able to measure milligrams of COUM in his extracts, i.e., 78 mg/kg [83]. The supplier also showed an estrogenic effect in mice and showed a large variability of phytoestrogen content from one batch to another. If such a supplement is to be used widely by the European consumers as it is proposed, the mean exposure to COUM will probably rise dramatically. However, in South Korea, it was reported in 2009 that the mean level of exposure was 0.3 mg per capita per day due to a local specific foodstuff consumption like soybean sprout and arrowroot [59].

3.3 Lignans

As already mentioned, lignans are not estrogenic in plants. The molecules present in grains and in vegetables are eventual precursors of estrogenic enterolignans depending on the composition and efficiency of the human gut flora. Therefore, the enterolignan exposure is difficult to assess because not all precursor sources are identified yet [49] and because not all consumers are able to produce them after ingestion. According to Zamora-Ros and co-workers [84], in European populations, lignans were the most abundant contributor of phytoestrogen intakes when the global intake is low. This study reports a low lignan intake (1.02 mg/day) in Mediterranean countries and even lower in Italy (0.67 mg/day). It also reported a higher intake (1.26–1.60 mg/day) in non-Mediterranean countries. The study also compared their data with those obtained in the Netherlands (1.24 mg/day), in Sweden (0.50–2.81 mg/day), and Finland (1.22 mg/day). Still according to [84], in other Western countries such as Mexico, the USA, and Canada, lignan intakes were considered to be much lower (from 0.35 to 0.86 mg/day). However, when pharmacokinetic studies are performed in humans, the enterolignan levels recorded in the blood of ENL producers are never null [85]. Moreover, in urine and in serum, of citizen of Western countries, they are of the same range concentrations with isoflavones [86, 87]. As an example according to [86] in the USA (Albany), the urine lignan concentrations range from 0.99 to 1230 ng/mL and were found in 94% of the population. In parallel, still in the same study, isoflavone urine levels range from 1.33 to 1290 ng/mL. The detection rate reached 100% for DAID in women. In the UK and according to [87], the enterolignans in urine sample ranged from 0 to 10,229 μg/mmol creatinine and isoflavones (DAID, GEN and equol) excreted in urine ranged from 0 to 1,442.6 μg/mmol creatinine. This shows that the sources of enterolignan precursors are far from being identified and that the exposure is only approached and most probably underestimated. In addition, this lignan intake cannot

be readily assimilated to a phytoestrogen exposure because the gut metabolism differs between consumers [88].

3.4 Resorcylic Acid Lactones

Because of a careful screening of plant matter, usually the exposure to the mycoestrogens, ZEN, α-ZOL, and β-ZOL in the European populations are considered to be low. More precisely based on a bio-monitoring approach linking the scarce pharmacokinetic data of ZEN in human and data obtained on urinary levels [89], it appeared that zearalenone daily exposure is most probably below the tolerable daily intake (TDI) of 0.25 μg/kg body weight in European study cohorts. However, some individuals from Haiti and in African countries, where corn is a major food source, may have an exposure that exceeds the TDI. Table 6 from [54] gives exposure calculations in different categories of European consumers.

4 Effects in Plants

4.1 Isoflavones

Isoflavones in plants act as phytoalexin [21]. They are antimicrobial and may have a role in plant protection. As an example, the antifungal activity of lupin isoflavones was demonstrated [90]. In soybean cultivars, an increase in isoflavone concentrations was shown to be a specific response to the attack of a saprophytic fungi *Mucor ramosissimus*. In the soybean strains resistant to the fungus, isoflavones (including glyceollins I, II, and III, glycinol, glyceocarpin, GEN, isoformononetin, and *N*-acetyltyramine) were induced by the fungal attack, all compounds possessing antifungal activity with the exception of GEN [91]. A contamination of a soy strain with the fungus *Diaporthe phaseolorum f.* sp. *Meridionalis* induced the accumulation of isoflavones (GEN, DAID), pterocarpans (glyceolins), and flavones (apigenin and luteolin) via a nitric oxide synthase pathway [92]. To go on with interactions of the plants with microorganisms, there is some evidence that the symbiotic relationship between *Rhizobium lupine* and *Lupinus albus* stimulates an increase in the production of prenylated isoflavones in the root nodules [93]. These prenylated isoflavones possess in vivo activities against a number of other *Rhizobium* species. Zhang and Smith [94] also showed that GEN plays a major role in the establishment of the symbiosis between *Bradyrhizobium japonicum*, the arbuscular mycorrhyzas such as *Glomus mosseae*, and their host, i.e., soy (*Glycine max*). Genistein is the soy recognition molecule inducing the greatest plant-to-bacterium signal. In fact, the binding of GEN to *B. japonicum* activates many of the bacteria nod genes.

There is solid proof that farming practices directly influence the levels of isoflavones in soy. As a matter of fact, irrigation was shown to enhance isoflavone content in soybean by as much as 2.5-fold [95]. A deficit in nitrogen fertilizer increases the estrogenic activity of a clover pasture [96]. On the other hand, a

supplementation in the same fertilizer decreases the occurrence of isoflavones with estrogenic activity in a clover pasture [96]. A study where soy cultivars (*Glycine max*) were bred for 3 years demonstrated that levels of isoflavones were related to both environmental and genetic characteristics and could be susceptible to selection [97]. The genomic regions implicated in this process have been identified [98]. Vyn and co-workers [99] showed that GEN, DAID, and glycitein contents in soy are correlated with potassium in roots and leaves and with crop management using potassium-rich fertilizers. Lindner in [23] gave an evolutionist theory about the ability of Leguminosae to produce estrogenic isoflavones. Indeed, it appears that isoflavonoid compounds are synthesized by the plants in response to bacterial or fungal attacks or to water stress. Estrogenic isoflavones can then be considered as protective compounds. In the case of overgrazing of a pasture by mammalian predators, the production of great quantities of estrogenic compounds which could impair predator reproduction would result in the reduction of the predator pressure. Finally, because estrogenic isoflavones are also specific attractants

for symbiotic bacteria of the *Rhizobium* gender and of mycorrhizal fungi of the *Glomus* gender, and because these bacteria can fix the atmospheric nitrogen, human selection against the production of isoflavones in pulses would result in the loss of one of their greatest interests in crop management.

5 Effects in Humans and Animals

5.1 Beneficial Effects

5.1.1 Beneficial Effects in Animals

Estrogens are used in cattle as anabolic agents. Therefore, some studies attempted to figure out if a phytoestrogen supplementation can enhance cattle or poultry growth and meat quality [100]. Beside a potential interest in antioxidant content of meat from animal raised on estrogenic food [100], it was seen that a DAID supplementation in the diet increased marbling meat score in steers [101]. If the meat quality was significantly improved considering several parameters, the carcass bone proportion was also greater probably reflecting a positive effect of phytoestrogens on osteoblast function. In another study [102] and at low doses, i.e., 300 and 400 mg/day, DAID was also shown to enhance immune function in late-lactation cows under heat stress. However, the DAID supplementation does not strictly mimic a legume intake since in all the roughages based classically on pulses, DAID or its precursor formononetin is present together with other compounds either estrogenic per se (GEN) or precursors of these estrogenic isoflavones (biochanin A) playing in interaction.

There is no positive effect reported for lignans, COUM, or ZEN on farmed animals although ENL was found in milk of cows fed with flaxseed or forages rich in ENL precursors [103].

5.1.2 Menopause in Women

Isoflavones

Menopausal symptoms encompass hot flushes, night sweats, vaginal dryness, mammary density, and mood fluctuations. Menopause is not a disease. In Western countries, menopausal symptoms were treated for more than 20 years using hormone replacement therapy (HRT). However, several studies including the Women's Health Initiative (WHI) showed that deleterious effects of the US treatments on breast or endometrial cancers and those on cardiovascular diseases may overcome their benefits [104]. More than 543 epidemiological studies were performed to examine if the consumption of soy and isoflavones with estrogenic activities may prevent hot flushes. This effect can be suspected since it is known that hot flushes and night sweats are controlled by the hypothalamus preoptic area implicated in the body core temperature regulation. In addition, the neurones in this region have estradiol membrane receptors involved in body temperature and energy homeostasis [105]. This area induces shiverings or sweatings when it records a body temperature over

a low and an upper threshold. The amplitude of the neutral zone situated between these thresholds is under serotonin and noradrenergic control. 17β-E_2 is known to induce the local synthesis of these two neuromediators as well as their respective receptors [106]. The recent meta-analysis of Chen and co-workers [107] showed a reduction in hot flushes with isoflavone intake. The study is based on 15 randomized clinical trials comparing phytoestrogens vs. placebo for which the mean age of the subjects ranged from 48 to 60.1 years. The number of participants was at least 30 and up to 252. The study duration ranged from 3 to 12 months. The meta-analysis of the 7 studies reporting the Kupperman index gathering 11 menopausal symptoms showed no significant effects of phytoestrogens as compared to placebo. However, the meta-analysis of ten studies showed a significant reducing effect of phytoestrogens on hot flush frequency compared to placebo. The meta-analysis of the five studies that planned to report side effects of phytoestrogens did not show any significant difference between the two groups. Menopausal symptoms are known to be influenced by psychological elements. Therefore, a placebo effect exists. Nevertheless, in accordance with an estrogenic effect in women especially when estradiol receptors are present, the phytoestrogen effect can be observed.

Coumestrol

In women some data exist linking the use of some herbal medicine, some of them containing COUM with other substances with or without estrogenic activities [108]. This is the case for clover or alfalfa preparations. However, menopausal symptoms are influenced by psychological factors [109], and some meta-analyses failed to really correlate isoflavones and/or COUM with a decrease of menopausal symptoms [110]. For COUM its level in the preparation is generally low even if it can also be highly variable. In addition, little is known about its serum bioavailability. Therefore, its effect is very difficult to truly associate to any observation.

Lignans

Only eight randomized, double-blind, placebo-controlled clinical trials were found trying to prove the effectiveness of flaxseed on the management of menopausal symptoms [111–116]. None of them, whatever the amount of flaxseed or secoisolariciresinol diglucoside (SDG) tested, whatever the age and number of volunteers involved, was able to show an effect over placebo treatment. This could be expected at least for two reasons. First, enterolignan precursors are ubiquitously distributed in human diet, and therefore the placebo group also receives estrogenic enterolignans in rather variable amount. See Table 2 and the known sources of lignans. This, of course, reduces the power of the interventional studies. Second, only END or ENL can possibly exert estrogenic effect, which could explain hot flashes relief. However, only a small portion of the population harbors the gut flora able to produce these enterolignans in sufficient amount [117]. Therefore, the enterolignan effect should only be seen if women able to produce enterolignans were compared to women unable to produce them. This would require a selective procedure at the entrance of the clinical studies and enterolignan monitoring in blood to account for the dietary exposure through casual diet. None of the studies done until now did undergo such

protocol. Note that urine measurements may not be precise enough since an eliminated compound is not an active one and that there may be interindividual variations in the elimination pathways of enterolignans.

Zearalenone
Zearalenone and its metabolites α- and β-ZOL as mycotoxins have not been tested in clinical intervention on menopausal symptom relief.

5.1.3 Bone Health in Women

Isoflavones
Two meta-analyses converge in saying that isoflavone from soy may be protective on bone density in menopausal women but only at high doses, i.e., over 80 mg/day. The first one [118] considered only supplementation by soy isoflavone extracts (not soy protein or foods containing isoflavones) on bone mineral density (BMD) in menopausal women. It was based only on randomized controlled trials published in English, Japanese, or Chinese reporting the effects of soy isoflavone extracts on lumbar spine or hip BMD in menopausal women. Only 11 studies in total were found to match the given criteria. The meta-analysis included data from 1,240 menopausal women. It revealed that daily ingestion of an average of 82 mg of soy isoflavones (aglycone) for 6 to 12 months significantly increased spine BMD. Treatment duration, geographic origin, and basal BMD had a major influence on the effect observed. No significant effects on femoral neck, hip total, and trochanter BMD were found, while soy isoflavone extract supplements increased BMD feature that was restricted to the lumbar spine in menopausal women. The second meta-analysis [119] included randomized controlled trials (RCTs) examining the effect of a soy isoflavone supplementation in women for at least 1-year duration. The main outcomes were BMD changes from baseline at the lumbar spine, total hip, and femoral neck. Ten RCTs gathering 896 women were found to be eligible according to the study criteria. A mean dose of 87 mg of soy isoflavones for at least 1 year did not significantly affect BMD changes. However, when doses were stratified, it was shown that only a large dose over 80 mg/day of isoflavone tended to have a weak beneficial effect on spine BMD. The BMD was not increased but preserved.

Coumestrol
*N*o data seem to exist on the effect of COUM on menopausal women bone health. Only one study tested the effect of this compound in rodents [120], showing a preventive effect against bone loss in an ovariectomized rodent model. The estrogenic activity of COUM in vivo on bone cells has also been shown on the prevention of osteoclast differentiation [121] and the enhancement of osteoblast formation [122]. These are classical estrogenic effects.

Lignans
The only study which was found dealing with the association of lignans and bone health is likely to be insufficient to prove any effect [111]. It deals with an exposure

evaluated from a dietary questionnaire, and since median intake of total phytoestrogens was estimated at 876 μg/day, the study most probably underestimated the exposure. Phytoestrogen plasma assays should have been done for this study to really help in determining the enterolignan effects. Nevertheless, the authors said that enterolignans estimated from food intake irrespective of the gut flora efficiency were positively associated with bone density in postmenopausal women. However, this association became nonsignificant when dietary Ca^{2+} was added to the model. In light of this finding, further data are needed before any definitive conclusion was drawn out.

Zearalenone

Because of the toxicity of the molecule and of its metabolites α- and β-ZOL, no study was performed and published in humans. As for COUM, some data can confirm the estrogenic effects of ZEN and metabolites on bone cells in vitro [123] but also in vivo in rodent models [124]. Again the main outcomes are characteristic of estrogenic effects, with a prevention of bone loss [125], although in some studies chromosome aberrations were also reported [126 and publications included].

5.2 Deleterious Effects

Looking at deleterious effects is a challenge since in several occasions it can be seen that the experts do not agree on what is adverse and what is safe. Before the 2010s hormonal changes were not always considered as adverse, and therefore two types of noneffective levels were defined for phytoestrogens: the no observable adverse effect level (NOAEL) and the no observable effect level (NOEL). Conventional toxicology relies upon measures of exposure that induce pharmacological or physiological adverse effects. Hence, the NOEL is the highest dose tested at which there is no measurable effect, and the NOAEL is the highest dose tested at which there is no measurable adverse effect. Then the definition of what is an adverse effect is crucial to consider. Nowadays, the concept of endocrine disruption has emerged, and all hormonal modifications especially those dealing with reproductive hormones can be considered as adverse. However, such adverse effects are usually observed on a long-term basis, and therefore multigenerational studies may sometimes be required to see an effect. For example, if chronic classical toxic effects are considered for GEN, the NOAEL on liver endpoint is 50 mg/kg/day. However, considering hormonal endpoints and according to McClain and co-workers, the NOEL is 5 mg/kg/day [6]. If hormonal effects are seen as endocrine-disrupting effects, then the NOAEL of GEN switches from 50 mg/kg/day to 5 mg/kg/day. This NOAEL is sustained by the recent studies of the National Toxicology Program (NTP) in the USA [4]. However, the NTP study also showed reduced birth weight and reduced weight at weaning of pups at all doses tested including 0.3 mg/kg/day in females and over generations. The authors concluded that if this effect is considered as a toxic effect, then the NOAEL is below 1.2 mg/kg/day in rat. It also showed a reduced anogenital distance reduction in pups of both sexes at various doses and in several

exposure conditions. Litter size was also impaired after several generation of exposure for the highest dose tested. These effects sign a physiological impairment which can have consequences on reproduction which is finely tuned by complex endocrine balances. Therefore, effects which could have been neglected in the past come to the front nowadays because science progresses. NOAEL and LOAEL (lowest observed adverse effect level) can be used to establish mean tolerable daily intake (MTDI). A TDI is an estimate of the amount of a substance that can be taken daily over a lifetime without appreciable health risk. TDIs are calculated on the basis of laboratory toxicity data to which uncertainty factors are applied. According to [127], reasonable uncertainty factors should be applied. When a NOAEL in rat is available in chronic study, this uncertainty should include a factor accounting for the difference of sensitivities among humans and a factor accounting for the relative sensitivities of animals compared to humans. In that case, the MTDI in human is 46 times lower than the NOAEL in rat. When only LOAEL are available, the uncertainty factor should also account for uncertainty in extrapolating from a low-risk level. Therefore, the global uncertainty factor between LOAEL and MTDI increases to 184. Here, the adverse effect can be considered to be a hormonal disruption. As TDIs are regarded as representing a tolerable intake for a lifetime, short-term exposure to levels exceeding the TDI is not a cause for concern, provided the individual's intake averaged over longer periods of time does not appreciably exceed the level set. The uncertainty factors used to establish a TDI provide assurance on the relative safety of the TDI. However, there should be concern if the TDI is substantially exceeded for long time periods. In order to have a quick overview of what can be said about the molecules retained here, we propose Table 7 which gathers NOAEL or LOAEL obtained in rat. It also gives an overview of the estimated exposure and a weight limit under which the exposure is due to overcome the MTDI. This table is partly deduced from that of Hendrich [128].

These data have to be considered with caution, since here again, science evolves and toxicological studies performed more than 10 years ago may not reach the standard of quality actually required. However, if they have not been reproduced recently, they should be considered as valid. The MTDI presented in this table are compared to the mean daily exposure expressed in mg/day. The values given here may be corrupted by many biases when they were estimated from food frequency questionnaires. First these questionnaires may not exactly reflect all population exposure, and second the large variability of the content in the phytoestrogen of interest may not be taken into account. Some food sources can be completely omitted as for isoflavones. Hence, as already mentioned, soy is nowadays ubiquitously present in industrially processed food, and the isoflavone intake is so common that they can be found in a large proportion of consumers' urine samples (100% in the US study by Mumford [5], 100% in the German study by Degen [66], 98% in the Israeli study by Berman [65]). Note that for lignans, no data of exposure were found in Asian consumers. This is due to the fact that many plants including plants used for personal care in Asia are sources of the estrogenic-enterolignan precursors. All these precursors are not known yet, and this has to be combined to the fact that not all the consumers harbor the competent gut flora for ENL production. Therefore, when the

Table 7 Summary of NOAEL or LOAEL of natural estrogenic substances together with the consumer estimated exposures and the limit at which the mean dietary tolerable intake can be overcome

The inferior weight limit for MDTI overcome is obtained dividing the estimated daily intake by MTDI
MTDI mean tolerable daily intake
[a]extrapolated from the LOAEL; *nd*, not determined

effect of ENL is analyzed, the substance is assayed in the urine, but the correlation of the urine dose to a dietary intake is far to be simple. Finally, when the dose is low, the detection technique may not be reliable enough to get good results. Therefore, looking at the exposure to lignans in Asia, it was impossible to find any published data. The last column of the table gives a figure which materialized the inferior weight limit for MTDI overcome. It is calculated by dividing the estimated daily intake by the MTDI. As an example, for GEN in the USA, considering a mean daily intake of 2.7 mg in the general population, it appears that all people, whose body weight is lower than 24.55 kg, overcome the MTDI. Because this limit is considered as safe, the concern about this situation can arise only from its chronicity and from the degree of overtaking from the MTDI. The MTDI is a mean of the population exposure, and some people can be exposed to much higher doses. The situation in Japan could be considered as worrying since the calculation indicates that all people under 454.55 kg overcome the MTDI, considering the daily intake estimation. In that case, a fertility problem over generation should be investigated because it is seen in experimentally exposed rats.

5.2.1 Reproduction in Animals

Isoflavones

Isoflavones were considered for many years as estrogenic endocrine disruptors and studied as such by several authors [137–144]. These compounds can be present at high doses in estrogenic pastures based on certain clover species or on alfalfa. In sheep on these pastures, estrogenic isoflavones were shown to induce permanent estrus, heavy vaginal secretion, uterus prolapse, early abortion, reduced prolificity in reproductive ewes, and mammary fluid production in nulliparous ewes and castrated males. Castrated rams also exhibited abnormalities in their reproductive tracts, including enlargement of the prostate, the bulbourethral gland, and the membrane of the *vasa differentia*. In ewes affected by clover diseases, clover isoflavones were shown to delay LH secretion via a GnRH interaction [142]. This LH delay in secretion, which led to progesterone secretion impairment, was considered to be responsible for early abortion. More recently, a renewed interest emerged among scientist for the soy and isoflavone effects on reproduction of domestic animals. This is because it was recently figured out that isoflavone deleterious effects on cattle could have been missed out because soy was progressively incorporated to cattle food while genetic selection was undertook to improve production features including reproduction. Therefore, the antagonistic effects of both processes could have partly masked each other. As an example, it was shown that soy isoflavones can prevent in cows as in rodent the response of the *corpus luteum* to GnRH [145]. This result obtained, in vivo, is confirmed by data recently obtained ex vivo on Prim Holstein cows [146]. In addition, clover isoflavones were shown to block the early progesterone synthesis in Holstein heifers fed with a *Trifolium alexandrinum*-rich roughage after insemination [147]. This disruption was thought to be responsible for lesser ($P = 0.054$) conception rate and the greater ($P = 0.062$) percentage of heifers returning to estrus when compared to the control silage-fed heifers. As demonstrated

for COUM, GEN and DAID are able to increase the secretion of oxytocin by cow *corpus luteum* [148]. This can induce early abortion in these females and reduce global fertility and hence financial incomes to farmers relying either on veal or milk production. Recently, it was shown that isoflavones intake through Egyptian clover (*Trifolium alexandrinum*) as estrogenic roughage exerted a deleterious effect on fertility. Comparing the estrogenic roughage to the control diet based on maize silage, the % of Holstein heifers returning to estrus was 7.70 (1/13) under the control diet, and it was 38.46 (5/13) when cows ate clover roughage. Still in cows, it was shown that soy phytoestrogens increase prostaglandin secretion in cattle during estrous cycle and early pregnancy [149]. The number of cows involved in the trial was low. However, it appeared that soy-derived phytoestrogens and their metabolites disrupt reproductive efficiency and uterus function by increasing the ratio of prostaglandin F_2-alpha (PGF_2-α) to prostaglandin E_2 (PGE_2). Therefore, phytoestrogens led to high, nonphysiological production of luteolytic PGF_2-α in cattle during the estrous cycle and early pregnancy. The consequence of this increased PGF_2-α production is a higher failure rate of pregnancy. In addition, in vitro but at physiological doses, GEN, DAID, and equol were shown to inhibit bovine adrenal 3-beta-hydroxysteroid dehydrogenase directly involved into the synthesis of progesterone [150]. This inhibition seems to be possible in vivo considering the active doses of isoflavones in vivo. On top of the LH disruption, this direct effect may be a way by which isoflavones reduce progesterone secretion in early pregnancy. This can cause early abortion.

The phenomenon is generally enough to have led to endocrine disruption also observed in lower vertebrates of economic importance like birds or fish. Although the isoflavone effect in hens and laying hens does not seem to be deleterious, some long-term effects were recorded in ducks [151]. Noteworthy, ducklings were significantly smaller at hatching when exposed maternally to DAID supplementation. The difference in size compared to control animals disappeared at 4 weeks of age. It was accompanied by changes in the secretion of metabolic hormones and expression of growth-related genes. Although the negative effect of maternal DAID on embryonic growth could be eliminated 4 weeks after hatching, the long-term effect of maternal DAID on reproductive function was noted. Namely, it was an obvious downregulation of hypothalamic GnRH mRNA expression observed in ducklings maternally exposed to DAID. Fish in fish farms fed with a soy-containing diet can also exhibit altered reproductive performances or at least endocrine-disrupting features [152–154]. These effects were recently confirmed in goldfish considered as a model for other cyprinids [155] and also in other species of commercial interest like catfish or sea bass [156, 157]. Both estrogenic and thyroid functions involved in smoltification were shown to be impaired by soy phytoestrogens in the Atlantic salmon [158].

Coumestrol

Coumestrol was shown to exhibit deleterious effects on grazing animal reproduction [159]. Coumestrol was also involved in the clover disease affecting ewe reproduction in New Zealand in the late 1940s, and these endocrine disruptions still attract

scientific interest [160]. According to Adams [161], cows are more sensitive to COUM than to isoflavones most probably due to differences in metabolism when compared to ewes. As an example, COUM was shown to increase the production of oxytocin by cows decreasing the ratio of progesterone to oxytocin. This endocrine modification induces a higher failure rate to pregnancy. Still in the same study, COUM was shown to decrease PGE_2 secretion. These endocrine-disrupting effects can increase the risk of early abortion in this species [162] and therefore can affect the % of females returning to estrus as well as the calving to calving interval. In mare, COUM exerts endocrine-disrupting effects on chronic exposure leading to ovulation impairment [163]. The authors conclude to a potential infertility syndrome due to estrogenic silage (clover and alfalfa) in mares. The first reports of the deleterious effects of COUM in rat were produced in 1970 [164]. Then the Whitten's group published several coherent data showing the estrogenic effects of dietary COUM on the rat puberty and cycle [165], on uterus development [166], on the embryo implantation [167], and on the pituitary and hypothalamus hormone disruptions [167]. They also pointed out the remaining effects after the end of exposure [168] as well as sexual behavior impairments [169]. Other studies showed reproductive adverse effects on males' semen production which could be explained by a precocious estrogenic effect affecting the pituitary hormones and steroid secretion [170]. According to Hendrich [128], there is no NOAEL for COUM, and the LOAEL is 4 mg/kg/b.w./day.

Lignans

There is few data on the role of estrogenic enterolignans in domestic animals. These lignans can be present in significant amount especially when linseeds are used to modify the meat quality toward a greater proportion of omega-3 polyunsaturated fatty acid (PUFAs). According to [171], ENL concentration is increased in follicular fluid from cows fed with flaxseed-rich diet, although the serum levels are not affected. These increased enterolignan concentrations are correlated with increased concentrations of estradiol locally addressing the question of an effect of ENL on follicular steroid biosynthesis. Still in cattle, [172] showed that ENL deriving from a flaxseed-enriched diet or given alone in parallel of specific mixtures of PUFAs can decrease PGE_2 and $PGF_2\alpha$ concentrations in endometrial, stromal, and epithelial cells. This reduction was associated with lower mRNA abundance of the PG synthase genes in stromal cells. An omega-3-enriched PUFA mixture increased the effect of ENL compared to ENL alone and PUFA mixture rich in omega-3 alone. The authors concluded that considering the known luteolytic properties of $PGF_2\alpha$, a reduction in endometrial $PGF_2\alpha$ secretion would favor the establishment and maintenance of pregnancy. Enterolignans were found in the early 1980s in human and cattle semen. In both cases, their concentrations were shown to be 2.5 times higher than the corresponding plasmas [173]. In rat they were found to alter pregnancy outcome and reproductive development [131].

Resorcylic Acid Lactones

Zearalenone and ZOL are known as endocrine-disrupting agents from fungi since the early 1960s [51]. In cattle, ZEN was shown to lower the conception rate of the heifers [174]. In addition, ZEN contaminating sugar beet pellets was considered to be responsible for a reduced embryo transfer efficiency from a dairy farm experiencing low success rates of embryo transfer [175]. More recently, thanks to better detection techniques, it was shown that low ZEN contamination (below the allowed limit in Japan) was able to modify anti-Mullerian hormone levels in cow showing an effect in the ovarian antral-follicle populations in cows [176]. In swine the deleterious effects of ZEN on reproduction have been studied scientifically as early as in the 1970s [177]. It was later shown that concentrations of 25, 50, or 100 ppm of 95% purified ZEN fed to groups of healthy, multiparous sows during pre-estrus or throughout the gestation period (or both) produced multiple reproductive deficiencies [178]. These disorders included infertility, constant estrus, pseudopregnancy, diminished fertility, reduced litter size, offspring's small size, offspring malformations, juvenile hyperestrogenism, and probably fetal resorption. Sows' reproductive organs exhibited lesions, and their uterus, uterine duct, and cervix showed marked epithelial changes, i.e., squamous metaplasia. Similar features were found in the vagina and mammary glands. Transgenerational effects were also documented in sows [179], and ZEN was shown to reduce the quantity of healthy follicles, which probably lead to premature oocyte depletion in adulthood. In rat toxicity studies were undertook using ZEN (in corn oil) at doses of 0, 1, 2, 4, or 8 mg/kg/b.w. in order to determine the NOAEL for in utero development [180]. The fetal and pups' body weights were decreased in a dose–response manner in both sexes. Fetal development was delayed in all treated groups and linked to maternal toxicity. Zearalenone delayed skeletal ossification at 4 and 8 mg/kg. Fetal anogenital distance was increased in all treated groups, and fetal viability was decreased at 8 mg/kg. The weight of several maternal organs was modified at 4 and 8 mg/kg doses. Gonadotrophins were only marginally affected. Prolactin was significantly increased at 8 mg/kg. Estradiol dose dependently decreases at 2, 4, and 8 mg/kg. Therefore, ZEN was maternally toxic and fetotoxic but not teratogenic. Based on the dose-related maternal and fetal toxicity in all treated groups, the NOAEL for reproductive and teratogenic effects was less than 1 mg/kg.

5.2.2 Reproduction in Human

Isoflavones

Fertility: Unfortunately, as regards the human fertility, no clear-cut data are currently available about the effect of the modern exposure to estrogenic isoflavones. In 2014, an epidemiologic study performed on Adventist populations [181] sorted into six groups of isoflavone consumers showed that in young women (26 years old on average), the highest exposure of >50 mg/day was associated with a significant decrease in the number of birth. The same isoflavone intake was also correlated to an increased risk in women over 50 years of never being pregnant. Fertility also depends on the ability of men to produce efficient gametes. Noteworthy, sperm

production is a long process, starting from spermatogonial recruitment, continuing by spermatogenesis in the testis, and ending by the capacitating steps into *rete testis* and epididymis. In men the first step in the testis lasts for about 74 days [182]. Sperm presence in the *rete testis* and epididymis can vary from 2 days up to 18 days. It is only after sperm has undergone all steps that it can be ejaculated for fertilization and studied for its ability to fecundate. Therefore, the whole process from production to ejaculation can be considered as lasting about 3 months [182]. Consequently, whenever the effects of any endocrine-disrupting compound need to be studied on sperm production in men, exposure to those compounds should exceed 3 months to avoid any effect remaining undetected. As the capacitating process in the epididymis requires adequate thermal conditions, environmental conditions can exert bias on the final sperm quality. It is well-known that sperm production is influenced by both androgens and estrogens and that environmental endocrine disruptors (androgens, antiandrogens, estrogens, antiestrogens) can disturb sperm production in quality and in quantity [183]. As certain interventional studies on sperm production and quality like those of [184] or [185] were, unfortunately, performed over a short duration (less than 50–60 days), those studies cannot be retained when arguing about the effects of isoflavones on full spermatozoa production. Interindividual variation in sperm production and release, over the study period, is also a confounding factor that is not always taken into account and which can explain unexpected results [186]. In addition, the exposing dose should be in the dietary range. The data given in [1] indicate that, if a deleterious effect should be confirmed regarding sperm production and fertility, this should be addressed at a demographic level with data from industrial soy-eating countries and traditional soy-eating countries being treated separately. Noteworthy, the two countries that are most exposed to isoflavones because they have been eating industrial soy since the 1960s are South Korea and Japan. IndexMundi in 2017 indicates that the total fertility rate being the average number of children that would be born to a woman over her lifetime is 1.41 for Japan and 1.25 for Korea. These figures are lower than those recorded in all other developed countries with the exception of China territories. In France the total fertility rate is 2.07, and it is 1.87, 1.44, and 1.89 in the USA, Germany, and the UK, respectively. Noteworthy and still from the same sources, the contraceptive prevalence rate for women between 15 and 49 in Japan is only 33% when it is 80% in South Korea, 88% in France, 74.1% in the USA, 66% in Germany, and 84% in the UK. In addition, in both Asian countries consuming industrial soy, the demography regressed since 1983, i.e., one generation after soy-processing industrialization. This is also concomitant with the massive introduction of plant protection products in crop production all over the world. Moreover, in all studies that did show a correlation between decreased sperm quality and isoflavone intake, it was never possible to definitively exclude the interacting effects of other steroidal estrogens (in the case of obese men [78]) or of other endocrine disruptors like plant protection products [5, 79, 80]. In addition in [5], Mumford showed a positive interaction of sperm abnormalities with BMI. This indicates that the deleterious action of isoflavones on sperm production is probably influenced by other endocrine disruptors, present or not in the environment, and by endogenous estrogens.

Plausible consequences of early exposure: From a physiological point of view, a significant exposure to estrogens of babies under 6 months of age comes with its inevitable load of consequences [187]. During that period, differentiating processes involving estrogens and androgens are still at work, and steroid receptors are present in the different target tissues. These steroids, which were shown to potentiate isoflavone actions, are well-known to be disturbed in animals [4, 188] or in vitro [189] by isoflavones. The study from Strom et al. [190] showed that early isoflavone exposure via soy-based infant formula led to an endocrine impact with ulterior consequence on menstrual cycle impairment. It should be noted that cycle impairments were noticed in the rats of the NTP study [4] that examined the effects of GEN on the reproductive physiology of rats. However, the subjects enrolled in [190] were too young to allow a fertility impact of early isoflavone exposure to be shown. Noticeably, the sperm quality and production of men exposed to early soy were not assessed either. The number of stillborns in the group of women fed with soy (3 out of 74 births) was not significantly higher than the number of stillborns in the cow milk-fed group (0 out of 149 births), because only a small number of women had given birth at the time of the study. In fact Gilchrist and co-workers [191] discovered that 4-month-old boys fed with soy-based infant formula (S-BIF) from 3 weeks of age had a lower testis volume than that of their counterparts fed with breast milk ($p < 0.03$). Their testes volume was lower but not significantly than that of boys fed with cow's milk. This can be explained by a decrease of LH and testosterone neonatal production due to isoflavone intake. This is sustained by the study of Sharpe et al. on paired twin marmosets fed with either breast milk or soy-based infant formula prepared for human infants [192]. The soy-fed baby marmosets had lower testosterone plasma levels than their twin brother fed with cow's milk formula. In marmosets the exposure was lower than in boys exclusively fed with S-BIF, and no differences were seen in testes histology when the monkeys reached adulthood [193]. Adgent and co-workers reported a masculinization of the play and toy preferences in girls fed with S-BIF from 3 weeks to 6 months of age [194]. The observation was done at 42 months of age and tended to vanish at 57 months apparently due to social pressure. This observation can be linked to the masculinization effects of estrogens on the sexually dimorphic area of the hypothalamus during neonatal exposure (see [11] for further details). In addition and still according to the same team, a subtle acceleration of menarche could be provoked by an early exposure to estrogenic isoflavones via S-BIF [195]. These results although not fully convincing could also be linked to data published by Kim and co-workers [196] associating high serum concentrations of DAID ($P = 0.0202$), GEN ($P = 0.0021$), and total isoflavones ($P = 0.0009$) with central precocious puberty in young South Korean girls. As already mentioned, South Korea is in 2017 the country with the world's lowest total fertility rate [197]. More recently, it was shown that S-BIF can epigenetically modify the promoter of the PRR5L exon 1 gene [198]. The role of this gene is not yet fully understood, but it seems to regulate cell migration via an interaction with mTORC2 and PKC-delta. The study essentially points out that early exposure to isoflavones can have noticeable consequences later in life. The reason why reproductive deleterious effects linked to early isoflavones intake were

not yet observed at population level is essentially because the appropriate studies have not so far been performed [68]. A longitudinal study, which could be the best approach, is unlikely to show significant effects, if it does not involve a huge number of subjects, especially during childhood reproductive dormancy [199]. In [190] Strom et al. were focused on too early a stage, before both adult men and women really want to have children, and the study was unable, therefore, to help in determining whether early soy feeding could induce a fertility problem. One consequence is that, even if no alarming effects have been reported so far, it is not because they do not exist but rather because they may be expressed long after the initial causal exposure. Accordingly, the effect of this initial exposure may be masked by other psychological, social, economic, or even chemical disrupting factors, inducing large interindividual variability. If a reproductive effect really exists, it should be seen in those populations which are largely exposed to isoflavones through industrial modern soy food and not in those consuming traditional soy. Because it is now recognized that there can be interactions with other anthropogenic endocrine disruptors [2] like bisphenol A or glyphosate [200], the effects of isoflavone exposure can be potentiated by other environmental chemicals. Careful monitoring, which would allow these effects to be separated, should be undertaken in order to discover what is really happening. The expected effects could induce lower sperm production in men and an increased incidence of abnormal menstrual cycle, of early or late abortion, and of larger uterine fibroids in women exposed during their infancy [190, 201]. According to [198], a higher risk of uterine cancer may be observed. If the percentage of infants fed with soy-based infant formula in a given population was monitored for many years, then it could be possible to check whether that percentage is maintained or increased in male adults consulting for fertility problems.

Physiological effects of actual exposure: Nutritional doses of modern soy isoflavones (45 mg/day) have estrogenic effects in women, which can lead to a modest lengthening of the menstrual cycle [57, 77]. Noteworthy, when the diet is fully monitored to avoid the presence of hidden isoflavones, the menstrual cycle of American premenopausal women can be significantly lengthened by 2 days [57]. This lengthening is due to a retardation of the LH surge at mid-cycle. The same consequence is also observed in ewes eating clover rich in isoflavones [142]. This phenomenon was also observed in Japanese women. In that case, the mean menstrual cycle length is 30 days as opposed to 28 days in the West [77], with the mean modern isoflavone intake in Japan and Korea currently being evaluated at between 45 and 60 mg [58]. In this context, Nagata and co-workers [77] showed that supplementing the current Japanese diet with 50 mg of extra isoflavones from soy juice can lead to a menstrual cycle length of 32 days. Although this lengthening may possibly be protective against estrogen-dependent cancers, it can also reduce, however, the opportunity of ovulation in fertile women. This may well contribute to reducing the reproductive efficiency of a given population. In addition, as shown in domestic animals, it can be hypothesized that modern dietary intake of isoflavones can impair embryo implantation and induce early abortion. In women so far, only luteal phase deficiency was associated with isoflavone intake among healthy eumenorrheic women. It is a modest correlation with an adjusted odds ratio (aOR) of 1.38 (95%

CI: 0.99, 1.92), $P = 0.06$, because the subpopulation studied was small. Because luteal phase deficiency can lead to miscarriages and impaired fertility, it may be responsible for a progressive demographic regression at the population level. Moreover, according to [202], high soy intake for long durations can have even more significant effects. In this study, the authors reported that high soy intake was responsible for abnormal bleeding in women under norethisterone (contraceptive pills). This means that their large soy intake was able to transform a contraceptive treatment based on progesterone into an estro-progesterone form of contraception. A similar case involving a 32-year-old woman who drank a liter of soy juice, 3 times a week, after her basketball training, was also observed by our team. Her cycle impairment regressed when soy intake was stopped. In [202], the authors also alerted against uterine fibroids and repeated endometriosis features in the three cases they followed. They reported that all the problems regressed when soy intake was stopped.

Vaginal and endometrial health: Both the vaginal mucosa and endometrium develop under estradiol stimulation and therefore bear all the known estradiol receptors: ERα, ERβ, GPER, as well as ERRs [203–205]. The estrogenic effects of isoflavones were first shown on the uterotrophic test and even before on the uterus maturation of the New Zealand ewes on clover pasture. Therefore, negating an effect of estrogenic isoflavones on the endometrium makes no sense. However, in animals, isoflavones effects were reported either in reproductive females or in female freshly ovariectomized. In all cases, this means that estradiol receptors were available to mediate an estrogenic effect of isoflavones. In humans, most of the studies were performed in menopausal women. Most often their distance to menopause was largely variable, and the availability of ERs in the vagina and endometrium, although known to decrease after the arrest of ovarian function [205, 206], was not checked. Therefore, no study showed a significant effect on the endometrium especially in Western postmenopausal women [207], and very few studies were able to show an effect on the vagina in postmenopausal women. Among them is that of Lima and co-workers [208] which showed a significant estrogenic effect of a vaginal gel containing isoflavones on vaginal dryness, on dyspareunia, and on maturing index of vaginal cells. The last endpoint evolves similarly in the isoflavone group and in the conjugated equine estrogen group [208]. Interestingly, a study performed in Japanese students by Watanabe and co-workers [209] dealt with the supplementation on normal Japanese diet with either 20 or 40 mg isoflavones. Considering the mean urinary levels at baseline, the basal isoflavone exposure was most probably close to 25 mg/day. In their study, Watanabe found that extra isoflavone lengthen the menstrual cycle by 2 days and lengthen menstruations and bleedings in a dose-dependent manner. They observed that not all students react equally to the treatment. On the blood samples collected from three volunteers, they did not show any significant modification of steroid or gonadotrophin hormones. This suggests a direct effect of isoflavones on the endometrial mucosa. To conclude, isoflavone effects on the vagina and uterus of premenopausal women must not be rejected although they require additional work for evidence. In postmenopausal women, a vaginal effect of isoflavones may be achieved, while an endometrial effect has never been clearly shown despite a large number on trials.

Coumestrol

Although there is a great deal of studies reporting the effect of COUM on rodent genital tract, there is little data in women. Only in epidemiology studies COUM is sometimes investigated. Each time the level of intake is usually low (a few μg per day) and can be omitted in front of other phytoestrogens considering its poor availability and its large distribution in human fluid. As an example, in the study by Xia [80], showing a deleterious effect of phytoestrogens in Chinese men presenting idiopathic infertility, the 19th percentile exhibiting the largest impairment presented 619.36, 408.86, and 504.90 μg/g of excreted DAID, equol, and GEN, respectively, while they excreted 4.04 μg/g of COUM. The total excreted isoflavones was then 1533.12 μg/g. This is more than 350 times higher than the dose of COUM.

Lignans

Because not all humans can produce the estrogenic metabolites of dietary lignans, only studies based on either blood or urine measurements can be taken into account while considering the effects of enterolignans on reproduction. Hence, urinary levels reflect an elimination process that reduces the blood bioavailability. Therefore, whenever possible plasma or serum levels should be preferred. Considering these restrictions, the study by Tang and co-workers [210] indicated that when sorted in four quartiles (i.e., 16.54, 85.53, 325.91, 891.7 μg/g of urine) in pregnant women at delivery, birth outcomes were significantly modified. The higher the enterolignans' urinary levels, the lower the gestation length. There is also a tendency toward lower birth weight with END. The decrease in gestation length can be explained by a precocious induction of oxytocin receptor production increasing the action of oxytocin at the time of labor delivery. This has been shown for estrogens, not yet for enterolignans [211]. The smaller birth weight can be linked to a vasoconstriction of placental vessels due to estrogens which are not harvested by the alpha-fetoprotein because their affinity for this protein is lower than that for the estradiol receptor [212]. In addition, it was also shown in American men that urinary END and ENL were associated with subtle deterioration of spermatozoa quality parameters in a dose–response manner [5]. However, it should be kept in mind that lignans are biomarkers associated with grain, vegetable, and fruit consumption. All these items can be contaminated by plant protection products, and this effect may reflect at least a synergistic effect between several endocrine disruptors. Contrarily to isoflavones, enterolignans are associated with better reproductive incomes in humans [213]. Likewise, Mumford and co-workers showed an association of urinary ENL and shorter time to pregnancy. This may be due to the specific effect of enterolignans on the ERα [45].

Zearalenone

There is little convincing information about the effects of ZEN in humans because such an effect could only be recorded on long-lasting exposure if an effect has to be correlated with a serum or urine level. Nevertheless, ZEN was pointed out in the occurrence of precocious puberty, in Italy [214] and Puerto Rico [215], although levels were not actually assessed in any biological fluid. In Hungary [216], an

increased incidence of early thelarche was reported in patients with serum ZEN levels of 18.9–103 μg/mL. In 2010 it was published that in Viareggio (Tuscany), the incidence of precocious puberty was 22 to 29 times higher than in the neighboring areas [217]. Among 63 cases, 6 of them had high serum ZEN (933.7 ± 200.3 pg/mL) and α-ZOL (106.5 ± 1.9 pg/mL). But only 5 of 36 patients with early thelarche presented detectable levels of mycoestrogens. In 2003, ZEN was associated with "endemic enlargement disease" in China [218]. All grains analyzed were contaminated by mold, and 34% exhibited *Fusarium* species and COUM. More recently it was found that mycoestrogens were detectable in a large proportion of the urine of the 163 girls, aged 9 and 10 years, participating in the Jersey Girl Study and enrolled in the survey by Bandera et al. [219]. The subjects presenting the highest values were also being significantly of shorter stature and less likely to have reached the onset of breast development. This may sign an estrogenic effect on the pituitary gland with resulting anti-FSH effect. Such effects were reported in rodents [220] and more recently in pigs [221].

6 Questions

6.1 Estrogen-Dependent Cancers

6.1.1 Isoflavones

There has been a long-lasting controversy about the positive or negative effect of isoflavones on breast, endometrial, or prostate cancers all considered being more or less estrogen-dependent. Their incidence is also lower in Asia.

Endometrium

As far as endometrial cancers are concerned, in 2015, the EFSA opinion [222] indicated that no definitive opinion could be given on any deleterious effects of isoflavones on uterine cancer. However, the study only concerns healthy peri- and postmenopausal women, because it was based on the scientific literature in which volunteers are recruited following specific inclusion criteria, and such criteria do not, therefore, exactly reflect the global population. No case studies were performed to see an effect on endometrial cancer, and therefore neither the quality of the population nor its number was designed to demonstrate an effect. According to [222], there are very few studies triggering specifically perimenopausal women, and the number of studies was insufficient to conclude on this specific population. No conclusion could be rigorously drawn out on perimenopausal women because they cannot be assimilated to postmenopausal women. Noteworthy, their production of endogenous estrogens was still active, and estradiol receptors were still present at the target tissues. On the opposite, there is a progressive decrease in endometrium estradiol-receptor bioavailability in postmenopausal women [206]. Therefore, a lack of action of isoflavones in the uterus of these women is expected, because the estrogenic effects of isoflavones require an interaction with the estradiol receptors. On top of other things, this tissue bears both alpha and beta subtypes of ERs [206], and

isoflavones affinity is greater for the beta subtype [223, 224]. As the activation of the ER-beta was shown to negate the proliferative action of the ERα [225], via its AF-1 function [226], normal soy intake is not likely to affect the rate of endometrial cancer of healthy postmenopausal women.

Prostate

For prostate cancer, there is also a controversy. If the incidence of prostate cancer is lower in Asian population, the postmortem tumor detection indicates that the frequency of prostate cancer is equivalent between Asia and the West [227]. To add to the controversy, Nakamura and co-workers [228] recently developed a patient-derived prostate cancer xenograft model. They grafted clinical prostatectomy samples into nude athymic mice fed with 0 or 2 or 10 mg/kg genistein. For these doses, they showed dose-dependent increases in lymph nodes and secondary organ metastases (liver, lungs). They also showed the aggregation of invasive malignant cells in the secondary organs of the genistein-treated groups and not in the control. Their data suggest that the effect of genistein may depend on the kind of prostate tumor considered. A recent meta-analysis [229], performed on 21 case-control and 2 cohort studies, found that GEN and DAID may, in some cases, be associated with decreased risk of prostate cancer. However, when studies were sorted out according to the way isoflavone intakes were assessed, it appeared that the risk was not reduced when isoflavones were assayed in the serum or urine, although it was reduced when GEN and DAID exposure was assessed via food questionnaires. Because this last method is less accurate than the assay in biological fluid, the validity of these results remains questionable.

Breast

Although things are still unclear for endometrial or prostate cancers, there are now enough data to conclude that both positive and negative effects can occur considering isoflavone effects on estrogen-dependent breast cancer. Sufficient data now exist to consider that isoflavone through soy intake may be preventive against the occurrence of breast cancer [230–232] playing its role during the initial phase of cancer development [1]. However, there are also many data indicating that estrogenic isoflavones exert a proliferative effect on breast estrogen-dependent cancer cell lines. These data now exist in vitro [233], in vivo in animals [234], and in women [235].

The mechanism by which cancer prevention occurs is not yet clear and may be related to different mechanisms including early cell differentiation [236, 237], oncosuppressor expression [238], or pro-oncogene depletion [239]. Unfortunately, not all the protective mechanisms were so far recorded in vivo, using plausible dietary doses. Nevertheless, this preventive effect of isoflavones is in accordance with the demonstrations made by Lamartiniere on rats exposed to dimethylbenz(a)anthracene (DMBA) in which the preventive effect of GEN appears during the initial phase [240]. This protective effect is also sustained by the study of the National Toxicology Program [241] examining the carcinogenic effect of GEN in rats. Hence, they found that females from the first generation exposed to 5 and 100 ppm of GEN from

conception exhibited lower incidences of combined mammary adenoma and adenocarcinoma than the control or than the 500 ppm group. The differences were not statistically significant, but they may support the idea that a low exposure from conception would protect against mammary tumor incidence. Of course, reducing the occurrence of cancer cells via inhibiting their occurrence by any pathway during the initial step would result in a decreased incidence of cancer at the population level.

However, most established breast cancers rely on the activation of the alpha estradiol receptor subtype cross talking with the IGF receptor [242, 243]. This means that 17β-E_2 and other estrogens act as growth factors of the tumors [40, 244, 245]. At least three studies showed an estrogenic effect of soy isoflavones at modern dietary doses (45–60 mg/day) on the mammary gland of premenopausal women [74–76]. The three studies were undertaken for short durations and showed a positive impact of the isoflavone dietary intake on estrogenic biomarkers (pS2, nipple aspirate apolipoprotein D, progesterone receptor). In premenopausal women, an interaction of isoflavones with endogenous 17β-E_2 could not be excluded. Therefore, this effect cannot be extrapolated to postmenopausal women. This does not, however, negate the estrogenic effect of 45–60 mg of isoflavones per day in premenopausal women. Such active doses in premenopausal women are sustained by other physiological data concerning the menstrual cycle length duration, as explained before. Unfortunately, when they can exert their estrogenic effect, isoflavones increase cell proliferation speed **on already established** estrogen-dependent cancer cells [233]. This was also shown in vivo in implanted nude mice [234]. This is also sustained by the study of Shike et al. [235] in women with a declared breast cancer. Examining the proliferative effect of soy isoflavones in women diagnosed with breast cancer is both very difficult and ethically disputable, which would explain why only one study [235] has been published so far. The study is not fully conclusive because of a short treatment duration (between 7 and 30 days) and a low compliance with the treatment. Therefore, the biomarkers followed probably reflect a large interindividual response to a large interindividual variation in exposure. Therefore, in [235], the authors relied on isoflavone plasma levels to sort the treated subjects and then went on to perform genomic analysis on proliferation markers. The results they obtained in vivo with plasma forms (i.e., conjugated forms) of isoflavones are consistent with the in vitro data obtained by many other authors, who showed an estrogenic effect of isoflavones on breast cancer cells (i.e., proliferative effect) when used in the μM range (0.2 to 5) [246]. Shike's study indicates that both in vivo and in humans the circulating forms of isoflavones can, as already shown, have estrogenic effects [74–76]. Hence, at modern dietary doses, they can act as growth factors for estrogen-dependent tumors. Although the studies in nude mice implanted with human breast cancer cells cannot help in determining an active dose, the NTP study [241], which showed a significant increase in adenocarcinomas in the mammary and pituitary gland of rats exposed to 500 ppm GEN from conception to sampling, is particularly important. This classical toxicology study was designed to define the mean tolerable daily intake in humans. In that case, the LOAEL is 100 ppm (5 mg/kg/day for rats), and the NOAEL is 5 ppm in the diet (1.2 mg/kg/day for rats).

Finally, some breast cancer cells can be triple negative for ER, PR, and Her2/neu. They are considered to be resistant to hormone therapy based on antiestrogens or on anti-aromatase and therefore to have particularly negative prognosis [247]. It was shown in some occasions that, in the absence of ER, breast cancer cells such as MDA-MB-231 did not proliferate under isoflavone treatments [248]. This triple-negative cell line only bears trace amounts of GPER [249]. However, some triple-negative cancer cell lines such as HCC1806 were shown to have a large proportion of GPER in their membranes [249]. Because of that although they were first considered as estrogen independent, they can proliferate under estrogen stimulation [250]. GPER can mediate rapid 17β-E_2-induced non-genomic signaling pathways. In addition, by the effect of transactivation of epidermal growth factor (EGF) receptors, GPER induces mobilization of intracellular calcium (Ca^{2+}) stores and activation of mitogen-activated protein kinase and PI3K signaling pathways [247]. Furthermore, when present in triple-negative cancer cells, GPER seems to be with poor clinical outcome. It has been shown to upregulate cyclins and BCL-2 genes favoring cell proliferation and survival. Therefore, GPER possibly plays an important role in the carcinogenesis process. The GPER-induced proliferation can also be blocked in vivo by inactivating GPER [251] with siRNA, using GPER antagonist like G-15 [252] or even better estriol [251], opening a new way for breast cancer therapy. In Egypt, where breast cancers represent 17.5% of all malignant tumors, it was observed that these mammary cancers were more aggressive than that encountered in the West [247]. In this country, it was shown by immunostaining that 65% of archival formalin-fixed paraffin-embedded cases of invasive ductal carcinoma were GPER positive. GPER as a membrane receptor of the rhodopsin-like family is activated by low doses of many xenoestrogens including bisphenol A (BPA) [253]. As mentioned earlier, GEN and DAID are ligands of GPER with affinity 2 to 3 times higher than that of BPA. The IC_{50} for GEN is 133 nM, which is only ten times higher than that of estradiol [253], and GPER pathway activation is achieved using 0.2 μM. This dose can be obtained in human blood with dietary soy intake. Equally, DAID is able to induce GPER pathways at doses as low as 0.1 μM [254]. Therefore, the effects of phytoestrogens on breast cancer should take into account the GPER pathway as another target for proliferation induction. Lastly, data on the effect of isoflavones on breast cancer cell lines through the estrogen-related receptors (ERR) α, β, or γ are presently too scattered to conclude on a clinical effect. When tested, the doses of isoflavones required for the ERR pathway activation do not fit with a dietary isoflavone intake [255].

6.1.2 Coumestrol

Because this substance is only anecdotally present in human food at least in Western developed countries, its effects on estrogen-dependent cancers are only scarcely examined. There is no interventional study that is strictly controlled, and there are a few observational studies mentioning COUM as a parameter which have been taken into account because it was above the assay detection limit in biological samples. In 2006, Hedelin and co-workers showed that COUM together with a precise Snp present in the promoter of the ERβ subtype was correlated with a strong

significance to a decreased risk of prostate cancer [256]. However, this correlation should be taken with caution since the COUM urine levels measured are close to the detection limit.

6.1.3 Lignans

Two major problems linked to the exposure evaluation of the estrogenic enterolignans can explain the paucity of clear data gathered on enterolignans and estrogen-dependent diseases. As already mentioned, not all sources of lignans are yet characterized in food [257], and secondly not all human being can efficiently transform lignan precursors into estrogenic enterolignans [258].

Prostate

It is in the late 1980s that lignans were correlated to reduced risk of prostate cancer [259]. Despite this early hope, in 2010, Saarinen and co-workers made a point on population and intervention studies dealing with enterolignans and prostate cancer and found no clear correlations at the population level [260]. In population studies even when ENL was followed in plasma and/or urine, a clear association with prostate cancer incidence, progression, or risk could be pointed out. However, three studies dealing with the administration of flaxseed in men with a diagnosed prostate cancer did show a decreased serum total PSA and proliferation rate of benign epithelium and a significant decrease in total testosterone and free androgen indices. Among men with Gleason score below 6, they reported decreased tumor proliferation index and increased tumor apoptotic scores when comparing the flaxseed group to historic controls. Finally, they also mentioned a significantly reduced tumor proliferation rates with flaxseed supplemented diets. Their conclusion was to say that enterolignans may have a protective effect on prostate cancer but that the normal dietary intake is currently insufficient to induce such protective effect. More recently the study by Azrad and co-workers [261] came to confirm that prostate cancer preoperating treatment with flaxseed supplement was associated with the decrease of several tumor biomarkers. Namely, there was a significant decrease in NFκB, Ki67, and VEGF. The authors conclude that flaxseed supplementation inhibits cancer cell growth and possibly reduces tumor angiogenesis in patients with prostate cancer.

Breast

Enterolignans have a greater affinity for the ERα receptor; however, ENL which is currently the most concentrated in human plasma was shown to better recruit the AF-2 transactivation factors and therefore to reduce the proliferative effects of compounds activating gene transcription through the AF-1 domain [45]. This in vitro mechanism was further confirmed in vivo on nude mice transplanted with MFC-7 cells [262]. In this study, ENL and END were tested alone and together with GEN. They were able to prevent the proliferation induced by GEN. Foods containing the precursors of enterolignans were also tested in the nude mice model [263]. The study showed that secoisolariciresinol diglucoside (SDG), the most

classical precursor of enterolignans in the scientific literature, was less efficient than sesamin in protecting against breast tumor proliferation. Sesamin was converted in vivo by the nude mice in unknown compound proportion that was able to increase significantly apoptosis of the cells. If the mice metabolism is involved in this effect, which is most plausible, then the result cannot be translated directly to human. Nevertheless, in some cases, studies showed that a higher intake of lignans was associated with lower risk of developing cancer. In several occasions, the receptor status of cancers was mentioned [264, 265]. The discrepancy between the studies can be explained by at least two factors: (1) not all women can produce enterolignans from their lignan precursors, and if no plasma or urine measurements are available, this induces confusion; (2) not all the sources of lignans are yet characterized, and this reduces the power of the analyses. To illustrate the first point, the study by Buck and co-workers [265] showed a better reduction in the breast cancer risk when data were collected based on an ENL measurement rather than on a lignan dietary intake. When the lignan intake was taken globally, the ER-negative tumors seemed to be more susceptible to a protective effect. Therefore, and because lignan intake was not systematically associated with estrogenic enterolignan production, the action may not be an estrogenic or antiestrogenic effect. Regarding an effect of enterolignans through the GPER pathway, there are too few such data to hypothesize any effect. However, several epidemiological studies gathered in the meta-analysis [266] showed overall that a decreased risk of death by breast cancer could be associated with serum ENL. This study performed on 2,182 patients divided the population into 4 quartiles based on their serum ENL levels. In each case, the highest quartile corresponding to serum levels over 70 nM was associated with lower risks. The endpoints which were monitored were all-cause mortality, breast cancer-specific mortality, distant disease-free survival, and risk of recurrence [266]. In this study and thanks to a large number of subjects, it was possible to see that enterolignans could have a positive effect per se, distinctive of a healthy lifestyle pattern. Finally, as for isoflavone, a preventive effect at the initial phase of breast cancer progression is plausible since it was shown that ENL at a dose of 10 mg/kg/day was able to decrease the occurrence and size of chemo-induced mammary tumors using DMBA in ovariectomized rat [267]. Because DMBA is able to transform a healthy cell in cancer cells, this effect of ENL triggers the initial phase of mammary cancer progression.

6.2 Other Side Effects

6.2.1 Thyroid

Links were made between soy consumption and alterations of fragile thyroid function. In the 1960s when the first soy-based infant formulas were commercialized, hypothyroidism goiters were observed [268] in infants and led to iodine supplementation in these formulas [269]. However, nowadays hypothyroid infants can still develop a goiter under soy-based infant formula, and their thyroid function is still difficult to manage under these soy-based formulas [270–272]. Generally speaking,

until now, whenever isoflavone effects were reported on hypothyroidism, it was always in persons with preexisting thyroid impairments [271, 273–275]. In parallel to these data is the case of a woman who was treated with Levothyrox for hypothyroidism. It showed that the intake of soy-based food supplements interacts with the drug absorption [274]. As a result, the doses required to balance her thyroid function had to be increased when soy-based food supplement was taken simultaneously with Levothyrox treatment. Consequently, in Europe, these medications are generally advised avoiding soy consumption. The mechanism of action is not fully characterized, but GEN was found to bind to thyroid hormone receptors [276] and to compete with triiodothyronine (T_3) on its receptor at concentrations of 1 μM which are dietary relevant. In addition, in the presence of iodide ions, genistein and daidzein blocked TPO-catalyzed tyrosine iodination by acting as alternate substrates in vivo [277]. This mechanism would explain the greater need of iodine for correct thyroid function in the presence of soy. Many other studies, however, showed no adverse effects from soy or isoflavones on thyroid function of healthy subjects [278–282]. In addition, in Japan, isoflavones are consumed at the highest rate on earth; until recently [283] no adverse effects were consistently reported. The exception [283] is the case of a 72-year-old woman with preexisting lymphocytic thyroiditis who was admitted to the hospital with acute hypothyroidism. It was due to the consumption of a health drink containing soy. Symptoms progressively disappeared after soy-based health drink arrest. However, the traditional Japanese diet is based on a large variety of seafoods which are rich in iodine. They may usually compensate for the effect of soy and/or isoflavones on an alteration of the thyroid function. Finally, for many years, it was unclear if any soy component or specifically isoflavones were responsible for the hypothyroid effect of soy. The study by Sathyapalan and co-workers [284] finally answered the question. When isoflavones were removed or added to soy, and fed to volunteers with preexisting mild hypothyroidism, the isoflavone supplementation clearly aggravated the hypothyroid symptoms. Taking all these data together, it seems that the adverse effects of soy isoflavones may occur only in persons with previous hypothyroidism. In that case, a balance in the thyroid function is more difficult to achieve medically.

6.2.2 Autoimmune Diseases

Autoimmune diseases occur when the immune system attacks and destroys the organs and tissues of its own host. Several autoimmune diseases occur with a higher frequency in women than in men [285]. Although links with several factors expressed by the X chromosomes have been related to the occurrence of autoimmune diseases [286], the role played by female sex steroids is currently under investigation. Hence, the incidence of autoimmune diseases is generally higher in premenopausal women than in children (girls) and decreases after menopause [287]. At the cell level, 17β-E_2 was shown to induce the expression of many different factors playing a role in the activation of autoantibodies. As an example, 17β-E_2 at physiological doses increases lymphocyte B and plasma dendritic cell differentiations in vitro [288, 289]. This process is inhibited by the pure antiestrogens ICI

182 780 or by tamoxifen. Plasma dendritic cell activation and IFNα production are enhance in vitro and in vivo by 17β-E_2 and reduced when the ERα receptor is reduced or blocked [289]. Autoimmune processes seem to be reduced during pregnancy, while progesterone is present in the body at high concentrations [290]. Testosterone also seems to exert a preventive effect [291]. For systemic lupus erythematosus (SLE), the sex ratio distortion is one of the highest with currently nine women and one man being hit by the disease in France [292]. In Japan, the ratio seems to be more in favor to men with eight women and two men being sick [287]. In addition, the disease evolves by flares which occurrence is still difficult to prevent because of unknown causes. Among other causes, environmental factors have been suggested to be involved [293, 294]. Dietary phytoestrogens, because of their estrogenic potencies and their mostly unknown sources of exposure in modern diet, are good candidates for further studies. In a transgenic mouse model of SLE, the MRL/Mp-lpr/lpr mouse GEN and DAID at nutritional doses were shown to aggravate the SLE-induced nephropathy and to induce earlier mortality when compared to a diet devoid of soy [295]. Noteworthy, at pharmacological doses, isoflavones seem to have the opposite effect [296]. Fort and co-workers [297] examined the incidence of autoimmune diseases in children fed with soy-based infant formula compared to their counterpart fed with other formulas in their infancy. They found out that the frequency of feedings with soy-based milk formulas in early life was significantly higher in children with autoimmune thyroid diseases (prevalence 31%) as compared with their siblings (prevalence 12% $p < 0.01$) and healthy nonrelated control children (prevalence 13%, $p < 0.02$). More recently working in rodent, Tran and co-workers [298] showed that GEN, DAID, or glycitein and a soy extract suppressed iodine uptake and stimulated the production of autoimmunogen in rat thyrocytes in vitro. However, cells were from rat, and the efficient doses were higher than 1 μM. Therefore, the transposition to the clinical situation should be taken with caution. Finally, Portman and co-workers [299] recently showed an association between soy and the incidence of Kawasaki disease (KD) in children. A significant increased KD risk was observed in children for total isoflavone intake (OR, 2.33; CI 95%, 1.37–3.96) and for genistein intake (OR, 2.46; CI 95%, 1.46–4.16), when comparing high-soy consumers vs. non-consumers. KD risk was also significantly increased in Asian-American children with the highest isoflavone consumption. Hence, total isoflavones were highly significantly correlated to an increased risk (OR, 7.29; CI 95%, 1.73–30.75), and this was also the case for genistein (OR, 8.33; CI 95%, 1.92–36.24) when compared to white children. The authors concluded that childhood dietary isoflavone consumption, but not maternal isoflavone intake during pregnancy and nursing, strongly relates to KD risk in an ethnically diverse US population. To conclude, the association of autoimmune disease with estrogens is clear, and progesterone and testosterone are most probably protective. Phytoestrogens being estrogenic, antiandrogenic [300], and able to reduce progesterone levels at dietary doses [301] can be good environmental candidate to solve the reason of unexplained autoimmune disease flares. However, additional studies are needed to ascertain this effect and therefore to go toward disease prevention.

7 Conclusion

Natural potent estrogens are ubiquitous in our environment. Resorcylic acid lactones and COUM, because of their strong known effects on rodent reproductive physiology, have been adequately monitored so far. Hence, the human exposure, except in specific circumstances, is not a cause of concern. Lignans, although leading to the eventual production of estrogenic compounds by the gut bacteria, are far less studied, and the exposure to the weak estrogen enterolignans is far from being correctly assessed. A large interindividual response is expected from the exposure to dietary lignans. However, as far as we can approach them with our current tools, these compounds act as SERMs, and their effects appear to be more beneficial than adverse. Their effects on reproduction appear to be positive, and they were shown to reduce the proliferation on estrogen-dependent breast cancer cell lines. Their exposure being associated with grain, fruit, and vegetable intakes does not seem to suppress the benefit of a diet rich in these foodstuffs. Inducing more concerns is the case of isoflavones. Their estrogenic effects in vitro range between ENL on one hand and COUM and ZEN on the other hand. Their bioavailability is the highest of all compounds listed here. Many effects, them being beneficial or having adverse effects, have been reported so far for these compounds. However, based on the assumption that they had always been part and parcel of the human diet, they were, until now, essentially considered as inactive. This discrepancy vanishes if it is admitted that the isoflavone exposure is modern and essentially due to changes in the cooking process of soy. Then the compounds can be considered for what they are, i.e., estrogenic compounds, possibly exerting endocrine-disrupting effects in synergy with other anthropoid compounds recently liberated in the environment. The actual data tend to indicate that their most pronounced deleterious effect is observed on reproduction. Their deleterious effects on already established estrogen-dependent cancers seem to occur at higher doses based on toxicology studies. These effects are counterbalanced by a preventive effect probably due to a favorable interaction at the initial step of breast cancer progression. More mechanistic data are required to ascertain this mechanism. Therefore, although more research is still required to take the best part of these compounds, the question of their endocrine-disrupting effect should be taken into consideration. Because the history shows that isoflavone can be reduced easily in food, this should be done for both human and domestic animals to reduce the exposure to endocrine disruptors and improve farmers' incomes.

Contents

Abstract

The jaboticaba is a fruit native to Brazil that grows in the wild throughout the country but is also cultivated on a low-scale basis by small farmers. Research is currently being reported that jaboticaba is a rich source of bioactive compounds, particularly the phenolic compounds. For example, high levels of the anthocyanins, cyanidin-3-*O*-glucoside and delphinidin-3-*O*-glucoside, and ellagitannins/ellagic acid are the predominant phenols present in jaboticaba and reside primar-

ily in the peel and seeds of the fruit. These substances have been linked to multiple health benefits, including the prevention and/or mitigation of oxidation, inflammation, atherosclerosis risk factors, cancer, and conditions involved with metabolic syndrome. The fruit, or substances therein, has also been shown to enhance the immune system and gut microbiome. Therefore, the objective of this manuscript is to review the health-promoting properties exerted by jaboticaba or the compounds that reside in the fruit demonstrated throughout the literature, with an emphasis on the phenols.

Keywords

Jaboticaba · Bioactive agents · Phenols · Flavonoids · Anthocyanins · Ellagic acid · Gallic acid · Health benefits · Dietary bioactivity · Ellagitannins

List of Abbreviations

ATP	Adenine triphosphate (ATP)
CD40	Cluster of differentiation 40 protein
CD83	Cluster of differentiation 83 protein
CD86	Cluster of differentiation 86 protein
DNA	Deoxyribonucleic acid
GI	Gastrointestinal
H_2O_2	Hydrogen peroxide
hBD-	Human beta defensin 2
HDL	High-density lipoprotein
HDL-C	High-density lipoprotein cholesterol
HIV	Human immunodeficiency virus
iNOS	Inducible nitric oxide synthase
LDL	Low-density lipoprotein
LDL-C	Low-density lipoprotein cholesterol
LOX-1	Lectin-like oxidized low-density lipoprotein receptor
MetS	Metabolic syndrome
MMP	Matrix metalloproteinase
NO	Nitric oxide
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SLP1	Secretory leukocyte protease inhibitor
TC	Total cholesterol
w/w	Weight/weight

1 Introduction

The jaboticaba (*Plinia* sp.) is an edible tropical fruit native to Brazil that grows wildly throughout the country with the Minas Gerais and São Paulo states reporting the highest yields. This tiny black berry belongs to the family, Myrtaceae, which is

the same family as the guava tree. The fruit has a thin, smooth skin and a moisty white, translucent squash-like center that is sweet and slightly acidic [1]. Chemical characterization of the jaboticaba, particularly the peel, has revealed the presence of multiple health-promoting compounds, including phenolic compounds (e.g., flavonoids and phenolic acids) and insoluble and soluble fiber (e.g., pectin) [2]. More specifically, ellagic acid and its derivatives are important phenolic molecules present in jaboticaba due to their powerful antioxidative properties [3]. Other flavonoid compounds predominant in the jaboticaba peel are the anthocyanins, cyanidin-3-*O*-glucoside and delphinidin-3-*O*-glucoside. Anthocyanins are a class of flavonoid pigments that are also powerful antioxidants but have other multiple cellular stresses and disease-preventing properties [4–6]. Finally, pectin is a heteropolysaccharide composed of galacturonic acid, arabinose, galactose, and rhamnose, which contributes to its high capacity for forming gel, thereby aiding in the digestive health. A decrease in macronutrient absorption, specially fats and sugars, potentially leading to glycaemia, or improving the plasma lipid profile, is yet another benefit of pectin intake [7]. As a climacteric fruit, the maturation process continues postharvest, resulting in the activation of many metabolic pathways that degrade or modify many of the previously cited beneficial compounds with the anthocyanins being the most affected [2, 8].

2 Distribution and Botanical Characterization

The jaboticaba is cultivated by small farmers on a low-scale basis but is ubiquitously distributed throughout Brazil, especially in the Atlantic Forest biome [2, 9]. The jaboticaba tree has novel characteristics that include white blossoms located on both the trunk and branches that develop into the berry [10] (Fig. 1). In addition, the fruit matures rapidly (between 40 and 60 days); this aspect is related to the scientific name of the first jaboticaba species discovered in Brazil (*Plinia cauliflora*). The jaboticaba has a spherical shape that is 2.0–3.5 cm in diameter and contains one to four seeds. The pulp is mainly white and sweet, while the peel is dark purple when mature [10, 11] (Fig. 1). The color of the jaboticaba peel is due to the presence of high levels of anthocyanin pigments, primarily cyanidin 3-*O*-glucoside and delphinidin-3-*O*-glucoside. Two other jaboticaba species are also indigenous to the Brazilian territory, i.e., *Plinia cauliflora* ("Jabuticaba assú," in popular language) and *Plinia jaboticaba* ("Jabuticaba sabará," in popular language). Differences between species are evident in the tree characteristics. The *Plinia cauliflora* is a small tree (3–6 m in height) with long leaves (2–6 cm in length), while the *Plinia jaboticaba* is a taller tree (6–9 m in height) with smaller leaves (2–4 cm in length) [11]. The *Plinia jaboticaba* is the most widely cultivated and recognized species that grows mainly in the states of Minas Gerais and São Paulo [2]. Jaboticaba postharvest shelf life is relatively short due to its high moisture levels along with a fragile skin requiring mild industrial processes. Jaboticaba perishability also affects the functional features of the berry.

3 Nutritional Composition of Jaboticaba

As stated previously, several studies have reported that the jaboticaba is a rich source of chemically diverse nutrients. For example, carbohydrates are the most abundant macronutrient followed by proteins and lipids [9, 12–17] (Table 1). High concentrations of fructose are located in the pulp [13], while higher fiber levels (soluble and insoluble) are present in the peel [14]. A wide variety of minerals are also present in jaboticaba with the predominant being potassium, magnesium, and phosphorus [13, 15] (Table 1). Moreover, whole fresh jaboticaba contain high levels of vitamin C [16] (Table 1). It must be emphasized that non-nutrients (as bioactive compounds) of the jaboticaba are currently receiving intensive interest, especially those that reside in the peel. These compounds are the secondary metabolites produced by the plant that provide protection against external hazards, such as disease, seed/insert pressure, and various types of bacterial/yeast infections. Similarly, these compounds have shown multiple human health benefits [12, 18–21]. Table 2 provides a summary of seminal research conducted on the health-promoting properties, while these and other studies are described in more details throughout the document on the fruit

Table 2 Bioactive compounds identified in jaboticaba

Species	Fruit part	Main bioactive compounds and concentration	Health effects	Ref.
Plinia jaboticaba	Peel	Cyanidin-3-*O*-glucoside (1541 ± 45.51 mg/100 g) and Delphinidin-3-*O*-glucoside (634.75 ± 1.83 mg/100 g)	In vitro: High antioxidant capacity, antiproliferative activity against tumor cells	[18]
Plinia jaboticaba	Peel	Gallic acid 4.03 mg/100 g	*Sprague-Dawley rats* fed with high-fat diet: ↓ lipid peroxidation in the brain	[19]
		Ellagic acid 348.08 mg/100 g	↑ antioxidant defenses in the liver	
		Quercetin 4.82 mg/100 g		
Plinia jaboticaba	Peel	Gallic acid 177.76 ± 2.26 μg/g	*Wistar rats* fed with high-fat diet ↑ antioxidant defenses in liver and plasma	[12]
		Ellagic acid 1581.61 ± 135.50 μg/g		
		Cyanidin-3-*O*-glucoside 34,242 ± 594.70 μg/g		
Plinia jaboticaba	Peel	Cyanidin-3-*O*-glucoside 1113.38 ± 19.37 mg/100 g	*Swiss* mice fed with high-fat diet: Improvement of cognitive function and prevention of insulin resistance and fat weight gain	[20]
		Ellagic acid 710.10 ± 33.77 mg/100 g		
Plinia jaboticaba	Peel	Cyanidin-3-*O*-glucoside 2866 ± 40.1 mg/100 g	In vitro: ↑ total antioxidant capacity (especially ellagitannins)	[21]
		Delphinidin-3-*O*-glucoside 356.3 ± 1.0 mg/100 g	In vivo: ↑ serum antioxidant capacity in humans	
		Ellagic acid 142.8 ± 11.7 mg/100 g		

and/or its components. Moreover, Fig. 2 shows the structure of the main phenolic components present in the jaboticaba. However, readers are referred to [10] for a comprehensive illustration of the multiple structures of the phenol compounds with only the primary phenols present in jaboticaba presented in Table 3.

4 Health Benefits of Jaboticaba or Its Components

4.1 Antioxidative Properties

The term "oxidative stress" is defined as imbalance in metabolism that leads to the accumulation of reactive oxygen species and/or reactive nitrogen species (ROS/RNS) in the cells [21]. Excessive levels of free radicals are able to overwhelm the endogenous antioxidant capacity, resulting in oxidation damage to structural, transport, and regulatory molecules, such as proteins, DNA, and lipids [21]. If left unchecked, oxidative stress can lead to the onset of chronic degenerative diseases

that include coronary heart disease and cancer, as reviewed in [18]. Dietary antioxidants have been shown to protect or mitigate oxidative stress by scavenging the free molecules and/or binding reactive metal ions [22, 23]. However, the phenolic antioxidants are more likely to aid in the activation or upregulation of antioxidative enzymes, such as superoxide dismutase or catalase, or inhibit or downregulate oxidative enzymes, such as xanthine oxidase or inducible nitric oxide synthase (iNOS) [24–27].

Several studies have demonstrated the potent antioxidant properties of the jaboticaba. For example, the antioxidant capacity of extracts obtained from seven Brazilian fruits was evaluated using the 1,1-diphenyl-2-picrylhydrazyl radical test and the β-carotene-linoleic acid-coupled oxidation assay [28]. While all the fruits exhibited high antioxidative capacity, jaboticaba produced the highest activity for both tests. From a potential human health perspective, Leite et al. [29] analyzed the antioxidant status of rats fed with a high-fat-inducing obesity diet but supplemented with freeze-dried jaboticaba peel (at 1, 2, and 4% (w/w)). Compared to the animals fed with the high-fat diet only, the supplemented diets resulted in lower serum saturated fatty acids, higher plasma antioxidant defenses, decreased

Table 3 Other phenols reported in jaboticaba

Phenol[a]	Classification
Hexahydroxydiphenoyl group	Ellagitannin
Hexahydroxydiphenoyl-galloyl-glucose	Ellagitannin
Casuariin	Ellagitannin
Casuarinin	Ellagitannin
Tellimagrandin I	Ellagitannin
Tellimagrandin II	Ellagitannin
Pedunculagin	Ellagitannin
Casuaricitin	Ellagitannin
Iso-oenothein	Ellagitannin
Oenothein C	Ellagitannin
Pedunculagin	Ellagitannin
Casuaricitin	Ellagitannin
2-*O*-(3,4-Dihydroxybenzoyl)-2,4,6-trihydroxyphenyl acetic acid jaboticaba	Depside
Syringin	Phenolic acid aglycone
Syringin-*O*-glucoside	Phenolic acid glucoside
O-Coumaric acid	Phenolic acid aglycone
Protocatechuic acid	Phenolic acid aglycone
Methyl protocatechuic acid	Methylated phenolic acid
Peonidin	Anthocyanin methoxy derivative
Peonidin-3-*O*-glycoside	Anthocyanin glucoside
Isoquercitrin	Flavonoid glucoside
Quercimeritrin	Flavonoid conjugate
Myricetin	Flavonoid aglycone
Quercetin	Flavonoid aglycone
Rutin	Flavonoid glucoside

[a]Information obtained from [11] but tabulated instead of illustrated

lipid peroxidation of the liver and brain, and higher antioxidative status of the kidneys, depending on peel dosage. Moreover, Calloni et al. [30] reported that extracts from the jaboticaba peel were able to reduce H_2O_2-induced mitochondrial oxidative stress in human lung fibroblast cells by mitigating the decrease in the activity of the mitochondrial complex 1 protein and ATP levels. The researchers proposed that this berry may provide protection to the mitochondria when exposed to dysfunctional conditions. Martins de Sá [31] showed that fermented jaboticaba beverages (red, rose, and white) exerted a significant vasorelaxant effect on isolated arteries, which was inversely associated with the antioxidative capacity of a given beverage. The red drink produced the highest antioxidative activity and the lowest vasorelaxant response followed by the rose and then the white fermented beverages. While other studies have also shown jaboticaba as a rich source of antioxidative agents, the above-discussed reports provide a representation of the related

experiments currently being conducted [18, 32–34] with the majority attributing the phenols as the responsible components in protecting against oxidation, especially the anthocyanins.

The basic structure of flavonoids consists of two phenolic rings (Fig. 1) with a center heterocyclic ring bonded to either hydrogen, water, hydroxyl groups, carbohydrates, or organic acids at carbon sites on the rings. The various type of hydroxyl binding to the rings and position of the rings is specific to a particular flavonoid class [35]. Individual anthocyanins are distinguished from other flavonoids by the number and position of hydroxyl and methoxy groups on its basic structure and also by the type and the number of bound sugars or acids (Fig. 1) [5]. Importantly, anthocyanins are the only flavonoid able to exist as a cation or anion [8], resulting in color changes from deep purple to red depending on the pH. Among the multiple in vitro and in vivo studies that have been conducted to understand the antioxidative benefits of anthocyanins [36, 37], the following studies are discussed to provide support, in part, to the hypothesis that anthocyanins are the dominant antioxidative protective agents in jaboticaba. Using rats subjected to hepatic ischemia-reperfusion to produce oxidative stress after consumption of an anthocyanin supplemented diet, Tsuda et al. [38] determined that the consumption cyanidin-3-glucoside and its aglycone form produced an antioxidant response similar to that of α-tocopherol, specifically in preserving the liposomes, liver, and erythrocyte membranes. Ramirez-Tortosa et al. [39] also utilized a rat model, but the animals presented with a vitamin E deficiency making the animal susceptible to oxidative stress. Yet, when treated with an anthocyanin extract supplementation, the plasma antioxidative capacity increased relative to the control. As a result, the damage caused by the vitamin E deficiency, lipid peroxidation, and DNA damage was reduced. Based on the French Paradox, this study was conducted on the anthocyanins present in red wine. Importantly, the researchers determined that dietary anthocyanins were able to protect against the risks associated with oxidative stress.

Ellagic acid may or may only slightly contribute to the antioxidant protective properties of jabocatica. While this molecule is able to scavenge free radicals [40] and other characteristics in terms of protection against lipid peroxidation and DNA damage and increasing the activities of the antioxidative enzymes that include super oxide dismutase, catalase, and glutathione peroxidase in the presence of an oxidant using cell culture models [41, 42], its antioxidant protection in human health is sporadic, especially compared to other phenols. Meyer et al. [43] showed that five different phenols were able to inhibit copper-catalyzed low-density lipoprotein (LDL). The flavan-3-ol, catechin, exhibited the highest antioxidant protection followed by the anthocyanin, cyanidin, which was similar to caffeic acid, followed by quercetin and finally ellagic acid. The differences were attributed to the structural dissimilarities of the compounds. Interestingly, when the phenols were combined, an additive response was obtained with the notable exception of ellagic acid, which exerted a substantial antagonistic response. Yet, ellagic acid was able to ameliorate the effect against negative effects of cisplatin, a cytotoxic agent drug used in chemotherapy, using a rat model administered with this drug through gavage delivery. Turk et al. [44] showed that rats supplemented with ellagic acid were

presented with decreased plasma, sperm, and testicular T-bar levels (a secondary oxidation indicator). The ellagic acid supplement also activated the activity of catalase and glutathione peroxidase.

4.2 Immune System Health and Anti-inflammatory Properties

The immune system is a complex network composed of a variety of molecules, cells, tissues, and organs that act to defend their host against multiple invading infectious agents or mechanistic dysregulations [45]. When the immune system is exposed to these external/internal stresses, the inflammation response is initiated, which is the body's way of dealing with localized tissue damage and infection, and thus is critical to our survival. As such, maintaining a robust immune system is essential to human health. According to recent studies, the diet plays an important role in either adversely or positively regulating the immune system. For example, researchers determined that chronic, or silent, inflammation stimulates a self-perpetuating immunological responses that are linked to nutrient overload intake, which, in turn, can lead to multiple health risks [46–48]. On the other hand, certain foods or their components can prevent the onset of harmful cellular stressors or diseases that enhance and strengthen the immune system by acting upon or preventing chronic inflammation.

Chan et al. [49] completed a study using monocyte-induced dendritic cells treated with gallic acid (a phenolic acid ubiquitous to many foods, including jaboticaba) followed by a cocktail of pro-inflammatory cytokines. The results showed that various markers involved in the maturation of dendritic cells were suppressed by gallic acid, such as the stimulatory proteins, CD40/CD83 and CD80/CD86 responsible for activating antigen-presenting cells and T cells via co-stimulation, respectively [49].

Moreover, consuming ellagic acid-rich fruits and vegetables may aid in maintaining oral homeostasis as this phenolic acid can also enhance the integrity of epithelial oral cells, as reviewed in more detail by Dale [50]. Ellagic acid consists of two resonant phenolic rings, each bound to para-hydroxyl groups and two heterocyclic [51] (Fig. 2). This compound has been shown to be particularly potent in protecting the immune system from a variety of onslaughts. A study completed by Fakhry et al. [52] used oral epithelial cells to determine that ellagic acid increased the expression of beta-defensin 2 and antileukoproteinase. Beta-defensin 2 consists of an antimicrobial factor produced by neutrophils that attaches gram-negative microorganisms [53]. Alternatively, antileukoproteinase protects epithelial cells from serine proteases, which if left unchecked, degrade peptide bonds of proteins, thereby contributing to damages to mucosal cells. Such a response to ellagic acid contributes to a healthy immune response as strong mucosal cells promote physical and chemical barriers against pathogens. The physical barrier consists of cell-to-cell attachments, while the chemical barrier is constructed by antimicrobial peptides,

cytokines, and chemokines [53]. Another important factor related to the health of mucosal cells as mediated by ellagic acid includes the prevention of HIV transmission. The human β-defensin peptide, Hbd2, and the secretory leukocyte protease inhibitor, SLPI, have been recognized as mediators that not only enable the mucosal to defend against microbial infections but also inhibit adenoviral infections, such as HIV, as demonstrated by QuiÃones-Mateu et al. [54]. Yet another study completed by Promsong et al. [55] used ellagic acid-treated primary human gingival epithelial cells and showed that this bioactive agent (in concentrations of only μmoles) was able to increase the expression of Hbd2 and SLPI by 3.7- and 2.5-fold relative to the control (untreated cells). In addition, Modi et al. [56] showed that the ellagic acid inhibits HIV-1 integrase enzyme, which is responsible for integrating the virus DNA to the genetic content of the host DNA. As approximately 90% of HIV transmission occurs via mucosal cells, ellagic acid-rich foods, such as jaboticaba, may be yet another important preventative measure for contracting HIV by acting on the cited potential targets.

Additionally, anthocyanins have been linked to immune health, particularly via their anti-inflammatory properties. By enlisting female subjects (18–76 year, $n \sim 1250$) Jennings et al. [57] determined their intake of total flavonoids as well as individual subclasses, including the anthocyanins by using a frequency questionnaire. In terms of chronic inflammatory, the high-sensitivity C-reactive protein marker was monitored and showed that higher anthocyanin intake was associated with lower levels of this marker. In fact, no other associate with total or other flavonoid subclasses occurred with this inflammation marker. In yet another study using human subjects (31–315), Hassellund et al. [58] monitored the effects of anthocyanins on inflammation risk factors in prehypertensive male subjects (35–51 year, $n = 27$). The men were divided into two groups with one provided an anthocyanin supplement (640 mg) and the other a placebo for 4 weeks followed by a 4-week washout. No beneficial responses were detected in multiple inflammatory cytokines monitored, but endothelial dysfunction improved with the anthocyanin supplementation. It must be noted that the sample size was small in this study and trial duration short. Yet, Mena et al. [59] provided a review on the potential of anthocyanins, a powerful anti-inflammatory agent.

However, foods are not purified compounds acting on single targets but rather complex mixtures that may affect many biochemical pathways. Nonetheless, studies remain limited on the benefits of the whole jaboticaba fruit or the peel with following exception to our knowledge. Batista et al. [19] used Swiss mice to determine the effects of a high-fat diet supplemented with only 4% of jaboticaba peel on multiple markers for development of tauopathies, including hippocampal inflammatory markers, tumor necrosis factor-α, and interferon-γ. Firstly, the added peel supplement did not adversely affect either inflammatory markers as the animals fed with the high-fat supplemented diets presented with significantly similar values as those on the normal diet. Yet, compared to the mice fed with the high-fat diet only, these markers were 100% lower for the animals fed with the jaboticaba peel supplemented diet. Along with the anthocyanins and ellagic acids, the ellagitannins may also have

exerted a positive effect to mitigate inflammation exhibited the jaboticaba as supported by the following review [60].

4.3 Cancer Prevention and Mitigation Properties

Cancer is leading cause of death in many western countries, including the United States, second only to heart disease [61]. This disease is caused by uncontrolled cell proliferation leading to the formation of tumors. Tumors are complex structures that are composed of cells that have altered regulatory processes allowing a given tumor to grow in most types of tissues and/or organs. Proliferating cells (or neoplastic cells) are capable of shutting down the senescence pathway of a normal cell securing their perennial life [62, 63]. Furthermore, cancer cells release chemical signals that promote angiogenesis around the tumor structure, thereby supplying oxygen, blood, and other nutrients needed for growth. These remarkable cancer features are the primary reason this disease leads to high mortality rates [62, 63]. Additionally, proliferating cells reach a development point where they are able to combine signaling with taxis capacity and, as a consequence, metastasize to other tissues different from their original point of origin, which is yet another lethal characteristic associated with cancer [63, 64].

An estimated one-third of the cancer deaths are related to lifestyle that include diet factors [65]. Yet, diets rich in various natural systems, such as tomatoes, carrots, and berries, have exerted impressive effects in mitigating cancer [64], with jaboticaba providing potent anticancer properties among the berries [66]. A recent study conducted by Wang et al. [33] tested different sections of the fruit to identify the fractions that exerted most effective anticarcinogenic response. In order to accomplish this aim, human oral carcinoma cells obtained from the apical layer of the epithelial tissue were treated with extracts (aqueous or ethanoic) recovered from the seed, stem, and peel of the jaboticaba. The results showed that the water-extracted seed fraction provided the most potent effects in lowering cellular proliferation compared to the control by acting as inhibitors of apoptosis. Leite-Legatti et al. [18] reported that polar and nonpolar peel extracts of jaboticaba were able to provide effective antiproliferative properties against leukemia cells (K-562) and prostate cancer cells (PC-3), respectively, of the 11 different cancer cell types tested. It is evident from these two isolated studies that more research is needed to determine the anticancer potency of the whole fruit or its individual parts in vivo as well as to characterize the anticancer mechanism.

Nonetheless, several studies have reported on the anticancer mode of action exerted by the primary bioactive agents in jaboticaba credited (ellagic acid, gallic acid, anthocyanins, and ellagitannins) as shown by the following seminal reports. Firstly, ellagic acid has been shown to initiate a cascade of events in normal human lymphocytes that resulted in declining rates of DNA synthesis during the cell cycle. Also, the acid induced cell apoptosis by generating DNA molecule fragmentation, thereby preventing the neoplastic cells from proliferating [51]. Losso et al. [67] evaluated the antiproliferative activities of ellagic acid against eight different cell

lines with doses ranging from 10 to 100 mol/L. The most susceptible cells to the antiproliferative activity of ellagic acid were those derived from the colon (Caco-2), but the breast and prostate lines were also strongly impacted. As evidenced by microscopic examination of the cell gross morphology, ellagic acid prevented proliferation via induction of apoptosis. Moreover, lower ATP levels were produced, which is essential for cancer cell viability, indicating that ellagic acid exerts both a selective cytotoxicity and an anti-proliferation effect. Finally, ellagic acid was able to prevent fetal bovine stimulation of cell migration at the highest concentration used, suggesting that this compound may also mitigate metastasis. Edderkaoui et al. [68] determined that ellagic acid induced apoptosis in pancreatic cancer lines, which, in turn, prevented proliferation by approximately 20-fold at a concentration of 50 mmol/L. These results were associated with the depolarization of the mitochondria, release of cytochrome C, and activation of downstream caspase, which were attributed to the ellagic acid dose-dependent decrease of the binding activity of the transcription factor, nuclear factor kappa β. For more information about the ellagic acid effects in response to cancer and potential mechanisms, refer to Stoner and Muktar [69], Maas et al. [70], and Landete [60].

Secondly, as the largest phenolic compound present in jaboticaba, ellagitannins do not absorb into the bloodstream but rather are physiologically hydrolyzed to ellagic acid in the large intestine by the microbiota (refer to Sect. 4.5), which, in turn, is metabolized to smaller metabolites, such as the urolithins [71]. Urolithins A and C in turn have shown to inhibit HT-29 (colon cancer cells) cell proliferation via B0/G1 and G2/M arrest followed by the induction of apoptosis. Urolithins are also advantageous to cancer prevention as they are able to remain in the colon through enterohepatic circulation [72]. As an outcome to its metabolism into multiple but potent health-promoting metabolites, ellagitannins have been shown to have multi-targeted effects [73]. For example, Seeram et al. [74] showed that 25 miRNA, including the let family members, MiR-370, MiR-373, and miR526b, were likely targets of preventing proliferation and differentiation of Hep-G2 liver cancer cells. Indeed, other studies have been completed to show the chemopreventive properties of ellagitannins against prostate, colon, breast, oral/gastric, liver, cervical, lung, and skin cancer as reviewed by [72, 73].

Thirdly, current research has shown that gallic acid has exceptionally potent anticarcinogenic properties due to its ability to act on multiple targets. For example, gallic acid is able to prevent cancer by targeting angiogenesis, which is accomplished by concurrently inhibiting its initiation and by preventing additional neovessel growth after angiogenesis has already commenced [68–75]. More specifically, Lu et al. [75] determined that gallic acid was able to reduce glioma cell-mediated angiogenesis, in addition to inhibiting cell viability, proliferation, and invasion with U87 and U251 glioma cells as the cancer models. Using nude mice that were subcutaneously injected with the prostate cell lines 22Rv1 and DU145, Kaur et al. [76] reported that gallic acid consumption reduced the microvessel density in tumor xenografts as compared to the control. This study also showed that gallic acid decreased cell viability in a dose-dependent manner in both cell lines primarily by apoptosis induction. A recent study completed by Ho et al. [78] showed that the

exposure of squamous carcinoma cells to gallic acid resulted in inhibiting the activation of two matrix metalloproteinase (MMP) enzymes, MMP-2 and MMP-9, which are responsible for modulating cytokines and growth factors involved in angiogenesis as well as the invasion and migration of cancer cells [79]. As such the gallic acid may execute an important function against the tumor development. For more information on the anticancer effects of gallic acid, the reader is directed to excellent reviews presented by Verma et al. [77] and Locatelli et al. [80].

Lastly, the anthocyanins protect against cancer development due, in part, to their ability to bind directly to cell cycle regulator proteins, such as p53, p21, and cyclins [81, 82] and thus preventing cell proliferation. Additionally, these bioactive agents are able to increase the membrane potential of the mitochondrial membrane l and induce the accumulation of ROS resulting in cell apoptosis [83]. Other studies have shown that anthocyanins are able to downregulate the expression of MMP, which, in turn, decreases the ability of the tumor cell to degrade the extracellular matrix and invade new tissues [84, 85]. Anthocyanins have been shown to target the regulation of various cytokines involved in angiogenesis [86]. (Wang et al. [87] provides an in-depth review of the anticancer mode of action by anthocyanins.)

4.4 Atherosclerosis Prevention and Mitigation

Atherosclerosis is a condition caused by accumulating lipids and fibrous compounds in major arteries [88, 89], resulting in narrowing the arteries and thereby reducing blood flow to vital organs. This cardiovascular state is responsible for approximately 50% of reported fatal heart diseases, including cardiovascular disease [90]. Atherosclerosis is diagnosed by established biomarkers, including total cholesterol (TC) that is highly associated with the ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL) levels. The higher the ratio, the more serious the condition as LDL is easily oxidized, which is a significant contributing factor to atherosclerosis [88]. Oxidized LDL molecules enhance the production of reactive oxygen species (ROS), decrease the formation of NO (nitric oxide, an endogenous antioxidant), and stimulate the endothelium to express adhesion molecules and chemokines, which in turn recruit monocytes and T cells to the arterial wall [91, 92] ultimately forming foam cells and perpetuating inflammation. Effective treatments must be able to decrease LDL cholesterol (LDL-C) and/or raise HDL cholesterol (HDL-C) in the bloodstream.

Natural alternatives to the commonly used treatments, mainly statin drugs, have been of intense interest for decades due, in part, to the side effects and cost of these drugs [93]. Because of the presence of several potent bioactive agents, jaboticaba is now being studied as a potential food or source of agents to protect against atherosclerosis, although research again remains limited on the fruit itself with the following exceptions. Batista et al. [94] evaluated the effects of obese rats fed with a high-fat diet (lard) supplemented with only 1, 2, and 4% dried jaboticaba peel on the lipid profiles present in serum, liver, and fecal material. Although hepatic and serum

lipid contents were not impacted by the peel, fecal triglyceride excretion increased, particularly for the animals fed with the 1 and 2% supplements. Most importantly, evaluation of lipid peroxidation of the liver showed that the 2% supplement was able to lower peroxide values by 28.35% compared to the positive control fed with the high-fat diet only. In contrast, Alezandro et al. [95] showed that total plasma cholesterol levels and triglycerides were reduced by 32% and 50%, respectively, in streptozotocin-induced diabetic rats fed with 1.0 and 2.0 g dry weight/kg of body weight of jaboticaba extracts. The difference in serum levels between the two studies may be due to the induction stressors used to elevate the lipids, with the dietary inducer being more resistant. Another report by Batista et al. [19], who again fed rats lard as the atherosclerosis inducer and freeze-dried jaboticaba supplements (2% and 4%), showed that that peel reduced serum saturated lipids, another risk factor for atherosclerosis [96].

Relative to specific bioactive agents present in jaboticaba, ellagic acid may be a primary candidate responsible for protecting against cardiac damage caused by atherosclerosis. Several studies have shown that this molecule acts directly on LDL oxidation responses by inhibiting the proliferation of aortic smooth muscle cells and decreasing the levels of induced ROS generation that, in turn, activate adhesion molecules [97–99]. To prevent ROS induction, ellagic acid downregulates the expression of the lectin-like oxidized low-density lipoprotein receptor 1 (LOX-1), which is also responsible for the expression of pro-inflammatory molecules, such as cytokines, and chemokines in the endothelial cells. Moreover, this phenolic compound suppresses the expression of iNOS, which catalyzes a pathway that produces nitric oxide (NO). Under normal conditions, NO regulates arterial wall homeostasis. However, when the production of NO is upregulated by the oxidized LDL, as in the case of the iNOS pathway, the NO molecules bind with tyrosine residues that are essential for the vascular tone, thereby remediating further complications to the endothelial dysfunction [100–102]. Ellagitannins most likely act in the same manner due to their hydrolysis to ellagic acid and the urolithins. For more information on vascular health in response to ellagitannins and its metabolites, refer to the [103].

In addition, Xia et al. [104] determined that anthocyanins exert a unique effect in mitigating the progression of endothelial dysfunction, namely, by reducing the risk for catastrophic ruptures by reducing or stabilizing plaque. In this study, animals prone to the formation of weakened plaques (apolipoprotein E-deficient mice) were treated with diets rich in anthocyanins. At the end of the 20-week feeding study, plaques decreased by 18% and were firmer in texture, and necrotic core was not enlarged compared to the control group. Although the mechanisms involved in this phenomenon are not clear, the authors proposed that the anthocyanins augmented the antioxidant levels inside the plaque leading to increased stability. Moreover, the action of the anthocyanins can be related to the lipid serum level improvement as the anthocyanin-fed animals presented with reduced plasma cholesterol, LDL, and triglyceride levels. As in most of the studies related to bioactive compounds, there remains a critical lack of information regarding the pathways involved in protecting

against atherosclerosis or related risk factors. Nonetheless, it is clear from several reviews [60, 105–107] that flavonoids and other types of phenolic molecule are able to prevent or ameliorate the atherosclerosis status.

Although not a phenolic compound, which this review has been the focus, pectin is particularly high in jabocatica and must be recognized as such, particularly on its effects on risks for atherosclerosis. Multiple studies that date back to the early 1960s have shown the advantageous impact of pectin consumption, which are reviewed in [108, 109]. The most commonly reported response is that pectin facilitates the excretion of cholesterol and by inhibiting bile acid absorption [110].

4.5 Gastrointestinal Health: Gut Microbiota Modulation

The symbiotic relationship between human health and the gastrointestinal (GI) microbiome is garnering intense research with diet playing a major role [111–114]. Although studies pertaining to gut microbiota health and jaboticaba have not been reported to our knowledge, related research has been conducted on the prevalent bioactive agents of this berry. Firstly, the ellagitannins and ellagic acid are partially absorbed by the intestinal tract as their bioavailability is low. However, the remaining unabsorbed compounds remain intact until each reaches the large intestine where it is metabolized by the bacterial population, resulting in smaller polyphenolic metabolites (Table 4) [115–118]. These metabolites have been reported to exhibit both anti-inflammatory and antiproliferative properties [118, 119], among other health-promoting properties [60]. In addition, ellagic acid has been shown to modulate the gut microbiome to a healthy state. For example, Selma et al. [120] compared the production of urolithin A, a metabolite of ellagic acid, and other GI metabolized components of human subjects fed an ellagic acid-rich extract of pomegranate extract. After analyzing the composition of their fecal material subsequent to consumption of the supplement, the researchers determined that only certain test individuals presented with elevated production of ellagic acid metabolites while levels of these agents were low in other subjects. Those subjects that produced high levels urolithin A also had elevated *Clostridium coccoides* populations. This difference in metabolite production and the simultaneous alteration in the microbiome composition suggest a strong relationship between the two factors [120]. Another study completed by Li et al. [121] analyzed the relationship between the production of urolithin isomers and the gut microbiota composition in response to duration of consumption of an ellagic-rich pomegranate extract. In the 1st week, urolithins were present in the stool of only 30% of the individuals. By the 4th week, 50% of the individuals who did not produce urolithin excreted significant amounts of ellagic acid. This difference provides additional evidence that ellagic acid is likely playing an important role in the alteration of the gut microbiota composition but is subject specific. The same study reported a change in the *Firmicutes*/*Bacteroidetes* ratio present in the fecal material of the test subjects after extraction administration. Those who were able to produce urolithin A

Table 4 Microbial metabolism of ellagitannins, ellagic acid, and anthocyanins

Ellagitannins	Ellagic acid	Anthocyanins
Ellagic acid	Nasutin A	m-Hydroxyphenyl propionic acid
–	Isonasutin	Isoferulic acid
–	Urolithin M-5	3,4-Dihydroxyphenylacetic acid
–	Urolithin M-6	Ferulic acid
–	Urolithin M-7	Catechol
–	Urolithin C	3,4-Dihydroxphenylpropionic acid
–	Urolithin D	m-Hydroxyphenylacetic acid
–	Urolithin A	Dihydroferulic acid
–	Urolithin B	Phloroglucinaldehyde
–	Isourolithin A	Vanillic acid
–	Isourolithin B	p-Hydroxybenzoic acid
–	–	Protocatechuic acid
–	–	Gallic acid
–	–	Tyrosol
–	–	Resorcinol
–	–	Pyrogallol
–	–	Caffeic acid
–	–	Homovanillic acid
–	–	Syringic acid
–	–	p-Coumaric acid

experienced a decrease in the *Firmicutes* population with a concomitant increase in bacteria from the genus *Prevotella*, which belongs to the phylum *Bacteroidetes*. The ratio between those two phyla has been shown to be closely related to lean and obese phenotypes with higher levels of *Bacteroides* and lower levels of formicates associated to lower body weight [122, 123]. This fact is useful in the development of functional foods, such as jaboticaba, as means to target obesity through gut microbiota modulation.

In the case of anthocyanins, multiple studies have been reported based on their ability to modulate the gut microbiota, as reviewed by Faria et al. [116]. Again, the majority of anthocyanin levels consumed are not absorbed by the upper GI tract, thereby reaching the lower intestinal microbiota. Similar to ellagitannins and ellagic acid, anthocyanins are biotransformed into smaller but multiple metabolites, which are then absorbed through the large intestine (Table 4). Once absorbed, these compounds have been shown to exert different biological properties compared to their parent counterparts [124]. Using an in vitro fecal fermentation approach, Hidalgo et al. [125] further reported that anthocyanins were able to modulate the gut microbiota. More specifically, malvidin-3-glucoside enhanced the growth of the putatively beneficial bacteria, *Bifidobacterium* spp. and *Lactobacillus* spp., but did not affect *Bactericides* spp. growth. However, the two predominant anthocyanins present in jaboticaba, delphinidin 3-glucoside and cyanidin 3-glucoside [18], were not studied in isolation in terms of their ability to modulate the gut microbiome.

Rather, they were combined with malvidin-3-glucoside, peonidin-3-glucoside, and petunidin-3-glucoside to monitor the combined response on the gut microbiota. The results showed even higher levels *Bifidobacterium* spp. and *Lactobacillus* spp. with latter growth even higher than the positive control, which used the proven prebiotic fructooligosaccharide [126]. The authors attributed these results to a synergistic effect exerted by the anthocyanins in combination. As such, it is reasonable to propose that the anthocyanins present in jaboticaba peel are capable of modulating the gut microbiota to a healthy community.

Pectin in jaboticaba may be able to modulate the gut microbiota to a health state. Jiang et al. [127] showed that apple-derived pectin supplement into a high-fat-inducing obesity diet prevented a decrease in the *Bacteroidetes* population and an increase in the *Firmicutes* phylum. Parkar et al. [128] investigated the effects of six different pectins obtained from kiwifruit on gut health in terms of influence on bacterial adhesion on intestinal epithelial cells (Caco-2 cells). The pectin which originated from the kiwifruit was more effective, enhancing the adhesion of *Lactobacillus rhamnosus* while decreasing the adhesion to *Salmonella typhimurium*. Still the adhesion of *Bifidobacterium bifidum* significantly increased in the presence of inulin and citrus pectin. Indeed, studies are needed on pectin present in jaboticaba to determine its effect on the microbiome as another study completed by Nazzaro et al. [129] further confirmed that pectin source affects gut microbe modulation.

4.6 Metabolic Syndrome: Obesity and Diabetes

Metabolic syndrome (MetS) is a cluster of conditions that involve risks for cardiovascular diseases and type 2 diabetes and is prevalent with obese state [130, 131]. Specific markers of MetS include excessive central adiposity, higher serum glucose levels, increased serum triglycerides and LDL-C, lower HDL-C, and high blood pressure [132–135]. (As the latter conditions have already been discussed previously, with the exception of central adiposity and serum glucose levels, this section will mainly focus only on health risks associated with obesity and diabetes.) According to the World Health Organization [133], obesity is defined an excessive accumulation of fat tissue that can cause various negative effects on the human body, such as chronic oxidative and pro-inflammatory states [134, 135]. Diabetes is defined as the dysregulation of glucose absorption and breakdown pathway leading to glucose resistance and further ketosis, tissue damage, and many other metabolic failures [135]. As this MetS is becoming a worldwide epidemic [136], researchers are now focusing their efforts on discovering bioactive compounds that could prevent or decrease the damages caused by these alarming clinical markers.

The relationship between cellular metabolic responses and the antioxidants present in the peel of the jaboticaba fruit is a main focus of several research studies. For example, in a recent study conducted by Lenquiste et al. [137], freeze-dried jaboticaba peel was administered at 1%, 2%, and 4% (w/w) of the diet as a supplement to

rats fed with a high-fat diet added to an AIN-93 M diet. Consumption of the high-fat diet + jaboticaba supplementation resulted in lower weight gain compared to the high-fat diet. Moreover, the antioxidant profile of the liver improved for rats fed with the high-fat + supplement diet, while those on the high-fat diet presented with significantly higher levels of lipid peroxidation. Meanwhile, serum insulin levels reduced by 47%, 57%, and 52% with respect to the animals fed with the 1%, 2%, and 4% freeze-dried jaboticaba peel supplemented diet. A previous study using freeze-dried jaboticaba peel supplement fed to a high-fat-induced obese rat model showed that incidence of type 2 diabetes was directly associated with plasma cholesterol ester levels and total short-chain fatty acids [19]. These factors are closely related to inflammation and insulin resistance [135]. In another study, Batista et al. [94] reported that high fat obesity induced animals fed three different concentrations of freeze-dried jaboticaba extracts (1%, 2%, and 4%) resulted in increased triglyceride output, decreased hyperinsulinemia, decreased hepatic inflammation, and improved insulin sensitivity. However, only the 4% diet exerted these benefits. The authors proposed that results were associated with a decrease in plasma short-chain fatty acids, which has been linked to a downregulation in the expression of lipogenic genes [83].

The anthocyanins present in jaboticaba may, in part, play a role in mitigating the risk factors of MetS by inhibiting the release of inflammatory adipokines secreted by the hypertrophic adipose tissue that contribute to insulin resistance as evidenced by Matsukawa et al. [138]; albeit only the anthocyanin, cyaniding-3-glucoside, was used. Still, this effect was attributed to the anthocyanin interacting with proteins involved in insulin signaling that induce a state of insulin resistance. Garcia-Diaz et al. [139] showed that anthocyanin-rich fractions obtained from blackberry and blueberry beverages were able to reduce intracellular fat accumulation when applied during the differentiation of 3T3-L1 adipocytes followed by the inhibition of lipolysis of the mature cells. Moreover, the blends partially restored the insulin-induced glucose uptake by the adipocytes. This effect was attributed to the interaction of the anthocyanins with proteins involved in insulin signaling that induce a state of insulin resistance. Using a mice model, Prior et al. [140] fed three groups increasing levels of fat that contributed to 10%, 45%, or 60% of their daily calories. The diets were supplemented with whole blueberries, strawberries, or purified anthocyanin extracts recovered from each of the fruits. The whole fruit, blueberry or strawberry, did not prevent the weight gain that accompanied the groups fed with the 45% and 60% high-fat caloric diets. Yet, consumption of the purified anthocyanins obtained in either fruits resulted in reduced obesity.

The above-discussed documents represent only a cross section of the numerous studies that have been reported on health benefits of anthocyanins as well as tannic, ellagic, and gallic acid on preventing or remediating MetS and/or its risk factors/conditions. Therefore, for more information on the possible mechanisms of action of these phytochemicals on MetS responses, the reader is referred to [141–143] for excellent reviews on this topic.

5 Conclusions

The jaboticaba fruit is an important crop indigenous to Brazil due, in part, to the numerous nutrients and phytochemicals that protect against multiple diseases currently afflicting western cultures. Despite its increasing importance, jaboticaba consumption is low in other parts of the world. This review provides information on jaboticaba, with an emphasis on their phenolic composition and links to human health benefits. Although our understanding of the latter health attributes is increasing, critical gaps in knowledge remain on the role that jaboticaba has on protecting against multiple disease risks or states. As jaboticaba contains multiple nutrients and other phytochemicals, they most likely exert these effects as synergists or additives within the complex berry system, but again research remains limited on the whole fruit with more data available on the peel. Such studies are particularly important considering that theses berries are consumed primarily as a whole product, with the market class and production location most likely affecting their compositional profiles and therefore its potential health effects.

However, the presented studies show the potential of the jaboticaba fruit as a highly effective functional food capable of providing multiple health benefits. Foods that have been branded as a functional food (or disease preventing/remediating foods), such as cranberries and grapes, have expanded approximately tenfold in the last decade, growing at three to four times the rate of conventional foods due to the increasing preference for natural interventions [144]. Based on this encouraging growth, expanding jaboticaba into the functional food category is expected to increase overall consumption and demand, which in turn can support and increase prices. By increasing the demand on the global scale for this currently underconsumed fruit, it is expected that a positive economic impact would affect all segments of the production and distribution chain.

Pomegranate Bioactive Molecules and Health Benefits

42

Saeed Akhtar, Tariq Ismail, and Anam Layla

Contents

Abstract

Fruits contribute an abundant supply of antioxidants to human diet and act as the first line of defense against the risks of chronic diseases occurrence. Pomegranate is one among the highly explored and appreciated fruits on account of its promising health-promoting and disease-preventing properties. Pomegranate fruit and its key components including rind, seed, and membranous network

have been evidently reported as carriers of a wide range of bioactive compounds including ellagitannins, hydroxycinnamic acids, hydroxybenzoic acids, flavons, flavonol-3-ols, anthocyanidins, anthocyanins, and conjugated and nonconjugated fatty acids, phytosterols, vitamins, and minerals. Traditional aspects of pomegranate exploitation as remedy against infections and gastrointestinal ailments have generated a basis for the modern-age research. Findings of the research carried out in the last two decades manifest fruit, flower, seeds, and peel of pomegranate as natural strategy to treat microbiological and parasitic pathogenesis and to act as a chemopreventive and therapeutic approach against inflammatory and infectious chronic ailments. Forthcoming sections of this chapter review fundamental biochemical composition of pomegranate and its anatomical fractions and provide recent updates on pomegranate perspective applications against the risks of various forms of cancers, cardiovascular diseases, diabetes, acute and chronic liver injury, renal disorders, impaired gut health, neurodegenerative disorders, microbiological pathogenesis, and parasitic infestation.

Keywords
Pomegranate · Ellagitannins · Inflammation · Cancer · Neurodegeneration

1 Introduction

Pomegranate (*Punica granatum* L; "seeded apple") was lauded in the Torah, Bible, and Al-Quran as a sacred fruit deliberating good luck, wealth, and power of fertility [1]. The mystical fruit traditionally implicated as folk or ethnic medicine to cure various health disorders [2]. The fruit-bearing plant is a predominant shrub of family Punicaceae that typically grows up to 12–16 feet and has several spiny branches with glossy lance-shaped leaves. The grenade-shaped fruiting body encloses clusters of delicious arils separated by pale white spongy mesocarp, with deep red leathery skin [1]. Since ancient times, the fruit is native and under cultivation from the northern Himalayas to Iran, Afghanistan, India, Pakistan, and China. The pomegranate cultivation was stretched from west of Persia (old name of Iran) over the entire Mediterranean region to Turkey and dried regions of American Southwest, Mexico, California, and Arizona [3].

The pomegranate plant, fruit, and their anatomical segments including flowers, fruit rind, leaves, bark, seeds, and roots encompasses a variety of biomolecules including phenolics, hydrolysable tannins, anthocyanins, flavonoids, and a wide range of essential micronutrients. The unique biochemical profile of the fruiting body and its major fractions attribute strong antioxidative, anti-inflammatory, apoptotic, and antimutagenic properties to curtail chronic maladies [4, 5]. Prophylactic properties of pomegranate are of broad spectrum and are anticipated to mitigate microbiological and parasitic pathogenesis [6, 7], gastric damage [8], cardiovascular disease [9], type 2 diabetes [10], several types of cancers [3], renal illnesses [11], liver complications [12], infertility [13], osteoarthritis [14], oral and dental health [15], and skin melanoma [16].

The consumption trend of fruit and associated structures is diversely alike fresh or dried arils, fresh or fermented juice, powdered extracts, rind powder tablets, capsules and soft gels, and extracts-based ointments and decoctions [5, 17, 18].

Pomegranate fruit waste including peel and seeds provides substantial amount of phytonutrients that can be exploited for their potent health benefits. The mechanistic properties of pomegranate fruit and peel extracts such as antioxidant, antimicrobial, flavoring, and colorant may also be implicated as a natural additive in the food industry for quality enhancement and food preservation [4, 19]. In addition, pomegranate seed oils and rind extracts deliberate photoprotective effect and can be utilized in cosmo care products [20]. The peel powders also have biosorption capacity for heavy metal from water and are capable of acting as phyto-remediating agent to ensure cost-effective waste water treatment and decontamination of chromium, nickel, and zinc contamination [21, 22].

A plethora of research has been conducted on health-promoting and food features of pomegranate and its anatomical fractions as in the last two decades. This chapter comprehensively covers the recent updates from research carried out to explore pomegranate fruit and its waste fractions' capability in delivering preventive and therapeutic aspects against certain human acute and chronic ailments of critical concern (Figs. 1, 2, and 3).

2 Biochemical Composition of Pomegranate

Globally, higher acceptability of pomegranate as a miraculous fruit is linked to its remarkable health benefits. Predominately, a unique biochemical profile ornamented with more than 124 phytochemicals is the differential factor responsible for a broad range of antioxidant, anti-inflammatory, and antimutagenic properties of

Fig. 1 Pomegranate flower

Fig. 2 Pomegranate ripened fruit

Fig. 3 Pomegranate edible fleshy sacs

pomegranate. Pomegranate fruit and its different anatomical fractions like flower, peel, juicy sacs, and seeds are referred as reservoirs of high molecular weight hydrolysable tannins, i.e., ellagitannins, alongside a wide range of anthocyanins, hydroxybenzoic acids, hydroxycinnamic acids, minerals, essential lipids, and complex polysaccharides [23–26]. Approximately 50% of the fruit weight is attributed to the rind portion that constitutes 30% of the fruit anthocyanidins contents.

Pomegranate peel, the waste fraction of the fruit, has been reported to carry 10% w/w crude polysaccharides that could further be exploited as a functional ingredient in attributing gelling and prebiotic properties to food formulations. A recent study from Tunisia reported 6.8–10.1% pectin contents in peel portion of four Tunisian pomegranate cultivars [27, 28]. Pomegranate seeds constitute 15–25% of the edible juicy arils and are considerably good sources of phytosterols, omega-5 fatty acids including punicic acids, tocopherols, and isomers of conjugated alpha-linolenic acid [29–31].

Variability in concentration of pomegranate bioactive compounds including phytochemicals of human health significance and their biological properties varies with the cultivar, anatomical part of the fruit, maturity period, type of extraction, and

mode of phenolics extraction. Low-cost and efficient recovery techniques of pomegranate phytochemicals, polyphenols, and seed oil have been introduced in the recent past including pulsed ultrasound-assisted extraction, green ultrasound-assisted extraction, ultrasound-assisted enzymatic extraction, enzyme-assisted supercritical fluid extraction, microwave-assisted extraction, microwave-treated supercritical CO_2, high-voltage electrical discharge, and hydroalcoholic extraction system [32–42].

Selection of a cost-effective, safer, and intelligent biomolecules extraction technique for pomegranate and its various fractions ensures higher rate of phenolics recovery with better ability of extracts/fractionated compounds in dispensing various biological promoting properties of human health concern (Table 1).

3 Health Benefits of Pomegranate and Its Fractions

3.1 Pomegranate Promotes Cardiac Health

Global estimates predict death toll due to cardiac complication to be 40% by the year 2020 [44]. Several epidemiological studies correlate inverse relation between adherence to relatively high intake of plant polyphenols and incidence of cardiovascular diseases (CVD). Experimental evidence suggested polyphenol-rich pomegranate fruits consumption to present modulatory effect in improving cardiac muscles tone, mitigating oxidative stress-mediated arterial hardening, and attenuating atherosclerosis. Healthy heart features are attributed predominately by the pomegranate ellagitannins especially punicalagin isomers α and β. Pomegranate hydrolyzable ellagitannins after being converted to ellagic acid are further metabolized into certain types of urolithins by intestinal microbiota. Studies on pomegranate consumption and association with improved cardiac health correlate urolithins as one among the known ellagitannins metabolites that stand responsible for attenuating various cardiac complications [9, 45]. Arterial lipid accumulation is a hallmark of atherosclerosis and is encouraged by low-density lipoprotein (LDL) cholesterol oxidation. A double-blind pilot scale study conducted in dyslipidemic obese patients receiving 500 mg pomegranate rind extract daily for a period of 8 weeks demonstrated a significant reduction in systolic blood pressure and improved lipid profile via reduced triglycerides and LDL levels and increased HDL level proclaiming pomegranates a potent antiatherogenic agent [46]. In a study conducted by Razani et al. [47], 100 hospitalized patients diagnosed with myocardial ischemia and unstable angina were randomly assigned to consume 220 ml pomegranate juice in addition to medical treatment; pomegranate diet therapy presented cardioprotective effect by significant reduction in serum level of malondialdehyde and troponin, intensity of angina pectoris, and attenuating reperfusion injury [47].

Pomegranate fruit and peel extracts have also been reported to exert an ameliorative role in vascular inflammation, oxidative stress, and elevated cardiac enzymes markers. Pomegranate extracts supplements (625 mg carrying 200 mg punicalagin) delivered to hyperlipidemic animal models have been found to prevent coronary

Table 1 Major biochemical constituents of pomegranate leaf, flower, fruit, peel, seeds, bark and root

endothelial dysfunction. The study further delineates inhibition of vascular inflammation and stress-mediated coronary DNA damage and stimulating Akt/endothelial nitric oxide-synthase pathway to improve vasodilatory values as the fundamental mechanism of pomegranate extracts in preventing coronary endothelial dysfunction [9]. Oxidative stress-mediated myocardial infarction results in coronary muscle atrophy and necrosis. Pomegranate fruit extracts have been found to present an ameliorative effect in isoproterenol-toxicated myocardial infarction by attenuating oxidative stress and level of cardiac enzymes markers, i.e., CK-MB and troponin [48]. Clinical findings are therefore suggestive of pomegranate fruit juice, seeds, rind extracts, and other derived products as potent source of antioxidants and nutrients offering cardioprotective and therapeutic properties.

3.2 Pomegranate and Its Role in Cancer Chemoprevention

Cancer is one of the leading causes of death in global perspective, and it has been reported that new cancer cases will increase by 70% at the end of 2030. Healthier eating practices and dietary preferences toward more fruits and vegetable consumption have been reported to reduce risks of cancer insurgencies and associated mortalities [49, 50]. Pomegranate ranks among the fruits that carry highest concentration of cancer chemopreventive and therapeutic biomolecules including

ellagitannins, flavonoids, and anthocyanins. Pomegranate polyphenols dispensed either in the form of crude, purified fruit extracts or as fruit juice furnish anticancer activities by inducing apoptosis, cell cycle arrest, antiangiogenesis, and anti-mutagenesis activities [49].

Pomegranate anticancerous properties alike other chemopreventive agents have been reported to be associated with antioxidant activities of biomolecules. Pomegranate juice prospectively contains 2 g/L ellagitannins of which punicalagin accounts 1500–1900 mg/L [51]. It's among the reasons that pomegranate juice adds three times higher antioxidant capacity in terms of inhibition of the production of DNA oxidation products, reactive nitrogen species, lipid peroxidation, and in scavenging reactive oxygen species [51–54].

Clinical findings are indicative of pomegranate biomolecules metabolites accumulation in prostate tissues of prostate cancer patients administrated with 250 ml pomegranate juice consecutively for a period of 4 weeks [55]. However, statistically nonsignificant impact of pomegranate juice administration on cancer development and progression markers was indicated probably due to shorter treatment duration. Another 18-month study wherein patients were provided with 1 or 3 g pomegranate extracts was found to extend prostate-specific antigen doubling time from 12–19 months and 12–17.5 months, respectively for low-dose and high-dose treated groups [56]. Inflammation – one among the cancer initiation factors activates cancer cells and induces DNA damages alongside epigenetic changes. Pomegranate as juice, fruit extracts, and individually fractionated biomolecules exerts significant impact on expression of inflammatory cell signaling protein in cancer cells [57]. A study carried out in human colon cancer cell line indicated pomegranate juice, pomegranate tannins, and punicalagin to significantly reduce expression of cyclo-oxygenase – 2 (COX-2) expression. COX-2 proteins stand responsible for production of prostanoids that induce inflammation [58]. Ellagic acid – another metabolite of pomegranate ellagitannins has been reported to inhibit intestinal inflammation by downregulating certain inflammation-mediating compounds such as COX-2 and iNOS and blocking cell signaling pathways including NF-kB, p38 MAPK, IL6, and STAT3 in tissues of the colon [59].

A study carried out by Mehta and Lansky [60] highlighted fermented pomegranate juice carrying 10 μg/ml polyphenols to exert chemopreventive properties by 90% suppression of mammary cancerous lesion formation [60]. Pomegranate extracts possessing up to 200 μg/ml bioactive phenolic compounds have been reported to reduce breast cancer cells viability and block mammary cancer cell cycle progression [61]. Pomegranate as fruit and peel extracts exhibits skin protection properties against UVA- and UVB-mediated reactions. Pretreatment with pomegranate fruit extracts protects skin fibroblast from UV-mediated cell death. A significant inhibition in production of UV-induced reactive oxygen species and increment in intracellular antioxidant levels however can only be achieved with too higher pomegranate polyphenols concentration, i.e., 500 to 10,000 mg/L [62, 63].

Albeit, a plethora of research have been undertaken to explore chemopreventive and therapeutic properties of pomegranate against various types of cancers including

breast, colon, liver, bladder, skin, lung, and cerebral cancer, yet the bioavailability of pomegranate bioactive compounds including ellagitannins, flavonoids, and anthocyanins in the target cells need to be determined. Furthermore, maximum tolerable doses of combined extracts and individual compounds capable of delivering chemopreventive and therapeutic role and exact underlying anticancer mechanism are yet to be explored.

3.3 Antidiabetic Properties of Pomegranate

Traditionally pomegranate fruit and associated structures alike flowers and leaves were recommended in conventional therapy of diabetes [64]. Since last decade, scientific work has consolidated effects of fruit in curing type 2 diabetes and its complications. Oxidative stress-mediated damage of pancreatic β-cell is one of the proposed mechanism involved in the onset of type 2 diabetes. Pomegranate being the healing fruit owing to its free radical scavenging properties has the ability to safeguard pancreatic β-cells from injury through neutralizing the effect of free radicals [65, 66]. In human trials, fruit juice and derived products presented a diabetes-preventive role that may be related with enhanced activity of antioxidative enzymes such as paraoxonase 1 (PON1), reduction of lipid peroxidation, and inhibition of inflammation mediator transcription factor NF-kB activation [67, 68]. Oral supplementation of pomegranate peel powder (200 mg/kg B.W) for 20 days substantially improved serum level of ALT and AST, glutathione and SOD contents, hepatic glucose-6 phosphate dehydrogenase activity, and regenerated pancreatic β-cells in streptozotocin-induced diabetic animal model [69, 70]. In vivo and in vitro application of fruit extracts and their individual components like punicalagin, punicalin, ellagic acid, and gallic acid exhibited anti-glycation properties and reduced levels of glycation products alike serum AGEs, hemoglobin A1c, and glycoalbumin [71]. Ellagic acid and its glycosides have a profound effect on insulin-sensitizing activity through increasing gene expression of PPAR-γ and GLUT4 that activate insulin signaling pathways for the glucose uptake in L6 myotubes [72]. Phenolic-rich pomegranate peel and flower extracts have been reported to offer α-glucosidase inhibitory activity with IC50 value of 5.56 μg/ml and 29.77 μg/ml, respectively. The studies further suggest ellagitannins to bind the active site of α-glucosidase surface rendering it inactive and delaying carbohydrate digestion that ultimately facilitate in lower glucose absorption [10, 73]. The fruit also exhibits ameliorative effect in treating diabetic nephropathy via improving blood glucose level, kidney hypertrophy index, strengthening glomeruli tubules, increasing basement membrane thickness, and reducing renal disease markers [74, 75]. On account of abovementioned exploratory features, pomegranate, fruit, and peel-derived extracts and fractionated compounds may be suggested as functional food and nutraceutical ingredient in diabetes care.

3.4 Hepatoprotective Role of Pomegranate

The liver is principally the metabolic powerhouse of the human body that stands responsible for the metabolization of nutrients and detoxification. Oxidative stress is among the mechanisms involved in liver pathogenesis and progression of chronic liver disease. Pomegranate fruit on account of its polyphenols including hydrolysable tannins, anthocyanins, flavonoids, and compounds of alike structure prevent progression of liver illnesses. Oral feeding of pomegranate (800 mg/kg B.W) for 2 weeks have shown to protect sepsis-mediated acute liver injury. The study further demonstrated free radical scavenging properties and anti-inflammatory activities of the fruit phenolics as the fundamental protection mechanism of pomegranate phenolics to protect and allay the risks of acute liver injury. Pomegranate phenolics consumed in the form of juice or extracts activate SOD and glutathione activity and reduce serum malondialdehyde contents that further help in mediating TLR4 and NF-*k*B inflammatory pathways [76].

Administration of pomegranate peel extracts rich in ellagitannins to animal models with clinical signs of steatosis (fatty liver) showed considerable protective effect on hepatic morphology, inhibited lipogenesis in cytoplasm of hepatocytes, and improved liver enzymes [12]. Ellagic acid, one of the key pomegranate phenolic attenuates alcohol-induced hepatotoxicity by reducing expressions of pro-fibrogenic and pro-inflammatory cytokines like interleukins, TNF-α, and TGF-β that are reported to increase in alcohol-induced liver fibrosis and inflammation [77, 78]. Pomegranate seed extracts alike peel extracts have been recorded to offer remarkable protective effect against xenobiotics (e.g., CCl_4)-mediated liver fibrosis. The mechanism might be correlated with secondary metabolites of ellagitannins like ellagic acid, urolithins, increased free radical scavenging activity, and inhibition of TGF-β1 level and collagen synthesis [77, 79].

3.5 Pomegranate and Brain Health

Brain aging is generally recognized by irreversible loss in gross motor and sensory neurons and associated physiological functions including cognition. Alzheimer's disease is a suboptimal neurodegenerative disorder symptomized with dementia and cognitive impairment. Senile plaque formation through accretion of amyloid β peptides and generation of neurofibrillary tangles are the hallmark lesions associated with Alzheimer's disease. Research findings have shown redox impairment to be involved in the amyloid β-associated neurotoxicity [80, 81]. Fruits like pomegranate bearing substantial free radical quenching properties could serve as a natural neuroprotective agent. A study conducted in transgenic amyloid precursor protein (APP) mutated mice models-associated diet consumption enriched with 4% pomegranate juice to generate significant impact on boosting cognitive performance of the animal models [82]. The study further witnessed pomegranate juice consumption to

anticipate improved memory, learning ability, and motor coordination and reduced anxiety level in treated mice model as compared to standard diet-fed mice. In another study wherein pomegranate peel extracts in combination with *Gmelina arborea* bark extracts were found to present gamma secretase modulatory and acetylcholinesterase inhibitory effect in reducing pathogenesis of Alzheimer's diseases, it concluded that the extracts derived from both plants offer neuroprotective effect in cognitive dysfunction [83]. Human trials further endorsed consumption of pomegranate juice (8 ounce/day) for a duration of 4 weeks to boost memory and brain functionality via strengthening brain antioxidants pool [84].

3.6 Anti-Inflammatory and Bone Health Promotion Properties

Inflammation is an undefined immune system hyperactivity that progressively triggers transcription factors, i.e., TNF-α and NF-*k*B, that elevate level of pro-inflammatory cytokines like prostaglandin E2 (PGE-2) and interleukin (IL-1, IL-6, IL-8) and overexcite production of reactive oxygen and nitrogen species [85, 86]. A recent study reported that punicalagin A & B, ellagic acid and gallic acid possess anti-inflammatory effect by exerting potent inhibitory effect on lipopolysaccharides stimulated macrophages that downregulate COX-2 protein release from RAW264.7 cells. Consequently, COX-2 protein expression inhibition reduces the level of pro-inflammatory mediators alike inducible NO (*i*NO), PGE-2, interleukins, and ROS [87]. Inflammation negatively affects bone health and compromises quality of life through pannus formation and bone destruction that might consequently lead toward disability. Long-term use of pharmacological preparations for bone rehabilitation alike cyclooxygenase inhibitor or nonsteroidal anti-inflammatory drugs (NSAIDs) contributes in cardiac complications or gastrointestinal discomfort [88]. Botanical extracts like those derived from pomegranate are referred as potent carrier of antioxidants and anti-inflammatory compounds that could further be exploited in bone health restoration. Rheumatoid arthritis affecting about 0.5–1% world population is a systematic autoimmune bone disorder of synovial joints. Higher infiltration rate of inflammatory cells in synovial fluid of patients with rheumatoid arthritis progresses toward irreversible cartilage and bone damage. Ellagic acid inhibits foot paw edematous inflammation [89]. The study conferred ellagic acid to attenuate etiology of adjuvant-induced arthritis (AIA)-linked pathogenesis by downregulation of pro-inflammatory cytokines IL -1β, TNF-α, and IL −17 and upregulation serum level of anti-inflammatory cytokines IL-10 and interferon γ (IFN-γ). Pomegranate fruit extracts offer protection against osteoarthritis by improving cartilage stiffness and physical fitness, decreasing level of cartilage catabolizing enzymes, and strengthening antioxidative defense system [14]. Osteoporosis is the structural deterioration of the microarchitecture array of the bone during remodeling phase and progressively leads toward bone fragility and bone loss. Pomegranate peel extract-enriched diet significantly improves bone mineralization by increasing

osteogenic transcription factors and stimulating activity of bone maker protein, i.e., alkaline phosphatase (ALP) [90]. Pomegranate seed oil (PSO) on account of its punicic acid (conjugated linolenic acid)-rich profile offers osteblastogenesis development and suppression of osteoclastogenesis in animal models fed with 5% PSO-supplemented diet [91]. Consequent upon pomegranate antioxidants and anti-inflammatory compounds bearing features, the fruit and its biomolecules can be suggested as functional food to prevent bone loss and associated disorders.

3.7 Microbial Pathogenesis Inhibitory Role of Pomegranate

Multidrug-resistant bacteria, pandemic viruses, and opportunistic fungi are well-known illnesses and life-threatening infections causing microorganism. Microbiological pathogenesis and infections urge to find an alternative therapy like botanical extracts for contending with widespread multidrug resistance among microorganisms of human health concern. Phytonutrients including polyphenols, flavonoids, tannins (condensed and hydrolysable), terpenoids, and phytosterols are extensively explored and exploited for their potential antimicrobial activity [92, 93]. Aqueous and methanolic extracts of pomegranate pericarp and rind holding up appreciable concentration of anthocyanins, punicalagin, ellagic acid, gallic acid, and other polyphenols have been widely explored for antimicrobial efficacy and in treating a wide range of contagions [6, 94]. Pomegranate peel methanolic extract (80%) presents inhibitory effect against hemorrhagic *Escherichia coli*, *Yersinia enterocolitica*, *Staphylococcus aureus*, *and Listeria monocytogenes* with minimum inhibitory concentration (MICs) ranging between 6 and 12 mg/ml [95, 96]. The toxicity of these phytonutrients against bacterial cell is due to complex formation with enzymes cofactors and sulfhydryl group of proteins that alter permeability of membrane and disturb respiratory chain [97, 98]. In vitro and in situ application of 80% methanolic extracts of pomegranate whole fruit, seed, and rind presented antifungal activity against *Penicillium citrinum*, *Aspergillus niger, Trichoderma reesei*, *Rhizopus oryzae*, and *Mucor indicus* [99]. The crude extract of pomegranate rind shows cytotoxicity at conidial and hyphal stage against dermatophytes, e.g., *Microsporum canis* and *Trichophyton mentagrophytes*, with MICs values of 250 μg/ml and 125 μg/ml, respectively. Polyphenols including punicalagin, catechin, and epigallocatechin being potential antifungal agents induce precipitation of microbial cell membranous proteins and intercellular leakage and alter composition of cytoplasm and outer cell membranes that inhibit fungal growth [100, 101]. Pomegranate hydroalcoholic extracts have also been reported to offer antiviral activity against human immunodeficiency virus type 1, herpes simplex virus 1, influenza A, adenovirus, and hepatitis C virus. The possible mechanism behind viral cell damage is a complex formation between condensed tannins and viral glycoprotein that affect viral attachment with host cell. This further suppresses viral transcription/translation and prevents viral replication [102–104].

3.8 Anthelmintic Activities of Pomegranate

Parasites (ecto- and endoparasites) depend on host for food and shelter rendering a compromised immune system to host, increased disease burden in human and domestic animals, and huge economic loss. Crude pomegranate rind, bark, and root extracts gained a lot of attention in curing parasitic infections since ages [105–107]. Pomegranate fruit extracts have been explored as anti-cestoda, vermifugal, and antiprotozoan mainly due to its tannins, triterpenes, sterols, glycosides, and alkaloids [108, 109]. Oral administration of 40 mg/ml of pomegranate rind crude extract to animals infested with tapeworms (*Raillietina spiralis)* and roundworms (*Ascaridia galli)* induced parasites paralysis and reduced death time in comparison with anthelmintics piperazine and albendazole. Ethanolic and aqueous extracts of pomegranate exhibit ovicidal and larvicidal properties against *Gastrothylax indicus* and *Hymenolepis nana* manifesting it a novel source of anthelmintic agent [7, 110, 111]. Pomegranate peel extracts show protective role against *Plasmodium*-induced parasitosis (malaria). Alongside its hepatoprotective effects, pomegranate extracts reverse signs of anemia provoked by plasmodium infestation through the hemoglobin, and erythrocytes count back to the normal level [112, 113].

3.9 Gut Health Promotion Properties of Pomegranate

Gut microbiota represent complex and mutualistic interplay of the human's largest microbial biome that considerably influence homeostasis and healthy conditions of the host. Dietary and other nutritional interventions have been shown to exert a modulatory effect on the composition of gut microbiota. Polyphenols-rich pomegranate juice and fruit extracts demonstrate beneficial effects on gut health and microbiome. The gut microbes transform intact phenolic compounds, e.g., ellagitannins and anthocyanins, into bioactive metabolites such as ellagic acid and urolithins. Intact ellagitannins and anthocyanins act as prebiotic and have a synergistic effect in promoting probiotics properties of *Lactobacilli* and *Bifidobacteria.* It further inhibits growth of pathogenic microbes and preserves gut microbiome balance [114, 115]. Incorporation of pomegranate peel at 10% of the animal diet exhibit modulatory effect on sodium oxide dismutase 1 (SOD1) and glutathione activity and reduced level of malondialdehyde (MDA) in the small intestine of the ruminant as compared to control diet. Pomegranate polyphenols particularly ellagitannins, punicalagin, and ellagic acid attenuate small intestine lipid peroxidation by strengthening free radicals ($\bullet O_2^-$ and H_2O_2) scavenging system and regulating enzymatic antioxidative pathways as the first-line defense system of the small intestine [116]. Pomegranate peel extracts and seed oil prevent chronic inflammation and necrotizing enterocolitis-mediated intestinal damage. Pomegranate polyphenols especially ellagitannins protect from ulcerative colitis through reducing ERK1/2 activity by downregulation of mTOR downstream pathway and inhibit production of pro-inflammatory cytokines at molecular level [117, 118]. Pomegranate seeds have been reported to be exploited as traditional remedy for the management of

diarrhea. Antidiarrheal activity is also supported by the findings of Souli et al. [2] suggesting methanolic extracts of pomegranate juice to significantly reduce gastrointestinal transit time and number of defecation against castor oil-induced diarrhea in dose-dependent manner. Pomegranate seed oil is a rich source of minerals that might help in regulating mineral balance in diarrheal episodes. Hydrolysable tannins offer protein denaturation properties and form a protein-tannate complex that encourages more resistance to intestinal mucosa, inhibits gastrointestinal transit, and reduces excretion favoring its antidiarrheal activity [119, 120].

3.10 Role of Pomegranate in Modulating Renal Disorders

The importance of kidney function in clearing blood wastes is very evident from the fact that they receive 20% of total blood supplies with each cardia beat to clear the waste. Kidneys eliminate xenobiotics including endogenous metabolites, exogenous chemicals, and drugs through urine and prevent loss of nutrients such as glucose, inorganic ions, and oligopeptides. While in elimination and detoxification, kidneys are utmost exposed to xenobiotics that might cause oxidative stress, nephrotoxicity, and lipid peroxidation [121, 122]. Pomegranate aril and peel extracts show protective effect against nitrosamine and CCl_4-induced apoptosis and kidney injury via inhibiting generation of reactive oxygen species, lowering lipid peroxidation, and enhancing host antioxidative defense mechanisms [123]. Cisplatin – a platinum based inorganic drug – is widely used in the treatment of carcinoma. The drug is reported to cause renal functions impairment through ROS generation, inhibition of protein synthesis, and mitochondrial dysfunction. Pomegranate seed oil being rich in polyunsaturated fatty acids and antioxidants has been suggested as potent dietary approach to avert the risks of cisplatin-induced kidneys dysfunction. Pomegranate seed oil also reduces serum urea, renal nitric oxide, and malondialdehyde levels and upregulate thiol contents [124]. Use of pomegranate accessions like flower extracts (25 mg/kg b.w.) also improves gentamicin-induced weight loss and renal toxicity [125]. Pomegranate juice consumption by the heavy smokers has also shown remarkable ameliorative effects against nicotine-induced hepatorenal toxicity [126]. Pomegranate juice and peel extracts orally administrated to animal models at the rate of 3 ml/kg b.w. and 200 mg/kg b.w., respectively, for a period of 8 weeks substantially reduced cytokines markers and significantly improved steroid-induced kidney inflammation [11]. The clinical trials on exploring renal protective role of pomegranate demonstrate bioactive constituents of the fruit and waste fraction as precursors to activate immune system and enhance cellular antioxidative enzymes production that protect kidneys from inflammation-induced injury and dysfunction [4].

3.11 Pomegranate Perspective Potential in Improving Fertility

Pomegranates have potent beneficial effects in strengthening reproduction through improving spermatogenesis and semen production, maturation of epididymal

spermatozoa, and increasing blood testosterone level [13]. Consumption of phytosterols, punicalagin, quercetin, ellagic acid, and vitamin A-rich natural beverages alike pomegranate fruit juice improves sperm cell abnormalities induced by oxidative stress, bisphenol A, CCl_4, and lead acetate toxicity [127, 128]. Pomegranate juice significantly improves changes in female sex hormone levels and reduces symptoms of polycystic ovarian syndrome [129]. Oral administration of isoflavonoid-rich extracts of pomegranate rind to the animal models at 0.5 g/kg b.w. increased fertility through improved sperm count, sperm motility, and sperm quality. Cautious intake of pomegranate whole fruit extracts up to 5 mg/mL avoiding higher doses has potential to promote fertility [130, 131].

3.12 Wound Healing Properties of Pomegranate Accessions

Wound healing is a distinct process of biochemical and cellular events that involves immediate inflammation after injury to achieve homeostasis, tissue granulation, and collagen formation that imparts tensile strength in the remodeling phase of skin regeneration [132, 133]. Pomegranate pericarp and epicarp are historically used in folk medicines for their ameliorative effects in various ailments including excised and incised wound healing. Biochemical and histological examination revealed that pomegranate comprises tremendous antimicrobial and antioxidant features that aid in epithelialization and production of hydroxyproline to regenerate wounds [134, 135]. Pomegranate pericarp and epicarp extract-based ointment and gels have been extensively explored in the recent past to calculate their wound healing potential. The findings of the studies suggest that topical application of pomegranate polyphenols and lipophilic fractions-based ointments on cutaneous wounds (sores and lesions) result in significant wound recovery notably in diabetic patients [136, 137]. Topical administration of 100 mg/kg pomegranate extracts for a period of 15 days to incised wounds in experimental animals reduces 95% wound area as compared to 85% in control petroleum jelly-based ointment [138]. Pomegranate extracts (10–20%) when topically applied to burn wounds have also significantly reduced period of epithelialization analog to standard drug [139]. Pomegranate pericarp and epicarp extracts contain effective bioactive ingredients that aid in skin epithelialization and regeneration and may be recommended as a natural remedy in wound healing.

3.13 Cosmo Care Properties of Pomegranate

The skin is the most targeted and exposed site for pathogenesis from exogenous factors especially ultraviolet radiations (UVA and UVB) and microbiological infections. Exogenous factors like UV radiations induce genotoxicity and oxidative stress consequently creating skin disorders including immunosuppression, skin carcinoma, sunburn, and photoaging [140]. Pomegranate a mystical fruit famed as *a pharmacy unto itself* owing to its polyphenolic compounds, hydrolysable tannins, and organic acid fractions has a tonic effect in skin care [141, 142]. Fluorescence microscopy and

anisotropic measurements present skin-protective effect of pomegranate seed oil and peel extracts nanoemulsions entrapped with punicic acid and polyphenol-rich ethyl acetate fraction against reactive oxygen species and UVB-mediated DNA and lipid bilayer biomembrane damage [143, 144]. Acne – a plaguing skin disorder – is recognized by sebaceous glands hyperactivity and inflammation leaving scars due to loss in equilibrium of symbiotic skin microbiota. Pomegranate fruit rind and bark rich in hydrolysable tannins (especially punicalagin) exhibit multiple anti-acne abilities including blood purification, antibacterial, anti-inflammatory, and anti-keratinocyte proliferation activity [145, 146]. Owing to photoprotective and eco-friendly effects of pomegranate, seed oils and rind extracts of the fruit can be utilized in skin beautification, combination cosmo care products, and as skin protection factor sunscreen [20, 147].

3.14 Pomegranate Role in Maintaining Oral Hygiene

Orodental health is mostly affected by plaque-forming biofilms and cariogenic bacteria that seek habitat in oral cavity. Several chemotherapeutic agents including chlorhexidine, bisbiguanides, and fluorides containing mechanical floss and gels have been formulated to ensure orodental hygiene [148]. However, long-term use of such chemotherapeutic agents develops resistance in bacterial strains and promotes tooth staining. Such a situation calls for the development of herbal products as an alternative therapy to orodental chemotherapeutic agents [149]. In vivo and in vitro studies have confirmed flavonoids, tannins, vitamins, and minerals-rich fractions of pomegranate as anticariogenic and anti-plaque natural formulations. Pomegranate polyphenols have strong tendency toward inhibiting growth of plaque-forming bacteria including *Streptococcus sanguis* and *Pseudomonas aeruginosa* [150, 151]. Use of pomegranate mouthwash effectively reduced gingivitis (gum bleeding) and periodontitis (gum infection) in comparison with 0.2% chlorhexidine standard mouth rinse [15, 152]. Topical application of oral gel containing 10% pomegranate extracts relieves pain and reduces time for wound healing in aphthous stomatitis (oral ulcer) disorder [153]. Pomegranate fruit extracts efficiently reduce production of bacterial secondary metabolites, sucrose catabolizing enzyme α-glucosidase activity, aspartate aminotransferase activity, and upregulation of ceruloplasmin that inhibits oral oxidative stress [93, 154]. Promising features of pomegranate extracts against several orodental distresses encourage development of pomegranate and its extracts-based natural oral care formulations as alternate to synthetic and chemo-therapeutic products.

4 Conclusions

Clinical trials in human subjects and animal models have demonstrated significant effect of pomegranate consumption in improving the body's inherited defense against various forms of infections, inflammatory, and non-inflammatory disorders.

In comparison with the fruits of the same and other classes, pomegranate has shown broader applicability against serious maladies. Unlike synthetic drugs, heterogeneous biochemical composition of pomegranate and its extracts has ability to manipulate multiple biochemical pathways that can further be exploited for the treatment of various complex disorders. Controlled and clinical trials on pomegranate and its hydroalcoholic extracts have been regarded as safe for human health at orally administrated doses supplying up to 2000 mg polyphenols per day. However, exploitation of pomegranate and derived bioactive compounds as therapeutic agent either alone or in combination calls for careful experimentation to rule out genotoxic response of the plant material.

Abstract

Diabetes mellitus is a disease that requires long-term management and sometimes last throughout the lifetime of the patient. Persistent hyperglycemia experienced in diabetes over long period results in diabetic complications, such as nephropathy, neuropathy, retinopathy and cardiovascular diseases. One of the mechanisms involved in the development of diabetic complications is glycation which caused the production of advanced glycation end products (AGEs). Therefore, any agent that prevents the formation of AGEs may be suitable for the management of diabetes and its complications. There is a plethora of studies on the antiglycation properties of many foods and their products, but there is no repository of their information. This is an attempt to review the available information on the role of antiglycation agents from functional foods in the management of diabetic complications. We hope this information will assist diabetic patients in the choice of their diets and stimulate further research on these foods.

Keywords

Glycation · Advanced glycation end products · Functional foods · Diabetes · Diabetic complications

List of Abbreviations

AGE	Advanced glycation end products
BSA	Bovine serum albumin
GOLD	Glyoxal-lysine dimer
MOLD	Methyglyoxal-lysine dimer
RAGE	Receptor for advanced glycation endproduct

1 Introduction

Diabetes mellitus is a metabolic disorder characterized by hyperglycemia due to defects in insulin secretion and/or action [1]. It causes alteration in the carbohydrate, lipid, and protein metabolism of its sufferers leading to a variety of micro- and macrovascular complications, which include nephropathy, neuropathy, and retinopathy [2]. Diabetes is a global problem affecting 382 million people in 2013, and this number is projected to increase to 572 million in 2035 [3]. The disease caused 5.1 million deaths and more than 21 million live births were affected by it during pregnancy, making it the third "killer" of mankind after cancer and cardiovascular diseases [3].

Persistent hyperglycemia experienced by diabetic patients promotes an unhealthy interaction between the excess blood glucose and some proteins like collagen, hemoglobin, and lens crystallins [4], and this is called glycation. Glycation is a spontaneous nonenzymatic reaction between the carbonyl group of reducing sugars and amino group of amino acids, peptides, or proteins to form a freely reversible Schiff base that rearranges to a more stable ketoamine called Amadori products [4]. This is then followed by complex series of reactions such as condensation and oxidative modification to produce several heterogenous products known as advanced glycation end products (AGEs) [5] (Fig. 1). Glycation is also referred to as nonenzymatic glycosylation or Maillard reaction because the process was first described by Louis Camille Maillard in 1912 [6].

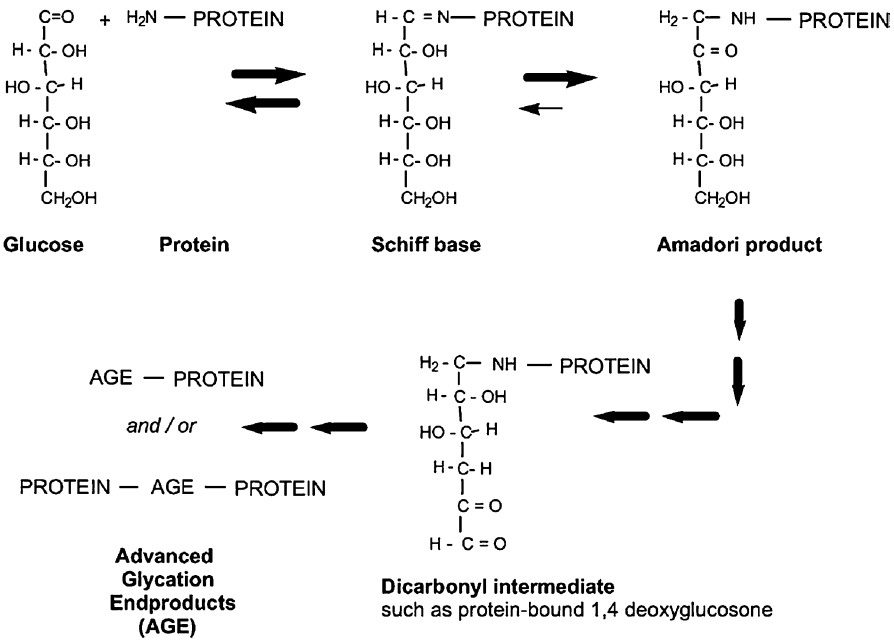

Fig. 1 Chemistry of glycation reaction to form advanced glycation end products [6]

The formation of AGEs may alter the physicochemical properties of the proteins, and in turn adversely affect their functional properties [7]. Excessive generation of AGEs is implicated in several pathological conditions, such as cardiovascular diseases, neurodegenerative diseases, inflammation, aging, and diabetes mellitus [4]. Previous studies have also established the role of AGEs in the development of diabetic complications [8–10]. Therefore the mitigation of protein glycation will be an effective medium of preventing or ameliorating these complications. There is a continuous demand for agents with antiglycation properties, as they may be useful in preventing diabetic complications [11, 12]. Though some synthetic antiglycation agents like aminoguanidine and pyridoxamine have been discovered, they have serious toxicity issues [8]. Therefore, food-derived antiglycation agents will be more appropriate in the management of diabetic complications due to their safety and availability to the general populace.

This review attempts to compile a repository of plant foods, which have been validated to display antiglycation potential (Table 1). This will serve as a guide to future references for researchers in institutions and pharmaceutical industries, for further studies aimed at isolation of their active components and large-scale production. It will also assist diabetics and their families in the choice of foods that will be consumed, in order to ameliorate the debilitating effects of diabetes and its complications.

2 Formation of Advanced Glycation End Products

AGEs are complex, heterogeneous molecules that cross-link proteins, exhibit browning, and generate fluorescence. The generation of reactive intermediate products, such as α-dicarbonyls, α,β-unsaturated aldehydes, dialdehydes, and keto-aldehydes, is very important in the formation of AGEs [6]. α-Dicarbonyls include 3-deoxyglucosone, glyoxal, and methylglyoxal. 3-Deoxyglucosone is formed by nonoxidative rearrangement as well as hydrolysis of Amadori product, and by fructose-3-phosphate. It rapidly reacts with protein amino groups to form AGE such as imidazolone, pyrraline, and carboxymethylysine [4, 13]. Methyglyoxal can be produced nonenzymatically from the spontaneous decomposition of triose phosphates, autoxidation of carbohydrates, glucose degradation, and also by several minor metabolic pathways, including the Maillard reaction [10]. In addition to reaction with arginine residues to form imidazolone adducts, methyglyoxal reacts with lysine residues in protein to form carboxyethylysine and the imidazolium crosslink, methylglyoxal-lysine dimer (MOLD).

Due to the variety of AGEs, they are broadly classified on the bases of their formation into three:

(i) Fluorescent cross-linking AGEs, e.g., pentosidine and crossline
(ii) Nonfluorescent cross-linking AGEs, e.g., Glyoxal-lysine dimer (GOLD) and methyglyoxal-lysine dimer (MOLD)
(iii) Noncross-linking AGEs, e.g., carboxymethylysine and pyralline

Table 1 List of functional foods with antiglycation potential

Name	Part	Extract	Test	Method(s)	Ref(s)
Bael	Fruits	Methanol	In vitro	BSA-glucose	[14]

(*continued*)

Table 1 (continued)

Name	Part	Extract	Test	Method(s)	Ref(s)
Rambutan	Fruit	Ethanol	In vitro	BSA glucose	[53]
	Fruit	Geraniin	In vitro	BSA glucose	[54]
Sickle senna	Seeds	Glucosides	In vitro	BSA glucose	[55]
	Seeds	Anthraquinones	In vitro	BSA glucose	[56]
Kokum	Fruits	Garcinol	In vitro	BSA fructose	[57]
Luobuma tea	Leaves	Flavonoids	In vitro	BSA glucose	[58]
Sangwhang	Fruiting body	Isolates	In vitro	HbA1c formation	[59]
Clove	Buds	Water	In vitro	BSA-fructose	[60]

However, AGEs can also be classified on the basis of their lifespan into long-lived and short-lived molecules. In addition, most AGEs are formed endogenously but some can also be derived from exogenous sources such as foods and tobacco [9].

3 Antiglycation Agents from Fruits

3.1 Banana

Banana (*Musa paradisiaca*) is an herbaceous plant used as foods by man worldwide. The flower and pseudostem are used for the culinary purpose in some countries [61], while the fruit is consumed raw, cooked, or fried in all parts of the world. The leaves are also used in the wrapping of foods which adds characteristic aroma to the food and prevents burning. The flower and inflorescence have been reported with antidiabetic activity [62, 63]. Methanolic extract and different solvent fractions of banana inflorescence were evaluated for their antiglycation activities using the BSA-glucose antiglycation model [16]. Methanol extract as well as ethanol, water, and butanol fractions displayed good antiglycation activities with IC_{50} 44, 31, 55, and 68 μg/mL respectively, and are comparable to standard antiglycation agent, aminoguanidine (IC_{50}: 61 μg/mL).

Also, the antiglycation effect of ethanol extract of banana flower and two compounds isolated from it was investigated [17]. Ethanol extract of banana flower, lupeol (Fig. 2a), and umbelliferone (Fig. 2b) inhibited the formation of early-stage glycation product (fructosamine) by 85–90% and protein carbonyl compounds by 80–86%. However, fluorescence study on the late stage glycation moieties (AGEs) showed that the extract and compounds inhibited it by 71–82%. The rate of inhibition by this extract and compounds were significantly higher than the standard, aminoguanidine.

To ascertain the antiglycation effect of banana in animal model, the effect of banana flower and pseudostem on serum fructosamine and advanced glycation end

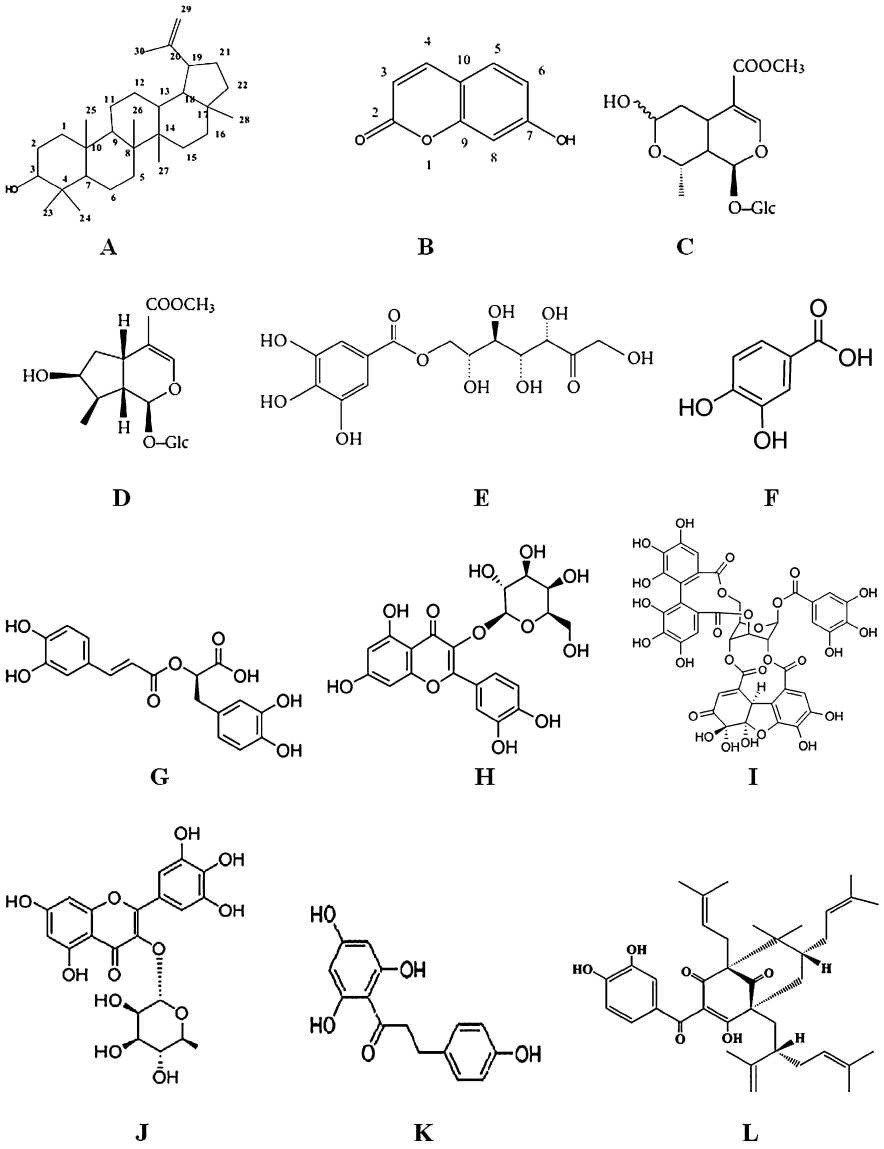

Fig. 2 Structures of some antiglycation compounds from fruits. (**a**) Lupeol; (**b**) Umbelliferone; (**c**) Morroniside; (**d**) Loganin; (**e**) 7-*O*-galloyl-D-sedoheptulose; (**f**) Protocatechuic acid; (**g**) Rosmarinic acid; (**h**) Quercetin-3-*O*-galactoside; (**i**) Geraniin; (**j**) Myricetin-3-O-rhamnoside; (**k**) Phloretin; (**l**) Garcinol

products (AGEs) in streptozotocin-induced diabetic rats was reported [18]. Supplementation of Wistar rat's diet with banana flower and pseudostem significantly decreased the serum fructosamine levels (2.15 and 2.37 moles/mg protein) compared with diabetic untreated rats (3.19 moles/mg protein). The concentration of serum

AGEs was also reduced by 61.5% and 51.2% in the banana flower and pseudostem fed rats compared with the diabetic control. This showed that banana exhibited antiglycation property in both in vitro as well as in vivo model, and this property may be due to the presence of umbelliferone and lupeol.

3.2 Cornelian Cherry

Cornelian cherry (*Corni fructus* or *Cornus officinalis*) is a common plant in China, Korea, and Japan, where it found usage as a functional food and as a component of traditional medicine [25]. Several studies have been carried out on the in vivo antiglycation potential of Cornelian cherry in rats. The beneficial effect of Cornelian cherry on AGE-mediated renal injury in streptozotocin-induced diabetic rats was reported [24]. Administration of 100 and 200 mg/kg of Cornelian cherry extract to diabetic rats for 10 days significantly reduced the renal AGE level to 5.32 and 4.92 IU compared with 6.19 IU in the diabetic control group. The renal AGE level of the diabetic rats administered 200 mg/kg cornelian cherry was similar to the group that received standard antiglycation agent, aminoguanidine.

Administration of 20 mg/kg iridoid glycoside and low molecular weight polyphenol fractions of Cornelian cherry to streptozotocin-induced diabetic rats for 10 days also showed that the iridoid glycosides fraction significantly reduced serum glycosylated protein (19.7 nmol/mg protein) and renal AGE (3.90 IU) compared with diabetic control (21.5 nmol/mg protein and 4.45 IU respectively), while the polyphenol fractions caused downregulation of receptor for advanced glycation end products (RAGE) to a value of 1.58 and 1.21-fold lower compared with the normal rats [24]. The active components of the iridoid glycoside fraction were identified to be morroniside (Fig. 2c), loganin (Fig. 2d), mevaloside, 5-hydroxymethyl-2-furfural, and loganic acid while the only component of the polyphenol fraction was 7-*O*-galloyl sedoheptulose (Fig. 2e).

In order to identify the compounds responsible for the antiglycation property of this plant, aqueous extract of Cornelian cherry and some of its active compounds (loganin, morroniside and 7-*O*-galloyl-D-sedoheptulose) were tested for their antiglycation activities using BSA-fructose model [23]. Out of this compounds, only 7-*O*-galloyl-D-sedoheptulose displayed good antiglycation activity (61.90%) at 25 μg/mL. Elsewhere, another component of the cornelian cherry fraction, morroniside, was also evaluated for its protective effect on renal damage in streptozotocin-induced diabetic rats [26]. Administration of 100 mg/kg of morroniside to diabetic rats for 20 days caused a significant reduction in the level of serum glycosylated protein (HbA1c) and thiobarbituric acid reactive substances, compared with the diabetic control. It also reduced the expression of AGE-related proteins such N-carboxylmethylysine and RAGE of the diabetic rats. It, therefore, implies that cornelian cherry exhibited antiglycation potential, which may due to the presence of its phytochemicals, 7-*O*-galloyl-D-sedoheptulose and morroniside.

3.3 Guava

Guava (*Psidium guajava* L.) is a widely cultivated plant in tropical and subtropical countries. The fresh fruit is eaten raw while the combination of its dried leaves and fruits are used in the preparation of drink known as guava tea [36]. Several compounds have been isolated from different parts of this plant, which include guavanoic acid, guavacoumaric acid, β-sitosterol-3-*O*-β-D-glucopyranoside, and jacoumaric acid [64]. The antiglycation potential of ethylacetate fraction of guava leaf extract in streptozotocin-induced diabetic rats was investigated [36]. Oral administration of 100 mg/kg of ethylacetate fraction of guava leaf extract to diabetic rats for 30 days caused about a two-fold reduction in the plasma glycated hemoglobin (HbA1c) (3.94%) compared to the diabetic control group (7.62%). Significant decrease was also witnessed in the serum fructosamine level of the guava-extract fed diabetic rats (227.97 μmol/L) compared with diabetic untreated group (258.30 μmol/L). This report is also corroborated by a similar study [37].

In order to evaluate the in vitro antiglycation effect of guava, guava leaf extracts and some of its active compounds were tested on α-dicarbonyl compounds-induced blood coagulation [35]. Guava leaf extract (0.001 mg/mL) significantly inhibited hypercoagulation induced by methylglyoxal but does not have an effect on the prothrombin clotting time. Guava leaf extract and its active compounds (gallic acid, ferulic acid, and quercetin) also protected antithrombin III from methylglyoxal-induced loss of activity. Guava leaf extract at the concentration of 50 μg/mL also exhibited strong inhibition (over 90%) of α-dicarbonyl compounds formation [34]. Catechin, gallic acid, and quercetin (from the guava extract) also displayed over 80% inhibitory effect on α-dicarbonyl compounds formation while ferulic acid did not. Both the extract and active compounds of guava leaf inhibited the formation of Amadori products (fructosamine) and AGEs from albumin in the presence of glucose. This α-dicarbonyl compounds formation was confirmed when the ethyacetate extract of guava leaf exhibited an IC_{50} value of 38.95 μg/mL for the inhibition of protein glycation, which is similar to the activity of standard antiglycation agent, aminoguanidine (IC_{50}: 33.82 μg/mL) [36]. Therefore, guava is a potent source of antiglycation agent, which may be due to the presence of phytochemicals such as gallic acid, quercetin, and ferulic acid.

3.4 Apples

Apples (*Malus domestica*) are one of the most important fruits in the world that are rich in phytochemicals, which include catechins, epicatechin, chlorogenic acid, *p*-coumaric acid, and protocatechuic acid [65]. Though apple is eaten raw as food, it is also processed into different products such as juice, nectar, and puree due to its health-promoting potentials. In a BSA-fructose antiglycation assay, aqueous extract of apple and green-tea fortified apple displayed anti-AGE formation activities of 15 and 48 mg/kg dry weight, respectively [15]. This implies that aqueous extract of apple displayed good antiglycation potential in-vitro, however fortification of apple with green tea increased its ability to inhibit AGEs formation.

3.5 Bael

Bael (*Aegle marmelos* L. Corr.), also known as golden apple, bael apple, wood apple, and stone apple, is native to India. It is a commonly used food with varieties of biological properties [66]. Several compounds isolated from the bael fruits, include aegelin, eugenol, marmelosin, lupeol, and fagarin [67]. It also contains tartaric acid, flavon-3-ols, anthocyannins, and flavonoid glycosides [68]. The fresh and dried fruits are used in the preparation of lemonade-like "soft drink" [14] while the leaves are eaten as salads. Methanolic extract of bael apple exhibited strong antiglycation potential with an EC_{50} value of 60.14 μg/mL in a BSA-glucose antiglycation experiment [14]. This suggests that consumption of bael fruits could help in the prevention and or amelioration debilitating effect of diabetes and its complications.

3.6 Bitter Melon

Bitter melon (*Momordica charantia* L.) is a plant which is consumed as food and used as an ingredient in some Asian curries. The stem and fruits could be a source of teas while the fruits are eaten raw mostly in Asia [69]. It is one of the popular plants used in the management of diabetes mellitus and its complications in different parts of the globe [70]. Several compounds have been isolated from its fruit, which includes charantin, momordicins, cucurbitacin, gentisic acid, and diosgenin [69]. A pilot study on the hypoglycemic and antiglycation potential of bitter melon was investigated in type 2 diabetic patients for 16 weeks [51]. The study involved the consumption of 6.0 g dried fruit powder of bitter melon daily by the diabetic patients throughout the duration of the experiment, which resulted in significant reduction in the levels of blood glucose, glycated hemoglobin (HbA1c), and serum AGEs of the patients by 9.49%, 6.69%, and 6.65%, respectively. It implies that consumption of bitter melon fruit can ameliorate diabetes mellitus and prevent the onset of its complications. However, there is a need for in vitro evaluation of the antiglycation activity of bitter melon and subsequent bioassay-guided fractionation of its active components.

3.7 Common Juniper

Common juniper (*Juniperus communis* and *oblonga*) is an evergreen shrub which is endemic to Europe, Asia, and North America. Common juniper is used as spice for food such as meat and as flavor in the preparation of alcoholic beverages [71]. Inhibition of protein glycation by essential oils of branchlets and fruits of common juniper was investigated [39]. Essential oils from the branchlet of male tree, female tree, and fruits inhibited the glycation of hemoglobin at all concentrations (200, 400, and 600 μg/mL) tested. However, the rate of inhibition of glycation is inversely proportional to the concentration of the oils which accounted for the highest inhibitory activities occurring at the lowest concentration (89.9%, 74.7%, and 62.8% for male branchlet, female branchlet, and fruit oils, respectively). Essential oil from the

fruit also displayed its highest inhibitory activity on insulin glycation at 200 μg/mL (78.4%), while that of the male (64%) and female branchlet (81%) inhibited it most at 600 μg/mL [40]. The antiglycation activity of common juniper may be due to the variety of components present in its essential oil. These include α-pinene, limonene, α-thujene, terpinen-4-ol, and isoterpinolene [39].

3.8 Grapevine

Grapevine (*Vitis vinifera* L.) is one of the largest food crops in the world due to its widespread consumption among people [72]. Its fruit is a berry which can be green, red, or purple in color, and can be taken fresh, processed to make juice and wine, or dried to produce raisins. It is a rich source of many phenolic compounds ranging from catechins, epicatechin, epicatechin-3-*O*-gallate, and procyanidins [72]. The inhibition of AGEs by red grape skin extract was investigated [47]. After 4 weeks of incubation, the grape extract (0.031–0.5 mg/mL) inhibited the formation of AGE by 55.23–63.52%. The extract (0.5 mg/mL) also reduced the level of fructosamine and carbonyl content generated by 10.5% and 41.7%, respectively. Incubation with 0.5 mg/mL extract also caused significant improvement (50.4%) in the level of protein thiol group and concomitant decrease (58.1%) in the carboxylmethylysine content. The study suggests that red grape extract inhibited all the stages (early, intermediate, and late stage) involved in the formation of AGEs, which makes it a veritable source of antiglycation agents.

3.9 Saucer Berry

Grey-leaved saucer berry (*Cordia sinensis* Lam.) is found in Eastern African and Middle Eastern countries of the World. The fruits and gum are consumed as food, while the fruits are also taken in many cuisines. Several chemical compounds have been isolated from this plant, which include transcaffeic acid, methylrosmarinate, protocatechuic acid (Fig. 2f), kaempferide-3-*O*-β-D-glucopyranoside, kaempferol-3-*O*-β-D-glucopyranoside, rosmarinic acid (Fig. 2g), and quercetin-3-*O*-β-D-glucopyranoside [43]. The evaluation of isolated compounds from grey-leaved saucer berry for their in vitro antiglycation potential was also reported [43]. All the compounds tested showed good antiglycation activities by exhibiting higher percentage inhibition of glycation which ranges between 68.0% (for protocatechuic acid) and 88.4% (methylrosmarinate). Though these compounds displayed good antiglycation activities, there is need for more tests to determine their IC_{50} values. This will enable comparison with similar plants and with standard antiglycation agents.

3.10 Lingonberry

Lingonberry (*Vaccinium vitis-idaea* L.) is a low shrub bearing bright red fruits which is most common in Russia and the Nordic countries. The fruits are eaten raw or

processed into jam, juice or syrup, and as an ingredient in dishes [73]. It is also used by the Cree population of Canada in the treatment of diabetic symptoms like frequent urination, abscesses, and snow blindness [74]. The inhibitory effect of lingonberry and its active compounds on the formation of AGEs was investigated [50]. Ethanol extract of lingonberry exhibited concentration-dependent inhibition of BSA-glycation which culminated in IC_{50} of 13.50 μg/mL. Four compounds isolated from this extract were also tested for their antiglycation activities. Quercetin-3-*O*-galactoside (Fig. 2h), cyanidin-3-*O*-galactoside, and catechin exhibited good anti-glycation potential with IC_{50} 2.86, 3.10, and 8.35 μg/mL respectively, while *p*-coumaric was not active. This study demonstrated lingonberry as an inhibitor of AGEs formation, however there is a need for validation of this property in animal or human model. The antiglycation activity may be due to the presence of phytochemicals like quercetin-3-*O*-galactoside, cyanidin-3-*O*-galactoside, and catechin.

3.11 Longan

Longan (*Dimocarpus longan* Lour.) is a tropical tree that produces exotic, attractive, and edible fruits. The fruit is a thin and indehiscent pericarp with succulent edible mesocarp and dark brown seed [75]. The fruits and seeds of this plant are rich in phenolic compounds, such as ellagic acid, corilagin, kaempferol, grevifolin, and gallic acid [76]. The fruit is also eaten by consumers globally due to its sweet juicy mouth feel and aromatic flavor [77]. The antiglycation activity of polysaccharides of longan fruit was investigated [41]. The study showed that polysaccharides obtained after ultrasonic treatment under different conditions exhibited a potent antiglycation effect in BSA-glucose glycation system. However, detailed characterization of the possible antiglycation property of this fruits is imperative.

3.12 Passion Fruit

Passion fruit (*Passiflora manicata*) is a tropical plant which is characterized with brightly colored flower and edible fruit. Its fruit is also used in the preparation of beverages, while the leaves are used for medicinal purpose as sedative and tranquilizer. The presence of chemical compounds such as vitexin, isovitexin (Fig. 4a), and orientin in the leaf extract of passion fruit was reported [78]. Coincubation of aqueous extract of passion fruit (1–100 μg/mL) with BSA-glucose medium caused significant reduction in the total glycated protein, and these results were similar to that of the standard phenolic compound, tannic acid [45]. HPLC analysis of the extract also showed the presence of active compounds such as isoorientin, vitexin, and isovitexin, which might be responsible for the antiglycation property of the plant.

3.13 Pomegranate

Pomegranate (*Punica granatum* L.) is a shrub or small tree which grows between 5 and 8 m tall, and possesses large berry fruits. The plant originated from the Middle

East and extends throughout the Mediterranean to Southern America [79]. All parts of the plant are useful, especially the fruit which is used in the preparation of juicy drink while the seeds are used as spice for food. Several chemical compounds are reportedly present in this plant, which include gallic acids, ellagic acid, caffeic acid, luteolin, apigenin, dephinidin, and pelargonidin [79]. The antiglycation property of polysaccharide fraction isolated from the fruit rind of pomegranate was investigated [46]. The polysaccharide fraction (10–20 μg/mL) was able to inhibit BSA glycation by only 28% as against 41% displayed by vitamin C. It also reduced the formation of fructosamine by 50% after 7 day incubation, which suggested mild antiglycation potential. The presence of polyphenols, such as gallic acid, ellagic acid, and caffeic acid, may be responsible for the antiglycation activity of this plant.

3.14 Shaddock

Shaddock (*Citrus grandis* L. Osbeck), also referred to as pomelo or pummelo, is one of the most cultivated crops in South-East Asia due to its consumption as food and usage in traditional medicine [80]. Previous study has showed this fruit is rich in bioactive compounds such hesperidin, naringenin, and naringin [81]. The effect of shaddock fruit on the concentration of AGEs, fructosamine, carbonyl carbonyl, and carboxymethylysine was reported [22]. The shaddock extract (0.25–2.00 mg/mL) significantly inhibited the formation of AGEs in concentration-dependent manner to a maximum of 90.68% on the 28th day. The extract also reduced fructosamine concentration by 3.7, 9.9, 17.5, and 30% at 0.25, 0.50, 1.00, and 2.0 mg/mL, respectively. Concomitant reduction was also witnessed in the formation of carbonyl and thiol compounds, following incubation with shaddock extract. The antiglycation activities of shaddock may due to the presence of phytochemicals like neohesperidin, naringin, hesperidin, and naringenin [22].

3.15 Rambutan

Rambutan (*Nephelium lappaceum* L.) is a tropical fruit which is native to South East Asia. It is mostly found in Malaysia, Indonesia, Thailand as well as Philippines, and spread to other parts of the world. Its fruit has a refreshing flavor and exotic appearance and can be consumed fresh or in processed form [82]. Some chemical compounds have been isolated and identified from this fruit, such as ellagic acid, corilagin, and geraniin [83]. The potency of rambutan in the management of hyperglycemia was investigated [53]. Ethanolic extract of rambutan inhibited the formation of AGEs by 43% in a BSA-glucose glycation model. This result was better than that of green tea (38%), which was earlier reported as better antiglycation agent than the standard, aminoguanidine [34]. Isolation and purification procedures on rambutan fruits yielded a pure compound, geraniin (Fig. 2i), which exhibited a very high (98%) inhibition of AGE formation [54]. It can therefore be concluded that rambutan displayed antiglycation activity, which is due to the presence of geraniin in it.

3.16 Water Apple

Water apple (*Syzygium aqueum* Alston) is a tropical plant which originated from Malaysia and Indonesia. It is cultivated for its sweet tasty, bell-like fruits called apples that are consumed fresh, and its leaves which are used as vegetables and in wrapping other foods [84]. The inhibitory effect of ethanol leaf extract of water apple on the formation of AGEs and the isolation of its active components was investigated [48]. The extract displayed strong inhibitory potential against the formation of AGEs (89%), which was higher than green tea (45%) which served as positive control. Six pure compounds were also isolated from the extract which included 4-hydroxylbenzadehyde, myricetin-3-*O*-rhamnoside (Fig. 2j), europetin-3-*O*-rhamnoside, phloretin (Fig. 2k), myrigalone-G, and myrigalone-B. Therefore, water apple exhibited good antiglycation potential, which may be due to the presence of the chemical compounds present in it.

3.17 Kokum

Kokum (*Garcinia indica* Choicy) is an underexploited tree distributed throughout the tropical Asian and African countries. Its fruit is characterized by pleasant flavor and sour taste, and is used as an acidulant in dishes as well as in the production of beverages and butter [85]. Phytochemical study showed that the fruits contain cyanidin-3-glucoside, cyanidin-3-sambubioside, garcinol (Fig. 2l), isogarcinol, and hydroxycitric acid [68]. The leaves and fruits are traditionally used in the treatment of different ailments like inflammation, diarrhea, dysentery, ulcers, and indigestion. The antiglycation activity of garcinol isolated from the fruit rind of kokum was investigated in BSA fructose model [57]. They showed that garcinol suppressed fluorescence and protein cross-link formation in the reaction system, better than aminoguanidine. Therefore, kokum leaves inhibited the formation of AGEs in vitro, which may be attributed to its phytochemical compounds especially garcinol.

4 Antiglycation Agents from Beverages

4.1 Black Tea

Black tea (*Camellia sinensis* L.) is one of the most popular beverages consumed worldwide, and is made by fermentation and drying of the leaves of the plant, *Camellia sinensis*. The fermentation of this tea converts catechins to theaflavins and thearubigins, thereby decreasing catechin content [86]. The main components of black tea include catechins (e.g., epigallocatechin gallate), quercetin, rutin, caffeic acid, theaflavins, and thearubigins [87]. The in vitro antiglycation and cross-link breaking potential of black tea from Sri Lanka was reported [19]. Black tea brew exhibited strong antiglycation (IC_{50}: 19.04 μg/mL) and AGEs cross-link breaking (IC_{50}: 82.89 μg/mL) activities, and these activities were similar to that of popular antiglycation agent, rutin.

4.2 Green Tea

The steaming of freshly harvested leaves of *Camellia sinensis* yields dry and stable product referred to as green tea [86]. Though it is obtained from the same plant as black tea, its chemical composition is quite different because it has higher quantity of catechins (epicatechin, epicatechin-3-gallate, epigallocatechin-3-gallate, and epigallocatechin) and do not possess theaflavins and thearubigins [86]. The reduction of protein glycation by ethanol extract of green tea in the cardiac tissue of streptozotocin-induced diabetic rats was reported [52]. Oral administration of 300 mg/kg green tea extract to diabetic rats for 4 weeks significantly reduced the extent of cardiac protein glycation from 235.70 mg/mg protein in diabetic control rats to 185.30 mg/mg protein in the green tea–treated diabetic rats. The study also revealed the extract contained 33.5%, 28.5%, 13.5%, and 3.8% of epigallocatechin, epigallocatechin-3-gallate, epicatechin-3-gallate, and epicatechin, respectively. This antiglycation property may be connected to the presence of catechins in the tea.

4.3 Luobuma Tea

Another tea plant with antiglycation potential is luobuma (*Apocynum venetum* L.). This plant is native to China but widely distributed in the temperate zones of Eurasia and North America. Its leaves are used in the preparation of beverage called luobuma tea in China, Japan, and the USA. It is also used in Chinese traditional medicine in the treatment of inflammation, hypertension, hepatitis, and diuresis [88]. Several phytochemicals have been isolated from this plant, which includes apocyanins A, B, C, and D, as well as apocynosides I and II [88]. Aqueous extract of Luobuma leaves exhibited better antiglycation activity than the standard, aminoguanidine with IC_{50} 37.2 and 59.2 μg/mL, respectively [58]. Furthermore, all the seven isolated compounds (catechin (Fig. 3a), epicatechin (Fig. 3b), gallocatechin (Fig. 3c), epigallocatechin, epicatechin-(4β-8)-gallocatechin, epigallocatechin-(4β-8)-epicatechin and procyanidin B-2) from this extract also displayed excellent antiglycation activities, with IC_{50} values ranging between 9.1 and 19.8 μg/mL. Therefore, antiglycation compounds from luobuma tea could be explored further as possible candidates for the development of antiglycation drugs in the treatment of diabetic complications.

4.4 Yerba Mate

Yerba mate (*Ilex paraguariensis* St. Hil.) is a popular tree in the South American countries of Paraguay, Uruguay as well as parts of Argentina and Brazil. It is used in the preparation of tea called Mate tea by the infusion of dried leaves of the plant. It is commercially packaged in tea bags or concentrates, for usage in the food and dietary supplement industries [89]. Due to its nutraceutical properties, mate is used as an ingredient in energy drinks, candy, and beer [90]. Coincubation of bovine serum albumin (BSA) and methylglyoxal with yerba mate extract caused a dose-dependent

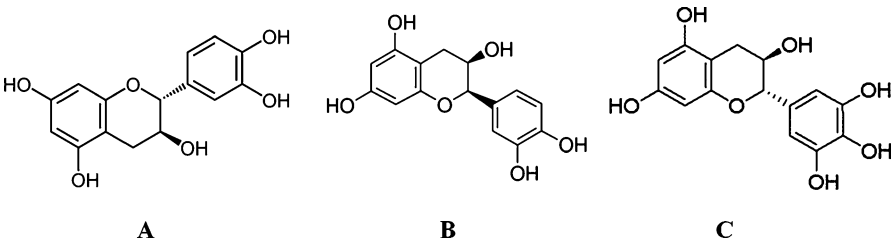

Fig. 3 Structures of some antiglycation compounds from beverages. (**a**) Catechin; (**b**) Epicatechin; (**c**) Gallocatechin

inhibition of glycation reaching up to 40% at 20 μL/mL of the extract, which implies good antiglycation effect [38]. This may be due to the presence of some phytochemicals, such as methylxanthines, matesaponnins, chlorogenic acids, and 4,5-dicaffeoylquinic acid [89], in the plant.

4.5 Dendrobii

Dendrobii (*Dendrobium huoshanense*) is another antiglycation tea plant which is endemic to Huoshan town, Anhui Province of China. It is used as spice in the preparation of foods such as soups and as herbal tea or functional beverage for the protection of the eye, liver, and stomach [91]. Phytochemical analysis revealed the presence of many compounds like polysaccharides, 6,8-di-*C*-glycosyl flavonoids, shikimic acid, and salicylic acid [92]. The antiglycation activity of polysaccharides extracted from dendrobii has been reported [29]. Polysaccharides from dendrobii inhibited the formation of amadori product in a dose-dependent manner to maximum of 72.54%, which was about 1.95 fold greater than that of aminoguanidine. The formation of intermediate dicarbonyl compound and AGEs was also decreased to a minimum of 51.9%, which was lower than that of aminoguanidine. The inhibition of glycation by these polysaccharides of dendrobii may be due to their antioxidant properties.

5 Antiglycation Agents from Legumes

5.1 Mung Bean

Mung bean (*Phaseolus radiata* L. Wilczek), also referred to as green gram or moong bean, is a legume which is native to the Indian subcontinent but widely cultivated in the Southeast Asian countries. The inhibitory effect of mung bean extract and some of its active constituents on the formation of AGEs was investigated [44]. Hydroethanol extract of mung bean displayed the highest inhibitory activity (80.4%) against AGEs formation compared to other variety of beans such as black bean (72.1%), soybean (70.1%), and cowpea (67.3%). Two active components isolated from mung bean, vitexin (Fig. 4a)

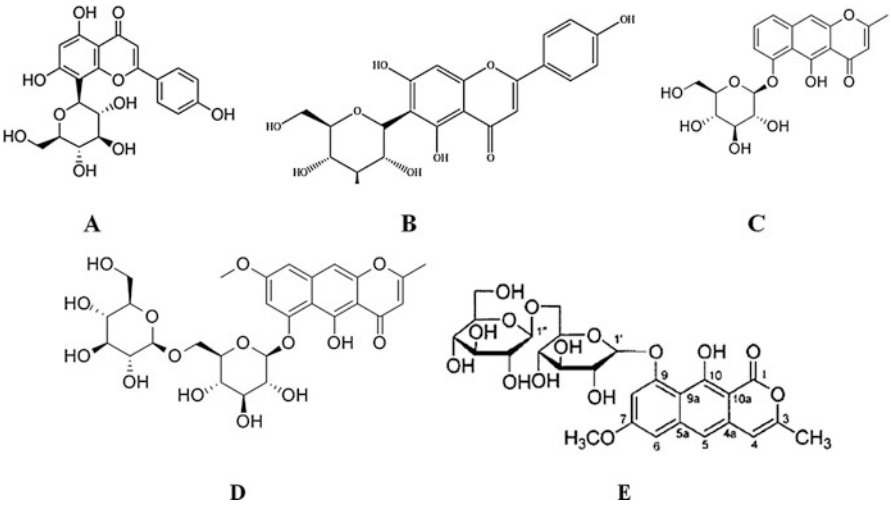

Fig. 4 Structures of some antiglycation compounds from legumes. (**a**) Vitexin; (**b**) Isovitexin; (**c**) Cassiaside; (**d**) Rubrofusarin-6-O-β-D-gentiobioside; (**e**) Toralactone-9-*O*-β-gentiobioside

and isovitexin (Fig. 4b) at 100 μM, also exhibited a strong inhibitory effect on fluorescent AGEs formation induced by methyglyoxal similar to the activity of 1 mM aminoguanidine [44]. However, both compounds have weaker direct methylglyoxal-trapping activities than aminoguanidine. Therefore, mung bean displayed antiglycation effect which may be due to the presence of phytochemicals like vitexin and isovitexin.

5.2 Buckwheat

Buckwheat (*Fagopyrum sp.*) is a plant that is cultivated for its seeds, which is used as food. There are two major varieties of buckwheat: common buckwheat (*Fagopyrum esculentum*) which is sweet, and tartary buckwheat (*Fagopyrum tataricum*) which has a bitter taste [93]. However, the chemical composition of both is similar which include chlorogenic acid, orientin, isoorientin, vitexin, isovitexin, and rutin [94]. Buckwheat is also a rich source of starch, protein, minerals, vitamins, dietary fiber, and antioxidants. The in vitro antiglycation activity of common buckwheat hull tea infusion was investigated [20]. The ready-to-drink buckwheat hull tea displayed lower inhibition (34.90%) of AGEs in BSA-glucose system compared to green tea.

Ethanol extract (200 μg/mL) of tartary buckwheat exhibited strong inhibition of AGEs (83%), fructosamine (50%), and α-dicarbonyl compounds (65%) formation [21]. It, therefore, reduced the generation of AGEs through the suppression of fructosamine and α-dicarbonyl compounds formation. This implies that tartary buckwheat possessed higher antiglycation activity than the common buckwheat, and this may be due to variation in the quantities of phytochemicals present in them.

5.3 Sickle Senna

Sickle senna (*Cassia tora* L.) is a leguminous plant found in the South East Asia and South West Pacific. The young leaves of this plant are cooked as vegetable while the roasted seeds are consumed as tea. It is used in the treatment of several diseases, such as bronchitis, leprosy, dyspepsia, hypertension, and cardiac disorders [95]. Three naphthopyrone glucosides, namely cassiaside (Fig. 4c), rubrofusarin-6-*O*-β-D-gentiobioside (Fig. 4d), and toralactone-9-*O*-β-D-gentiobioside (Fig. 4e), isolated from sickle senna seeds displayed antiglycation property and showed better inhibition of AGE formation (IC_{50}: 6.4–32.2 μg/mL) than the standard antiglycation agent, aminoguanidine (IC_{50}: 34.6 μg/mL) [55]. Nine anthraquinones isolated from the seeds of sickle senna were also evaluated for their antiglycation activity, out of which only obtusifolin (IC_{50}: 28.9 μM) and emodin (IC_{50}: 118.0 μM) displayed significant inhibition of AGE formation, which were also more potent than aminoguanidine (IC_{50}: 961.0 μM) [56]. Therefore, the antiglycation activities of sickle senna may be due to the presence of naphthopyrone glucosides, as well as obtusifolin and emodin.

6 Antiglycation Agents from Vegetables and Spices

6.1 Black Nightshade

Black nightshade (*Solanum nigrum* L.), also called hounds berry or stubble berry, is a common food plant in Africa, Asia, and Europe. Its leaves and fruits are used in the preparation of foods such as soup, jam, salad, and fruit juices [96]. This plant is reported to contain steroidal glycosides (e.g., solarmargine, desgalactotigonin) and steroidal saponins (e.g., solanigrosides as well as nigrumnins I and II) [97]. The antiglycation property of ethanolic extract of the leaves of black nightshade and two of its isolated compounds, solamargine (Fig. 5a) and solasonine (Fig. 5b), were investigated [30]. The result revealed that 95% ethanolic extract of black nightshade inhibited the generation of AGEs in a dose-dependent manner, via the lowering of fructosamine and α-dicarbonyl compounds formation. Solasonine also exerted stronger antiglycation activity for attenuating AGEs, fructosamine, and α-dicarbonyl compounds formation than solarmargine. This implies that black nightshade leaves possess antiglycation effects which may be due to the presence of solasonine.

6.2 Sangwhang

Sangwhang (*Phellinus linteus*), also called black hoof mushroom, is one of the mushrooms that are considered functional foods in Japan, China, and South Korea, though it is also found in tropical America and Africa. It is used in Asian herbal medicine for the management of several diseases such as liver disorder, oral ulcer, allergies, and diabetes mellitus [98]. Nine compounds (protocatechuic acid, protocatechualdehyde, caffeic acid, ellagic acid, hispidin, davallialactone (Fig. 5c),

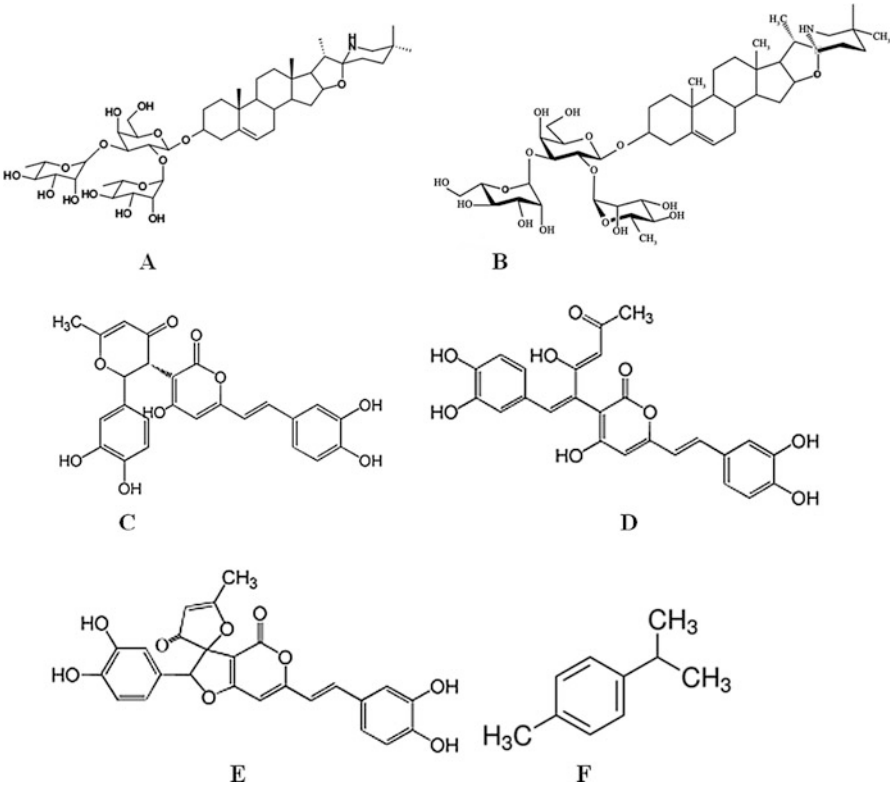

Fig. 5 Structures of some antiglycation compounds from vegetables and spices. (**a**) Solamargine; (**b**) Solasonine; (**c**) Davallialactone; (**d**) Interfungins A; (**e**) Inoscavin A; **(f)** p-Cymene

hypolomin B, interfungins A (Fig. 5d), and inoscavin A (Fig. 5e)) isolated from the ethylacetate fraction of sangwhang were evaluated for antiglycation activities [59]. Davallialactone (50.2%), interfungins A (63.1%), and inoscavin A (45.7%) exhibited inhibitory effect on HbA1c formation, while protocatechualdehyde (IC_{50}: 144.28 μM), davallialactone (IC_{50}: 158.66 μM), and inoscavin A (IC_{50}: 213.15 μM) prevented methylglyoxal-mediated protein modification. However, only interfungin A (IC_{50}: 1.15 mM) inhibited protein cross-link formation even better than aminoguanidine (IC_{50}: 11.93 mM). Therefore, sangwhang displayed good inhibitory potential against AGEs formation which is due mainly to the presence of interfungin A.

6.3 Turmeric

Turmeric (*Curcuma longa* L.) is a rhizomatous plant which is distributed in the Asian continent especially India. It is used in the preparation of foods as spice, preservatives, and coloring agent [99]. It is also used in folk medicine for the

treatment of various ailments like anorexia, cough, rheumatism, hepatic disorder, and diabetic wounds [100]. Several compounds have been isolated from this plant, which includes curcumin, demethoxycurcumin, bisdemethoxycurcumin, and ar-turmerone [101]. The antiglycation potential of hexane, ethylacetate, methanol, and aqueous extracts of turmeric rhizome was reported [49]. Ethylacetate (IC_{50}: 0.09 μg/mL) displayed highest inhibitory effect, followed by methanol (1.48 μg/mL), and aqueous (10.42 μg/mL) extract, while the hexane extract had no effect. In fact, the antiglycation potential of the ethylacetate extract was about 800 times higher than that of ascorbic acid, which is the standard. Therefore, turmeric is an excellent inhibitor of glycation and AGEs formation.

6.4 Lotus

Lotus (*Nelumbo nucifera* Gaertn.) is an aquatic plant cultivated mostly in China and India but distributed throughout Asia. The young leaves, seeds, and rhizome of the plant are used as vegetables while the matured leaves are used as functional foods [102]. The leaf is also used as ingredients in the preparation of healthy beverages and tea bags in China [103]. It is rich in several phytochemicals, which include dauricine, lotusine, nelumboside, pronuciferine, anonaine, and arbutin [104]. The inhibitory effect of lotus leaves, stamens, seeds, embryos, and rhizomes on the formation of advanced glycated end products was investigated [42]. Only the methanol extract of the leaves and stamens demonstrated good antiglycation activities with IC_{50} values of 110.5 μg/mL and 125.5 μg/mL, respectively, compared to the standard, aminoguanidine. However, only the ethylacetate fraction of the leaf effectively inhibited AGE formation (IC_{50} 28.18 μg/mL). Though lotus exhibited good antiglycation effects, further study is required to isolate the bioactive compound(s) from its ethylacetate fraction.

6.5 Ginger

Ginger (*Zingiber officinale* Roscoe) is one of the commonly used plants as spice or condiments in food preparation. It is a functional food which provides medical benefit to its consumers, in addition nutritional function [105]. This is why its rhizome is widely used in food processing and pharmaceutical industries. Major chemical constituents of this plant include 6-gingerol, 6-shogaol, 6-paradol, α-zingiberene, and cineole [106]. The inhibition of protein glycation by ginger extract in an in vitro model was investigated [31]. Ethylacetate extract of ginger at varying concentrations (100–500 μg/mL) displayed dose-dependent inhibition of albumin glycation, which culminated in its IC_{50} value 290.84 μg/mL for the antiglycation activity. This is in conformity with our study on the antiglycation potential of polyphenol extract of ginger, where the IC_{50} value for the antiglycation effect was 285 μg/mL [32]. We also investigated the antiglycation effects of polyphenols extracted from ginger in streptozotocin-induced diabetic rats [33]. Oral administration of 500 mg/kg of free and bound polyphenols of ginger to diabetic rats for 42 days significantly reduced the glycated hemoglobin (HbA1c) level (7.10%)

compared to the diabetic control (10.33%). The formation of AGEs in the serum was also drastically decreased from 6.80 μg/mL in the diabetic control rats to 1.98 μg/mL in the ginger-treated diabetic animals. These reports suggest that ginger possessed antiglycation property both in vitro and in vivo, which may be due to the presence of polyphenols such as gingerol and zingiberene.

6.6 Cumin

Cumin (*Cuminum cyminum* L.), commonly called jeera, is a widely used spice condiment in vegetarian and nonvegetarian foods mostly in Asian countries [107]. It is also used in folklore medicine as an analgesic, antihypertensive, carminative, purgative, and antidiabetic [108]. Its essential oil components include α- and β-pinene, *p*-cymene (Fig. 2f), limonene, safranal, as well as α- and γ-terpinene. The antiglycation potential of aqueous extract of cumin was tested on fructose-induced glycation [27]. Coincubation of fructose with cumin extract resulted in dose-dependent reduction of AGE fluorescence and prevented the formation of predominant AGE, carboxymethylysine. The presence of the extract also prevented the formation of glycation mediated protein cross-links, thereby displaying potent antiglycation activity. Methanolic extract of cumin seed was also tested for its inhibitory effect on glucose-induced BSA glycation [12]. Cumin extract exhibited concentration-dependent inhibition of BSA glycation and subsequent formation of fluorescent glycation products, culminating in low IC_{50} of 1.17 mg/mL.

The in vivo antiglycation activity of cumin in streptozotocin-induced diabetic rats was reported [27]. Supplementation of diabetic rats' diet with 0.5% cumin powder for 8 weeks significantly decreased glycated hemoglobin (HbA1c) level of the rats (5.1%) compared to the diabetic control rats. It also caused protein carbonyl concentration to reduce from 8.1 to 6.3 nmol/mg protein in the cumin-fed rats. Feeding diabetic rats with cumin-supplemented diet also prevented the hyperglycemia-mediated formation of protein cross-links and improved the total and soluble protein levels. Administration of methanolic extract of cumin seed to diabetic rats for 28 days also caused significant reduction in their serum glycated hemoglobin (8.39%) and renal AGE (2.25 IU/mg protein), compared to the glycated hemoglobin (15.39%) and renal AGE (10.09 IU/mg protein) of the diabetic control respectively [12]. Treatment with the extract also reduced glycated and rat tail tendon collagen of the diabetic rats.

In order to identify the antiglycation agents present in cumin, one of its active components, cymene, was investigated for its effect on glycation [28]. The coincubation of 100 μM cymene in BSA-glucose system caused drastic reduction in fructosamine formation and its effect was similar to that of 2 mM aminoguanidine. This implies that cymene is 20 times more potent as an antiglycation agent than aminoguanidine. Varying concentrations (25–100 μM) of cymene also elicited a significant decrease in the protein-bound carbonyl compound formation. Cymene (100 μM) also caused 56.6% and 49.16% reduction in the formation of total AGEs and pentosidine in the BSA-glucose system. Administration of 20 mg/kg cymene to streptozotocin-induced diabetic rats for 60 days also caused significant reduction in

their glycated hemoglobin (HbA1c) level (6.1%) compared to the diabetic control (11.3%). The concentration of serum fructosamine was also decreased significantly from 3.98 mM/L to 2.32 mM/L, which means 58.29% reduction was obtained. It can be concluded that cumin possesses antiglycation property in vitro and in vivo, which may be due to the presence of cymene.

6.7 Clove

Clove (*Syzygium aromaticum* (L.) Merr. & Perry) is a plant which is native to tropical America and Australia. It is popularly used as spice in food preparation and in the treatment of diseases, including inflammation, infections, toothache, and respiratory and gastrointestinal disorders [109]. Chemical compounds present in this plant include eugenol, limonene, β-pinene, ferulic acid, and kaempferol [110]. The inhibition of AGEs formation by clove extract was investigated [60]. Clove extract (0.25–1.00 mg/mL) inhibited the formation of AGEs to a maximum of 95.2% as against the standard, aminoguanidine (91.5%). It also caused 72.8% reduction in the formation of N-carboxymethylysine [60]. Coincubation of the clove extract with the glycation reaction system also decreased the formation of protein carbonyl content by 73.7%, as compared to aminoguanidine (60.0%). However, it significantly elevated the level of protein thiol group better than the standard. This implies that clove extract inhibited all the stages involved in the formation of AGEs, and therefore can be consumed to prevent diabetic complications.

7 Possible Mechanisms of Antiglycation by Foods

The inhibition of glycation and subsequent formation of AGEs by food plants may occur through one or more mechanisms. This includes cleavage of the AGE-crosslink or blocking of the AGE receptor, trapping of reactive dicarbonyl species, as well as through antioxidant activities [9, 11]. Other possible mechanisms of antiglycation are inhibition of aldose reductase and reduction of blood glucose level using hypoglycemic agents, such as acarbose and metformin [4, 6]. Antiglycation agents either function as AGE inhibitors, AGE breakers, or receptor for AGE (RAGE) blockers. AGE inhibitors include aminoguanidine, benfotiamine, and pyridoxamine. N-phenacyl thiazolium compound and alagebrium are AGE breakers while cerivastatin is an example of RAGE blocker [6]. Some antioxidant compounds have also been validated as antiglycation agents, which include vitamin C and E [8].

8 Conclusion

The incidence of diabetic complications ranging from diabetic foot, kidney dysfunction, and cardiovascular disease, which may be due to nonenzymatic glycation, is on the increase. Synthetic drugs manufactured to ameliorate these conditions are

bedevilled with serious side effects and nonavailability, which necessitated the search for antiglycation agents from food plants. Beverages, fruits, legumes, vegetables, and spices, with antiglycation potential, are presented in this review. However, further study will be required to isolate the bioactive component(s) of these foods for possible drug development.

Acknowledgments The support of Lagos State University, Ojo, Lagos, Nigeria, is gracefully acknowledged.

aromatic properties. Usage of these plants is very popular in everyday diet because of their documented health benefits. Apiaceae are a very important source of phytochemicals – chemicals with biological activity. However, phytochemicals are non-nutritive plant chemicals, also called nutraceuticals. They are widely used for prevention, treatment or cure of conditions or diseases. Bioactive compounds with nutraceutical potential are polyphenolic compounds, polyacetylenes and terpenoids. The aim of this review is to represent selected plants of Apiaceae family currently used as nutraceuticals and describe their nutritional benefits.

TPC	Total phenolic contents

1 Introduction

Apiaceae (Umbelliferae) family is large, with over 3.000 species worldwide cultivated for food, as vegetables, herbs, spices or for medicinal purposes. Some plants in this family such as carrots, parsley, parsnip and celery are common vegetable crops, while other members like anise, caraway, coriander, cumin, fennel, lovage, angelica and dill are famous for their medicinal and aromatic properties [1].

The plants from Apiaceae family are mainly temperate herbaceous annual (anise, caraway, coriander, cumin, dill, sweet fennel), biannual (carrot, parsley, parsnip, celery) or perennial (angelica, lovage, bitter fennel). Leaves are alternate on stem or arranged in leaf rosette (mainly in the first year of development in biannual and perennial members). In all the mentioned species, stem is erect and hollow, and in the upper part is branch. Each branch finishes with an inflorescence. The small and simple flowers are generally arranged into compound umbels. They have five petals that are usually white or yellow, with five stamens, and an ovary with two carpels. The fruit that develops from this ovary varies considerably between the spices. Generally the fruit are schizocarps, which contain two seeds.

All Apiaceae plants contain a well-developed secretory system in all plant parts, such as schizogeneus secretory cavities in the root, phloem in the stem and leaves and clearly-delimited tissue known as vittae in the fruit. These structures are important for depositing essential oils, which give the specific odor and flavor to

each plant. Due to their flavor, a large number of plants from this family are used as vegetables or spices [2].

Plants from the Apiaceae family are a very important source of nutraceuticals. Their usage is very popular in everyday diet because of their documented health benefits. The figure below shows members of Apiaceae family and their parts which are usually used. For example, caraway, cumin, aniseed are exclusively used as seed, while dill and coriander are used as seed and leaves, and from carrot seed and root. In case of fennel, apart from seed and leaves, succulent leaf stalks are also used. Celery is used in a similar way. From lovage, parsley and angelica, the root is also used together with above-ground parts (Fig. 1).

2 Bioactive Compounds of Apiaceae

Bioactive compounds can be divided into two groups: phytochemicals which are non-nutritive plant chemicals, also called nutraceuticals, and nutrients which include minerals, proteins, fibers, carbohydrates, fats, etc. However, nutraceuticals possess biological activity, while nutrients affect the growth, development and function of the human body.

Nutraceuticals can be designated as food with medical benefits; as indicated by its name which is derived from “nutrition” and “pharmaceutics”. They include polyphenolic compounds, polyacetylenes and terpenoids [3]. Nutraceuticals are widely used for prevention, treatment or cure of conditions or diseases [4, 5, 6]. The high antioxidant activity of nutraceuticals is the basis for many potential benefits, among which many for degenerative and chronic diseases [7].

2.1 Phenolic Compounds

Phenolic compounds, as one of major bioactive nutraceutical ingredients in plants, are responsible for the organoleptic characteristics of plant-derived foods and beverages, particularly color and taste properties and they also contribute to the nutritional qualities of fruits and vegetables [8]. The phenolic metabolites include: anthocyanins, anthochlors, benzofurans, chromones, coumarins, flavonoids, flavonones and flavonols, isoflavonoids, lignans, phenols and phenolic acids, phenolic ketones, phenylpropanoids, quinonoids, stilbenoids, tannins and xanthones [9]. The antioxidant property in many plants is related to the presence of phenolic compounds. Nutritionally, these compounds are responsible for increasing the shelf life of foods as well as slowing the lipid, protein and enzymatic oxidation, as well as for providing protection against development of cancers, cardiovascular and liver diseases, diabetes, osteoporosis and neurodegenerative diseases in humans [10, 11, 12, 13, 14]. However, the content of biologically active substances, among them polyphenols in plants, depends on various factors such as: area in which the plant is grown (agrochemical characteristic of soil), climatic conditions in the region during the growing season, cultivation technology but also the variety [15]. Apart from this,

Fig. 1 Plants from Apiaceae family with their parts which are usually used in nutrition

total phenolic contents depend also on postharvest processing (fresh, dry, freeze herb), solvents used for extraction (water, ethanol, acetone, etc.) and significantly varies due to plant material (seed, herb, root) etc. Review of total phenolic content according to literature is shown in Table 1.

Table 1 Phenolic compound from selected plants from Apiaceae family

Plant	Phenolic compounds
Anethum graveolens	TPC in dill seed methanolic extract is 773.14 mg GAE 100 g^{-1} dw, while TFC is 231.84 mg QE 100 g^{-1} dw [16]. On the other side, TPC in fresh dill herb acetone extract is 35.23 mg GAE g^{-1} dw, and content of TFC is 30.39 mg CAE g^{-1} dw [17]. However, TPC in dry dill herb varied from 55.46 to 71.29 mg GAE g^{-1} dw depend on solvents [18]. Further, fresh dill herb acetone extract contains 19.49 mg QE g^{-1} dw phenolic acids, and the dominant are chlorogenic and benzoic acids [17]
Angelica archangelica	TPC in angelica roots is 11.8–17.3 mg GAE g^{-1} extract, while content of coumarins is 0.91 mg 100 g^{-1} extract [19]. The dominant are coumarin derivatives among which isoimperatorin, oxypeucedanin, imperatorin, ostruthol, angelicin, bergapten, scopoletin, isopimpinellin, and xanthotoxin [20, 21]
Apium graveolens	TPC in celery seed methanol extract is 825.85 mg GAE 100 g^{-1} dw, and TFC is 177.57 mg CE 100 g^{-1} dw, while content of tanins is 243.36 mg CE 100 g^{-1} dw [22]. The dominant flavonoids are apigenin, luteolin, and kaempferol, while the dominant phenolic acids are caffeic, p-coumaric and ferulic acid [23]
Carum carvi	TPC in caraway seeds is 3.99 mg GAE g^{-1} dw with 42 phenolic compounds [24]. The dominant flavonoid constituent from caraway seed is quercetin 3-glucuronide, isoquercitrin, quercetin 3-O-caffeylglucoside and kaempferol 3-glucoside [25]. Phenolic acid content in caraway seed is about 65 μg g^{-1} dw, with dominant chlorogenic, p-coumaric and caffeic acid [24]
Coriandrum sativum	TPC in coriander leaves extracts is 1.12 mg GAE 100 mL^{-1} [26], and the main flavonoids are quercetin-3-*O*-rutinoside, kaempferol and acacetin, while identified phenolic acids are vanilic, ferulic and p-coumaric acid [27, 28]. Coriander seed contain TPC 0.72 g GAE 100 g^{-1} extract [29]. Rutin, quercetin, chlorogenic and caffeic acid were separated and identified flavonoids in the methanolic and ethanolic extracts of coriander seed [30]
Cuminum cyminum	Acetone extract of cumin seed contains TPC between 16.50 and 18.60 mg GAE g^{-1} dw, TFC between 4.99 and 5.91 mg CE g^{-1} dw and tannin 80.23–83.23 mg CE g^{-1} dw [31]. The main phenolic compounds from cumin are quercetin, p-coumaric, rosmarinic, vanillic and trans-2-dihydrocinnamic acids, as well as resorcinol [32]
Daucus carota	TPC in the carrot root varied considerably from 19.8 to 342.2 mg GAE 100 g^{-1} fw depend on root color [33], and from 81.25–113.69 mg GAE kg^{-1} fw depend on variety [15]. However, carrot contained high amounts of phenolic acids, flavonoids, and carotenoids. Content of ß-carotenes vary between 24.58 and 124.28 mg kg^{-1} fw [15] while total ascorbic acid ranged from 41.12 to 58.36 mg 100 g^{-1} fw, whereas 5-caffeolquinic acid ranged from 30.26 to 65.39 mg 100 g^{-1} fw [34]
Foeniculum vulgare	TPC in seed methanolic extract was 1017.29 mg GAE 100 g^{-1} dw, while TFC is 695.52 mg QE 100 g^{-1} dw [16]. Further, also TFC in seed methanolic extract is 9.325 mg QE g^{-1} dw, with dominant gallic acid (277.131 μg g^{-1} dw), caffeic acid (166.062 μg g^{-1} dw), ellagic acid (99.476 μg g^{-1} dw), quercetin (781.986 μg g^{-1} dw) and kaempferol (92.856 μg g^{-1} dw) [35]. From the other side, fennel herb contains two phenolic compounds, 3.4-dihydroxy-phenethylalchohol-6-*O*-caffeoyl-β-D-glucopyranoside and 3′0.8′-binaringenin [11]

(*continued*)

Table 1 (continued)

Plant	Phenolic compounds
Levisticum officinale	TPC in lovage leaves ranged between 359.75 and 1601.87 mg GAE 100 g^{-1} dw, while TFC varied between 551.01–3548.33 mg CE 100 g^{-1} dw, depending on postharvest treatment (fresh, frozen, dry). Phenolic compounds present in lovage leaves are: rutine, catechin, caffeic, chlorogenic, coumaric, sinapic, and ferulic acid [36]
Pastinaca sativa	The total phenolic acid in parsnip is 5.7 mg 100 g^{-1} fw, while the major soluble phenolic acid is chlorogenic acid [37]. Total content of coumarins ranged from 115.7 to 408.5 mg 100 g^{-1} dw. In vegetative plant parts the dominant are isopimpinellin and psoralen, while imperatorin was dominant in fruit [38]
Petroselinum crispum	TPC in parsley seed is 0.62 g GAE 100 g^{-1} extract, while in leaves it is 0.92 g GAE 100 g^{-1} extract [29]. However, another study shows that TPC in parsley leaves ranged from 15.20 to 54.20 mg CE g^{-1} extract, while TFC is between 4.50 and 42.1 mg QE g^{-1} extract [39]. Flavonoids isolated from aqueous extract of parsley leaves: apigenin, apigenin-7-O-glucoside or cosmosiin, apigenin-7-O-apiosyl-(1–2)-O-glucoside or apiin and the coumarin 2,3-dihydroxyfuranocoumarin or oxypeucedanin hydrate [40]
Pimpinella anisum	TPC in anise seed is 46.17 mg GAE 100 g^{-1} dw, while TFC is 17.43 mg CE 100 g^{-1} dw [41]. Another study shows that TPC is 42.09 mg g^{-1} extract, and identified mainly flavonoids (28.08 mg g^{-1} extract) and phenolic acids (14.01 mg g^{-1} extract). Morerover, apigenin and luteolin derivatives, as well as caffeoylquinic acid derivatives were determined [12]

2.2 Polyacetylenes

Polyacetylenes are a group of phytochemicals that have attracted significant interest in medicine and pharmaceutical industry in recent years due to their range of potential health-promoting bioactivities. Polyacetylenes isolated from Apiaceae plants include antifungal and antibacterial activity [42, 43], as well as anti-inflamatory [44] and anticancer [45, 46] properties. They also display antidiabetic [47] effects and have potential in the treatment of endotoxemia and inflammation accompanied by the overproduction of NO [48]. Apart from this, they possess neurotoxic, anti-platelet-aggregatory activity and are responsible for allergic skin reactions [49, 50, 51]. However, polyacetylenes have a major impact on the bitter taste in roots of parsnip, celeriac, parsley and carrot, as well as fennel bulbs [52, 53, 54, 55, 56, 57, 58, 59]. The review of polyacetilenes present in plants from Apiaceae family according to literature is shown in Table 2.

2.3 Terpenoids

Terpenoids, especially monoterpenes and sesquiterpenes are the main constituents in essential oils which, as volatile compounds, give fragrance to many aromatic plants [64]. Some terpenoids are very typical for plant species from the Apiaceae family as

Table 2 Polyacetylenes from selected plants from Apiaceae family

Plant	Polyacetylenes
Anethum graveolens	Dill roots contain polyacetylenes such as panaxynol ($C_{17}H_{24}O$) and falcarindiol ($C_{17}H_{24}O_2$) [60]
Angelica archangelica	Many species from genus Angelica contain polyacetylenes. For example, polyacetylene from *A. purpuraefolia* is (+)-9(Z), 17-octadecadiene-12,14-diyne-1,11,16-triol [61], while *A. furcijuga* contain (−)-falcarinol and falcarindiol [62]. *A. gigas* contains: octadeca-1, 9-dien-4, 6-diyn-3, 8, 18-triol (1), 18-acetoxy-octadeca-1, 9-dien-4, 6-diyn-3, 8-diol (2) and 3, 8, 18-triacetoxy-octadeca-1, 9-dien-4, 6-diyn (3) [48]
Apium graveolens	Celery root contains polyacetylenes: falcarindiol, falcarinol, panaxydiol and 8-*O*-methylfalcarindiol [44, 49]
Carum carvi	Aliphatic C17-polyacetylenes of the caraway are falcarinol, falcarindiol, falcarinolone and falcarindione [52]
Coriandrum sativum	In coriander, polyacetylenes are detected but not identified [52]
Cuminum cyminum	No data in the available literature
Daucus carota	The most abundant polyacetylenes in cultivated orange carrots is falcarindiol (16–84 mg kg^{-1} fw, followed by falcarinol (8–27 mg kg^{-1} fw) and falcarindiol-3-acetate (8–40 mg kg^{-1} fw) [59]
Foeniculum vulgare	The amount of polyacetylenes in fennel bulb ranged from 0.04 to 0.24 mg g^{-1} of freeze-dried plant material [49]. Polyphenoles detected in fennel bulb are falcarindiol, falcarindiol-3-acetate, and falcarinol [57]
Levisticum officinale	Polyacetylenes from lovage roots are: 3(*R*)-Falcarinol (3(*R*)-(−)-1,9-heptadecadien-4,6-diin-3-ol] (1) and 3(*R*)-8(*S*)-falcarindiol [3(*R*)-8(*S*)-(+)-1,9-heptadecadien-4,6-diin-3,8-diol] (2) [43]
Pastinaca sativa	Polyacetylene compounds from parsnip root are falcarinol and falcarindiol occurring in the highest concentrations (1600 and 5770 mg kg^{-1} freeze-dried material, respectively), followed by falcarinone and falcarinolone. Moreover, parsnip seeds contain polyacetylenic C18 ketoaldehyde [55]
Petroselinum crispum	Polyacetylene from parsley root are falcarindiol (up to 2320 mg kg^{-1} freeze-dried material), falcarinol, 8-O-methylfalcarindiol (350 mg kg^{-1} freeze-dried material) and panaxydiol (120 mg kg^{-1} freeze-dried material) [55]
Pimpinella anisum	Polyacetylenes have been reported to be present in some Pimpinella species, such as falcarinol in *P. pruatjan*, pentadeca-2,4,6,8-tetraene (1), 2,8-decadiene-4,6-diene-1-al (2), 2,8-tridecadiene-4,6-diene-10-ol (3) 2,8,10-tridecatriene-4,6-diene (4) in *P. major*, and 2-tridecaene-4,6-diene-8-ol-10-on in *P. saxifraga* [63]

they are the source of the familiar taste, for example carotol in carrot, *trans*-anethole in anise and fennel, carvone in caraway and dill [65, 66, 67]. Due to their aromatic qualities, these plants are used as supplements in everyday food in order to enhance the smell, taste and biological values. For this reason this group will be in the focus. Essential oils have been known to possess antioxidant and antimicrobial activities, thereby serving as natural additives in foods and food products [68, 69]. Anti-oxidative properties of essential oils are responsible for healing or improving degradation processes in many diseases such as cancer, rheumatoid arthritis,

Table 3 Terpenoids from selected plants from Apiaceae family

Plant	
Anethum graveolens	Dill seed essential oil contains carvone and limonene as the dominant compounds [73], while the main compounds in the herb essential oil are *α*-phellandrene, apiole, dill ether, limonene, geraniol and *p*-cymene [74]
Angelica archangelica	The main components of angelica roots essential oil are *α*-pinene, *δ*-3-carene, *β*-phellandrene and limonene, while in seed it is *β*-phellandrene, *α*-phellandrene, *α*-pinene, myrcene and *α*-copaene [75, 76]
Apium graveolens	Celery essential oil contains limonene and selinene. However, the important flavor constituents of the oil responsible for the typical aroma are phtalides (3-n-butyl-4-5-dihydrophthalide (sedanenolide), 3-n-butyl phthalide, sedanolide, and sedanonic anhydride) [77]
Carum carvi	Caraway seed essential oil is comprised from carvone and limonene, constituting more than 90% [66, 78, 79]
Coriandrum sativum	Coriander seed essential oil contains mainly linalool [80, 81, 82], while coriander herb oil has a significantly different composition with decanal, *trans*-2-decenal, 2-decen-1-ol, cyclodecane and *cis*-2-dodecenal as the main compounds [83]
Cuminum cyminum	The distinctive flavor and aroma are originate from essential oil, the dominant compounds of which are γ-terpinene-7-al, cumin-aldehyde, β-pinene and γ-terpinene [84, 85, 86, 87]
Daucus carota	Carrot root essential oil contains mainly geranyl, linalool, myristicine, pentacosane, spathulenol and *trans*-*γ*-bisabolene. The major compounds of aerial parts' essential oil is alismol, *trans*-*β*-caryophyllene, myrcene, *α*-humulene and *β*-ionone [88]. The major constituents of essential oil from carrot seeds are carotol, sabinene, *α*-pinene followed by aromadendrene, *β*-farnesene, sesquisabinene, *trans*-caryophyllene and myrcene [67]
Foeniculum vulgare	The dominant compound in fennel seed and herb essential oil is *trans*-anethole which gives them similar scent as to aniseed [89]. However, fennel has two varieties: sweet and bitter. Sweet fennel (var. *dulce*) apart of *trans*-anethole (more than 80%), contains estragole (less than 10%) and fenchone (less than 7.5%). Bitter fennel (var. *vulgare*) apart of *trans*-anethole (55–75%) contains fenchone (12–25%) [90]
Levisticum officinale	The lovage flavor, like the celery one, originates from essential oil where the dominant compound is *β*–phellandrene, while phthalides are present in small amounts and give the characteristic fragrance [91]
Pastinaca sativa	Root essential oil had the two major constituents, myristicine and terpinolene [92]. Aerial parts contain essential oil with dominant *cis*-*β*-ocimene, hexyl butanoate, *trans*-*β*-farnesene and lavandulyl acetate [93]
Petroselinum crispum	Major compounds in parsley essential oil are apiol, myristicin and *β*-phellandrene [94, 95]
Pimpinella anisum	Anise contains essential oil with the most abundant component, *trans*-anethole, above 96% which exhibits sweet and licorice taste with a herbal anise and fennel nuance [89, 96]

cirrhosis and arteriosclerosis as well as in degenerative processes associated with aging [70]. Essential oils also showed antimicrobial properties, which makes them efficient alternative antibiotics and antimycotic agents [71, 72]. Review of terpenoids present in Apiaceae according to literature is shown in Table 3.

3 Nutraceutical Potential of Apiaceae

The aim of this review is to represent members of Apiaceae family currently used as nutraceuticals and describe their nutritional benefits. Investigation of nutraceuticals from this family is very attractive because of their extensive application in everyday diet. Review of their chemical composition and biological activity highlighted their importance as food with health benefits.

3.1 *Anethum graveolens*

Dill seed and leaf are the parts which are mainly used. Dill seed is used in pickled cucumbers, bread, processed meats, sausages, cheese and condiments. Dill leaves are used in pickles, while fresh are used for garnish or to flavor salads, vegetable dishes, sea food, soups, yogurt and mayonnaise [2]. Dill has been used in traditional medicines worldwide since the ancient times. It is used to relieve colic pain in babies and flatulence in young children, as carminative (improves appetite), mild diuretic, galactogogue, stimulant and stomachic. It is also used for treatment of diarrhoea, astma, neuralgia, dysuria, dysmenorrhoea, gallbladder disease and insomnia [97, 98]. However, a great number of pharmacological studies show that dill possesses significant biological activity. Because of the high antioxidative potential [18, 99], dill can be used to improve biochemical processes in patients who suffer from diseases in relation to metabolic syndrome [100]. Studies show that dill can be used for managing diabetes and cardiovascular diseases because it possesses hypoglycemic properties [101, 102, 103]. It is documented that dill decreased total cholesterol without any side effects [104, 105, 106]. Apart from this, dill has hepatoprotective properties [107, 108, 109, 110, 111, 112]. Dill exhibited great anti-cancer activity on oral cavities and breast cancer cells lines [113]. Dill is a good antimicrobial agent [114, 115], which makes it a very significant plant in herbal medicine, especially as a base for the development of novel antimicrobial phytoremedies [116].

3.2 *Angelica archangelica*

Angelica root is used in herbal liqueurs and bitter spirits, in flavoring meat and canned vegetables, while the seed is used in alcoholic distillates. However, chopped angelica green parts (leaves and herb) can be added to fruit salads, fish dishes and cottage cheese, they are used for decorating cakes and pastry and to flavor jams and jellies, confectionaries and liqueurs [2]. The species is well known and has been cultivated since the ancient times for treating certain diseases, such as gastrointestinal problems, like a carminative or in flatulent colic, as well as diaphoretic and diuretic [117]. Applied externally, angelica is good as a counter-irritant, for treatment of rheumatic diseases [118]. New investigations of this plant show that it possesses good antioxidative [119, 120, 121] and antimicrobial activity [72, 75, 122, 123]. This indicates

that angelica can be used as a botanical preservative against molds, aflatoxin contamination and oxidative deterioration of walnut samples [124], as well as a control agent for plant pathogenic fungi in natural formulations [125]. Angelica root water extraction revealed a significant antioxidant role beside its chelation potency of lead ions, so it can be used as a natural chelator in case of lead poisoning [126]. Clinical investigations show that angelica expressed hepatoprotective activity [119, 127] as well as cytotoxicity in human pancreas cancer cells and mouse breast cancer cells [128]. Angelica also shows anxiolytic activity, so it can be used for nervous disorders and cerebral diseases, for example for epilepsy treatment [129, 130].

3.3 *Apium graveolens*

Celery has different forms and uses. Turnip-rooted celery, also called celeriac, is used mainly as grated raw salad, as well as cooked vegetable in stews and soups. Leaf celery, called smallage, is chopped and used for garnishing and flavoring, either fresh or dried. The succulent leafstalk, often with a part of leafblade, is used for the preparation of sauces, vegetable juices, stews, soups, salads, etc. Celery seed is used as condiment, in pickling vegetables, salad dressings, breads, biscuits, soups, spice mixed with salt, as bouquet garnish [2]. In traditional medicine, celery is used to treat many diseases. Traditionaly, celery is mainly used as a diuretic and as a treatment for arthritis and rheumatism. Celery also has sedating effect and has been used in herbal medicine to treat nervousness, hysteria and various other conditions [131, 132]. However, investigations show that celery possesses good antioxidant activity [133, 134, 135] as well as antimicrobial activity [136, 137]. Significant hepatoprotective activity [138, 139, 140, 141, 142], and anti-inflammatory effect of celery are reported [143, 144]. Hypoglycemic effect of celery is also reported, as well as that its potent role in ameliorating stressful complications accompanied by diabetes mellitus [145, 146]. Celery acts as an intestinal smooth muscle relaxant in the digestive tract [147]. Also, it has antihypertensive properties, and can be considered as an antihypertensive agent in chronic treatment of elevated blood pressure [148]. Celery showed a significant diuretic effect that accentuates the excretion of urinary calcium [149].

3.4 *Carum carvi*

Caraway seed is used in creams, cakes, baked goods, cheese, confections, fresh cabbage, meat dishes, rye bread, salads, while essential oil obtained from seed is used to flavor chewing gum, candy, soft drinks and alcoholic beverages [2, 150]. Caraway seed essential oil has been reported to have potential therapeutic effects, mainly due to its high antioxidant activity [151]. Considering the radical scavenging [152] and good antioxidant profile [153, 154], it has been recommended for its multifaceted pharmacological properties [155]. Caraway has been used to treat digestive disorders for a long time. It can be used successfully for establishing normal intestinal motility, for healing chronic constipation, gastric ulcer, dysbiosis,

dyspeption and heartburn [156, 157, 158, 159, 160, 161, 162]. The application of caraway fruits significantly inhibits the increase of total cholesterol and levels of triglycerides [163, 164, 165]. Apart from this it can be used in the treatment of hyperglycemia [166, 167]. Caraway fruit shows strong antibacterial and antifungal activities [168, 169, 170]. It also has anti-inflammatory properties [157] and anti-stress activity [171]. Caraway significantly increases urine output, and the total volume of urine excreted [172]. In addition, the aqueous extract of caraway fruits decreases the level of glucose in serum, urea, creatinine, total urinary protein and microalbuminuric levels. Caraway possesses strong anti-oxidant activity which provides renoprotection against diabetes and its complications [173]. It is established that the essential oil also protects the kidneys from damage which occur as a consequence of diabetic nephropathy [174].

3.5 *Coriandrum sativum*

Coriander leaf is used to make chutneys and sauces, green salsas, dips, snacks, soups, while the seed is used in couscous, stews and salads, as a condiment in pickle spices, seasonings, curry powders, sausages, cakes, pastries, biscuits and buns. Seed essential oil is used in beverages, baked goods, condiments, relishes and meat products [2]. However, leaf and seed have different aromas because of the different chemical composition, but both oils possess good antioxidative [175, 176], as well as antimicrobial activity [177, 178]. Studies indicated that coriander enabled development of a novel broad spectrum of antibacterial herbal formulations, and that it has potential for new natural antifungal formulations [179]. However, bioactive compounds present in coriander are used in traditional and modern medicine, as well as in everyday nutrition [69, 180, 181]. In folk medicine, coriander seed is used as an aromatic, carminative, stomachic, antispasmodic and against gastrointestinal complaints such as dyspepsia, flatulance and gastralgia [179]. It is often recomanded for insomnia and anxiety [182, 183, 184]. Its use is recommended for healing the urinary system, ie uretritis, cystitis and urinary tract infections [185]. It has also been used in heavy metal detoxification [186]. It is used as an analgetic and antirheumatic agent [187]. Coriander is effective against hyperlipidemia [188, 189, 190] and hyperglycemia [191, 192]. It also acts as a hepatoprotectant [193, 194, 195, 196, 197, 198] and anticancer agent [199, 200, 201]. Apart from this, coriander can also be used as an anthelmintic [202, 203].

3.6 *Cuminum cyminum*

Cumin seed is used as a flavoring component in beverages, confectioneries, baked goods, meat and meat products, condiments and relishes, gravies, snack foods, gelatins and puddings [2]. It is generally used as a food additive, popular spice, and flavoring agent in many cuisines [204]. Cumin seeds have also been widely used in traditional medicine for treatment of several health disorders and diseases, such as

toothaches, dyspepsia, diarrhea, epilepsy and jaundice. Hovewer, the literature presents ample evidence for the biological and biomedical activities of cumin, among which strong antioxidative [205, 206] and antimicrobial activity [207, 208]. Because of this, it is an important natural food preservative. Further, there is scientific proof that cumin shows antistress, antioxidant, and memory-enhancing activities, that its traditional use as a culinary spice in foods is beneficial in combating stress and related disorders [209]. Cumin possesses hypolipidemic [210, 211], as well as hypoglycaemic potential [212, 213]. Investigations show that cumin possesses hepatoprotective properties against drugs and chemically induced hepatotoxicities, by increasing the level of antioxidant enzymes in the liver [214, 215, 216]. The finding also suggests that it possesses anticancer activity against several carncer cell lines. These studies convey the use of cumin as a helper in the therapy or the control of colon, liver and prostrate cancer. Also, the use of cumin in diet may reduce the risk of cancer [217, 218]. Apart from this, phytochemical constituents from cumin seed show analgesic and anti-inflammatory activities [219].

3.7 *Daucus carota*

The carrot is mainly consumed as a root vegetable, primarily raw, in juices, salads, or for pickling, while it is used cooked in soups and stews, as well as for cakes. Carrot seed is used for essential oil distillation. Obtained oil contains carotol as the dominant compound, and is used as a flavoring agent in food products, mainly in beverages, baked goods, condiments, relishes and meat products [2]. Lately, a number of studies pointed out that the aerial parts are also a source of phytochemicals and could be economically important, for example antioxidants and for blood pressure lowering [220, 221, 222]. The ethnobotanical uses of this species also included applications in the treatment of cough, diarrhea, dysentery, cancer, malaria, tumors, as an antiseptic, abortifacient, aphrodisiac, carminative, stimulant, stomachic and tonic [223]. Studies show that root, as the part mainly used, act as an antioxidant [224, 225, 226], hepatoprotectant [227, 228, 229] and gastroprotectant [230, 231, 232, 233, 234]. Carrot is a good antiinflammatory [235, 236] and anticancer agent [46, 237, 238, 239, 240]. Also, it possesses hypoglycaemic and hypolipidemic properties [47, 241, 242, 243]. Carrot seeds appear to be a promising candidate for improving memory and it would be worthwhile to explore the potential of this plant in the management of Alzheimer patients [243]. Apart from this, carrot seed shows antinoceptive and antiinflamatory [244], as well as hypoglycaemic and hypolipidemic properties [245, 246, 247].

3.8 *Foeniculum vulgare*

Fennel seed is used in meat dishes, curries, spice blends, soups, vegetables, breads. Fresh and chopped leaves can be used as garnish for fish dishes, sauces, salads, stews and curries. Leaf stalk, also called pseudobulb, is used raw in salads, stuffing, soups, sauces; it can be baked or blanched. Seed and herb essential oil is used in beverages,

condiments, relishes, baked goods, frozen dairy, gelatines, puddings, meat products and candies [2]. Fennel has a wide range of bioactivity and has proved to be a good source for traditional medicine. Mainly, it is used as galactagogue and emmenagogue. Because of its diuretic activity, it is useful for kidney and bladder diseases. It is also relieves nausea and vomiting. It is useful for chronic fever and eliminates obstructions of internal organs especially those in liver, intestine and respiratory tract [248]. It provides a noteworthy basis in pharmaceutical biology for the development and formulation of new drugs and future clinical uses [249, 250]. However, investigations show that fennel has efficient antimicrobial activity against bacteria [35, 251, 252], fungi [253, 254, 255] and viruses [256]. Fennel also possesses good antioxidative potential [257, 258], because of hat it is used as food additive to provide protection against oxidative degradation of foods by free radicals, but also used to protect humans from oxidative stress damage [249, 259]. Fennel also possesses anti-inflammatory [260, 261], anticancer [262] and hepatoprotective activity [263, 264]. Further, hypolipidemic and hypoglycaemic potential are also proven [263, 265], as well as diuretic potential and beneficial effect on renal function [266, 267].

3.9 *Levisticum officinale*

The lovage root is used for producing soup seasonings, finished flavorings in liqueurs; the leaf is used for seasoning sauces, meat dishes, while the seed is used as spice, for flavoring cakes, soups, salads, for pickled vegetables (especially cabbage and cucumbers) [2]. Lovage has the strong, characteristic seasoning-like principle of the herb, aromatic odor and taste [268]. Lovage is one of the herbs that have been traditionally used for treatment of many diseases, as diaphoretic, expectorant, stomachic and stimulant [269]. Apart from this, lovage is used in treatment of kidney stones and urinary tract infections [270]. These uses are approved by pharmacological studies, i.e. lovage significantly decreased levels of urine cysteine, creatinine and volume [271]. Hovewer, clinical experience shows that lovage in combination with other plants can be used for treatment of urogenital and gestrointestinal diseases [272]. Lovage exhibited significant antimicrobial [43, 273, 274] and antioxidative activity [36, 275]. Investigations show that lovage is an inexpensive source of natural antibacterial substances for use in pathogenic systems to prevent the growth of bacteria and extend the shelf life of processed foods [276]. Apart from this, lovage possesses anticancer activity, i.e. inhibits human head and neck squamous carcinoma cells growth [277] as well as human liver cancer cell and breast cancer cell lines [278]. Lovage also shows neuroprotective activities, i.e. alcoholic extract has both repair and restoration effects on peripheral nerves [270], as well as antiinflamatory activity [278].

3.10 *Pastinaca sativa*

The parsnip is a root vegetable resembling white carrot. The root is used in soups, stews, cakes, pies and puddings, while leaves and young leafstalks can be used

cooked with other greens as a vegetable or added to soups. The seed is used as a condiment in making beer, wine or distilled spirits [91, 279]. Parsnip has a sweet, distinct, aromatic flavor, similar to nutmeg and cinnamon. This plant is used in traditional medicine worldwide, mainly as a carminative, spasmolytic and diuretic. Also, their usage in treatment of epilepsy is mentioned. Investigations show that parsnip shows anticonvulsant activity due to the presence of a furanocoumarin compound, xanthotoxin [280]. Apart from this, parsnip has anticancer activity, because it contains falcarinol which proved to be the most active compound with a pronounced toxicity against acute lymphoblastic leukemia cell line [49]. Also, parsnip possesses antimicrobial activity against the most common human gastrointestinal pathogenic microbial strains [93]. Parsnip shows significant antibacterial activities on phytopathogenic bacteria, so it might potentially be used as a biological pesticide [92]. The results showed that the addition of parsnip could effectively reduce lipid oxidation, maintain or improve sensory attributes and extend the shelf-life of beef burgers during refrigerated storage. Therefore, it is suggested that parsnip, as a natural herb, could be used to extend the shelf-life of meat products, providing the consumer with food containing natural additives, which might be seen as a healthier option than those of synthetic origin [281].

3.11 *Petroselinum crispum*

Parsley, like celery, has different forms and uses. Roothy form is mainly used as a vegetable, while the leafy form has two varieties, broad-leaved and curly-leaved. The parsley root is used as a vegetable to enhance flavor in soups, stews and condiments, while the leaf is used as a garnish (for salads, soups, boiled potatoes and egg dishes), blended in dips and cooked sauces. Seed is usually used for essential oil extraction. Obtained oil is used to flavor meat sauces, pickles, spice blends, baked goods, oils and fats, processed vegetables, soups, gelatines and puddings [2]. Parsley can be used fresh and dried. Parsley has a pungent, warm, spicy, herbaceous-scent. However, smell and taste in dried spices are different from the fresh ones due to changes in volatile profile during the drying process [282]. Parsley is mainly used in food industry as a vegetable and spice, while in etnopharmacology application as an appetizer, carminative and diuretic. However, investigations show that parsley shows potential to prevent oxidative stress-related diseases and can be developed into functional food or alternative natural antioxidants [283, 284]. Parsley showed a hepatoprotective effect against acute liver injury induced by chemical agents [285, 286, 287, 288], as well as injuries due to the complication of diabetes [289] or chronic changes induced in non-alcoholic fatty liver disease [290]. Parsley is a good diuretic and has antihypertensive effect [291, 292]. Apart from this, parsley shows antiurolithic effects against calcium oxalate stones [293].

3.12 *Pimpinella anisum*

Anise is used in beverages, baked goods, condiments, relishes, oils and fats, frozen dairy, gravies, meat products and soft candy. Seed essential oil is used in chewing gums, gelatines, puddings, soft and hard candies [2, 150]. Anise, like fennel, has an aromatic and sweet taste. It is used in folk medicine in many countries for treatment of digestive, respiratory and neurological diseases, as well as natural estrogen [294, 295]. New investigations show that anise is rich in phytochemical contents, which possess high antioxidant [296, 297] and antimicrobial activities [71, 299]. A new interesting approach to develop plants as natural source and preservative for the food industry is considered. Treatment with anise is effective in reducing the level of some of biochemical parameters and ameliorate behavior of intoxicated by lead [298]. Apart from this, anise possesses strong anticancer activity on human prostate cancer cell line [300], as well as on gastric cancer cell line [301]. Thus, anise could be one of the foods that attribute to cancer prevention and treatment. It could also be a natural source of novel anticancer compounds with anti proliferative and/or apoptotic properties. Anise also possesses hypoglycaemic and hypolipidemic properties [302, 303]. Investigation shows hepatoprotective activity, too [304, 305]. High range of active potentials leads to various applications of anise, such as health supplement and pharmaceutical benefits [41]. This is conditioned by significant content of synergistic action of the bioactive compounds present in the seed [12, 306].

4 Conclusion

Phytochemical screening of spices and vegetables which are usually used in diet, shows that they possess bioactive constituents of pharmaceutical importance. Therapeutic activity is especially important in prevention and treatment of modern diseases which are directly related to oxidative stress, such as aging, cancer etc. Nutritionally induced acute and chronic diseases such as diabetes, hyperlipidemia, liver diseases and others, can be prevented or relieved by using plants. Thereby, promoting optimal health, longevity and quality of life can all be achieved by plants, i.e. nutraceuticals present in them.

It is known that many plants have been used as food additives and in folk medicine for treating numerous diseases worldwide since the ancient times. However, only recently has there been a huge number of pharmacological and clinical studies about the positive effects that plants have on the human health. These studies have awakened people's interest in the plant's usage. Plants from Apiaceae family are used in almost all national cuisines, both as a vegetable (carrot, celery, parsley, parsnip, fennel) or as spice or condiment (dill, cumin, anise, coriander, lovage, angelica). Due to the complex chemical composition, they show significant therapeutic activity, while their aromatic properties enable their wide application in

everyday nutrition. All economic studies imply that nutraceuticals will play an important role in the future development of food with therapeutic properties.

Contents

Abstract

There is growing evidence that functional components (bioactives and phytochemicals) of food play an integral role in the link between food and the prevention of diseases. Although some functional components were labelled anti-nutrients, their role as potential healthy biochemical components of diets for the prevention of degenerative pathologies have been scientifically elucidated.

J.-M. Mérillon, K. G. Ramawat (eds.), *Bioactive Molecules in Food*, Reference Series in Phytochemistry, https://doi.org/10.1007/978-3-319-78030-6_39

Some properties which link functional components to potential health-modulating roles and functions can be classified into anti-oxidation, anti-cancer, anti-diabetic, anti-inflammatory, cardiovascular, anti-microbial, immunomodulatory and anti-hypertensive. However, the mechanisms through which they impact on human health are not completely clear. Food processing techniques exercise effects on functional components of food. While some processing techniques increase their concentration in food, others decrease them. Therefore, in this era when the role of a healthy diet in preventing degenerative, non-communicable and chronic diseases is well accepted, the borderline between food and medicine is becoming very thin. Thus, the concept of food has obviously gone beyond basic nutrition only. While products intended to cure diseases are classified as medicine, a healthy diet consisting of foods with functional components can help optimize health and promote well-being as well as reduce or prevent the risk of developing certain diseases.

Abbreviations

AK1	Adenylate kinase1 encoding gene
CAT	Catalase
CLA	Conjugated linoleic acid
CR3	Complementary receptor3
DF	Dietary fiber
DHA	Docosahexaenoic acid
DNA	Deoxyribonucleic acid
DP	Degree of polymerization
EGC3G	Epigallocatechin-3-gallate
EPA	Eicosapentaenoic acid
FOS	Fructo-oligosaccharide
GP_X	Glutathione peroxidase
GR	Glutathione reductase
HD	High density lipoprotein
HG-2	Human hepatoma cells G2
HPP	High pressure processing
HTLV-1	Human T-celllymphotroic virus type1
HWE	Hot water extract
IL-1	Interleukin-1
LAB	Lactic acid bacteria
LacCer	Lactocylceramide (a bioactive lipid)
LDL	Low density lipoprotein
MAPK	Mitogen activated protein kinases
MP2	Microphage inflammatory protein2
*m*RNA	Messenger ribonucleic acid

MyD88	Myeloid differentiation primary receptor gene 88
NFAT	Nuclear factor of activated T cells
NF-kB	Nuclear factor kappa light-chain-enhancer of activated β cells.
NK	Natural killer
Nrf2	Nuclear factor2 pathway
NTP	Non-thermal processing
PEF	Pulsed electric field
Pi3k	Phosphatidyl inositol-4,5-biphosphate-3-kinase
PKC	Protein kinase C
PUFA	Poly-unsaturated fatty acid
RNS	Reactive Nitrogen species
ROS	Reactive oxygen species
SIGNR3	Specific ICAM (intracellular adhesion molecule)-3 grabbing non-intergrin-related antigen
SOD	Superoxide dismutase
syk	Spleen tyrosine kinase encoding enzyme gene
TLR	Toll-like receptors
TNF-α	Tumor necrosis factor alpha
TRAF6	TNF receptor associated factor6
WBC	Water binding capacity

1 Introduction

Food is any substance consumed to nourish and refresh the body [1]. It is the most imaginable sets of complicated biochemical substances ingested into the body to provide nutritional support and refreshment necessary for the health, growth, and normal functions of every living organism. Essentially, food is a mixture of chemicals or nutrients which can be separated into different components with one or more different functions in the body including energy generation; growth and repair of worn out cells and tissues; regulation of processes and protection against diseases and invasion by pathogens. The two major components of food are nutritive or primary metabolites (consisting of the macronutrients that are present in relatively large amounts, such as proteins, carbohydrates, lipids and micronutrients present in small amounts, such as vitamins, minerals, and water which are essential for the sustenance of normal body functions, e.g., energy generation, growth, repair, regulation, etc.) and non-nutritive or secondary metabolites (these are bioactives or phytochemicals which possess properties with potentially positive effect on health beyond basic nutrition. These non-nutritve substances are known as functional components. A combination of the right types of food optimizes health and impacts positively on wellness. Dietary guidelines around the world recommend increased consumption of fruits and vegetables, as good sources of beneficial plant chemicals and essential nutrients to improve health and reduce the risk of chronic diseases [2]. Accordingly, daily intake of at least 400 g of vegetables and fruits have been recommended by experts [3].

The non-nutritive components of food are variously referred to in different contexts as functional or bioactive components (biomolecules present in food that exhibit the capacity to modulate one or more metabolic processes, which results to health benefits and promotion of well-being) or phytochemicals (plant-derived, biologically active chemicals that function in the body to prevent certain disease processes) [4, 5]. There are over a 1000 phytochemicals found in foods, and one serving of about 120 g of a fruit or vegetable may have as many as 100 different phytochemicals [6]. Research has established a relationship between functional components in food, health and well-being [7]. Consequently, functional components have health-promoting roles at various stages of disease control that are associated with multiple progressive steps, from initiation to development. Thus, they can be effectively applied in the treatment and prevention of diseases [8]. These days, as a result of the acceptance of the role of a healthy nutrition based on the right choice of diet in preventing diseases, the difference between food and medicine is no longer obvious [9].

Previously, it was thought that functional components occur only in plant foods including whole grains, nuts, seeds, spices, fruits, and vegetables. However, probiotics, polyunsaturated fatty acids (PUFA) such as conjugated linolenic acid (CLA), long-chain omega-3, -6 and -9 fatty acids including eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA) and bioactive peptides are equally found in animal products such as milk, fermented milk products and cold-water fish. They also have multiple metabolic activities allowing for beneficial effects on several diseases and target tissues in the body [5]. Table 1 presents some functional components of food, their common sources, and potential benefits.

This chapter therefore presents functional components of food in the light of their medicinal properties, impact and mode of action in optimizing health and well-being. In addition, the different types, nature, functions, source, and the effect of processing techniques on functional components of food are discussed.

2 An Overview of Functional Components of Food

Functional components are mainly the non-nutritive secondary metabolites in food. Although some functional components are labelled as anti-nutrients, their role as potential healthy biochemical constituents of diets for the prevention of degenerative pathologies have been scientifically elucidated [10]. Functional components were mostly ignored until recently when their potential metabolic effects were first detected. For example, flavones were found to protect against heart diseases and soy-based estrogens against cancer [10]. The bioactivity and chemistry of other non-nutritive compounds in foods such as red wine, coffee, nuts, seeds, whole grains, spices, herbs, fruits and vegetables have been investigated to determine their biochemical effects and potential health benefits [11]. They are essential for normal growth, development and defense of plants [12] and seem to replicate the same functions in humans. To date, different types of secondary metabolites have been identified in plants [13]. Chemically, these compounds are either nitrogen-containing alkaloids or nitrogen-deficient terpenoids and phenolics [14].

Table 1 Some functional ingredients of food, their sources, and potential benefits

Bioactive components	Source	Potential benefits
Carotenoids		
Alpha-carotene/beta-carotene	Carrots, fruits, vegetables	Neutralize free radicals which may cause damage to cells
Lutein	Green vegetables	Reduce the risk of muscular degeneration
Lycopene	Tomato products (ketchup, sauces)	Reduce the risk of prostate cancer
Non-starchy polysaccharides		
Fucoidan	Mushrooms (maitake and reshi), brown seaweeds	Immune modulation; apoptosis of cancer cells; stimulates brain development; anticlotting effect; lower blood cholesterol levels; decrease high blood pressure, stabilize blood sugar
Insoluble dietary fiber	Wheat bran	Reduces risk of breast or colon cancer
Soluble dietary fiber (β-glucans)	Oats, barley, psyllium	Reduces risk of cardiovascular disease; protects against heart disease and some cancers; lower LDL and total cholesterol
Fatty acids		
Long chain omega-3 fatty acids (DHA/EPA),	Salmon and other fish oils	Reduce risk of cardiovascular disease; improve mental and visual functions.
Conjugated linoleic acid (CLA)	Cheese, meat products	Improve body composition; decrease risk of certain cancers
Phenolics		
Anthocyanidins	Fruits	Neutralize free radicals; reduce risk of cancer
Catechins	Tea	Neutralize free radicals; reduce risk of cancer
Flavonones	Citrus	Neutralize free radicals; reduce risk of cancer
Flavones	Fruits/vegetables	Neutralize free radicals; reduce risk of cancer
Lignans	Flax, rye, vegetables	Prevention of cancer; renal failure.
Tannins (proanthocyanidins)	Cranberries, cranberry products, cocoa, chocolate	Improve urinary tract health; reduce risk of cardiovascular disease
Phytosterols		
Stanol ester	Corn, soy, wheat, wood oils	Lower blood cholesterol levels by inhibiting cholesterol absorption
Prebiotics and probiotics		
Fructo-oligosaccharides (FOS);	Jerusalem artichokes, shallots, onion powder,	Improve quality of intestinal microflora; gastrointestinal health
Lactobacillus; Biofidobacterium	Yogurt, other dairy products	Improve quality of intestinal microflora; gastrointestinal health
Soy phytoestrogens		
Isoflavones: Daidzein genistein	Soybeans and soy-based foods	Menopause symptoms such as hot flashes; protection against heart disease and some cancers; lowering of LDL and total cholesterol

Groups of plant secondary metabolites are diverse and usually occur in multiple and complex forms such as methylated, ethylated, glycosylated, esterified, thiolated, or hydroxylated [15]. These include about 8000 varieties of phenolics including flavonoids and non-flavonoids; about 25,000 terpenoids, carotenoids, xanthophylls, and iridoids; about 12,000 alkaloids; and several sulfate-containing compounds such as isothiocyanates [11]. To date, numerous studies of the capacities of functional components as phytochemicals including glucosinolates, phytosterols, tocopherols, tocotrienols, allyl sulfides, and non-starch carbohydrates including soluble and insoluble dietary fiber and fucoidan, as antioxidation, anticancerous, anti-inflammatory, antiviral, immune modulating, and antihypertensive agents are widely reported in literature [16–18]. The list is never exhaustive as new compounds beneficial to human health are constantly being discovered [19].

Functional components exhibit the capacity to modulate one or more metabolic processes, which results to optimal health benefits and promotion of wellness in humans. In addition, they have been shown to exert multiple bioactive functions including scavenging of reactive oxygen species (ROS), dynamic regulation of metabolic functions of proteins, enzymes, transporters, receptors, and signal transduction processes related to various lifestyle-related diseases. Thus, allowing for beneficial effects on several degenerative and non-communicable and chronic diseases as well as target tissues [11, 15]. Therefore, functional components have potential positive impact on health beyond basic nutrition. An overview of the types, functions, medicinal properties and sources of some food functional components as reported by Abuajah et al. [20] is as follows:

2.1 Non-starch Carbohydrates (Examples Dietary Fibers, Fucoidans)

Basically, these are structural and storage carbohydrate polymers of simple sugars including glucose, galactose, fructose, xylose, arabinose, etc., but are not starchy in nature (i.e. their sugar units are not linked by either α-(1 → 4) or α-(1 → 6) glycosidic bonds. Thus, they are not hydrolysable by the human digestive enzymes but undergo fermentative modification by the probiotic microbes in the colon. There are several kinds of non-starch carbohydrates including dietary fibers and fucoidans.

(a) **Dietary fibers**: Dietary fibers (DF), which could be either soluble or insoluble, are non-starchy polysaccharides and structural materials of the cell walls of cereals and microorganisms. They are the indigestible part of plant foods composed of long linear and branched chains of glucose molecules held together by bonds that cannot be hydrolyzed by human digestive enzymes. Chemically, DFs are glucose polymers in hetero-structural configuration of β-(1 → 3:1 → 4) or β-(1 → 3:1 → 6) bonds depending on their sources (Fig. 1). Cereal and bacterial DFs are primarily linear with large regions of β-(1 → 4) linkages

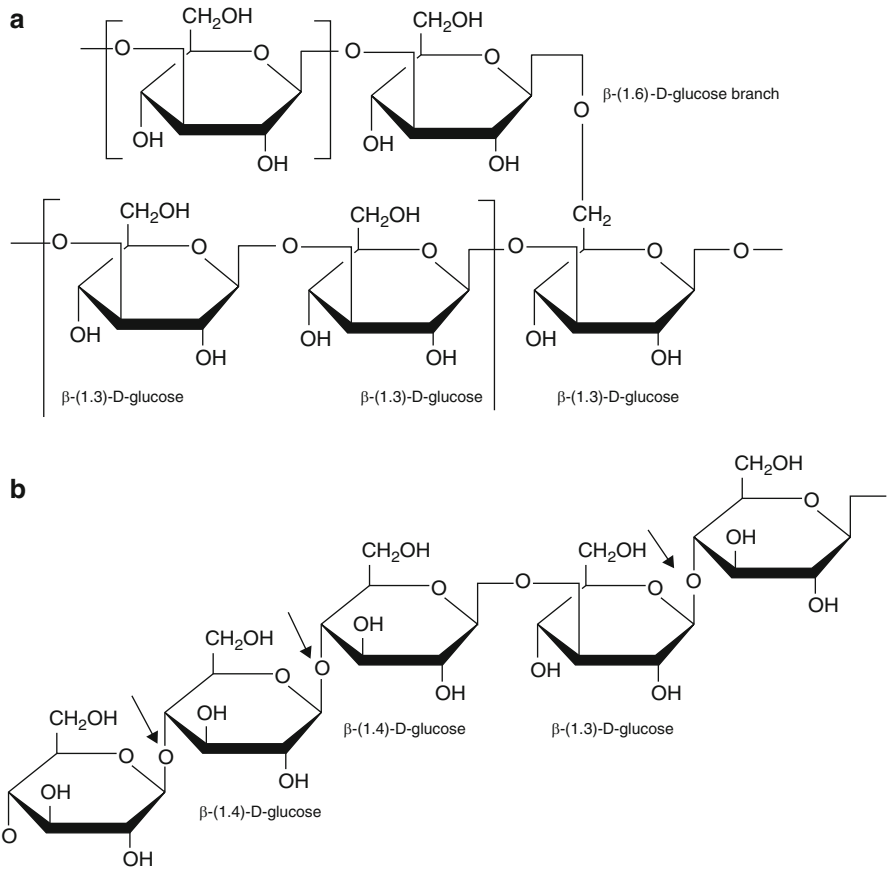

Fig. 1 Structures of β-glucans. (**a**) Fungi β-glucan (**b**) Cereal β-glucan

separating shorter stretches of β-(1 → 3) structures. Fungi β-glucans (e.g., mushroom) have short β-(1 → 6)-linked branches coming off the β-(1 → 3) backbone whereas those of yeast have β-(1 → 6) branches that are further elaborated with additional β-(1 → 3) regions. These structural differences do have large implications and impact on their properties, e.g., water solubility.

Also, differences in the length of the polysaccharide chain, extent of branching, and the length of those branches result in differences in hot water extracts (HWE), level of viscosity and differences in molecular weights [9, 21–23]. The water-soluble fibers are mainly β-glucans, gums, pectin, mucilage and arabinoxylans while the water-insoluble fibers are composed of lignin, cellulose and hemicellulose [24–26]. Specifically, the mixed-linkage structure of β-glucans and length of the polysaccharide chain or degree of polymerization (DP) are responsible for their physical properties and characteristics including viscosity, solubility, molecular weight,

water binding capacity (WBC), and foamability (foam capacity and stability). These linkages prevent compact folding of β-glucan chains, making them soluble in water [27, 28]. To maintain their functional attributes, it is important that the processing of β-glucans does not destroy their structure because these large macromolecules are mechanically sensitive and can be broken at high shear rates [28].

(b) **Fucoidans**: Fucoidans are non-starchy but sulfated polysaccharides which occur in various species of brown algae and brown seaweed such as mozuku, kombu and bladderwrack. Different forms of fucoidan have also been discovered in animal species, including sea cucumber [29]. Fucoidans have a complex structure which varies according to its source. It is primarily a polymer of α-(1 → 3) linked fucose pyranose sugar units with sulfate groups substituted at C-2 and C-4 positions on some fucose residues. In addition, fucoidan backbone could be of α-(1 → 3)-linked α-*l*-fucopyranose sugar or of alternating (1 → 3)- and (1 → 4)-linked α-*l*-fucopyranose sugar residues, which may also include sulfated galactofucans with backbones built of β-(1 → 6)-*d*-galacto- and/or β-(1 → 2)-*d*-mannopyranose sugar units with fucosepyranose or fuco-oligosaccharide units forming branched points (one for every 2–3 fucosepyranose residues within the chain) with glucuronic acid, xylose or glucose substitutions [29, 30]. Two structural features which distinguish fucosepyranose from other six-carbon pyranose sugars present in mammals are the lack of a hydroxyl group on the carbon at the 6-position (C-6) and its l-configuration [31]. Basically, fucosepyranose is equivalent to 6-deoxy-*l*-galactose. A simple structure of fucoidan polymer and a non-substituted fucosepyranose sugar unit are shown in Fig. 2.

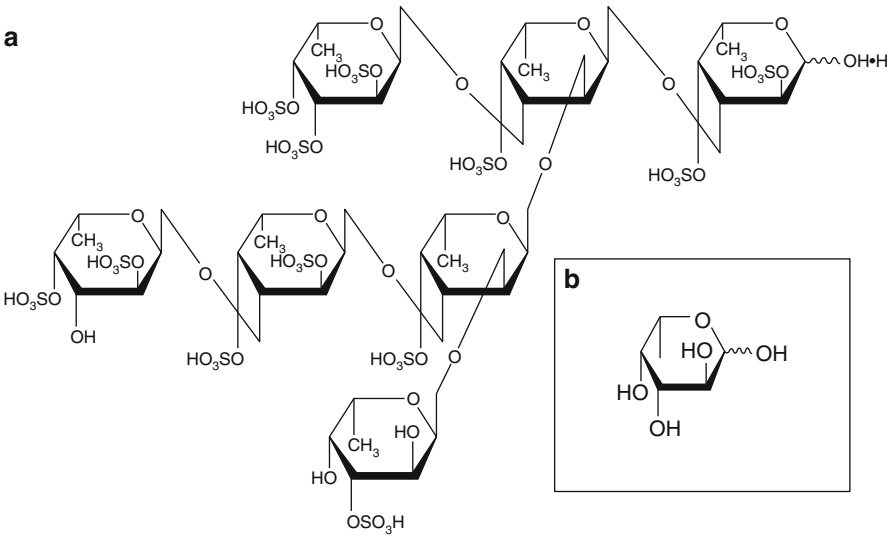

Fig. 2 Structures of (**a**) Fucoidan (**b**) Non-substituted fucose pyranose unit

2.1.1 Functions

The long fibrous structures of dietary fiber allow them to entrap harmful toxins and carcinogens in the digestive tract. Cereal β-glucan (a soluble dietary fiber) has gained special attention for their many health benefits including its viscous nature that slows down the passage of food through the gut thereby reducing the rate of glucose absorption in the intestine, thus lowering the glycemic index (blood glucose level) and serum cholesterol. In addition it possesses the characteristics of good water retention capacity, gelling ability and hydro-colloidality and these properties have influenced their use as substitutes for fat [32]. β-Glucans act as anticytotic, antimutagenic, antitumoregenic and immunomodulatory agents in the human body. Fungi β-glucans, a family of diversified structures found in the cell wall of yeast and molds, enhance leucocytes activity that is responsible for enhancing body defense mechanism. They have been reported to act as immune system activators and cell response modifiers. Innulin has successfully replaced fat in dairy products [6, 22, 23, 28, 33]. Soluble dietary fiber can dissolve in or absorb water and is effective in binding toxins and cholesterol in the intestinal tract. Based on data from in vitro and in vivo animal studies, β-glucans enter the proximal small intestine rapidly and are captured by the macrophages after oral administration. The β-glucans are then internalized and fragmented into smaller sizes and are carried to the marrow and endothelial reticular system. The small β-glucans fragments are then released by the macrophages and taken up by the circulating granulocytes, monocytes and dendritic cells (Fig. 3). This turns on the immune response system [22, 34].

β-Glucans are captured by macrophages via the Dectin-1 receptor with or without toll-like receptors 2 and 6 (TLR-2 and 6). The large β-glucan molecules are then internalized and fragmented into smaller sizes within the macrophages. They are carried to the marrow and reticulo-endothelial system and subsequently released. These small β-glucan fragments are eventually taken up by the circulating

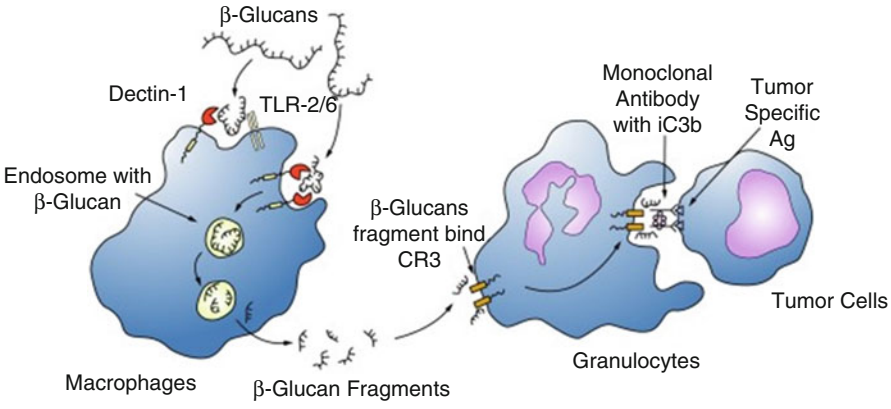

Fig. 3 β-Glucans and resistance to infections

granulocytes, monocytes or other macrophages via the complementary receptor 3 (CR-3). This turns on the immune response; one of its actions being the phagocytosis of the monoclonal antibody tagged tumor cells.

Similarly, β-glucans can bind and act on a diversity of immune specific and related receptors including Dectin-1, complement receptor cells (CR3), cytokines, chemokines, transcriptional factors and growth factors to trigger a wide spectrum of immune responses. The targeted immune cells of β-glucans include macrophages, neutrophils, monocytes, natural killer (NK) cells and dendritic cells. Thus, a cascade of information transduction system is initiated that stimulates the entire immune system against unwanted cell growth. The immunomodulatory functions induced by β-glucans involve both innate and adaptive immune responses [21, 22, 35, 36]. Simplified illustrations of these mechanisms are shown in Fig. 4. Insoluble dietary fiber, on the other hand, cannot dissolve in water and is effective in adding to fecal bulk and increasing the rate of passage of food through the intestinal tract. Insoluble dietary fiber also dilutes out potential carcinogens and decreases contact of toxins and carcinogens with the intestinal tract and speeds up their passage out of the body [23, 27, 28].

β-Glucans act on a variety of membrane receptors found on immune cells. By their actions various signaling pathways are activated and their respective simplified downstream signaling molecules are shown. The reactor cells include monocytes, macrophages, dendritic cells, natural killer cells and neutrophils. Their corresponding surface receptors are listed. β-Glucans also trigger a cascade of cytokines release, such as tumor necrosis factor alpha (TNF)-α and various types of interleukins (ILs). The immunomodulatory functions induced by β-glucans involve both innate and adaptive immune responses.

Fucoidans offer various potential bioactive and functional benefits. It is used as an ingredient in some dietary supplement products. The bioactive properties may vary depending on the source of seaweed, the compositional and structural traits, the content (charge density), distribution, and bonding of the sulfate substitutions, and the purity of the fucoidan product. Fucoidan inhibits the spread of cancerous cells by preventing the adhesion of tumor cells to the extracellular matrix as well as induce apoptosis, or programmed self-destruction, in human T-cell leukemia virus type I (HTLV-1) which is responsible for adult T-cell leukemia. The polysaccharide paves way for apoptosis by inactivating NF-kB, a naturally occurring substance that regulates anti-apoptotic proteins [31].

Fucoidan have also been shown to stimulate the phagocytic action of macrophages and synthesis of several immune cell types, which increase protection against infection [21, 22, 37]. The nutritional makeup of fucoidan could be likened to that of breast milk which is the most perfect immune-supporting food known. The polysaccharide gives the immune system a big boost by enhancing phagocytosis, the process through which white blood cells attack and destroy pathogens. Fucoidan also increases the number of mature white blood cells that are circulating in the body, activity against hepatopathy, uropathy and renalpathy, protective effects on gastric organ and gastric mucosa as well as therapeutic potential in surgery [29], bolstering the first line of defense against infections and diseases

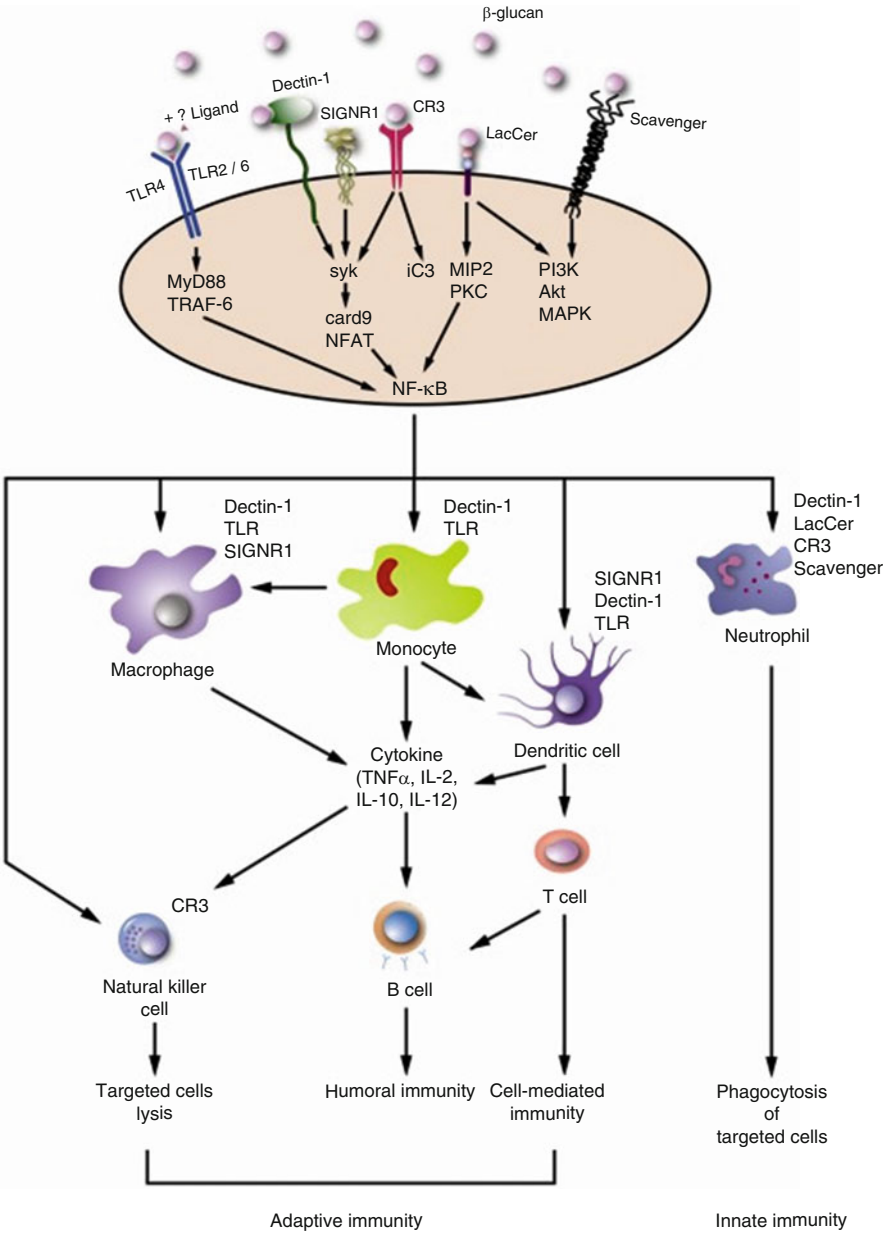

Fig. 4 Immune activation induced by β-glucans

[37]. In addition, several other bioactivities associated with fucoidan have been reported in literature including anti-coagulant and anti-thrombotic activity of blood plasma, antivirus, anti-inflammatory, reduction of blood lipids, anti-oxidation, and anti-complementary properties.

2.1.2 Sources

Foods rich in soluble dietary fiber (DF) include apples, cranberries, mango, oranges, asparagus, broccoli, carrots, peanuts, walnuts, most legumes, oats, and psyllium while those rich in insoluble dietary fiber are apples, bananas, berries, broccoli, green peppers, spinach, almonds, sesame seeds, most legumes, brown rice, whole-wheat breads and cereals. In addition, cereals (e.g., oats and barley) and bacteria are rich sources of β-(1 → 3:1 → 4)-glucan (a DF with strong colloidal properties which is considered as good functional ingredient in foods for its cholesterol-lowering and low-glycemic index functions). β-(1 → 3:1 → 4)-Glucan is present in cereal bran (e.g., 2.2–7.8% in oat and 2.5–11.3% in barley). Brown seaweeds and some medicinal mushrooms are high in fucoidan [38]. Polysaccharides of mushrooms and yeasts such as β-(1 → 3:1 → 6)-glucan have been in focus for their anti-tumor activity and the chemical diversity of these glycans ranges from homopolymers to highly complex heteropolymers. Varieties of sugars such as glucose, galactose, mannose, xylose, arabinose, sucrose ribose, glucouronic acid etc. are involved in the formation of such polysaccharides. Some of the glycans which form conjugates with proteins and peptides show higher potent anti-tumor activity [21, 22, 39].

2.2 Carotenoids, Phenolics, Phytosterols, Tocopherols/Trienols and Organo-Sulfur Compounds

Carotenoids, phenolics, phytosterols, tocopherols/trienols and organo-sulfur compounds are classes of phytochemicals commonly referred to as antioxidants. Antioxidants are bioactive compounds which neutralize free radicals, reactive oxygen species (ROS), and reactive nitrogen species (RNS) in the cell. A free radical is an atom that has an unpaired electron and is highly charged and unstable and causes damage to the cell. Free radicals can form in lipids, proteins, and carbohydrates. Examples of antioxidants are as follows:

(a) **Carotenoids (examples Lycopene, Lutein)**: The carotenoids are lipid-soluble plant pigments that are either oxygenated or non-oxygenated hydrocarbons containing at least forty carbons and an extensive conjugated double bond system. Alpha-carotene, beta-carotene, and lycopene are the predominant non-polar functional carotenoids and lutein is the primary polar functional carotenoid. Carotenoids can be found esterified to fatty acids or un-esterified in plant tissues. Lycopene are the most active oxygen neutralizer with potential chemopreventive activities (Fig. 5). The total carotenoid content of fruits and vegetables varies with age and storage [40].

(b) **Phenolics (examples Apigenin, Rutin)**: Phenolic compounds, commonly known as polyphenols, are the most numerous and widely distributed group of functional molecules. They are diverse groups of plant substances that contain one or more (benzene) rings and varying number of hydroxyl (OH), carbonyl (CO) and carboxylic acid (COOH) groups. They commonly exist in conjugated forms with one or more attached sugar residues. They are classified as flavonoids which comprise

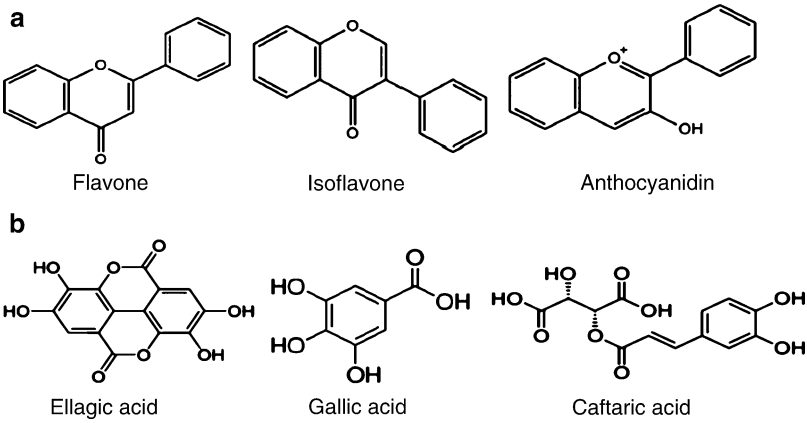

Fig. 6 Structures of polyphenols (**a**) Flavonoids (**b**) Nonflavonoids

of flavonols (kaempferol, quercetin), flavones (apigenin, luteolin), isoflavones (daiazein, genistein), flavanones (naringenin, hespertin), anthocyanidins (malvidin, cyaniding) and flavan-3-ols (catechin, epicatechin), and non-flavonoids including chlorogenic acids such as quinic acid and tartaric acid [40, 41] (Fig. 6). Phenolics content can vary tremendously between food sources and within foods of the same type. The following ranges were reported for total polyphenol content in some food materials and fruits: barley and millet (590–1500 mg 100 g^{-1} dry matter); oats and corns (8.7–30.9 mg 100 g^{-1} dry matter); fresh onions and leeks (20–20.25 mg 100 g^{-1} dry matter), fresh brussel sprouts (6–15 mg 100 g^{-1} dry matter), blueberries, strawberries, cranberries, and raspberries the total polyphenol content is about 37–429 mg 100 g^{-1} dry matter [42].

(c) **Phytosterols (example Stigmasterol)**: Phytosterols are the plant equivalent of cholesterol in animals. Their structures are similar. However, the side-chain in plant sterols contains additional double bonds and methyl and/or ethyl groups.

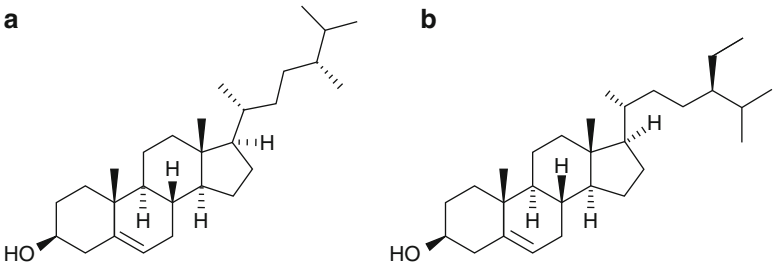

Fig. 7 Structures of phytosterols (**a**) campesterol (**b**) Beta-sitosterol

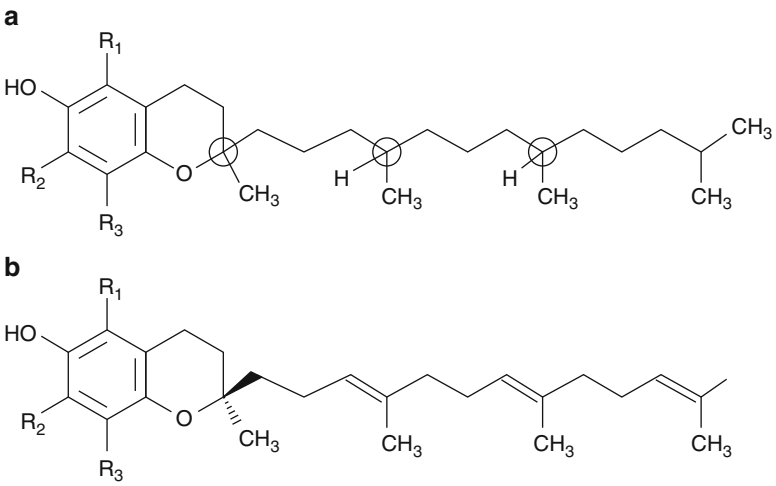

Fig. 8 Structures of (**a**) Tocopherol (**b**) Tocotrienol

The most common bioactive phytosterols are beta-sitosterol, kampesterol and stigmasterol (Fig. 7). A daily non-vegetarian diet contains approximately 250 mg of unsaturated phytosterols while a vegetarian diet contains over 500 mg. The saturated derivatives of plant sterols are plant stanols such as sitostanol [5].

(d) **Tocopherols/Tocotrienols (example Vitamin E)**: The tocopherols and tocotrienols are lipid-soluble functional components which contain a phenolic-chromanol ring linked to an isoprenoid side chain that is either saturated (tocopherols) or unsaturated (tocotrienols) (Fig. 8). There are also four primary forms of tocopherols and tocotrienols: alpha, beta, gamma, and delta that differ in the number and position of methyl groups on the phenolic-chromanol ring. In addition, tocopherols have three asymmetrical carbons at positions 2, 4, and 8 of the isoprenoid side chain. Consequently, there are eight isomeric forms of tocopherols, of which RRR-a-tocopherol has the greatest bioactivity and is also the most abundant in human blood and tissues [6, 40].

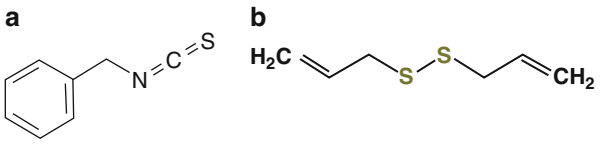

Fig. 9 Structures of organo-sulfur compounds (**a**) Benzyl isothiocyanate (**b**) Diallyl disulfide

(e) **Organo-sulfur compounds (example Diallyl sulphide)**: The organo-sulfur compounds are commonly found in cruciferous vegetables such as broccoli, cauliflower, and brussel sprouts or allium vegetables (vegetables in the same family or class with cabbage, onions and garlic) such as leeks. Organo-sulfur compounds contain sulfur atoms that are bound to a cyanate group or a carbon atom in a cyclic or non-cyclic configuration. The functional ingredients of foods containing organo-sulfur compounds are obtained only after cutting, chewing or crushing has disrupted the cells to expose them. In cruciferous vegetables, various isothiocyanates such as sulforaphane, phenyl isothiocyanate and benzyl isothiocyanate (Fig. 9a) are formed from glucosinolyates by the action of myrosinase. In alliums, allicin is formed from allin and then rapidly converted to diallyl sulfide, diallyl disulfide (Fig. 9b) or diallyl trisulfide by the action of allinase. In both cruciferous and allium vegetables, these hydrolytic breakdown products are the health-promoting functional components [5].

2.2.1 Functions
