Foreword

People with Intellectual Disability (ID) are a diverse group of people with individual needs. Aetiological factors associated with ID have an impact on the origin and course of mental health problems and on the type of therapeutic interventions that would be most appropriate for them.

Historically, it was believed that people with ID were being incapable of having mental health problems. However, epidemiological studies over the last few decades consistently disproved this, showing that people with ID have a higher frequency of mental health problems than the general population. The occurrence of mental health problems in people with ID varies according to methodology used for their estimation. An increased vulnerability to mental health problems for people with ID is likely to be due to an increased incidence of brain abnormalities including associated epilepsy, physical and sensory problems, social and psychological hardships, and misfortunes. The severity of ID, adaptive behaviour and social skills deficits are also related to the presence of mental health problems for people with Autism Spectrum Disorders (ASD).

The current textbook of "Psychiatry for Intellectual Disability and Autism Spectrum Disorder" is a welcome addition to the few existing textbooks related to mental health problems for people with ID. Written by a large group of international multi-professional contributors and edited expertly by experienced editors, led by the recognised expertise and proficiency of Dr Marco Bertelli, under the auspices of the World Psychiatric Association (WPA), presents the up-to-date evidence base in the field. Dr Marco Bertelli is credited with his long-standing systematic contribution for the enhanced involvement of the World Psychiatric Association to mental health problems of people with Intellectual Disability. He was fellow at the 12th (Yokohama 2002) and 13th (El Cairo 2005) WPA World Congress, chair of the WPA Section on Psychiatry of Intellectual Disability and WPA Lifetime Honorary Member since the 15th World Congress (Buenos Aires 2015).

The authors of the different chapters provide arguably a worldwide perspective of the research summarising the key topics in the mental health of ID field. A distinct difference of the current textbook includes several contributions on conceptual, cultural, ethical and spiritual issues as well as human rights and broad health issues relating to people with ID. There are also important contributions relating to people with ASD who are known having a high prevalence of comorbid anxiety, obsessive compulsive and attention deficit hyperactivity disorders (ADHD). In reviewing each area, the authors have included recent advances, and many have offered pointers to further progress. In addition, this book is a comprehensive resource for clinical practice including those underpinning assessment, management and service delivery.

The process of deinstutionalisation and the development of community care of ID services, which took place in the latter part of the 20th century, brought up the complexities of meeting the mental health needs

of people with ID. The introductory chapters on definition, new terminology of Intellectual Developmental Disorders, nosology, epidemiology and prevalence offer insight into the underline debate and conceptual concerns. Considerable improvement has been documented for the assessment and diagnosis of mental health problems for people with ID. This is highlighted in this volume by leading experts of international recognition. Reliable tools and methods that have been developed and are used in clinical practice and research for the assessment and diagnosis of mental health problems in both adults and children with ID are lucidly described.

The aetiology, symptomatology and treatment methods of the core psychiatric conditions are presented on an updated evidence and practice base. The controversy on psychiatric versus behavioural problems or challenging behaviour remains a thorny issue that is further explored. Challenging behaviour, such as aggression, is often the primary reason people are referred to ID and mental health services, and they can often fluctuate over years and be chronic in duration. The overlap between psychiatric conditions and challenging behaviours in people with ID and low-functioning autism should neither be over nor under-played because it has significant clinical and service implications. In clinical practice, it is not always possible to precisely separate psychiatric conditions from behavioural problems in people with ID. It is likely that there is a combination of biological, social and environmental factors interacting with cognitive and adaptive deficits to make people with ID vulnerable to mental health and behavioural problems.

As the population of ID survives longer into old age, aspects of mental health previously not considered relevant have become more prominent. For example, in adults with Down syndrome who now are surviving well into their sixties, a considerable percentage at the age of 50 years have a clinical diagnosis of Alzheimer's disease. This issue is also discussed from research and clinical points of view.

The need for a bio-psychosocial approach, including coordinated multidisciplinary input, is of paramount importance. After decades of community care, unanswered question remains about the appropriateness of generic mental health services versus specialists services for meeting the mental health needs of people with ID. The arguments and the existing evidence base in favour and against mental health systems are rehearsed in this volume and should be of help to policymakers, practitioners and researchers. The number of possible interfaces between services is increasing. Together with existing uneven financing systems, these interfaces are increasingly struggling to manage personalised care pathways adjusted to the needs of people with ID and mental health problems, their careers and families.

The needs of people with ID and offending behaviour, several of whom having also additional mental health problems was overlooked with the deinstitutionalisation. Service provision has lagged developments for local services in countries such as UK, resulting in many people with ID and forensic needs to have been placed in residential facilities a long way from their local communities and at times in unnecessary restrictive environments. The authors of the relevant chapter, having

extensive knowledge and experience, suggest that care for people with ID and forensic needs requires strong interfaces and partnership between ID, mental health and forensic services.

The concluding chapters of the book refer to cultural, spiritual and human rights issues. Cultural aspects vary together with deep-rooted traditions and values that are reflected in the quality of care for people with ID and or ASD. Furthermore, people with ID have the right to spiritual expression and practice of beliefs. The protection of human rights is of utmost importance where prejudices and barriers are removed and everyone can live without being stigmatised.

A strategic approach needs to be adopted to ensure effective person-centred services where there are care pathways that connect health and social care, support and education services as when a person might need these services. Despite progress, there is still a need for clear interfaces with services, joined-up working between different agencies, proactive commissioning strategies, development of academic centres and further research into service models and outcomes.

This volume presents an evidence-based comprehensive publication for the mental health problems of people with ID and or ASD. An obvious question is how the outcomes produced by research can be translated for the benefit of people with ID, their families and their careers. The transformation of care for people with ID over the last half a century includes the movement towards integration, participation and choice as well as civil and human rights movements on a national and international level. There is now a consensus on the need to respond more adequately to mental health needs in this population. The current trends are geared towards community integration and schemes with service users' participation at all levels, including design and implementation by using a person-centred approach. Despite the existence of policies and services for people with ID, recognition of and provision for their mental health needs carry low priority. This gap is greater in low and middle-income countries, where the burden of disability needs to be recognised to plan for and meet the needs of those with developmental and intellectual disabilities across their lifespan. It remains to be seen how people with ID experience the reality of equality and absence of discrimination and whether stigma and negative attitudes by others will be eliminated.

Nick Bouras
Institute of Psychiatry, Psychology and Neuroscience,
King's College London, London, UK

Preface

Since I entered University to become a medical doctor, I have always loved research. I think research is fundamental for clinicians to the same extent to which clinical challenges represent a base for research. Medical research is also a unique opportunity to identify or operationalise things that can improve humans' health and quality of life.

Halfway through my training in medicine, I felt that most of the medical specialisations would not have met my interest in philosophy and humanities developed during my previous studies at the high school, but fortunately I discovered psychiatry as a discipline implying a complex approach to human suffering and thus able to combine all my interests. I thought that entering the mind of persons with schizophrenia or other major psychiatric disorders and helping them to recover could be the most satisfactory thing I could ever do as a medical doctor. Thus I was very disappointed when in response to a request for a topic for my graduation thesis, the Professor of Psychiatry imposed me a research on intellectual disability, mental retardation at that time, which was largely considered the "Cinderella of psychiatry".

Nevertheless, I was looking forward to working as a psychiatrist in a real clinical way and my main desire was to complete my training and to graduate, so I decided to accept. I can now say that this apparently unlucky obligation was one of the greatest opportunities of my life. In fact by entering the field of mental health of intellectual disability, I increasingly realised that I was getting in touch with the most complex pathogenic and phenomenic aspects within psychiatry and the best chances to help other persons to soothe their mental suffering and bring a contribution in life to make a better world.

In the last century, intellectual disability and autism have been neglected by psychiatry for a long time and still are, although in the previous century psychiatry had a well-established and well-documented role in promoting an appropriate care for what was called mental retardation. According to Frank Menolascino, who can be considered one of the founders of modern psychiatry of intellectual disability, this withdrawal resulted "in a number of stereotyped views or blindspots …, that are: uncritical acceptance of mental age as an adequate description of a person; treatment nihilism … associated to the overriding focus on chronicity and irreversibility; and excessive focus on the severely retarded in contrast to the mildly retarded".

In the last 15 years, the interest in autism has grown a lot in the psychiatric field but not that for people with the greatest need of support, such as those with minimal verbal ability or low IQ, to whom the main attention is given in this textbook. In most countries across the world, persons with intellectual disability and low-functioning autism still face great difficulties in accessing mental health service and in receiving adequate assessment and care. Specific training of mental health professionals is also lacking, at both undergraduate and graduate levels.

This neglect has always been unfair and inappropriate to me. Unfair because persons with intellectual disability and low-functioning autism

would deserve, as persons, at least the same attention as all other persons, but even more for their higher difficulties and risks in daily life and higher vulnerability to the full range of psychopathological features.

Many of the current limits to an appropriate mental health care and more generally to community inclusion are linked to the conceptualisation of intelligence, as a unitary capacity which defines human nature in its most important transcendental component. The persistent IQ reduction confines persons with intellectual disability into a condition of eternal sickness or eternal childhood as well as into a persistent position of inferiority and unworthiness, which many persons with intellectual disability end up identifying with. In reality, it has never been demonstrated that unitary intelligence is an entity of nature and not a mere human construction. Nor has it ever been proven that the mind and the body represent two dichotomous realities.

The study of the human psyche has been characterised for many years by a clear separation between body and mind but also between affectivity/emotionality and cognition/intelligence. In traditional cognitivism, body processes were seen essentially as by-products of cognition, and as too little specific to be able to contribute to the variety of emotional experiences. The embodied vision of the mind has not yet been adopted in theories of emotionality, despite the fact that the body has always occupied an important place in the study and characterisation of emotions, from Darwin onwards. To date, the level of knowledge on the inter-relationship between emotionality, corporeality and cognition absolutely does not allow us to consider people with intellectual disabilities and autism as limited in their humanity.

In addition to being unfair, the scientific community's neglect of the mental health of people with intellectual disabilities and low-functioning autism has also been inappropriate because the development of scientific knowledge in this area has general important implications for the entire neuroscientific field, such as the understanding of the link between early specific cognitive deficits and psychopathological vulnerability, the definition of the grade of adjunctive functional impairment and clinical distress associated with the co-occurrence of psychopathological conditions, the possibility to identify psychiatric symptoms in patients with cognitive and communicative limits, basing on observable and behavioural changes from the baseline, and to distinguish them from the features characteristics of the developmental conditions. Furthermore, psychiatry of intellectual disability and autism is looking for the most useful way to combine developmental/idiographic (narrative) and nomothetic approaches to mental suffering and to implement person-centred outcome measures, such as generic quality of life. Even models of care (residential care, respite care, multidisciplinary approach to care, etc.) and social issues of health (stigma and labelling, self-advocacy, etc.) that were first developed in the intellectual disability field are now widely used in general psychiatry and other neuroscientific disciplines. Many contributions are also being brought on how individual cognitive, emotional, behavioural and relational characteristics emerge and change across early and lifetime development of the brain, and how they can be altered and manifest as mental health conditions or mental health

problems. Recent findings in neuroscience display that many of what have been traditionally considered to be distinctive forms of psychopathology have features in common with one another, co-occur, present in the same person across the life span or represent age-adjusted variations of common underlying dispositions. Genome-wide association studies increasingly show that copy number variants of several syndromes including intellectual disability and autism are present also in many other major psychiatric disorders such as schizophrenia, bipolar disorder and major depressive disorder. Most developmental, psychiatric and neurological disorders have recently been proposed to be part of a unique group of disorders affecting neurodevelopment.

Thus, the present textbook places intellectual disability and autism at the very centre of neuroscience in general and psychiatry in particular, anticipating a position that will soon be embraced by the entire scientific community.

People with intellectual disabilities and autism are an asset to the world community on many levels. On a conceptual level, because they value the diversity and fragility foreseen by nature for the neuropsychic system of the human being, on a concrete level, because in the right context they can make their own contribution to society, and on an evolutionary level, because they help the humankind to overcome its limits and to acquire increasing capacity for attention and balance with the essential aspects of their existence.

This textbook represents for me a major milestone in the long path of research and clinical practice. Its preparation spanned over 4 years, amidst numerous difficulties, unforeseen events, the COVID-19 pandemics (after which we added a chapter focusing on teletraining and teleassistance) and the need to keep updated the chapters already completed. This book was inspired by the will of sharing knowledge and transmitting passion to colleagues, especially young and future colleagues. In fact, it is intended for use by graduate students and trainees of university faculty, practitioners in clinical disciplines or management roles in developmental disabilities services and education, and to a lesser degree, undergraduate students, parents, attorneys and advocacy groups. Faculty will find this book particularly useful as a primary course text at the graduate level. Researchers will find the coverage contained herein useful for a summary of current knowledge about a subarea of psychiatry of intellectual disability and low-functioning autism that is new to them or that intersects their own specialty in the wider field of developmental disabilities. Practitioners and educators can use the textbook as a resource to point to when there is a doubt or a debate regarding diagnostic issues, appropriate treatments or intervention practices.

The overall purpose of this textbook is to provide readers with a complete and up-to-date overview of the state of knowledge in the field of psychiatry for persons with intellectual disability and autism.

I have invited the wide majority of most authoritative authors to contribute to the textbook in order to provide readers with the very best and up-to-date knowledge, and to reflect the growing awareness of the mental health needs of people with intellectual disability and autism across many countries and cultures.

Authors were asked to yield foundational conceptual information on their assigned topic, to identify valuable studies in the related literature, to emphasise the latest research findings and to provide clear conclusions and interpretations.

There is variation across the chapters in terms of length and focus, which is mainly a reflection of the evidence base available on specific issues. I have also allowed some overlaps, as for the numerous and strong links between the different aspects of mental health in this field and an interdisciplinary approach.

Not all the issues concerning the complex field of psychiatry of intellectual disability and autism have been deepened as I would have liked. I hope that I will still be given time and energy to produce increasingly precise and useful updates and insights in the coming years. Nevertheless, as far as my knowledge, the present work represents the most comprehensive and up-to-date textbook worldwide in the field of mental health of neurodevelopmental disorders, with the highest number of chapters and eminent authors from across the world. It has been realised under the aegis of the World Psychiatric Association within its 2021–2023 action plan.

It can be considered an essential reading also for future prospects, as it displays how we started moving into a new century of discovery, evolution, and high-quality care for people with intellectual and developmental disabilities.

Marco O. Bertelli, Leading Editor
Florence, Italy

Acknowledgments

This textbook has been realised thanks to the precious contribution of a stellar group of world-renowned authors, 116 leading experts in the field of mental health of intellectual and developmental disorders from around the world. I am deeply grateful to all of them for their diligence in writing the chapters and for their willingness to accept my recommendations, integrations and various other requests along the way. Special thanks go to Dr. Shaun Gravestock, who worked on his part until a few days before passing away from COVID-19, and his partner, Darren Ward, who took care to find and pass on Dr. Gravestock's work to me in times of extreme grief.

Thanks also to the co-editors, Professors Shoumitro (Shoumi) Deb, Angela Hassiotis, Luis Salvador-Carulla and Kerim Munir, who have generously shared their insights, suggestions and thoughts. Particular appreciation goes to Professor Shoumi Deb, who has been remarkably active and has provided huge unwavering support at the times when it was needed most. The making of this textbook took more than five years, but it would have taken even longer without him.

The present textbook represents an important outcome in my long path through the field of psychiatry of neurodevelopmental disorders, which started with Dr. Giampaolo La Malfa and Professor Pier Luigi Cabras at the Operative Unit of Psychiatry, Department of Neurological and Psychiatric Sciences of the University of Florence, Italy, during which I met many people who have fuelled my passion, informed my knowledge and inspired my research and clinical activities. I want to thank them all.

My career in the World Psychiatric Association (WPA) has begun in 2001 at the Antalya (Turkey) WPA Regional Meeting, where I delivered a speech in substitution of Professor Giovanni Stanghellini and where I met Professor Juan Mezzich who encouraged me to apply for a fellowship for the 2002 Yokohama World Congress (Japan). I am deeply grateful to Professor Mezzich for this opportunity and for his constant presence during my WPA career. During the Yokohama fellowship and the following one at El Cairo, Egypt, I had the extraordinary opportunity to be trained by leading international experts and to share opinions and experiences with young colleagues from all around the world. I could also progress my activities within the WPA Section "Psychiatry of Intellectual Disability" which I had started few years before the Antalya congress. Professor Nick Bouras and Professor Luis Salvador-Carulla have been my guides within the Section and other related assignments. I want to thank them for the knowledge and the constant support they provided to me during my tenure as the Section chair and the other commitments within the WPA, including the creation of this textbook. I received an extraordinarily intense albeit brief contribution from Professor Ludwik Szymanski in a meeting with him that represented a physical contact with the origins of the Section and the history of psychiatry of intellectual disability.

Thanks also to Professor Mario Maj, the WPA President during 2008–2011, and his Executive Committee, who awarded me the WPA lifetime honorary membership at the end of the first of my two terms as Section chair and who helped to sustain my enthusiasm to write this textbook. Other WPA leadership figures who have shown respect for me and whom I want to thank are Professor Norman Sartorius, the WPA President during 1996–1999 who was my mentor all along my WPA training, Professor Levent Kuey, the WPA Secretary General during 2008–2011, and more recently Professor Afzal Javed, the current WPA President, who has included mental health needs of people with neurodevelopmental disorders in the priorities of the 2020–2023 WPA action plan and who entrusted me with the chairing of the working group on autism spectrum disorder, one objective of which is to produce this textbook. I also thank Professor Michel Botbol and Professor Norman Sartorious for their particular interest in the production of this textbook and highlighting its cultural and scientific importance on the world scene.

Another part of the knowledge and passion that I have put into this work has developed thanks to the valuable persons I met along my journey in the European Association for Mental Health in Intellectual Disability (EAMHID) such as Anton Dosen, founding father of the association together with Professor Nick Bouras, Germain Weber, Roger Banks, Herman Woiters (my super-efficient and loyal secretary during my presidency and a person of extraordinary kindness and moral fiber), Jane McCarthy, Johan DeGroef, Raymond Ceccotto and Tanja Sappok. I would like to express further thanks to Tanja for protecting the importance and visibility of this textbook by refusing the invitation of various publishers to write a similar book. Intellectual honesty and corporate spirit of this kind are hard to find these days.

My ideas and arguments have also benefited from enormously helpful feedback I have received in presenting parts of these textbooks at the EAMHID International Congress I organised in Florence in September 2015 and at the last three WPA World Congresses, in Mexico City, Lisbon and Bangkok (virtual). The rich ideas and discussions at these meetings have broadened my scientific and cultural horizons and have given me a new critical perspective on my work.

My understanding of neurodevelopmental disabilities, both as lived experience and as an area of academic and clinical practice, has been greatly enhanced through the dialogues and interactions with persons with intellectual disabilities and/or autism spectrum disorders and their family members as well as through the conversations with professionals and scholars within and beyond the mental health field. I want to acknowledge Professor Giovanni Stanghellini for his extraordinary insights and innovative perspectives in psychopathological phenomenology and philosophy, Dr. Carlo Francescutti, whose views increased my research attention to the interdisciplinary working in daily practice and whose passion for this field continues to encourage me, Dr. Maria Luisa Scattoni for her extraordinary neuroscientific knowledge that ranges from basic research to the multidisciplinary organisation of interventions and services, Dr. Serafino Corti for his invaluable assis-

tance and involvement in both the reform of national scientific societies and the increasing strengthening of the activities that emerged, and Professor Ivan Brown, who introduced me to the deeper dimensions of whole-person quality of life and their importance in evaluating the outcomes of any intervention. I also want to offer special thanks to two fellow psychiatrists who I am honoured to count among my closest friends, Dr. Michele Conte, whose great culture, critical spirit, and "visionary" skills have challenged my convictions and stimulated important improvements on several occasions, and Dr. Michele Mancini, whose ample experience in clinical research has animated many productive discussions on some of the key topics of this work.

I am fortunate to have found in the last decade welcoming intellectual home at "Fondazione San Sebastiano della Misericordia di Firenze", whose General Director, Dr. Leandro Lombardi, and the whole board of directors shared my belief that clinical research, detection of needs and dissemination of new knowledge represent a greater gift to others than material goods. Thanks to Dr. Alessandro Burberi, President of the San Sebastiano Foundation, and all the members of the scientific committee of CREA (Research and Clinical Center), who have always appreciated the production of this textbook and eagerly awaited its realisation.

Almost eight centuries have passed since "Misericordia di Firenze" was founded, during which it has never interrupted its mission of charity and solidarity, constantly trying to keep up with the times without disrespecting the historical and social context in which it was called to operate, blending modernity and tradition. Special thanks go to Dr. Andrea Morino and Dr. Alvise Revedin, respectively Vice-secretary and Secretary of "Misericordia di Firenze", who strongly supported the establishment of CREA and valued its activities, including the realisation of this textbook.

Thanks to Ludovica Carraresi, CREA's secretary, Mara Bicchierai, and to all the other workers of the "Fondazione San Sebastiano della Misericordia di Firenze" who have contributed to preparing a suitable condition for the realisation of this volume.

I am grateful to Dr. Luciana Forte, Dr. Paola Fruscoloni, Dr. Nicole Andreini and all the other students and trainees who passionately partook in the drafting or checking of some paragraphs, references and other elements of the textbook, and I am deeply fond of my wonderful researchers, Dr. Annamaria Bianco, Dr. Daniela Scuticchio, Dr. Elisa Rondini, Dr. Michele Rossi, Dr. Giulia Vannucchi and Dr. Micaela Piva Merli, with whom I have shared ideas, passion, deadlines, working nights and weekends, hunts for missing contributors, friendship and good pastries around the white table of the CREA meeting room. Immeasurable adjunctive thanks go to Dr. Annamaria Bianco, who has constantly been by my side along the whole planning and realisation of this work, always ready to go through the texts with me and to give not only fundamental technical support but also timely energetic impulse and reassuring smiles. Words are not enough to express the wonderful person she is and how appreciative I am for sharing this journey with me and making so many other research projects and publications possible.

Thanks to my family, especially to my wise and loving parents, Piera Bonciani and Giancarlo Bertelli, and to my grandmothers, Genny Mori and Laurina Lippi. This book gives voice to ideas and convictions that I learned from them and that I have come to appreciate in sharing my life with them such as the belief in the beauty and dignity of human beings, the importance of empathy, kindness and respect, the value of loving relationships, and the possibility of hope and improvement. Also, their teachings on rising from falls, never complaining and persevering have been particularly helpful in this endeavour. I hope that this and my other publications will at least partially fulfill their wish for me to make a contribution to the world that could go beyond the time length of our lives.

Thanks to my loved ones and friends who have tolerated my absence over the years of working on this book and in the many others dedicated to mental health research in neurodevelopmental disabilities.

To Dr. Catherine Mazars, Medicine Books Continental Europe & UK editor at Springer, who believed in this editorial project from the very beginning and who constantly supported it, showing understanding and patience even in the most difficult of times.

To everyone else who has contributed to the realisation and dissemination of this textbook, from publishers, proofreaders, press officers, marketers, booksellers, librarians to those of you reading this now and suggesting it to colleagues as a reference for learning and clinical practice: thank you!

Marco O. Bertelli

Contents

About the Editors

Marco O. Bertelli, MD is the scientific director of the Research and Clinical Centre (CREA) of Fondazione San Sebastiano, Misericordia di Firenze, Florence, Italy. He acted and still acts as a consultant psychiatrist to various service providers for people with neurodevelopmental disabilities and mental health problems. He worked as an adjunct professor at the University of Florence, and taught and still teaches in several Italian and international courses. Dr Bertelli is the current president of SIDiN (Italian Society for Neurodevelopmental Disorders) and past president of both the Psychiatry of Intellectual Disability section of the World Psychiatric Association and the European Association for Mental Health in Intellectual Disability. For the World Psychiatric Association, he is currently chairing the Working Group on Autism Spectrum Disorder. He has been a member of the Working Group on Classification of Intellectual Disabilities of the WHO International Advisory Group for the revision of ICD-11. For the World Health Organization is also worked within the Development Group for Autism Spectrum Disorders to the creation of the WHO Package of Interventions for Rehabilitation. He is an editorial board member of some scientific journals in the field, such as the *Journal of Intellectual Disability Research*, and author of around 200 journal articles and book chapters. Since 2017, Dr Bertelli is member of the scientific committee of the Italian Observatory for Disabilities. In 2011, he was awarded with the Honorary Membership of the World Psychiatric Association for excellence in service, and in 2021, he received the Leon Eisenberg Award of the Harvard Medical School for outstanding leadership and stewardship in the field of neurodevelopmental disorders.

Shoumitro (Shoumi) Deb, MBBS, FRCPsych, MD is Visiting Professor of Neuropsychiatry at the Imperial College London, UK. Prior to that, he was a substantive full time Clinical Professor of Neuropsychiatry at the University of Birmingham, UK, for many years. He led the development of the International (*World Psychiatry,* 2009,8(3),181–186) and the National Guidelines on the use of medication for problem behaviour among adults with intellectual disabilities and produced the first ever freely available online accessible psychotropic medication leaflets (► http://www.ld-medication.bham.ac.uk). He led the development of the first ever European guideline for the assessment and diagnosis of mental disorders among adults with intellectual disabilities which has recently been updated (*European Journal of Psychiatry*, 2022,36,11–25). He was part of the group that developed the first ever evidence-based practice guidelines in intellectual disabilities in the UK NHS. He developed a screening instrument for dementia in people with intellectual disabilities (DSQIID), which has been translated into more than 24 languages and validated for worldwide use. He developed the first-ever online training programme, SPECTROM (► https://spectrom.wixsite.com/project), for support staff to help reduce overmedication of adults with intellectual disabilities. He has around 300 publications (citation index: 7357, h-index: 46, i10 index: 96); done over 250 conference presentations nationally and internationally, including keynote speeches and chairing of sessions; received research grants from the UK NIHR, Wellcome Trust and other charities; led a research/teaching team of over 14 staff; led several masters' courses in UK universities (neuropsychiatry, epilepsy, psychological medicine etc.); and was the co-chair of SPID WPA, a member of the WHO ICD-11 workgroup on intellectual disabilities and a member of several NICE guideline development groups in the UK.

Kerim Munir, MD, MPH, DSc, DFAACAP is Director of Psychiatry at the University Center for Excellence in Developmental Disabilities in the Division of Developmental Medicine, Boston Children's Hospital, and William A. Hinton Society Fellow in Global Health at Harvard Medical School, Boston, Massachusetts, USA. His research focuses on autism spectrum disorder (ASD) and intellectual developmental disorders (IDD) across the lifespan, with an emphasis on understanding determinants of developmental psychopathology and comorbidity. He served as a member of the WHO International Classification of Diseases, 11th edition (ICD-11) Review Group on Intellectual Disabilities, as well as the WHO Development Group on Rehabilitation 2030. He chairs the World Psychiatric Association (WPA) Section on Psychiatry

of IDD, as well as the WPA Presidential Action Plan 2021–2023 Working Group on IDD. Dr Munir has been a vice president of the International Association of Child and Allied Professionals (IACAPAP), and a distinguished fellow and faculty member of the American Academy of Child and Adolescent Psychiatry (AACAP) IDD Institutes. He has directed numerous National Institutes of Health (NIH) federally funded research and research training programmes for over two decades in global child mental health and developmental disorders, as well as in research ethics in the USA, Turkey and Euro-Central Asia region. He is a recipient of the George Tarjan Award by AACAP for contributions in intellectual and developmental disorders, and the Klaus Peter Award of Harvard Medical School in international medical education. Dr Munir chaired the Autism Forum of the World Innovation Summit in Health (WISH) in Doha, Qatar, and serves on the international advisory board of the NeuroGAP research partnership funded by the Broad Institute and the Stanley Center for Psychiatric Research of MIT/Harvard spanning Ethiopia, Kenya, South Africa and Uganda, and the advisory group of the Global Mental Health@Harvard interdisciplinary initiative that aspires to elevate the profile of mental health as a fundamental public good and universal human right. He has advised administrations in numerous countries, including Turkey and France, on health, inclusive education, and social care of persons with ASD and IDD.

Angela Hassiotis, FRCPsych, MD, PhD is Professor of Psychiatry of Intellectual Disability at the UCL Division of Camden Intellectual Disabilities Service, London, UK, and an honorary consultant psychiatrist at the same establishment. She is chief investigator of several NIHR-funded studies focused on clinical interventions for a wide range of mental health conditions in people with intellectual disabilities across the lifespan. She supervises MSc and PhD students on projects relating to autism, stigma, dementia and population mental health, and lectures widely nationally and internationally. She is the author of more than 200 publications and has contributed to change in clinical practice via membership of national guideline development groups and the Faculty of Intellectual Disability at the Royal College of Psychiatrists. She is a recipient of the NADD Stephen Reiss Excellence in Research Award, a member of funding panels and study advisory bodies, and the current editor of the *Journal of Mental Health Research in Intellectual Disabilities*.

Luis Salvador-Carulla is Professor of Mental Health and the deputy director of the Health Research Institute at the University of Canberra. He is also honorary professor at the National Centre for Epidemiology and Population Health, Australian National University, and at the Menzies Centre for Health Policy, University of Sydney. He was Professor of Disability and Mental Health at the University of Sydney (2012–2017) and head of the Mental Health Policy Unit at the Brain and Mind Centre, University of Sydney (2014–2017). His main field of interest is health taxonomies and classifications and the use of decision support tools for the analysis of complex health systems and policy in public health with a special focus on mental health, ageing, disability and intellectual developmental disorders. Prof Salvador-Carulla has intensively participated in the development of international networks in mental health, person centred medicine, healthy ageing, and bridging and knowledge transfer. He has been advisor to the World Health Organization (WHO). He coordinated the European Commission (EC) project eDESDE-LTC for the development of a European classification of services for mental health and for persons with disabilities. He has been principal investigator in over 60 projects in Australia, Europe, the USA, Canada, Mexico and Chile. Prof Salvador-Carulla chaired the WHO working group on the classification of intellectual disabilities at Chapter V of the International Classification of Diseases (ICD-11). He has published over 400 scientific publications. Prof Salvador-Carulla received the Leon Eisenberg Award of the Harvard Medical School in 2012 for his contributions in the field of neurodevelopmental disorders.

Learning Objectives

This chapter describes the evolution of the construct of intellectual development disorder from its earliest historical descriptions to the current diagnostic criteria. It also includes a detailed treatment of adaptive functioning, intelligence, and specific cognitive functions, as key aspects for an effective dimensional approach to this clinical condition. A specific section will concern the interdisciplinary issues of the multidimensional assessment.

1.1 Introduction

Intellectual disability (ID), intellectual developmental disorder (IDD) or Disorders of Intellectual Development (DID), according to the most recent terminology [1, 2], is a common condition with consequences across the lifespan, including a considerable burden on families and caregivers, and high need for service provision. ID/IDD is the leading condition in health and societal costs, not only in the mental health sector, but in all medicine, at least in the Western countries [3–5]. In spite of its global burden, ID/IDD has a non-prominent position within psychiatry. Training in ID/IDD is not included in the psychiatric curriculum of many countries, and the majority of psychiatrists are not prepared to deal with the specific health needs and demands of persons with this condition [6].

1.2 Historical Evolution

Intelligence and ID/IDD might not be a natural kind but the result of a historically contingent human attempt of self-definition and self-characterization [7].

The earliest descriptions of ID date back to ancient Egypt. Two papyri of the sixteenth century BCE, the Edwin Smith papyrus and the Ebers papyrus, document early treatment of wounds, surgical operations, and identify, very likely for the first time, the brain as the site of mental functions. These papyri also show that, despite innovative thinking about disease, magic and incantations were used to treat ID/IDD and other mental conditions that were of unknown origin, often thought to be caused by supernatural forces such as demons or disgruntled divine beings [8].

However, the first important reflections on innate mental faculties were produced by the civilization of Ancient Greece. During the fifth century BCE, the Greek physician Hippocrates challenged the long-held belief that ID/IDD and mental illnesses were caused by supernatural forces and instead proposed that they stemmed from natural occurrences in the brain. A few decades later the philosopher Plato compared intelligence (nous) to a block of wax, which can vary in size, hardness, humidity, and purity. Intellectual defects would have been caused by alterations in this block of wax, which could be too small, too hard, too soft, too wet, or too impure. He described memories as imprints in this wax block and associated memory impairment with what is currently called ID/IDD. In a famous passage in the Phaedrus, Plato compares the intellect to a charioteer who holds the reins, guides, and directs, while emotion and will are compared to the horses that supply the motivation power to the chariot. In his masterpiece, the Republic, Plato seems to approve the alleged Spartan practice of depositing defective newborns at the foot of Mount Taygetos. However, the text is ambiguous, and it is not clear how the Spartan practice could refer to anything except visible physical malformations. In fact, Plato's conception of intellectual functioning does not seem to be compatible with such a cruel method. He distinguishes three types of impairment: simple-mindedness, civic ignorance, and ultimate ignorance. Simple-mindedness is used for those who judge things by appearances and sense perception rather than by appreciating their "ideal" forms. Civic ignorance is more severe and refers to lack of mental skills that one needs to function as a citizen, including good conduct toward the state, one's family, and oneself. Ultimate ignorance represents the greatest threat to the city-state or *polis* and can be further differentiated in lack of knowledge (agnoia) and abuse of personal power over others (amathia).

1

Aristotle interpreted what is now named ID as a natural predisposition to slavery, according to his wider attempt of characterizing human beings in economic and politic terms. Nevertheless, he considered "slaves by nature" (doulos phusei) to be "partners in their masters' lives," without explicit references to an inferiority criterion. Aristotle considerably extended the concept of intellect learned at the Plato's academy by identifying two indivisible components (hylomorphism), a passive component, similar to matter, and an active one, similar to form. Intelligence is associated with logical and knowledge skills, which represent the main aspects of the Aristotelian interpretation of the psyche not defined simply as acts of receiving "contents" (acquiring information) but as points of contact (principles) with the outer world. He contrasted the cognitive or intellectual capacities with the "orectic" ones and simplified Plato's threefold classification by grouping together emotion and will.

Athens continued to be the Western world's main center of knowledge until the second century CE, when Rome and Alexandria started to host a variety of new philosophical and medical schools. At the end of the first century BC, the Roman orator, politician, and scholar Cicero merged the Platonic and Aristotelian concepts of intellect and cognitive functioning into the one of "intelligentia," with the main reference to acquired knowledge rather than natural disposition or innate ability. For these latter aspects, he used the term "ingenium," better explained as the complex of capacities and virtues through which humans "surpass what lies in their sensory awareness" and discern the world around them. For Cicero, the activity of ingenium "consists of catching sight of relationships and likenesses among things" to create meanings that meet our needs in the natural world [9]. Around one century later Avicenna, or Abu Ali al-Hussein ibn ʿAbdallah ibn Sīnā, physician, scientist, statesman, and one of the greatest Islamic philosophers, claimed that each human soul is a simple, independent combination of substance and form, created by God, and immortal by nature. In the second century CE, the physician, surgeon, and philosopher Claudius Galenus, often Anglicized as Galen, criticized the Stoic assumptions on the composition and localization of the psyche and, following Plato's idea, theorized mental functions to be organic facets of the brain, and intellectual alterations not to be ultimately fixed or determined in any individual. The many versions of his masterpiece "The Art of Medicine," also known as the Articella, had an enormous influence on the world medicine for centuries, together with Avicenna's Canon, and reached a cultured readership well beyond the medical realm.

Thus, the idea of intelligence as a measure for sizing up persons does not seem to belong to the classic culture, although the long pursuit of the old civilizations has included negative attitudes toward physical disability as part of mental illness. The seeds of intelligence as a measure for classifying humans were sown at the end of the twelfth century, with the expansion of towns and trade and the consequent onset of state and ecclesiastical administration. In the Middle Ages, intelligence was conceived as an entity hanging between heaven and earth, and divine and human. In the thirteenth century, Thomas Aquinas interprets human intelligence as a defective derivation of the divine intelligence and attributes the comprehension skill of less intelligent persons as a greater lack of completeness and universality than that of the general population. It is the medieval scholasticism that used the term intellect to translate the Greek word "nous" (understanding), as opposed to reason ("dianoia"). The concept of human *nous* somehow stems from its cosmic reference, which is not just a recipient of order, but a creator of it. Similarly, the brain is matter "configured" (shaped, structured) by the soul, which itself is a "configured" thing, but also a "configurer" for the brain.

According to Galen, the brain is instrumental in transforming the "vital spirit" (one of the three-part system of spirits derived from the Arabic philosophy) into the "animal spirit," which controls both peripheral and central neural activities, from sensation and movement, to imagination, cognition, and memory. In his work "De animalibus,"

Albertus Magnus, described by his contemporaries as one of the greatest philosophers ever and named by Pope Pius XII patron saint of scientists, described "idiotae" as people who "do not discern the universal from particulars" and who are not able to make abstractions. During the Middle Ages, the distinction between mind and body was more complex and more fluid than in post-Cartesian thought, complicated by different views on the soul, the relationship between thought and affect, and the position of mental functions in the body.

During the Renaissance, further development of urbanization and commerce was associated with increasing demands for quality and speed of performance, as traceable from standard medical textbooks, especially the many commentaries on The Art of Medicine. Most humanist writers extended Cicero's concept of "ingenium" in a normative way and used it as a reference to differentiate persons in terms of cleverness and speediness, while some other exponents of the humanistic medicine pioneered a new descriptive meaning and defined ingenium as an operation of the intellect. In his reinterpretation of the Articella, Niccolò da Lonigo (called Leoniceno), the leader of the humanistic movement which overcame the medieval setting, used ingenium for "quickness of apprehension," with a specific reference to the everyday cleverness, as opposite to the scholastics' meaning. Paracelsus and Felix Platter, and other eminent Renaissance physicians, introduced the concept of "feebleminded[ness]," as a condition to be differentiated from "foolish[ness]" and mental illness [10, 11]. Platter included "weakness" (imbecillitas), slowness of wit (ingenium) in his four headings of cognitive alterations, together with "consternation" (absence), "defatigation" (about sleep), and "alienation." He is also considered as a pioneer of psychiatry of ID/IDD as he was the first to offer a multi-level description of ID and to consider associated behavioral epiphenomena in terms of possible co-occurrent "syndromic" symptoms or sets of related symptoms. Other Galenist medical writers of the Renaissance described mental ill-health as the result of excesses or deficiencies of invisible material elements, such as "humors" and "animal spirits" (also called "soul spirits"). They associated the lack of one or more of these matters with different mental alterations having in common only some kind of slowness, such as lethargy, melancholy, and stupidity.

In the seventeenth century, speediness continued to have a central place in the evaluation of mental skills, and mental disability was increasingly considered as the opposite of mental geniality. The success of Descartes' theories strengthened this contraposition and attributed to slowness (and disability) an extremely negative meaning. In Descartes' thought, the mind, the source of mental functions, is no longer made of invisible matter (humors or soul spirits), but of a nonphysical and non-spatial substance. Cognitive speed and other intellectual functions are independent of the body because intellection is an operation of the mind alone. Ingenium takes on such importance to become the marker of the human species and lose any element of overlap with the medieval concept of "divine intelligences."

In 1664, Willis, an Oxford philosopher and pioneer of brain anatomy, described "stupiditas" and "idiocy" as disease-like states and proposed various etiological factors, including heredity, trauma, other diseases, and "animal spirits" [10, 11]. In theology, the term idiota continued to be used until the eighteenth century, with the meaning of someone lacking religious wisdom, or uneducated (indoctus). In 1690, the English philosopher John Locke [12], regarded as one of the founders of the Enlightenment in the eighteenth century, postulated that the mind at birth is a blank slate, with thoughts, beliefs, and personality being not innate, but learned through senses and experience. This revolutionary theory implied that person with learning disability could benefit from corrective experiences, and set the stage for the modern conception of rehabilitation. Locke also extended Albertus Magnus' point on "idiocy" as a lack of abstract skill and differentiates mental disabilities from physical ones, although his idea of mental disability overlapped with that of madness, especially in reference to intellectual and affective

1

deficits [13]. Speed of cognitive performance and learning lost most of the previous significance in Locke's psychology and his eighteenth-century readers. In "The Improvement of the Mind," the theologian, logician, and educator, Isaac Watts states "presume not too much upon a bright genius, a ready wit, and good parts; for this, without labour and study, will never make a man of knowledge and wisdom … When they have lost their vivacity …, they become stupid and sottish" [14]. The British philosopher David Hartley proposed to classify individual intellectual performance by strength, vividness, intensity, and educability, but not speed. He interpreted ideas as the result of physical "vibrations," basing on principles of Newton's Optics [15]. In the mid-eighteenth century, the term "changeling" was used routinely for persons with ID. It was introduced by John Locke as an alternative for "idiot," to describe a creature which is human only in the body but without mind or soul.

Although speed of learning and other qualities of cognitive performance lost importance in the eighteenth-century theories of the mind, they gained a central position in the definition of the social status and social hierarchy. With the industrial revolution, more and more people fled to cities, working for slave wages and living in squalid conditions. Persons with ID were increasingly marginalized and left homeless and jobless. Parish authorities often bargained with factory owners to take one "imbecile" with every 20 workers. Together with the philosophers Rousseau and Hobbes, Locke argued against the idea that some individuals could prevail on or even subjugate other persons on the basis of their innate superior (sometimes divine) mental characteristics. However, it was the critical philosophy of Immanuel Kant [16–19] with its emphasis on autonomy, which laid the foundations for a truly persistent sociocultural revolution: "Every person is worthy of dignity not because of status or innate properties, but simply because of their human nature."

Kant argued that mental functions, including cognition, understanding, judgment, and reason, are immaterial active processes that convert raw sensory data into meaningful, ordered experiences through the instrumentality of innate abilities (*categories*). Things in themselves cannot be known; human beings perceive the world only the way their minds represent them. For the same reason and for their lack of substance, "reason," "cognition," and other mental operations are difficult to assess empirically as are deficiencies associated with these mental operations as additions to mental disorder [20].

The scientific attention given to ID/IDD began to increase at the end of the eighteenth century, after the French and American revolutions had restored value to human freedom and dignity and declared principles of equality, natural and imprescriptible rights. In 1793, Philippe Pinel, the leading French psychiatrist of his time, was the first to affirm that most persons labeled as "mentally deranged" were affected by a disease rather than being sinful or immoral by nature. Along with the English reformer William Turk, he created the method of "moral management," using gentle treatment and patience rather than physical abuse, chains, and other restrictions on the inmates of the Bicetre asylum, and later on those of the Salpetriere.

Jean Marc Gaspard Itard spent 5 years (1801–1806) on the education and rehabilitation of Victor, the wild boy from Aveyron [21]. Although the results of rehabilitation were only partial, his studies and methods were recognized by the French Academy of Sciences as notably worthy and opened the avenue for practice and research that spread widely to other countries in Europe and North America. On the thrust of Itard's work, Edouard Séguin, already sensitized to the ideas of Henri de Saint-Simon, deepened some techniques of qualification and started the study of the causes of ID, then called "idiocy." He founded the first private school in Paris dedicated to this area and in 1846 published the first systematic textbook. One year earlier, Jean-Étienne Dominique Esquirol, in his treatise on mental illness, had distinguished idiocy from imbecility, characterizing the former with a serious impairment of intellectual and moral abilities, the latter with a less marked limitation, in which knowledge and social relations did not reach an appropriate level for their age and education received [8, 22]. Seguin included this distinction in his textbook and

added two other categories which he termed mental weakness and superficial delay [8]. Further distinctions, both clinical and etiological, were made in the following years by Wilhelm Griesinger, John L.H. Down, and Desire-Magloire Bourneville, with references to cretinism, ethnic differences, and tuberous sclerosis [8, 23]. In 1891 at the Sorbonne University, Paris, Binet, and Simon developed the first intelligence test, specifically aimed at measuring children's abilities during different stages of development.

In the United States during the colonial and early republican periods, inhabitants of newly emerging small towns did not expel or denigrate persons who were slow to learn or to mature until 1840, when the concept of productive citizenship was claimed and idiots became a social and state problem. Before the civil war, care and control of persons with ID had already assumed a curious linkage [24]. It was Samuel Gridley Howe who challenged the widespread belief that "idiots" could not be taught and who established an experimental boarding school in South Boston for "Idiotic and Feeble-Minded Youth." Like Seguin, Howe firmly believed in the importance of community inclusion and wanted his schools to prepare children with ID/IDD to live within the wider society.

Intelligence and intellectual disability (ID) or intellectual developmental disorder (IDD), according to the most recent terminology, might not be natural kinds but the result of a historically contingent human attempt of self-definition and self-characterization. The seeds of intelligence as a measure for classifying humans were sown at the end of the twelfth century, with the expansion of towns and trades while a scientific attention toward ID/IDD started at the end of the eighteenth century, after the French and American revolutions had restored value to human freedom and dignity and declared principles of equality, natural, and imprescriptible rights. The first corrective interventions and the stage for the modern conception of rehabilitation were introduced during the Enlightenment period.

1.3 Definition and Terminology

The definition and the terms used for ID/IDD have always had relevant implications for research and clinical practice as well as for sociocultural attitudes and health policies. Definitions of ID/IDD have been provided across history in accordance with changing conceptualizations, but a scientific discussion on description and terminology started together with the advent of the international classification systems of mental disorders. The use of terms such as idiocy, imbecility, cretinism, moronity, feeblemindedness, mental subnormality, defectiveness, and mental deficiency has been maintained in these classification systems until the end of the mid-twentieth century [7, 8, 22, 23, 25, 26].

In 1904, Martin Barr published the first textbook on ID/IDD using the term "Mental Defectives" in the title. He differentiated between an idiot and imbecile by attributing to the former a considerably higher severity of impairment ("see nothing, feels nothing, hears nothing, and knows nothing") (p. 18) and summarizing different causes and prognoses. Idiots were considered as affected by an untreatable disease and sent to assistance only, while imbeciles were considered to be mentally defective and were trained to learn daily living skills through step-by-step, easy, and concrete instructions [25]. In 1908, Tredgold extended Barr's concepts and provided educational resources for professionals on appropriate diagnosis, treatment, eligibility for services, and long-term placement.

In 1952, the American Psychiatric Association [27] published the first Diagnostic and Statistical Manual (DSM-I) classifying this disorder as "chronic brain syndrome with mental deficiency" (p. 14) and "mental deficiency" (p. 23). In 1961, the American Association on Mental Retardation (AAMR), formerly American Association on Mental Deficiency (AAMD), introduced the term "mental retardation" to replace the previous terms, which became gravely stigmatized. This coincided with the introduction of the first definition and diagnostic criteria to be nearly universally adopted. The definition stated that the disorder "refers to subaverage general intellectual functioning

1

which originates in the developmental period and is associated with impairment in adaptive behaviour" [28]. In 1973, the AAMR changed the term "subaverage" with "significantly subaverage" and the terms "impairment in adaptive functioning" with "concurrent with deficits in adaptive behavior." These changes were based on the need to increase the intelligence quotient (IQ) standard deviation from the population mean, which had been found to be overly inclusive and to determine excessive assignment of students to special education, and because the adaptive behavior criterion had been ignored in clinical practice. The 1983's definition included the IQ's standard measurement error and emphasized the importance of clinical judgment in the diagnostic process as well as the impact of social milieus in facilitating or impeding the development of intelligence.

A paradigm shift occurred in 1992, when the AAMR moved the emphasis of the definition from a disorder (neither mental nor medical) to a disability: "mental retardation refers to a particular state (not a trait, Ed.) of functioning that begins in childhood in which limitations in intelligence coexist with related limitations in adaptive skills" ([29], p. 9). The focus of the disability construct is defined by stating that the individual condition is expressed through an interaction between the affected person and the environment ([29], p. 9). The impairment of adaptive functioning was defined by the presence of significant disabilities in at least two out of ten specific adaptive skills, which replaced the previous deficits in adaptive behavior. The DSM maintained its definitions aligned with that of the AAMR in the third and fourth editions.

In the second half of the last decade of twentieth century, the terms "mental retardation" coexisted with "intellectual disability," which was considered to be more aligned with the new conceptualization of the developmental condition. ID/IDD was increasingly accepted and included in the name of some scientific journals and international scientific organizations, such as the International Association for the Scientific Study of Intellectual Disabilities, the Section of Psychiatry of Intellectual Disability of the World Psychiatric Association, and the European Association for Mental Health in Intellectual Disability.

In 2002, the AAMR updated its definition by specifically stating that mental retardation is a disability and aligning its position with that of the World Health Organization's (WHO) International Classification of Functioning (ICF). It emphasized that mental retardation implies significant limitations in the areas of intellectual functioning and adaptive behavior, with the two areas having equal footing and the latter being organized into the conceptual, social, and practical domains. In 2007, the AAMR changed its name to American Association of Intellectual and Developmental Disabilities (AAIDD) and in 2010 included the term ID in its updated manual, putting the construct of disability first and leaving the consideration of the developmental impairment as an invariant trait of a person. The primacy of the concept of disability implies the social–ecological context to have a main causative role for the difficulty of the person with developmental impairment to achieve a good adaptation to the environment as well as self-worth, well-being, and self-determination [6, 30]. In this model, the grading of ID severity is represented by "patterns and intensity of supports needed" (i.e., intermittent, limited, extensive, and pervasive), with a considerable difference from the DSM severity codes. In 2013, the AAIDD revised the fidelity of its approach to the ICF model by proposing a more complex functionality approach, which includes health issues and the need for disease classification codes [31].

In the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) [1], the American Psychiatric Association (APA) replaced "mental retardation" with "intellectual disability" and the parenthetical name "intellectual developmental disorder," to harmonize with the first proposal of the WHO working group for ICD-11 and to underline that diagnosed deficits in cognitive and adaptive skills begin in the developmental period. The ICD-11 [2] has adopted the term "disorders of intellectual development (DID)."

Difficulties in defining and positioning the ID have been maintained up to the new sys-

tems of international classification of diseases and disorders [DSM-5 [1] and ICD-11 [2]] and in recent years have raised a more heated scientific debate than ever before.

Currently, there are two main approaches: the first, promoted by the AAIDD and aligned with the international classification of functioning (ICF; [32]), focusing on disability as characterized by significant impairment of intellectual functioning and adaptive behavior; the second, supported mainly by the Section of Psychiatry of Intellectual Disability of the World Psychiatric Association (WPA-SPID), is instead polynomial-polysemic, multidimensional approach which interprets ID as a condition to be defined in accordance with different contexts. With specific reference to the classificatory systems, it should be defined as a meta-syndromic group of "intellectual development disorders" in the ICD, and as a condition of complex "intellectual disability" in the ICF.

Extreme positions in this debate might have extremely negative implications. The conceptualization of ID uniquely as a "disability" would be followed by its exclusion from the ICD, and consequently by an enormous reduction of eligibility for specific healthcare, particularly mental healthcare (see ▶ Chap. 9 for the extent of mental health needs) as well as for educational and social services [33]. In fact, it is the ICD and not the ICF that is used by the 194 WHO member countries to define the responsibilities of governments to provide healthcare and other services to their citizens. Furthermore, the removal of ID from the ICD would have a major impact on both national and global health statistics as well as on health policy and service availability to this vulnerable population [34]. Interventions related to dietary intake (i.e., for disorders such as phenylketonuria), psychopharmacotherapy, or education are addressed for attenuation of overall deficits and related activity functioning and social participation. On the other hand, the consideration of ID solely as a health condition would have an extremely negative impact on the provision of social and educational services, as well as public attitude, policy formulation, and future legislation. Furthermore, it would be inconsistent with the current position of many governments, international organizations, and advocacy groups.

The choice of DSM-5 to adopt the term ID, but to accompany it (in parenthesis) by IDD also reflects the ongoing difficulties in definition and positioning. Moreover, the USA has not adopted ICF.

In 2013, the first WHO working group on mental retardation for the ICD-11 provided a valuable attempt to overcome these issues by proposing a polysemic-polynomial approach [6]. Specifically, it has been proposed that a distinction is needed between "intellectual developmental disorder" (a clinical meta-syndrome coded at ICD) and "ID" (its functioning/disability counterpart coded at ICF), since these terms have different scientific, social, and policy applications, although they describe two different but related aspects of the same construct (IDD/ID). Indeed, according to the WHO working group, these two terms should be regarded as "semantically similar" but not as "mirror codes" [35]. It has to be considered that in most countries, service eligibility and treatment selection for people with ID/IDD are heavily influenced by diagnostic classification, and a reliable, valid, and feasible diagnostic system seems needed to guarantee better health services for persons with ID. Conversely, in low- and middle-income (LAMI) countries, mental health professionals of any kind maybe lacking, and often not even physicians are available for people with ID/IDD. Therefore, the priorities of identifying and providing tools to enable a widespread, efficient, and accurate identification and prioritization of service needs for people with ID/IDD are among the aims of the ICD-11. Moreover, it is important that the ICD-11 provides the basis for documenting the prevalence of ID and its functional consequences, because many individuals remain undiagnosed for years especially in LAMI countries. For the development of healthcare programs, it is also important to consider the amount of resources available for diagnosis as opposed to treatment. However, it must be understood that any marked changes to the ICD may not be incorporated into clinical practice in many countries for some years;

1

therefore, it is preferable to keep assessment as user-friendly as possible to encourage its use.

Different definitions of ID/IDD have been provided across history in accordance with several conceptualizations. Currently, there are two main approaches: the first prioritizes the aspects associated with the concept of "disability" such as intellectual functioning and adaptive behavior over those associated with the concept of "disorder"; the second advances a polynomial-polysemic, multidimensional approach that interprets ID/IDD as a condition to be defined according to the different classificatory contexts such as classification of diseases and classification of functioning.

1.4 Nosology

As mentioned earlier, in the DSM-I [27] ID/IDD was split into "chronic brain syndrome with mental deficiency" and "mental deficiency" (p. 23). The former disorder was defined by the presence of "a defect of intelligence existing since birth, without demonstrating an organic brain disease or known prenatal cause." This group included "only those cases formerly known as familial or 'idiopathic' mental deficiencies."

In 1961, with the introduction of the term mental retardation, the AAMR, formerly AAMD, proposed more objective diagnostic criteria, including tests and reference scores for the assessment of intelligence and adaptive skills. The main criterion was an IQ lower than 84 or one standard deviation below the average of the general population. The impairment of adaptive functioning was divided into four severity levels: mild, moderate, severe, and profound retardation [28].

The diagnostic criteria for mental retardation (MR) remained unchanged until 1965 when the WHO included it in the International Classification of Diseases, Eight Revision (ICD-8), with some considerable changes from the DSM [36].

The DSM Third Edition (DSM-III) in 1980 [37], and the DSM Third Edition-Revised (DSM-III-R) in 1987 [38], included MR under "developmental disorders," which were considered as personality issues and placed in Axis II.[1]

In 1992, the AAMR introduced a multidimensional classificatory approach aligned with the above-mentioned conceptual shift from a disorder-centered model to a disability-centered model, which included the four dimensions of (a) intellectual functioning and adaptive skills; (b) psychological/emotional considerations; (c) biomedical, social, behavioral, and education factors; and (d) environmental considerations. Furthermore, the 1992 AAMR diagnostic manual proposed to arise the IQ ceiling from 70 to 75 and to replace IQ with support need in the definition of diagnostic subcategories, which was not accepted by the wide majority of the American scientific community [39].

The DSM-IV [40] aligned itself with the AAMR in defining mental retardation, while it departed from the upper limits of the severity range, which were kept at lower levels, and in multiaxial rather than multidimensional classification. This Axis II positioning was maintained in DSM-IV and DSM-IV-TR [41], where MR was included under the Chapter "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence."

The diagnostic criteria of the AAMR manual were revised in 1973 and 1983, the former comprised a reduction of the IQ cut-off to two standard deviations below the average of the general population and an extension of the age of onset to 18 years, and the latter consisted of an insertion of the IQ standard measurement error [42]. These criteria were basically embraced by the DSM-III (Diagnostic and Statistical Manual of mental disorders—III edition, [37]) and the ICD-10 (International Classification of

1 A complete DSM-III diagnosis enabled coding on five separate axes. All clinical psychiatric syndromes were coded on axis I, with the exception of specific developmental disorders and personality disorders, which were coded on axis II. Axis III was used for coding physical disorders or physical conditions, axis IV for coding severity level of psychosocial stressors, and axis V for the highest level of adaptive functioning in the past year.

Diseases—tenth edition, [43]), and used for the first time in almost the whole world.

In the ICD-10 ID/IDD appeared with the name "mental retardation" in the chapter V (Mental and Behavioural Disorders), with some disability aspects being regarded as psychiatric symptoms. Genetic syndromes including ID/IDD, such as Prader–Willi or Fragile X, were coded in the ICD independently from associated cognitive impairment.

In 2009, the WHO established a Working Group for the new classification of MR (WHO WG-MR) reporting to the WHO International Advisory Group for the Revision of ICD-10 Mental and Behavioral Disorders in the ICD-11. Strikingly, the WHO WG-MR was the first international and multidisciplinary expert group established by an international organization to debate the issue of the classification of ID/IDD and to produce an international consensus document incorporating views of representatives of the main professional, scientific, and self-advocacy organizations, including an APA delegate to harmonize with the ongoing DSM-5 Task Force. The WG-MR produced a position paper in 2011 [44] with an extensive consensus report, which represented the basis for the official recommendations sent to the WHO Advisory Group on ICD-11 in 2012.

The terminology, nosology, and the positioning of ID/IDD within the taxonomy of mental disorders have long been controversial; indeed, the debate has continued for more than two decades in parallel to the dispute on the concepts of intelligence, human functioning, and disability [45]. ID/IDD is regarded as a cluster of syndromes that typically emerge early in life and imply different patterns of severe and persistent cognitive impairments together with altered adaptive behavior and personal skills. Despite the high variability of clinical presentation, this cluster of syndromes has been associated with a complex array of neurodevelopmental underpinnings. Classification and diagnostic criteria are therefore crucial issues and have important implications for epidemiology and interventions as well as outcome measures, service provision, and planning. Moreover, the debate on ID/IDD has implications for the classification of other neurodevelopmental disorders such as autism spectrum disorder where a specifier "with or without accompanying intellectual impairment" is required.

As already explained for the naming, the question of whether ID/IDD should be considered a health condition, a disability, or even a life condition is still debated in many contexts. For example, different interpretations of the condition exist in different fields, such as psychology, sociology, anthropology, and education. These interpretations still influence the classification of ID/IDD and consequently the choice of diagnostic criteria.

The main issues which are still debated are the age-at-onset cut-off, the consideration of specific cognitive functions as alternative to overall IQ, and the relationship between cognitive impairments and adaptive skills.

In DSM-5, ID/IDD is included under the meta-category of neurodevelopmental disorders to make clear that the focus is on the disorder category and not the disability construct. There, the diagnostic criteria are (a) overall intellectual functioning significantly (two standard deviations) below the mean of the general population; (b) deficit in adaptive functioning (without continuous support), with particular reference to the sociocultural standards of personal independence and social responsibility; and (c) onset of intellectual and adaptive deficits during the development period, typically before school education. Deficits in adaptive functioning have to refer to at least one of the daily activities of life, such as communication, social participation, or autonomy, in different contexts, such as home, school, work, and community [1].

General intellectual functioning is defined by the IQ (IQ or IQ equivalents) obtained through evaluation with one or more standardized, individually administered intelligence tests (e.g., the Wechsler Intelligence Scale, the Stanford Binet, the Evaluation Battery of Kaufman or, in people with communication problems, the Leiter scale). An intellectual functioning significantly below the general population mean is defined by an IQ of about 70 or less.

Since before the publication of the DSM-5 [1], the severity of ID (then "mental retarda-

tion") was defined almost exclusively on the basis of IQ: mild for values between 50–55 and 70 (50–69 in the ICD-10), moderate between 35–40 and 50–55 ("medium," 35–49 in the ICD-10), severe between 20–25 and 35–40 (20–34 in the ICD-10), profound for values below 25–20 (<20 in the ICD-10). In the DSM-5, the severity levels are defined on the basis of adaptive functioning and not on the IQ, especially for the forms that fall in the lower part of the range of deficits, with specific reference to conceptualization, social and practical domains.

In the ICD-11, the primary parent category for ID/IDD is that of "Neurodevelopmental Disorders." In the last decade, the neurodevelopmental focus has represented one of the aspects upon which the whole international scientific community has agreed most. IDD encompasses a broad grouping of heterogeneous developmental conditions which result from significant interference with the growth and maturation of the brain, especially during the prenatal and perinatal periods. The disorders included in this meta-structure are not mainly organized by the criteria of onset in childhood and adolescence, as in ICD-10 or DSM-IV, but by etiopathogenetic factors, such as genetic alteration or abnormal neural circuit development, and clinical aspects, such as dysfunctions in cognition, learning, communication, behavior, early emergence, co-occurrence, and lifespan course.

The ICD-11 has renamed ID/IDD with "Disorders of intellectual Development" with reference to "a group of etiologically diverse conditions originating during the developmental period characterized by significantly below average intellectual functioning and adaptive behavior that are approximately two or more standard deviations below the general population mean (approximately less than 2.5 standard deviation), based on appropriately normed, individually administered standardized tests. Where appropriately normed and standardized tests are not available, diagnosis of disorders of intellectual development requires greater reliance on clinical judgment based on appropriate assessment of comparable behavioural indicators" [2, 33].

The nosographic approach to ID/IDD has considerably changed across time, passing from a unitary and scarcely defined diagnosis of "mental deficiency" to a group of lifespan conditions characterized by early onset significantly below average intellectual functioning and adaptive behavior.

1.4.1 Diagnostic Criteria

1.4.1.1 Early Cognitive Impairment

Intelligence, according to the ICD, is considered as an umbrella term that is age-appropriate and includes cognitive functioning, learning, adaptive behavior, and skills, meeting the standards of culture-appropriate demands of daily life.

ID/IDD can be envisioned as an early cognitive "meta-syndrome" analogous to the syndrome of dementia in later life [6]. The two meta-syndromes share similar characteristics: a variety of causes can lead to the two above-mentioned conditions, they can involve extensive impairment of core cognitive functions required for daily living, and the clinical evaluation process involves a broad consideration of biological, personal, and environmental factors.

Particularly, ID/IDD is a condition that involves the entire lifespan. ID/IDD is characterized by a marked impairment of core cognitive functions necessary for the development of knowledge, reasoning, and symbolic representation and that deserves the consideration of the developmental phases and life transitions of the person. Therefore, a developmental approach that accounts for the complex causal factors known to impact the acquisition of cognitive abilities and adaptive behaviors is necessary to understand ID/IDD and to provide the appropriate interventions and long-term care [46].

To note, there is still no conceptual map or hierarchy of the key cognitive functions and domains to be considered in ID/IDD [47], and different terms are often used for the same functions, and vice versa. Nevertheless, a series of cognitive domains are significantly impaired in persons with ID/IDD. These core cognitive domains mainly include percep-

tual reasoning, working memory, processing speed, and verbal comprehension [48, 49].

However, it has to be considered that different combinations of cognitive impairments and atypical features can manifest in ID/IDD [50]. For example, persons with Down syndrome usually manifest impairments in specific areas of language, long-term memory, and motor performance, while showing relative strengths in visuospatial construction [51]. In contrast, persons with Williams Syndrome show deficits in attention, visuospatial construction, short-term memory, and planning [52], while showing a distinctive pattern of auditory processing and relative strengths in auditory processing and concrete language [53].

The assessment of cognitive functions in ID/IDD is generally performed using an IQ test, a score derived from an intelligence test which should be used for diagnosis only with consideration of locally standardized norms. Usually, an IQ score of 70 or below is indicative but not sufficient to diagnose ID/IDD. Other alternative clinical and cognitive assessments could be used including locally standardized developmental tests. Indeed, cognitive assessment should not be limited to standardized IQ but also include neuropsychological testing, for example, assessment of executive functioning in order to determine an individual's profile. Moreover, retesting during critical life periods is recommended, as distinct cognitive developmental trajectories have been identified in different conditions of ID/IDD and because there may be cognitive losses related to aging. Besides the identification of cognitive impairments, the diagnosis of ID/IDD should also be associated with the assessment of difficulties in different domains of learning, including academic, social, and practical knowledge. For example, objectives of the elementary school curriculum are expected to be difficult to meet for persons with ID/IDD. Reading, writing, and calculating are hard tasks to achieve and will need considerable effort and repetition. These difficulties can also vary across levels of cognitive functioning and other aspects of the disability and of the environment, as well as across different etiological conditions. Indeed, persons with Down syndrome show more problems in motor learning compared with other IDD syndromes [49].

1.4.1.2 Limitations in Adaptive Behavior

The person diagnosed with ID/IDD also manifests limitations in the context of adaptive behavior that is, meeting the demands of daily life expected of same-age peers, as well as demands of cultural and community environment. These difficulties include limitations in relevant skills for daily life, previously categorized into conceptual, social, and practical skills [54]. According to ICD-11, "conceptual skills are those that involve the application of knowledge (e.g., reading, writing, calculating, solving problems, and making decisions) and communication; social skills include managing interpersonal interactions and relationships, social responsibility, following rules and obeying laws, as well as avoiding victimization; and practical skills are involved in areas such as self-care, health and safety, occupational skills, recreation, use of money, mobility and transportation, as well as use of home appliances and technological devices" [2].

Becoming independent and self-directed or having adequate self-care in the context of everyday life will require practice and long-term monitoring, coaching, and support. Practical examples can be represented by dressing skills and how to appropriately interact with others. Moreover, persons with ID/IDD often have difficulties in managing their behavior, emotions, and interpersonal relationships, and maintaining motivation in the learning process.

1.4.1.3 Severity/Extent (Subtypes)

Though the degree of cognitive deficits and adaptive skills vary from person to person, in most instances it is possible to categorize ID/IDD into one of the four following clinical severity levels: mild, moderate, severe, and profound. The prevalence is higher for mild, followed by moderate subtypes, while severe and profound subtypes show similar lower rates [55, 56].

In the ICD-11, the severity of an ID/IDD is assigned "on the basis of the level at which

the majority of the individual's intellectual ability and adaptive behaviour skills across all three domains (i.e., conceptual, social, and practical skills) fall. For example, if intellectual functioning and two of three adaptive behaviour domains are determined to be 3 to 4 standard deviations below the mean, Moderate Disorder would be the most appropriate diagnosis. However, this formulation may vary according to the nature and purpose of the assessment as well as the importance of the behaviour in question in relation to the individual's overall functioning" [2].

1.4.1.4 Age of Onset and Course

ID/IDD is an early-onset syndrome generally manifesting in infancy, childhood, and extending into adolescence. No specific temporal qualifier is necessary for the diagnosis [57]. The ICD-11 states that "among adults… who come to clinical attention without a previous diagnosis, it is possible to establish developmental onset through the person's history, i.e., retrospective diagnosis" [2].

Although ID/IDD is usually a stable diagnosis, it is considered a dynamic health condition, since there can be significant variability in cognition and functioning across different clinical severity levels throughout the lifecycle [58] and may show high individual and condition-related variation in developmental trajectories (e.g., the development of sensory and cognitive functioning in adults with Down syndrome). Therefore, it is highly recommended to perform reassessment of the individual at key developmental phases, life transitions (e.g., at school entrance, puberty, transition from educational to occupational setting, with changes in living arrangements, early and later adulthood), and after significant life events and/or traumatic events. The experience of life events and trauma can be particularly challenging for a person with ID/IDD who has limitations in adaptive functioning. While the timing and type of life transitions vary across societies, generally individuals with ID/IDD need additional support to adapt to changes in routine, structure, educational, or living arrangements. Traumatic life events (e.g., learning of the sudden death of a family member, being in a life-threatening accident, being physically or sexually assaulted) are important predictors of psychopathology in this population [57].

ID/IDD is influenced by many factors including the maturation of the brain, gene–environment interactions, environment, culture, education, availability of supports and training opportunities as well as by the physical and mental health of the person [59]. To note, most individuals with ID/IDD continue to acquire skills and competencies, especially with optimal care, training, supports, education, and opportunities for learning. A summary of the most important ID/IDD features and vulnerability factors across different age periods are provided in ◘ Table 1.1.

ID/IDD refers to a group of etiologically diverse conditions originating during the developmental period characterized by deficits in intellectual functions and adaptive behavior. These characteristics can vary significantly across individuals at different clinical severity levels throughout the lifecycle. Therefore, it is highly recommended to perform reassessments of individuals with this condition at key developmental phases, life transitions, and after significant life and/or traumatic events.

1.5 Clinical and Functional Properties

The alignment of ICD-11 with ICF enables professionals to explore and compare the conceptual, clinical, and functional properties of IDD and ID and to explore differences across age groups, life situations, and settings. As described earlier, "intellectual developmental disorder" (IDD, clinical meta-syndrome coded in ICD) and "intellectual disability" (ID, its functioning/disability counterpart coded in ICF) describe differently, but related aspects of the same construct. Therefore, it can be assumed that the disorder category (IDD) and the concept of intellectual disability (ID) may not necessarily always represent

Table 1.1 Main IDD features and vulnerability factors across the lifespan

Adolescence	Puberty and adolescence may cause increased social, emotional, and behavioral difficulties for individuals with ID/IDD. During this stage, major transitions take place in physical growth and sexual maturation. There may be also additional changes in educational and/or care settings
Young adulthood	During young adulthood, individuals with mild or moderate ID/IDD often have difficulties with personal relationships, managing finances, and planning. In most societies, there are also other significant life transitions for the person with ID/IDD (e.g., moving to adult services, moving from living at home to a group home, moving from an educational to an occupational setting, or getting married), and this can put an individual with ID/IDD at increased risk for problem behaviors and psychiatric illness. Indeed, psychiatric illnesses may have their onset in young adulthood. It is important to note that persons diagnosed with mild ID/IDD in childhood may no longer meet criteria for ID/IDD in later life, as their skills may be better suited to the new environmental demands or because of new brain maturation and learning. Even in this optimal group, individuals with a BIF diagnosis will require specific health attention and support in areas such as education, work, and the justice system. Unlike most people without ID, people with ID/IDD often do not move out of parental home at this age, which has implication for their family caregivers
Adulthood	Many older adults with mild ID/IDD may continue to work and live independently. There may be known condition-specific health risks that should be checked for in mid-adulthood [60]. For example, older adults with Down syndrome have a higher prevalence of Alzheimer's disease and epilepsy. Family life transitions include bereavement of older family members and parents
Old age	In addition to the onset of condition-specific health problems, age-related health conditions occur in old age [61]. Dementia occurs at a higher rate in adults with ID/IDD compared with the non-ID general population [62]. In general, aging is accelerated in many genetic conditions associated with ID/IDD, for example, in Down syndrome. Early retirement is available for persons with ID/IDD in countries with extensive social inclusion programs

the exact same functional characteristics. A minimal set of ICF codes to record manifestation and other functional properties of IDD is available within the ICD-11.

The ICD-11 Content Model [63] lists "functioning properties" as one parameter to capture knowledge that underpins the definition of an ICD entity. According to the ICD-11 reference guide, "signs and symptoms in the ICD are aligned with body functions in the ICF" (see 3.3 Functioning in ICD and joint use with ICF, [64]). For IDD, assumingly "signs and symptoms" (manifestation properties) would refer to the ICF Category "b117 Intellectual functions." Consequently, the "supplementary section for functioning assessment" of the ICD-11 does not include "intellectual functioning" in any of the three subsets: (1) ICF items represented in the WHODAS 2.0 36 Item version, (2) ICF items proposed for a "Brief Model Disability Survey (MDS)," and (3) a set of ICF items considered "Generic functioning domains" (Body functions, activities, and participation domains, excluding codes already included in (1) or (2)).

The "Clinical Descriptions and Diagnostic Guidelines (CDDG)" for ICD-11 (ICD-11 CDDG, developed in close coordination with DSM-5 diagnostic criteria; [65]) define essential features of IDD as problems with "intellectual functioning" and with "adaptive behavior" (DSM-5: adaptive functioning). The CDDG for ICD-11 go beyond the manifestation property (IQ as indicator of intellectual functioning) by considering how people function in daily life [66]. The "adaptive behavioral indicators" and "intellectual functioning behavioral indicators" are grouped into three domains ("Communication skills," "Social skills," and "Daily living skills") with separate

indicators for "early childhood," "childhood and adolescence," and "adulthood" [67]. These indicators can be used to group individuals on the basis of one of four severity levels (i.e., "mild," "moderate," "severe," and "profound") across all domains. The rationales for two separate sets of functional indicators (intellectual functioning and adaptive functioning) are low correlations between the two, especially in high functioning ID, and, therefore, the need to use both to identify ID [68, 69]. A more precise mapping of adaptive functioning is important to differentiate between a range of neuropsychiatric syndromes [45], but also to understand changes in functioning across the lifespan and as a result of intervention and service provision. Independent of manifestation and functional properties of IDD, ICF categories may be selected to describe additional functional problems of specific individuals or groups or to identify areas of strengths. The assignment of ICF categories largely depends on the setting and the assessment or documentation purposes. Environmental and personal factors might be considered as potential contributors to the overall life experience and to identify intervention strategies to improve service provision.

To document functional characteristics with ICF codes and explore the dynamics of functioning and disability requires compatible assessment instruments to collect valid and reliable data. The use of the ICF as an information system is guided by data generation (i.e., assessing disability) and knowledge creation (i.e., theorizing disability) processes. The ICF is able to represent assessment data from diverse sources (e.g., tests, interviews, observation) in a coherent information system, but also helps to clarify constructs such as "intelligence" or "disability" by mapping definitions or models into the ICF. In other words, assessment information is aggregated into the ICF, and functional information represented in the ICF is used to describe the problem of an individual or group (data-information-knowledge hierarchy) [70]. For example, the CDDG for ICD-11 include functioning properties based on the "Vineland Adaptive Behaviour Scale" [71] to define the concept of "adaptive behavior" [67]. The choice of assessment tools, therefore, does not only predetermine the information, but also implicitly guides knowledge creation processes (clinical sense-making, decision-making, intervention, or service planning). The definition of functional properties, therefore, depends on conceptual models, on the purpose of identifying functional properties and on the choice of assessment tools. "Intelligence" is assessed with standardized psychometric tests (e.g., WISC-IV, WAIS-IV, K-ABC, etc.), but "cognition" or "cognitive functions" may be more relevant constructs to understand specific functional problems associated with learning and problem-solving [45]. "Cognition" as assessed by the WHODAS 2.0 includes interview questions for "attention function," "memory functions," "solving problems," "basic learning," "communicating with—receiving—spoken messages," and "conversation." In conclusion, the functional properties of IDD or ID largely depend on the choice of underlying concepts, choice of assessment methods, and the purpose of assessment.

Lastly, it should not be forgotten that mapping functioning and disability is also about understanding people's life experiences, not only about defining IDD or exploring functional problems associated with ID. The subjective "lived experience" includes concepts such as well-being that are beyond the ICF, but conceptually compatible with it [32]. Psycho-educational, sociocultural, and justice perspectives complement the biomedical perspective to approach IDD [72]. For example, article 24 of the Convention on the Rights of Persons with Disabilities [73] demands that states create educational opportunities to support the development of personality, talents, and creativity of persons with disabilities. The human rights perspective emphasizes issues of personal freedom, availability of choices, and subjective well-being. What gives meaning to the lives of people? Which strengths, skills, aspirations, and talents lie dormant and are not yet mobilized? What is a person's potential to develop functioning not yet developed? Static assessment methods used to document current functioning are inadequate to generate information about a person's potential to develop functioning. Dynamic assessment

methods may be more appropriate to fully explore communication abilities [74] or search for potentials [75]. Dynamic assessment includes experimental approaches to expand abilities [76] and to reflect on the interactive nature of disability as conceptualized by the ICF. The "locus of disability" may be more adequately described as a gap or discrepancy between personal competence and environmental demands [72] than as "functional properties" of the individual. For example, problem behaviors such as aggression or self-injurious behavior associated with IDD and ID [33] may be indicators of such a gap or mismatch.

Defining functional properties of IDD is an ongoing process guided by further development of underlying concepts and the choice of assessment tools and strategies. Identification of individuals and groups also depends not only on the selection of adequate functioning components, but also on the choice of indicators and cut-off or threshold criteria. The perspective assumed by professionals will have an impact on disaggregating complex life situations into functioning and disability components, environmental, and personal factors. If an interactive approach to understanding disability is adopted, the functioning of social systems may be more relevant than the functioning of an individual.

Signs and symptoms of ID/IDD as described in ICD-11 are aligned with body functions in the ICF. Further definition of individual functioning can be obtained through evaluation of life experiences and well-being as well as other psycho-educational, sociocultural, and justice aspects.

1.6 Adaptive Behavior and Skill

Adaptive behaviors are the everyday skills we learn and perform to meet the expectations and societal demands [77]. These expectations and demands increase in complexity as the individual's chronological age increases. Hence, we expect different adaptive behaviors from a child, than from an adolescent or an adult. Adaptive behavior consists of a broad set of skills, encompassing conceptual skills (e.g., functional academics, money and time concepts, communication, self-direction), social skills (e.g., interpersonal skills, social problem-solving, following social rules and laws), and practical skills (e.g., personal hygiene, home living skills, work skills). Empirical support—using a sample composed of both people with and without intellectual disability—supported this three-factor structure of adaptive behavior [78]. Although related to some extent to intellectual functioning, adaptive behavior remains a separate and independent construct [79–82]. A person's inability to learn and/or be able to independently perform these skills may be an indicator of the presence of a neurodevelopmental disorder. The condition that is diagnosed when there is manifestation of significant deficits in adaptive behavior, along with significant deficits in intellectual functioning occurring during the developmental period, is intellectual disability [1, 77] or disorders of intellectual development. Overall, intellectual disability and disorders of intellectual development refer to the same condition or disorder and include the same individuals.

Deficits in adaptive behavior may be attributable to any number of factors, including (a) the person's incapacity to learn and/or perform some skills despite sufficient and appropriate opportunities; (b) a lack of exposure or opportunities to learn and perform some skills; (c) motivational deficits that results in the person choosing not to learn and/or perform some skills; and/or (d) the presence of a comorbid disorder that interferes with the person's learning and/or performing some skills.

1.6.1 Assessment

According to Coulter and Morrow [83], the assessment of adaptive behavior has historically been done for two primary purposes: establish a diagnosis/eligibility determination (i.e., does the person present with significant deficits in adaptive behavior) and identify intervention areas (i.e., individual education plan, individual support plan, identify strengths, and weaknesses). Doll [84, 85] is

seen as the author of the first standardized measure of adaptive behavior, called the Vineland Social Maturity Scale. Since the publication of the Vineland Social Maturity Scale, more than 200 measures of adaptive behavior have been inventoried at different points in time [86, 87]. A vast majority of these measures are used for the assessment of discrete adaptive skills for the purpose of measuring skills deficits with the goal of planning didactic training or implementing or evaluating skills acquisition program. These instruments might be a brief inventory, checklist, or questionnaire focused on a specific area or ability (e.g., social skills, communication skills, toilet training, work skills). These assessments typically involve obtaining information from a third-party respondent (e.g., parent, teacher, direct support professional), but a limited number of assessments involve a direct measure of the person's knowledge of adaptive skills (e.g., Independent Living Scales [88], Street Survival Skills Questionnaire [89]), while others may be administered as a semi-structured interview with the assessed person who provides a self-report of their skills (e.g., Adaptive Behavior Assessment System [90]).

Generally speaking, for the purpose of conducting a robust assessment of adaptive behavior aimed at making a diagnosis of intellectual disability, a number of elements are strongly recommended. The assessment should include, when possible, information obtained from a comprehensive and psychometrically robust standardized assessment tool for adaptive behavior, informed by direct observations from multiple respondents [77, 91]. There are less than a handful of standardized scales that are sufficiently robust for use when the purpose of the assessment is for making a diagnosis or determination of intellectual disability [67, 91]. These recommended instruments include Adaptive Behavior Assessment System—Third Edition (ABAS-3; [92]), Adaptive Behavior Diagnostic Scale (ABDS; [93]), Diagnostic Adaptive Behavior Scale (DABS; [94]), Scales of Independent Behavior, Revised (SIB-R; [95]), and Vineland Adaptive Behavior Scale—Third Edition (Vineland-3; [71]). All these standardized assessment tools are sufficiently psychometrically robust and comprehensive to provide a good standardized measure of a person's adaptive behavior for the purpose of determining ID/IDD.

Alternative sources of adaptive behavior information can be obtained from clinical interviews with people who have lived with or have recently observed, on a regular basis, the person function in their home, school, work, and/or community. Other records that might provide helpful corroborating adaptive behavior information include social and family history, medical records, school records, educational and psychological evaluations, work records, etc. Tassé and his colleagues [67] proposed a number of behavioral indicators of adaptive behavior to guide clinicians in assessing adaptive behavior when standardized adaptive scales are not available.

1.6.2 Intervention

Teaching and promoting the acquisition of adaptive behaviors should be an essential goal of any intervention. The outcome of increasing a person's repertoire of adaptive behavior will often lead to greater independence, personal autonomy, and self-direction as well as a reduced perception among laypeople that the person is disabled. The DSM-5 [1] moved away from using the level of intellectual functioning and proposed relying on the person's level of adaptive functioning as the determinant of the severity of intellectual disability, because adaptive behavior is a better estimate of the person's overall functioning and level of support needs. With the proper level of instruction and support, people with intellectual disability can learn new adaptive skills throughout their life and their overall functioning will generally improve [77].

Adaptive behavior is a complex separate and independent construct of intellectual functioning and equally essential in documentation of ID/IDD. It includes conceptual, social, and practical skills, which can be assessed through a number of robust and reliable instruments. Teaching and promoting the acquisition of adaptive behavior should be an essential goal of

any intervention. Adequate and personalized supports can improve one's adaptive skills as well as his/her overall functioning and quality of life.

1.7 IQ and Cognitive Functions

Measurement of intelligence on the basis of the IQ score plays a central role in the classification of ID/IDD and often represents the only measure undertaken to assess persons with early cognitive difficulties. As mentioned above, an IQ significantly below the general population mean of the population (usually >2 standard deviation units) is the common reference for ID/IDD, and this score is assumed to estimate a person's ability to manage environmental demands and produce adaptive behaviors. This process can result in the burden of diagnostic labels that may fail to capture performance on specific cognitive functions. In fact, evidence from neuropsychology, genetics, neuroimaging, and functional anatomy has demonstrated high variability across different cognitive abilities within individuals [96, 97], thus challenging the current concept of unitary intelligence and the use of IQ.

1.7.1 Uni-component Models of Intelligence

Historically, Spearman [98] was the first to propose a uni-component model of intelligence. He observed that test scores on different cognitive tasks correlated with each other and concluded that this was explained by one underlying common factor, that is, "g factor." In the last 30 years, several studies found statistically significant correlations between neural activation, particularly within the frontal lobes, and performance on a number of tests of reasoning and intelligence [99, 100]. Other researchers found more widespread gray and white matter regions, distributed across several lobes of the brain, to be associated with performance on intelligence tests, a theory which has prevailed to the current day [101, 102]. Research involving individuals with focal brain damage has found activations associated with both the g factor [103] and executive functions, such as working memory, verbal comprehension, and perceptual organization, in both frontal and parietal cortices [104], supporting a distributed intelligence network.

Studies have also reported that executive functions underlying the g factor could vary independently of each other, and that IQ score stability could also hide marked variations in verbal and performance abilities [102]. Furthermore, gray matter co-varying with the g factor does not always belong to those cortical regions suggested to be the seat of general intelligence [103].

In evaluating the utility of psychometric theories supporting a uni-component model, it is necessary to consider whether a deficit in a single cognitive function may have a neuropsychological overshadowing effect, resulting in an artificially lower IQ score, or whether a low IQ score is incorrectly assumed to be the explanation for any anomaly of neuropsychological functioning [105]. These potential pitfalls arise, given that the tools for assessing IQ were not originally developed to evaluate below average performance, but to measure a child's abilities that might be predictive of academic achievement that would indicate the need for additional support. For the same reasons, such tools cannot measure IQ below 40. Hence, this floor effect precludes investigation of how different severities of ID/IDD may be associated with distinct and heterogeneous forms of cognitive functioning, as well as the associations with other variables of interest, such as genetic factors or vulnerability to psychopathological features.

1.7.2 Multicomponent Models of Intelligence

Many scientists theorized that human cognition could not be explained by a unique factor. Luria [106] postulated the existence of three basic units, resulting from interactions between different brain structures: attentional–arousal, integration-sensory input, and executive planning organization. Gardner [107] questioned the validity of IQ and IQ tests as indicators of cognitive functioning,

1

claiming that the representation of the intelligence requires a combination of multiple, specific abilities, which he called "talents." With the theory called "Planning, Attention, Simultaneous, and Successive—PASS," Das and Naglieri [108–110] proposed the existence of interdependent but separate functional systems and developed a measure of individual differences on the basis of cognitive processing, called Cognitive Assessment System (CAS; [111]). Finally, in Goleman's theory of emotional intelligence [112], there is a wide array of competencies and skills which are theorized to drive adjustment and satisfaction in life. According to Anderson's Minimal Cognitive Architecture model [113], cognitive functions represent hierarchically organized and interconnected schemas, according to their role in executing a task or behavior. Individuals who are faster in cognitive processing and in gathering information are more likely to solve problems and have higher IQ [114]. The most widely accepted model of multicomponent intelligence was prompted by Cattell and Horn's theory of fluid and crystallized intelligence and subsequently integrated it within Carroll's concept of triple stratification. This model, upon which the most recent versions of WISC and WAIS have been developed, postulates the existence of nine functions at a broad level, and over 70 more specific, narrow skills. Broad functions include quantitative reasoning, auditory and visual processing, processing speed, reading and writing skills, and long- and short-term memory [115]. As theories of intelligence have evolved over the years, from a single factor to more differentiated intelligence structures, new instruments for measuring IQ have increasingly included scores for subindices, but their utility to describe cognitive profiles of persons with ID across the range of severity has remained questionable.

1.7.3 Specific Cognitive Functions and Executive Functions

There is little consensus on what executive functions actually mean and how they are distinguished from specific cognitive functions. In the neuropsychological literature, they are described as higher order abilities involving (1) volition—determining what one needs or wants and conceptualizing its future realization; (2) planning and decision-making—organizing the steps needed to carry out intentions and/or achieve goals; (3) purposive action—maintaining, switching, and stopping activity in an orderly and integrated manner; and (4) self-regulation—reduction of erratic responding and flexibility of responding to shifting task demands [116]. According to the International Classification of Functioning, Disability and Health (ICF: [32]), a cognitive profile should include both specific functions, such as memory, attention, perception, thought, space–time orientation, and executive functions, such as planning, decision-making, inhibition, regulation/correction, and action.

There are many studies reporting correlations between neuroanatomical areas and specific cognitive functions, independent of general intelligence [97]. Pascual-Leone combined various neurophysiological and brain-imaging techniques in order to identify the correlates of functioning with respect to different areas and neural systems, demonstrating that the brain represents a modular structure, and that focal damage causes only a limited impairment of overall intellectual functioning [117]. The prefrontal cortex has repeatedly been found to be active during attention switching tasks, and prefrontal cortex injury, especially on the left side, causes impairment in attention switching [118, 119]. Poor performance in switching tasks was also found in patients with lesions in the language cortex [120] or in the inferior frontal gyrus of the right hemisphere [121, 122].

In evaluating executive functions in children with ID/IDD through the Behavioural Assessment of the Dysexecutive Syndrome (BADS-C, [123]) and the Cambridge Executive Functioning Assessment (CEFA, [124]), Willner et al. [125] found scores on both tests to be only weakly related to receptive language skill, and even more weakly to IQ. Interestingly, working memory—the ability to keep something in mind while manipulating it simultaneously (e.g., repeating a string of random numbers in reverse order)—seemed to play a key role in this floor effect.

Several other studies have found significant associations between executive functions, particularly working memory, and general intelligence [96, 126]. However, some more precise assessments indicate that only updating working memory correlates with intelligence, whereas inhibiting responses and shifting mental sets do not; these two functions seemed to be related with IQ only via their covariance with updating [96, 127, 128]. Gansler and collaborators [129] found that assessment of intelligence based on executive functions accounts for more variability in activities of daily living is better predicted by health status, and was predicted less well by educational status than traditional IQ measures.

In the field of ID/IDD, researchers have found that the investigation of relationships between brain structure and specific cognitive functions to be more informative than the IQ per se.

In a recent literature review [45], neuroimaging studies of persons with Down syndrome or Fragile X syndrome were shown to be based on specific cognitive or executive functions more than on overall intelligence. Specifically, none of the five studies of persons with Down syndrome and 12 of the 15 studies of persons with Fragile X syndrome identified in the review included any overall measure of intelligence [45].

To date, knowledge on alterations of very specific cognitive functions is limited, as well as their impact on "higher order" executive functioning abilities. The most frequently studied functions are working memory and executive functions and more specifically orientation response and attention switch [45].

The case for using specific cognitive functions in defining ID/IDD is also supported by findings of recent research on cognitive and behavioral phenotypes. Different genetic syndromes with comparable IQs were associated with very different cognitive phenotypes, with respect to both relatively intact and impaired functions [45]. Similarly, general IQ scores of children with Williams–Beuren syndrome, Prader–Willi syndrome, and Fragile X syndrome, with similar sociocultural and socioeconomic backgrounds, were found to be associated with significant differences in verbal IQ and verbal and performance subtests. Vocabulary and comprehension subtest scores were significantly higher in Williams–Beuren syndrome in comparison with Prader–Willi and Fragile X syndromes, and block design and object assembly scores were significantly higher in Prader–Willi syndrome than in Williams–Beuren and Fragile X syndromes [130].

Variability between and within phenotypes is also present in autism co-occurring with ID/IDD. Of particular interest is the finding that in people with autism, low IQ scores are not necessarily associated with impairment of overall cognitive functioning, but with abnormalities in information processing, which in turn have pervasive effects on the overall functioning of the individual [131, 132].

In summary, individual differences in specific cognitive functions are highly relevant in differentiating ID/IDD phenotypes, and in understanding their biological underpinnings, whereas IQ measures do not provide such differentiation.

Unfortunately, to date, knowledge of alterations of very specific cognitive functions in ID/IDD of different origins is limited, as well as the impact of such specific functions on "higher order" executive functioning abilities. In one of the few studies aimed at this, Scerif and collaborators [133] compared visual attention in Fragile X and Williams syndrome, showing that early manifestations of inhibitory deficits affect disengaging and set-shifting abilities in Fragile X syndrome and selective attention in Williams syndrome, with different implications for impulsivity and self-control, working memory, and organization of thoughts and behavior to reach a goal (planning, self-correcting, verifying, and adapting).

1.7.4 Integration of Cognitive and Emotional Processes

Assessment of IQ does not include measurement of emotional skills. In spite of this omission, the reciprocal influence between emotion and cognition has received considerable attention, with very interesting models being proposed, including those by Ciompi, Plutchik,

1

or LeDoux [45, 134–137]. It has been suggested that an emotionally charged activating stimulus or a condition of emotional distress may affect the quality of an individual's cognitive performance [138], particularly memory recall [139].

Investigation of the interplay between emotional and cognitive processes has been fostered by a new conceptualization of mental disorder proposed in a project titled Research Domain Criteria (RDoC, [140]). The RDoC defines the relationship between behaviors and brain activities, and correlates clinical phenomena to the functioning state of neurobiological circuits [140]. The RDoC framework proposed the "construct" as the basic unit of analysis, which summarizes all data related to a specific domain of functioning, that is, genetic, molecular, anatomical, behavioral, and symptomatology. This model pays particular attention to the study of emotion, motivation, and social processes and their relationships with cognitive functioning. Five constructs were defined, such as negative affectivity, positive affectivity, cognition, social behavior, and arousal/regulator system. The "cognition" construct includes major cognitive functions, indicated by the prevailing literature, to comprise the neural basis of behavior, that is, attention, perception, working memory, declarative memory, language, and cognitive control.

In recent decades, the relationship between cognition, emotion, and social interaction has increasingly become the object of study in many areas of psychology and cognitive neuroscience with the name of "social cognition." Social cognitive processes have been clustered in three main domains: (a) perceptual processing of social information such as facial expression and emotional body language (social perception), (b) grasping others' cognitive or emotional states (social understanding), and (c) planning behaviors and acting taking into consideration one's own and others goals (social decision-making) [141]. Impairments in one or more of these domains represent a prominent concern in the several cases in which ID/IDD co-occur with autism spectrum disorder.

Another relationship between cognition and affect, not measured by IQ tests, has been theorized by Salovey and Mayer and further developed by Goleman through the concept of emotional Intelligence [142, 143]. According to Mayer and Salovey, emotional intelligence is "the ability to perceive emotions, to access and generate emotions so as to assist thought, to understand emotions and emotional knowledge, and to reflectively regulate emotions so as to promote emotional and intellectual growth [143]." Goleman focused on the more functional aspects of interpersonal and personal strengths and agreed with Salovey and Mayer in dividing emotional intelligence into the following five components: self-awareness, self-regulation, internal motivation, empathy, and social skills [112]. Self-awareness is the ability to recognize and understand personal moods, emotions, and drives, as well as their effect on others. Hallmarks of self-awareness include self-confidence, realistic self-assessment, and a self-deprecating sense of humor. Self-regulation consists of the ability to control or redirect disruptive impulses and moods, and the propensity to suspend judgment and to think before acting. Hallmarks include trustworthiness and integrity, comfort with ambiguity, and openness to change. Internal motivation is a drive to action linked to an inner vision of what is important in life, a joy in doing something, curiosity in learning, and a disposition to pursue goals with energy and persistence. Hallmarks include a strong determination in achieving aims and optimism even in the face of challenges. Empathy consists of the ability to understand others' emotional makeup and treating people according to their emotional reactions. Social skills are expressed by aptitude in managing relationships and building social networks, mainly through the identification of a common ground with others. A common hallmark of social skills is represented by effectiveness in building and maintaining between-individuals and group relationships. According to Goleman, emotional competencies within each component of emotional intelligence are not innate, but rather learned capabilities that must be worked on and can be developed to achieve outstanding performance [142]. The concept of emotional intelligence and its measures have been criticized,

for (a) not being a construct of intelligence or cognitive ability; (b) lacking correlations between its components; (c) being a merger or conflate of previous psychological constructs, such as relational skills and emotional states; (d) having little predictive value for success in higher education, work, long-term romantic relationships, etc.; and (e) not having validated measures [144–146].

There is a dearth of research examining emotional intelligence in persons with ID/IDD. A few studies focusing on younger individuals found difficulties in domains like social cognition and emotional knowledge, although explicit reference to the term *emotional intelligence* is limited to two studies [147–152]. On the other hand, a recent literature review concludes that persons with ID possess emotional capacities similar to persons with typical development, with some exceptions depending on specific cause and severity level of ID/IDD [153].

A construct in the social cognitive sciences to explain the association of cognitive and emotional processes in respect to social understanding is represented by the "Theory of Mind" (ToM) mechanism, which is defined as the ability to understand and take into account another individual's mental state [154–156]. Although there is still disagreement about the precise nature of the ToM mechanisms, there is a widely accepted consensus that what needs to be explained about social understanding is the capacity for the so-called mentalizing or mindreading, which has been considered to include at least three relatively distinct cognitive abilities: to (a) attribute mental states to the hidden minds of others, (b) explain the behavior of others in terms of these hidden mental states, and (c) predict their future behavior accordingly [157]. A large number of studies show that ToM develops over the lifespan [158–160], but most of the research has been conducted with children of preschool and elementary school age, displaying low levels of ToM development [161–163]. ToM has also been criticized and other processes, for example, embodied interaction, have been proposed to play an essential role in social understanding [157].

Further descriptions of ToM and characterization in persons with autism spectrum disorder (ASD) are provided in ▶ Chap. 16.

1.7.5 Concluding Considerations on IQ and Cognitive Functions

IQ scores alone can be limited when used as an indicator of the complexity and dynamic nature of human cognitive functioning [164]. A common and comprehensive model of intelligence, which fully reconciles both general cognitive capacity and specific cognitive abilities, is lacking. Even though there is evidence to support both the uni-component and multicomponent models of intelligence, the latter appear to be more appropriate for explaining the high variability of cognitive functioning in ID/IDD. Indeed, experimental data indicate that the same IQ score can correspond to very different cognitive profiles as well as functional capacities.

Neuropsychological studies indicate that traditional intelligence tests have notable limitations, most notably capturing those cognitive functions and sub-functions in which the literature has supported as being more sensitive to individual abilities, brain injury, and disabilities [116]. The most frequently used assessment tools may provide incomplete and non-personalized data, lacking real-world validity in clinical practice with persons with ID/IDD. Cumulative scores, referring to macro-areas of cognitive functioning (e.g., verbal abilities, perceptual abilities), often fail to capture the effectiveness or importance of single skills and cognitive domains (e.g., self-control, learning ability). The DSM-5 indicates that "IQ test scores are approximations of conceptual functioning but may be insufficient to assess reasoning in real-life situations and mastery of practical tasks" and that consequently "a person with an IQ score above 70 may have such severe adaptive behaviour problems" . .. that their "actual functioning is comparable to that of individuals with a lower IQ score."

Full-scale IQ is a metric that many researchers and clinicians consider to be

outmoded and ready to be augmented by more meaningful indicators [165–167]. The WPA-SPID and the first working group for ICD-11 proposed a diagnostic approach complementing measurement of IQ with assessment of specific cognitive functions, and a contextualized description of consequent adaptive and learning difficulties [33, 44, 168]. This approach was adopted also by the DSM-5; in the chapter on diagnostic features of ID (Intellectual Developmental Disorder), it states that "Individual cognitive profiles based on neuropsychological testing are more useful for understanding intellectual abilities than a single IQ score. Such testing may identify areas of relative strengths and weaknesses, an assessment important for academic and vocational planning." Within this approach, cognitive skills should be assessed in the most comprehensive way possible, through direct clinical examination, semi-structured observations, and tests, referring to complex executive functioning, including perceptual reasoning, processing speed, verbal comprehension, as well as to very specific cognitive functions, such as attention orientation, attention switch, visual–spatial perception, or working memory.

The evaluation should aim to identify the neuropsychological characteristics that have the greatest impact on the person's quality of life, not only via cognitive skills but also associated behaviors, personal skills, adjustment, and autonomy. This would require professionals to be familiar with several instruments, in order to quickly select the most appropriate ones on the basis of the person's characteristics and the evaluation context, and cultural background.

This approach may favor the understanding of the link between cognitive alterations and psychopathological vulnerability across the lifespan, as well as bring enormous advantages to a more inclusive cultural attitude toward ID/IDD and other neurodevelopmental disabilities, providing a paradigm shift from "intellectually below average IQ" to "neuropsychological characterization of relative strengths and weaknesses." According to this paradigm, every person would have a neuropsychological profile specific to themselves. However, some people with and without ID/IDD could even share one or more specific cognitive dysfunctions and be distinguished only by their severity and their impact on individual functioning.

IQ scores alone can be limiting when used as an indicator of the complexity and dynamic nature of human cognitive functioning. Even though there is evidence to support both the uni-component and multicomponent models of intelligence, the latter appears to be more appropriate to explain the high variability of cognitive functioning in persons with ID/IDD. Indeed, experimental data indicate that the same IQ score can correspond to very different cognitive profiles. A comprehensive consideration of cognitive functioning may favor the understanding of the link between cognitive alterations and psychopathological vulnerability across the lifespan, as well as bring enormous advantages to a more inclusive cultural attitude toward ID/IDD and other neurodevelopmental disabilities, providing a paradigm shift from "intellectually below average IQ" to "neuropsychological characterization of relative strengths and weaknesses."

1.8 Development

A multitude of meanings is associated with the term "development," which can be regarded as the process of change in the person's acquisition of skills and abilities finalized to ultimately reach their human potential and to understand their role in the society. Although there can be a great variability, in its typical course the developmental process of children brings them progressively from the condition of complete dependency on others to achieving independence of their needs and well-being. Starting from these premises, by definition children with ID/IDD are those who develop at a rate significantly below average and make progresses at a rate that is

significantly slower than the one expected for children of the same age. Nevertheless, also the development of children with ID/IDD varies from person to person, since many conditions underlying ID/IDD have unique developmental trajectories [169]. Moreover, dynamic interactions between biological and environmental factors can influence the course of the development over time [170]. Indeed cognitive, language, emotional and social abilities, and competences are specifically influenced by experience and environmental factors, generally following a hierarchical sequence in their evolution [171]. Consequently, the timetable and rates of achievement of developmental milestones for children with ID/IDD can be difficult to predict as well as eventual resulting outcomes in the adult age and the acquisition or the disruption of the skills specifically associated with each developmental period can present unique challenges for a child or adolescent with ID/IDD and his/her family or caregivers (Table 1.2).

Divergence from typical developmental sequences may be particularly evident when secondary to the presence of specific genetic syndromes. For example, severe to profound ID/IDD and an early period of developmental regression preceded by a phase of normal development are typically present in Rett syndrome [172]. Therefore, an early diagnosis of ID/IDD is critical, also because children with delayed or no identified diagnosis usually progress poorer than those with a clear diagnosis [173]. Finally, clinical attention should not only be paid to childhood but also to all developmental critical periods [174, 175], since understanding the dynamics of development in different sensitive periods can guide the timing of interventions in order to improve the trajectory and global outcome of development [176].

1.8.1 Infancy

The presence of ID/IDD can modify or disrupt the typical development of attachment [177–180], self-regulation [181], and environmental awareness and exploration during infancy. For example, some functions linked to the strengthening of attachment, such as eye contact or social smile, can be absent in children with ID, and the presence of an autism spectrum disorder often linked to ID/IDD can further present obstacles to the attachment process [182–184]. Moreover, postnatal hospitalizations and prolonged medical interventions in cases of severe neurological or physical conditions can secondarily interfere with normal attachment. Conversely, delays in motor coordination and/or comorbid medical disorders, such as seizures, often create a status of dependence on family members or caregivers that can result in excessive parental vigilance. In this context, families that receive a diagnosis of ID/IDD for their child often experience anger, denial and grief, and frustration and can question their parental skills, with feelings that can interfere with the attachment processes [177, 178, 185, 186].

1.8.2 Early Childhood

When not identified during infancy, ID/IDD can be usually diagnosed during early childhood.

Language development is frequently delayed or altered in children with ID/IDD, and deficits in communication development have been proven to be early predictors of behavioral difficulties in persons with ID/IDD. Indeed, frustration at not being able to fully or entirely communicate needs or desires may lead to disruptive or self-injurious behavior [183, 187, 188]. Moreover, poor social cues can also be secondary to an inability to successfully drive the communication process apart from the difficulties in following the flow of the communication. As a consequence, social withdrawal, isolation, or increased reliance on selected caregivers may be inadvertently reinforced. Therefore, great clinical attention has to be paid to language difficulties, since early interventions must not be delayed. Moreover, children with specific language disorders may develop effective alternative communication systems to express their needs [189].

1

Table 1.2 Main developmental stages and issues associated with ID across the lifespan

Infancy	Attachment Self-regulation Environmental awareness Exploration Overdependence on caregivers Social withdrawal
Early childhood	Self-care skills delay Personal mastery and self-esteem Frustration and tension with parents Overprotection and inhibition of individual initiative Communication needs if not met properly can lead to challenging behaviors Isolation or increased reliance on selected caregivers Delay or lack of spontaneous play, substituted by undirected or self-stimulatory behavior
Childhood	Taunting and rejection by peers Increasing awareness of one's limitations Social withdrawal and isolation Depression Externalizing or acting-out behavior Difficulties in meeting language and abstract concepts demands Learning skills
Adolescence	Academic failure Education goals change from life skills to vocational activities Difficulty in adapting to life changes Dependence on parents, effect on self-esteem, and learning of social skills Increased relationship and emotional difficulties Issues related to delay of puberty and sexual development Risk of abuse and bullying
Adulthood	Independent living Self-reliance in fulfilling roles Employment and other vocational activities Intimacy and reciprocity in relationships Psychopathological vulnerability Parental aging and ill-health issues
Aging	Emotions are more predictable and less labile Investments toward meaningful others increase Negative emotions become more infrequent Emotions associated with negative life experiences may be more intense and affect physiological functioning Aim of control processes shifts from changing the world to changing the self Vulnerability to age-related physical and mental health problems Increase in support needs

Considering the type of play typical for the age, the beginning of spontaneous and meaningful play may be delayed or completely missing in children with ID/IDD [190]. Indeed, in severe forms of ID/IDD, undirected or self-stimulatory behavior can be present instead of appropriate play. In the case of children with mild/moderate ID, some forms of symbolic play may develop when they are about to enter school, and also isolated or parallel play may predominate especially when communication skills are significantly impaired.

The presence of fine and gross motor delays can interfere with the acquisition of self-care skills. For those with more severe forms of ID/IDD, there is the possibility of a lifelong inability to perform activities of daily

living [191]. In the case of less severe forms of ID/IDD, self-care skills acquisition can only be delayed or is partially incomplete compared with children of the same age without ID/IDD [192].

Finally, many factors during early childhood can influence the development of the child's personality [193]. The acquisition of adaptive, communication, emotional and self-regulation skills, and how caregivers contribute to the entire process can have significant implications. Indeed, parental response, both emotionally and in terms of expectations, can greatly impact children in the development of personal mastery. The parent–child relationship may suffer from unrealistic expectations by the family and/or caregivers, while minimizing expectations may inhibit the acquisition of skills and generate frustration and lack of initiative in the child with ID [194]. For example, children with less severe ID/IDD may express the desire to perform different tasks without the appropriate skills, and this can lead to increased conflict with family members and/or caregivers. For children with milder severity of ID/IDD, self-esteem and perceived trust can form the basis of interpersonal relationships and can help to build a sense of self in the world. For children with more severe delays, the caregiver's ability to assist the child effectively in helping to regulate the different responses to internal and environmental stimuli can contribute to create a better lifelong style of behavior.

1.8.3 Childhood

Entry into school may coincide with the first exposure for children with ID/IDD to peers without disabilities. Therefore, it can be regarded as a challenging time, particularly for children with mild ID/IDD. This can be the first time for a child with ID/IDD to encounter terms such as "slow learner," or to feel different, or to experience peer taunting or rejection, although increased academic mainstreaming has elevated the awareness of many typical children regarding disabilities [195, 196]. As a consequence, isolation and social withdrawal can be expected, as well as depression or anger with externalizing and/or acting-out behaviors [197]. Most children with ID/IDD need special resource support in the classroom, since they may particularly struggle with progressively more demanding language concepts and abstract tasks. In this regard, teachers caring for many children with different special needs are challenged to work on specific communication and behavioral skills of the individual child [198, 199].

1.8.4 Adolescence

For youth with ID/IDD and their families, adolescence represents the most challenging developmental phase within the whole lifespan. Issues related to the transition from childhood to adulthood may be delayed or exaggerated, especially in becoming independent from parents, self-esteem, and social skills [200, 201]. Relationships inside and outside the family become more complex, and environmental factors have a deeper impact on the person's development than in previous ages, with consequent relational and emotional difficulties much greater than in adolescents of the general population. Problems in adapting to life changes are often expressed behaviorally, since the adolescent may be unable to communicate their ensuing frustration and confusion. These difficulties are further worsened by the delay of puberty, sexual development, and related body changes [202, 203], and the acquisition of social skills in comparison to peers. This gap increases the risk of abuse and bullying [204]. Also, families' experiences become even more challenging than before, since the person with ID may exacerbate their problem behaviors and increase the family burden and stigma [205].

During adolescence, academic failures can be common. In the case of the presence of more severe delays, the education program of the adolescent will shift from preparation to higher education to the acquisition and consolidation of life skills [206, 207] and vocational activities. Moreover, this life period is also typically characterized by the participation in extracurricular and community activities. In this context, the preparation of the

adolescent to the achievement of developmental tasks related to the social role and expectations of the society in general are crucial to ease the transition to adult life.

1.8.5 Adulthood

Key developmental milestones of adult life include emotional autonomy, independent living, self-reliance in fulfilling roles, employment, intimacy, and reciprocity in relationships. Delays and difficulties in reaching these stages, which depend on interaction of a number of personal and environmental factors, can determine or aggravate problems of self-esteem, environmental mastery, emotional control, adaptation, and stigma [208–210]. A common causal factor is represented by an overprotective or custodial attitude, which can contribute to delay the acquisition of autonomy and favor the development of a sense of insecurity and inadequacy, which can in turn reinforce submissive, renouncing, or obstinate and challenging behaviors [211].

In many cases, the continuation of these psychological adversities can contribute to the onset of psychopathological co-occurrences, especially in the context of anxiety and mood disorders [212–214].

1.8.6 Aging

During aging, experienced emotions are more predictable and less labile. Social networks narrow, but investments toward meaningful others increase. Negative emotions become more infrequent, but those associated with negative life experiences may be more intense and affect physiological functioning and ultimately physical health.

In general, primary control processes directed at modifying the environment to meet one's wishes leave the scene to secondary control processes during late adulthood, with a shift to change the self in order to be in line with the environment [215]. In the case of persons with ID/IDD, this observation is not frequently true, since they often lack resort to secondary control strategies of adjusting expectations and therefore have a high probability to fail to pursue more attainable goals when certain primary control goals become unattainable during aging.

Furthermore, psychophysical decline associated with aging occurs earlier and more intensely in people with ID/IDD than in the general population [216]. Sensory declines are common and can negatively impact communication and social interaction. Physiological functioning is regulated less well and physical reserves decrease, although occasionally some protection can be given by improvement of self-regulation. Age-related psychophysical problems and consequent contextual changes require more support, especially in case of parental death, and many people with ID/IDD have to end their lives in community residential settings [217]. In the last decades, life expectancy of people with ID/IDD and low-functioning ASD has progressively increased, reflecting a proportionate rise of issues related to moving from the family home after the death of parents and the mourning process [218].

It has been acknowledged that the experience of bereavement in people with ID/IDD is globally similar to that in the general population [218, 219], although there are some studies indicating relevant differences, especially in terms of prolonged and atypical grief which is often unrecognized [220–222], and a definitive position is yet to be reached.

Particular conditions related to ID/IDD are associated with life-shortening and degenerative illnesses, such as Down syndrome, which is linked with the early onset of Alzheimer's disease [223].

1.8.7 Emotional Development

The importance of emotional aspects in the definition of the developmental level for every person with ID/IDD has been underlined by many authors [224–226], with some of them going so far as to say that persons with ID are emotionally impaired or follow a different emotional development in respect to typically developing persons [227–229]. Generally, individuals with ID/IDD pass through the same

periods of emotional development as typically developing persons do, although with an increased risk of delay and incompleteness [227, 230–234]. The level of emotional development seems to correlate with the severity of ID/IDD and the co-occurrence of ASD [234]. Nevertheless, quality of evidence on emotional development in persons with ID/IDD is very limited, and no consensus has been reached on definitions and assessment procedures or on the relationship with adaptive skills, cognitive level, behavioral issues, and co-occurrence of psychopathology.

Some authors suggest that at each level of emotional development, different emotional needs and motivations, coping abilities, adaptive skills, and consequently different behavioral patterns can be found [227, 235–237], in combination and interaction with the well-known social, sensorimotor, and cognitive functions [238–241].

Newborns perceive and respond to a wide range of stimuli by expressing simple emotions; later, the emotional response begins to be modulated by the effect of the caregiver or interacting partner [242, 243]. The subsequent development of "joint attention," which denotes the emergence of affective sharing, appears around the second year of life [244, 245]. Around the third year of life, emotion regulation achieves more complex stages, and children become able to manipulate the emotional states of others [246]. Preschool children begin to have a basic insight into the causes and consequences of emotions and are able to differentiate and regulate their affective states, while further development of empathy, pro-social and moral thinking, and behaviors are observed in school-aged children [247].

The most famous developmental model specific for people with ID/IDD is the one developed by Anton Došen and collaborators. It includes five levels of socio-emotional development, which are aligned to the above-mentioned milestones of the developmental trajectories and the associated maturation of the respective brain circuits [227, 233, 248].

1.8.8 Conclusive Considerations on Development

The longitudinal trajectory of ID/IDD can be variable and distinct from that of typical development, especially when specific etiological conditions are taken into account [249, 250]. The different patterns of the longitudinal course can include a progressive trajectory often associated with metabolic disorders (e.g., the manifestations of the underlying process occur after birth and evolve over time into a progressively deteriorating course); an acquired trajectory with normal course of development up to the point of an insult with subsequent modification of the course of development (e.g., traumatic brain injury or severe psychosocial deprivation); and a non-progressive linear trajectory especially in environmental-related disorders with fluctuating developmental course, with periods of stress, and periods of nurturance, or positive intervention, or both [33]. The consideration of these different developmental patterns has relevant consequences for the diagnostic process. Indeed, "at any given cross-sectional encounter point with convergence of the various possible trajectories it is difficult for a clinician to make an informed decision about the developmental course of ID/IDD." Since many genetic, metabolic, and environmental factors can lead to the development of ID/IDD across the lifespan, it is, therefore, especially vital to undertake full medical history, physical examination, and requisite workup, to determine the principal cause of ID/IDD [251]. In this context, the introduction of a longitudinal developmental perspective is likely to improve the understanding of how different presentations of ID/IDD, with or without a known etiology, may change and evolve over time. In addition, this approach could lead to a better definition of how different genotypes of known conditions associated with IDD may lead to specific behaviors and cognitive profiles during specific periods of the lifespan [33]. For example, young children with Down syndrome show increasingly better receptive language skills in advance of

expressive abilities [252, 253], while boys with Fragile X syndrome show more pronounced patterns of higher level abilities in simultaneous processing than in sequential processing over the course of their development [254].

- Persons with ID/IDD develop at a significantly below average rate and slower than the general population, depending on a dynamic interaction between several biological and environmental factors. Nevertheless, the timetable and rates of achievement of developmental milestones can vary considerably from one person to another. An early diagnosis and monitoring of ID/IDD and associated developmental and psychopathological issues is crucial, since the understanding of the dynamics of development in different sensitive periods can guide the timing of interventions and improve the global outcome.

- In recent years, increasing attention is paid to emotional aspects in the definition of the developmental level.

1.9 Integrated Assessment

1.9.1 Integrated (Multidimensional) Assessment

As described above, persons with ID/IDD present a complex multidimensional and multi-systemic vulnerability, which expresses itself through a high rate of physical and mental ill-health, as well as problem behaviors. Thus, a well-timed, sensitive, and comprehensive assessment represents a fundamental process to define their overall health condition appropriately. This assessment should include as many aspects as possible within all health-threatening areas, such as biological, psychological, and socio-environmental.

To date, scientific evidence confirms that integration of different aspects of care has many advantages, including improvements in personal outcomes and diagnostic and prognostic abilities of health professionals ([255, 256]; see also ▶ Chap. 13).

With the term "integrated assessment," we refer to a comprehensive process aimed to collect quantitative and qualitative data through the use of multiple standardized and informal instruments and procedures. Comprehensive assessment data obtained should be integrated, interpreted, and summarized, including indirect and preexisting sources. The primary aim of this kind of assessment is to enable multidisciplinary team to make accurate diagnoses and to define a profile of the person's strengths, weaknesses, and needs, in order to plan the most effective interventions.

To conduct an integrated and multidisciplinary assessment, different professionals must work together to build up a shared project with the person and his/her family; these professionals must also be able to create connections of meaning and value concerning information collected, personal history, and his/her experiences. Bio-psycho-social approaches encourage the use of multidisciplinary case formulation to integrate different information, to explain the development and maintenance of physical and mental health problems, and to plan adequate interventions to address those problems [257].

1.9.2 Comprehensive Assessment and Evaluation

Professionals conducting a comprehensive and integrated assessment should have a good knowledge of the condition of ID/IDD in order to identify individual peculiarities and the need for specific adjustments.

No single data source is sufficient: the use of different informants, records, measures, procedures, and practices is necessary to enable multidisciplinary teams to have a comprehensive and reliable assessment.

The first step to carry out the assessment process is to collect a detailed history of both personal and medical aspects. Then, the condition of ID/IDD itself has to be well defined, including level of IQ, specific cogni-

tive impairments (i.e., attention orientation, attention switch, working memory, etc.), language, functioning, adaptive skills, and physical issues, before moving to the assessment of current physical and mental status, including behavioral profile, and concluding with the evaluation of person-centered general features, especially quality of life.

1.9.2.1 Medical and Personal History

Information on an individual's medical history should consider the following aspects: maternal pregnancy, delivery progress, abnormalities at birth, specific investigations, diagnosis of ID/IDD, presence of organic/cognitive/behavioral disorders, hospitalizations, and pharmacological and non-pharmacological treatments. Primary care and community services should aim to ensure that older people with ID/IDD and or ASD can see the same healthcare practitioners, wherever possible, to help practitioners to become familiar with the person's medical history, to build a good relationship with the person, and to understand his/her usual behavior and communication needs.

Personal history should be targeted at least at the following:

- Family: original and current composition of the family, cultural and economic status, quality of relationships between members, most significant relationships, and average state of health, and psychiatric familiarity
- Social belonging outside the family: relationships outside the family with individuals and groups, quality of these relationships, level, and quality of participation in community life
- Life conditions: place of birth, quality of the housing and environment (including the level of external stimulation, the involvement in various activities, etc.) in which the person lived, home/house moving, level of education, supports for learning, training conducted, the current employment status, and preferred places
- Personal interests
- Strengths and weaknesses

1.9.2.2 Definition of the Condition of ID/IDD

Assessment of cognitive functioning provides information about a person's intellectual strengths and difficulties. Intelligence testing is usually undertaken using the Wechsler Adult Intelligence Scale (WAIS-IV, [258]). This tool is designed to measure intelligence in adolescents and adults aged between 16 and 90 years. The WAIS-IV determines four individual scores, which are combined to derive the IQ score. The four individual scores are related to verbal comprehension, working memory, perceptual reasoning, and processing speed. The Leiter International Performance Scale-Revised (Leiter-R; [259]) is another standardized nonverbal measure of intelligence, often used to estimate the nonverbal problem-solving potential of individuals who do not use speech. The test is particularly suitable for children and adolescents, from 2 to 20 years, with cognitive impairment and or verbal disorders. The Leiter-R is composed of standardized batteries: Visualization and Reasoning (VR), which consists of 10 subtests for the measurement of nonverbal cognitive skills related to visualization, spatial abilities and reasoning, and Attention and Memory (AM), also consisting of 10 subtests.

Assessing and empowering personal functioning of people with ID/IDD is crucial in planning rehabilitative interventions. In the International Classification of Functioning (ICF; [32]), disability and functioning are viewed as outcomes of interactions between health conditions and contextual factors. The latter includes both external environmental factors and internal personal factors, which refers to personal characteristics such as gender, age, coping styles, social background, education, profession, past and current experience, overall behavior pattern, and other factors that influence how the person experiences disability. ICF classifies three levels of human functioning: functioning at the level of body or body part, the whole person, and the whole person in a social context. According to this classification, disability involves dysfunctioning at one or more levels: impairments,

1

activity limitations, and participation restrictions. The definitions of these components of ICF can be summarized as follows: body functions (including psychological functions), body structures, impairments, activity, participation, activity limitations, participation restriction, and environmental factors.

Language

Communication Assessment Profile (CASP) [260] assesses the communicative abilities of adults with severe to mild learning disabilities. It examines eight aspects of language and communication, including the person's understanding and use of everyday words and sentences. Sound discrimination and conversational skills are also assessed.

Another tool that can also be used with people with ID/IDD is the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4) [261]. It is one of the most commonly used assessment tests that measure verbal ability in standard American English vocabulary. It measures the receptive processing of examinees from 2 to over 90 years old.

Adaptive Skills

Adaptive behavior refers to the set of conceptual, social, and practical skills that have been learned by the persons to function in their daily life [262].

The Vineland Adaptive Behavior Scales (Vineland-3; [71, 263]) and the Adaptive Behavior Assessment System (ABAS II; [264]) are the best known and most widely used tools for the assessment of adaptive skills. They detail conceptual, social, and practical domains into a variety of areas, including conceptual skills (i.e., arithmetic skills, knowing numbers and shapes), communication (i.e., comprehension and production of written and oral language), daily living skills (i.e., self-care, home living, professional activities), socialization (i.e., interpersonal relationships, social problem-solving, recreational activities, respect of social norms, community use), health and safety (i.e., following safety rules, showing caution when needed, staying out of danger, and knowing when to get help), leisure (i.e., playing, hobbies, following rules in games, planning fun activities), self-direction (i.e., self -control, making choices, starting and completing tasks, following a routine, and following directions), and motor skills (both gross and fine).

ID/IDD is a condition which is maintained throughout the lifespan, and it complicates individual transitions between ages, which are often difficult in itself (e.g., from adolescence to adulthood, from adulthood to seniority). Different contexts that are commonly associated with the different life phases may represent significant obstacles for people with ID/IDD. Nevertheless, consideration of these transition phases and, in general, the adoption of a lifespan perspective by healthcare services is often limited. All the professionals involved should be aware of the critical points of transition and their responsibilities.

Emotional Development

Emotional aspects deserve a place in the assessment of every person with ID/IDD. In fact, emotional impairment or peculiarities in emotional development are common in many people with ID/IDD. Furthermore, emotional development is reported to influence and be influenced by changes occurring in other areas, like the motor or linguistic, cognitive, and social [33]. The most common assessment tool of emotional development in people with ID/IDD of any age is the "Scheme of Appraisal of Emotional Development" (SAED) [227], a semi-structured interview that evaluates the achieved developmental level in 10 basic aspects of emotional development, with the following domains: Dealing with his/her own body, interaction with a caregiver, experience of self, object permanency, anxiety, interaction with peers, handling of material objects, verbal communication, affect differentiation, and aggression regulation. According to the five possible developmental levels (adaptation, socialization, individuation, identification, reality awareness), values from 1 to 5 can be assigned in this ordinal scaled measure corresponding to certain developmental achievements and age equivalents in typically developing children. Two modified versions of the SAED have been produced during the first half of the last decade Scale for Emotional Development—Revised (SED-R) [265] and

Scale for Emotional Development—Second Revision (SED-R 2) [266], keeping the same five-stage model of emotional development, but adding three domains. More recently, a short, psychometrically sound and adult-oriented version has also been developed, with the name of SED-S (Scale of Emotional Development—Short) [267].

1.9.2.3 Physical Assessment

In persons with ID/IDD, the identification of physical health problems is usually more complex than in the general population. This occurrence is due to several peculiarities in the perception, presentation, and communication of symptoms. In particular, the discrepancy in primary healthcare received by people with ID is due to the following barriers: mobility and sensory impairments, behavior problems, language difficulties, and inadequate knowledge and attitudes of staff. First of all, in order to conduct an appropriate and comprehensive assessment, healthcare professionals have to make some adjustments so that people with ID/IDD may have equal access to medical care. Practitioners should explain clearly to a person with ID/IDD what will happen during any medical appointments or examinations. If the person agrees, they should also share the information with his/her family member, carer, or advocate. This evaluation should be carried out in a place that is familiar, welcoming, and appropriate to personal needs. Managers in healthcare settings should provide adequate information to family members and carers so that they can help people with ID/IDD to find an appropriate service. Alternatively, they should identify a practitioner with experience in the field to contact people with ID and their family members, carers, and advocates [268]. In the context of assessment, professionals should discuss changes that may occur with age with persons with ID/IDD and their family members, asking them about symptoms of common age-related conditions or changes in any existing conditions, including blood pressure and serum cholesterol level, diabetes, hearing loss, and sight problems, osteoporosis, malnutrition, dementia, or mental health problems. They should give people accessible and clear advice about keeping well as they grow, for example, telling them about, and helping them access, services such as breast screening, smear tests, testicular and prostate checks, dental checks, hearing and sight tests, and podiatry [268] (see resource section in ▶ https://spectrom.wixsite.com/project and also ▶ https://www.nds.org.au/images/resources/Supporting-Practice-Leadership%2D%2D-A-collation-of-resources.pdf).

1.9.2.4 Mental State Assessment

In persons with ID/IDD, the assessment of mental functioning and evaluation of psychopathology is even more challenging than physical assessment. There are further difficulties associated with the lack of laboratory and instrumental markers for the co-occurrence of psychiatric syndromes. Besides the identification or exclusion of psychopathology, a comprehensive assessment should also focus on social conditions and psychosocial stressors.

Family relationships may significantly affect social and psychological well-being even after the person with ID/IDD has left their family home. The family environment can be seen as the primary agent of socialization. The needs, resources, priorities, and concerns of the family should also be identified. The family assessment is usually conducted through an interview with the parents.

Another factor to take into account is the exposure to life events, traumatic experiences, and environmental stressors, which seems to be particularly high in people with ID/IDD [269] (see ▶ Chap. 3). Several studies have shown that multiple life events can have an impact on behavior and mental health, determining changes in a person's emotional well-being, and quality of life [57, 270–273]. Therefore, professionals who conduct the integrated assessment should pay particular attention to these aspects, recording all the events considered relevant for the person, both positive and negative.

A detailed description of the mental state examination and the way it has to be carried out in persons with ID/IDD and low-functioning autism spectrum disorder is provided in ▶ Chap. 16.

1.9.2.5 Assessment of Problem Behaviors (ABA and Others)

As previously discussed, problem behaviors (PBs) are common in individuals with ID/IDD and can upset an individual's social, occupational, or academic daily functioning [274]. Mental health professionals who evaluate PBs should collect information about their topography, frequency, duration, intensity, and potential functions. There are three main types of behavioral assessment: standardized assessment, descriptive assessment, and functional analysis. Standardized assessment involves the administration of measures in which parents or other caregivers provide information about the person's behavior; in descriptive assessment, professionals evaluate situations in which the behavior occurs by observing the person in his/her natural setting and recording events that precede and follow behavior. Functional analysis methodology focuses on the identification of variables that influence the occurrence of problem behavior [275]. It is a process that identifies specific targeted behavior, the purpose of the behavior, and what factors maintain it. For assessment of internal and external predisposing, precipitating, and perpetuating factors for problem behavior, the Comprehensive Assessment of Triggers for behavior Scale (CATS) could be used (see ► https://spectrom.wixsite.com/project) (see ► Chap. 7).

1.9.2.6 Support Needs (Support Intensity Scale and Similar Measures)

Supports are resources and strategies that promote the development, education, interests, and personal well-being of a person and enhance individual functioning [262]. The term "support needs" refers to the pattern and intensity of supports necessary for a person to participate in activities linked with normative human functioning.

The Support Intensity Scale (SIS) [276] measures the individual's support needs in personal, work-related, and social activities to identify and describe the types and intensity of the support a person requires. The SIS was designed to be part of person-centered care processes that help all individuals identify their unique preferences, skills, and life goals (► https://aaidd.org/publications/supports-intensity-scale#.Ww6sLTihcdU).

The SIS is composed of three sections that investigate different aspects as follows: the first section asks about the support people may need with various activities (e.g., activities at home, in the community, and in the workplace), health and safety, social activities, and learning during the lifespan; the second section asks about a person's protection and advocacy-related support needs; and the third section investigates the person's unique medical and behavioral support needs.

Individual needs change over time; therefore, support must change as well. They must be developed and provided in age-appropriate settings, always considering that the person with ID/IDD should have the opportunity to engage in daily activities just like any other person, regardless of their intellectual abilities or impairments. Examples of other needs assessment instruments for people with ID/IDD are (a) Learning Disability version of the Cardinal Needs Schedule (LDCNS) [277] and (b) Camberwell Assessment of Need for Adults with Developmental and Intellectual Disabilities (CANDID) [278].

1.9.2.7 Quality of Life

An integrated assessment, as described above, promotes a holistic vision in which health and social problems are interconnected, allowing the identification of links between the different systems. Integrated approaches assume fundamental importance in evaluating personal well-being, experiences, satisfaction, and aspirations of people with ID/IDD and must be carefully considered for the implementation of interventions that translate into improvements of individual Quality of Life (QoL). The most recent literature suggests that the evaluation of QoL as the outcome measure of therapeutic interventions has discriminative capacity and sensitivity; moreover, its ability to indicate the real well-being of the person has resulted in being superior to all the efficacy parameters previously used [279, 280].

Thus, all the assessors should share results and feedback, including with the person with ID and their family members (see ► Chap. 15).

General References for an Integrated (Multidisciplinary) Assessment

Instruments and Procedures for Comprehensive Assessment and Evaluation

Accurate information about a person's status and needs must be derived from a variety of assessment tools and procedures to obtain a comprehensive set of quantitative and qualitative data. A comprehensive, integrated assessment should

1. Use a valid and the most current version of standardized assessment instruments.
2. Use multiple measures and data sources, including case history and interviews with parents, carers, relevant professionals, and the person with ID (if appropriate), the information provided by parents; direct observations or data-based information in multiple settings and on more than one situation; and standardized tests that are reliable and valid, as well as culturally, linguistically, developmentally, and age-appropriate.
3. Examine functioning and or ability levels across domains of motor, sensory, cognitive, communication, and behavior, including specific areas of cognitive and integrative difficulties in perception; memory; attention; sequencing; motor planning and coordination; and thinking, reasoning, and organization.
4. Integrate standardized and non-standardized data collected.

Professionals should evaluate personal functioning and skills across domains of motor, sensory, cognitive, communication, and behavior, including impairments in perception, memory, attention, planning and coordination, and reasoning. Finally, interdisciplinary team members should integrate and discuss the information gathered from using both standardized and non-standardized instruments.

Box 1.1 Advice for a multidisciplinary approach and inter-agency collaboration

- Sharing information on a need to know basis with everyone involved in the care of the person with ID/IDD including their family caregivers and where appropriate with the person with ID/IDD themselves
- Interdisciplinary and inter-agency case management and formulation of intervention
- Sharing assessment paths with all relevant services and stakeholders, including educational and disability services
- Sharing inter-agency and interdisciplinary resources for an effective outcome of assessment and intervention
- Promoting educational and training activities involving components of the mental health service network and subsequently of all the other sectors involved in the support of the person with ID/IDD (services for disability, health, education, and inclusion in the community)

Families and Advocates

Staff working with adults with ID/IDD should work in collaboration with their families and caregivers, providing the necessary support and trying to establish a good relationship with them, characterized by trust and empathy.

It is extremely important to involve parents in the assessment to obtain detailed information regarding the person's past. Important background information includes past psychiatric or medical information, past drug and other treatments, family history of psychiatric and medical problems, and details of the person's skills and abilities. It may also be appropriate to involve additional informants, such as other relatives and caregivers.

It is also useful to involve various professionals in the role of evaluators and to search for different informants. Health services

should increase information for families, carers, and other advocates on key components of the comprehensive assessment and evaluation process, expanding meaningful ways in which they can be involved in the process itself.

Consent and Participation in Assessment

Professionals who conduct the assessment should consider several factors which can influence a person with ID's ability to understand and to express his/her opinions (► www.intellectualdisability.info/mental-health/articles/classification-and-assessment-of-psychiatric-disorders-in-adults-with-intellectual-disabilities).

The seriousness and the type of disability influence individual's communication skills, together with a series of factors, such as neurological factors, psychiatric disorders, drug side effects, the setting, and the communication style of the others. Also, the tendency to acquiescence may represent a limitation to the collection of information. Therefore, all these factors should be taken into account to improve communication (see ► Box 1.1 and ◘ Table 1.3). Service providers should ensure that care and support for people with ID are tailored to their needs, strengths, and preferences.

In order to provide an effective and complete assessment, professionals should find out how the person prefers to communicate and receive information; give people written information (such as appointment letters and reminders) in an accessible format (see examples of accessible psychotropic medication leaflets; ► https://spectrom.wixsite.com/project); use visual aids and short, clear sentences during consultations and conversations; and talk to the person's family members and carers if appropriate, and with the person's consent. If necessary, services should provide an independent interpreter so that people can communicate in their first language.

Healthcare and social care practitioners should encourage people to express their views and make their own decisions, assess their capacity to make decisions, and involve family members, carers, and advocates, when appropriate. With the person's consent, they should actively involve members of the person's support network in the planning and delivery of their care and share information with their family members, carers, or advocate, for example, about any changes that might be needed to their support. It is crucial to determine the needs and preferences of the person, ensuring these are not overshadowed by the preferences of others, including when the person lacks capacity. Consent and participation in assessment have to be pursued also taking into account local legal rules, such as the mental health act and mental capacity act in the UK or the Law 180 in Italy.

Concluding Considerations on Assessment

Resources for effective assessment (e.g., appropriate and current assessment tools, continuing professional development), evidence-based and high-quality instructions, time for data collection and analysis, and collaboration should be provided. Services providers should take responsibility for making available to people with ID and their families professionals with experiences and support that promote the implementation of positive practices based on research. Policy-makers, administrators, and educators should examine the findings of the assessment to ensure that people with ID/IDD are provided with opportunities to perform at achievement levels beyond their chronological age or grade. Each member of the team must consider the person's cultural and linguistic background when choosing and interpreting assessments. Behaviors that may be viewed as part of autism spectrum disorders or symptomatology in one culture may have a different interpretation in another culture (e.g., not establishing eye contact is often considered a characteristic of autism, while in some cultures direct eye contact can be viewed as disrespectful or rude) [281, 282]. The assessment team will need to become familiar with the pattern of behaviors demonstrated by the person. Working as a team, the professionals involved in the assessment should also observe the person's behavior and performance across different environments.

Table 1.3 Advice for an optimal setting to assess persons with ID/IDD

Context	Offer a time frame which is appropriate to the characteristics of the person
Environment	Provide a relaxing, familiar/friendly environment (for example, the person's home) Minimize physical barriers Use sittings suitable for the disability of the person Position yourself in a way which is adequate to communicate with the person and his/her carers (e.g., continually looking at them or do not stay too far). Minimize environmental noise (close the window, switch off the TV, etc.)
Considering the presence of sensory disabilities	
In the case of vision problems: Attract/focus the person's attention, for example, by starting the sentence with his or her name or touching his/her hand or arm gently before speaking In case of hearing problems: Position yourself so that the person can see your mouth and face; in case of unilateral impairment, position yourself on the side where the hearing is better Check that the person wearing his hearing aid is turned on, and the battery is not discharged Articulate clearly and slowly Use all the communication devices that the person has at his/her disposal Ensure that you have caught the person's attention before starting to speak, for example, touching his/her hand or arm	
People with ID/IDD with verbal communication skills	
Be an active listener Ask for clarifications to verify that you understand correctly Use clear language and short sentences Avoid technical terms Avoid intellectually complex concepts (to be concrete) Avoid sentences with complex constructions, such as those with conditional verbs Repeat the questions and, if necessary, reformulate them in a simplified Verify that the person has understood the question Allow the person with ID/IDD time to answer before moving to the next question Prefer open questions Articulate clearly	
People with ID without verbal communication skills	
Look at the person you are communicating with Use intonation, body language, and posture for encouraging the person to express himself/herself Support interaction with drawings and symbols (having available materials like illustrated volumes can be useful) Some people can communicate through sign language, both standardized and personalized Some people need tools and technological supports Some people may need the help of a speech therapist, a communication facilitator/partner, or another professional Ask the person's communication partner what is the person's prefer the way of communication	
Interview techniques	
A. Making some simple questions at the beginning of the interview will help the person with ID/IDD feel comfortable B. Evaluate any discrepancy between expressive and receptive language C. In some cases, the use of images, drawings, or other communication methods maybe necessary D. When possible, avoid using direct questions (e.g., avoiding questions like "you do not like living here, do you?" In favor of "how are you at home?") E. Use simple and appropriate language F. Avoid double senses, metaphors, idiomatic expressions, medical jargon, etc. G. Make sure that the person understands H. If necessary, repeat the question several times	

1

- Well-timed, sensitive, and comprehensive assessment represents a fundamental process to appropriately define overall health condition of persons with ID/IDD and a profile of strengths, weaknesses, and needs, in order to plan the most effective interventions. Most relevant aspects to be assessed include personal and medical history, the condition of ID/IDD itself (specific cognitive impairments, language, adaptive skills, functioning), current physical and mental status, behavioral profile, personal experiences, and quality of life.
- To conduct an integrated and multidisciplinary assessment, different professionals must work together to build up a shared project with the person and his/her family.

Tip

It is hoped that future research and practice will give increasing importance to the condition of ID/IDD, as it currently represents a disregarded topic in psychiatry and, to a lesser extent, in overall medicine.

ID/IDD represents a complex syndrome grouping (meta-syndrome), which needs a polynomious-polysemic approach to be named and defined for different audiences and purposes. The evolution of its diagnostic criteria attempted to maximize clinical consensus but masked a wide degree of heterogeneity between and within individuals for many aspects. To understand this multi-level heterogeneity, future research and practice should follow a transdiagnostic approach utilizing organizing concepts that move beyond unitary intelligence and developmental comorbidity. This is particularly relevant in the current neuroscientific context, which is progressing toward precision medicine, person-centered, lifespan-informed, shared decision-making, and collaborative planning of care to provide holistic support for each unique individual with ID/IDD.

Key Points

- The nosographic approach to ID/IDD has considerably changed across time. The present chapter reports the evolution of definitions and diagnostic criteria.
- ID/IDD refers to a group of etiologically diverse conditions originating during the developmental period characterized by significantly below average intellectual functioning and adaptive behavior.
- Models of specific cognitive functions reflect more faithfully the characterization and the efficiency of individual intellectual profile than IQ measure only.
- Dynamic interactions between biological and environmental factors can influence the course of the individual development over time, generally following a hierarchical sequence in their evolution.
- A multidimensional and interdisciplinary assessment is fundamental to appropriately define overall health condition of persons with ID/IDD and a profile of strengths, weaknesses, and needs as well as to plan the most effective interventions.

Learning Objectives

The primary objective of this chapter is to provide an overview of the epidemiology of intellectual disability by providing data from more recent research. The aim was not to be comprehensive but to provide the reader an understanding of the prevalence, incidence, mortality rates, risk factors, and mental health services–related epidemiology and identify the major gaps in knowledge that require further research. Aetiology and treatment modalities are dealt with in more detail in subsequent chapters, but this chapter provides a broader perspective on some aetiological causes and availability and quality of public mental health services related to intellectual disability across different countries.

2.1 Introduction

Communities understanding of intellectual disability (ID) and its definition have varied over the centuries [1–4]. The way the community has treated people with intellectual disabilities (PWIDs) has also been chequered with numerous instances of abuse and neglect [5]. Even now, PWIDs continue to be ostracized and abused in many communities, and even their families suffer stigma and negative perceptions. However, given these negative perceptions, there are also positive developments that have happened over the decades to improve the lives of PWIDs. First, new screening methods have not only led to early detection of genetic abnormalities but also led to taking corrective steps where possible. Second, numerous evidence-based mental health services and supportive care facilities, including academic and vocational skills training, have been developed to cater to the needs of PWIDs. Third, both national and international policies have been framed to safeguard the interests of PWIDs globally.

The definition of ID has also evolved over the decades as more was understood about aetiology of ID, and ability of PWIDs to adapt to their disability and function within the society. Currently, ID is defined as "a disability characterized by significant limitations both in intellectual functioning and in adaptive behaviour, which covers many everyday social and practical skills" [6]. The onset of ID is determined by a mix of genetic and environmental factors and often manifests in early childhood. With age, PWIDs adapt their behaviours to their needs. This depends on the severity of their disorder and support systems available to them. They are able to participate at different function levels in the community, participate in routine activities and professional or academic activities and contribute effectively to the society. Current norm for assessing ID takes this into account and includes a detailed evaluation of adaptive behaviours, besides an intellectual quotient (IQ). Adaptive behaviour includes "conceptual skills [such as] language and literacy; money, time, and number concepts, and self-direction; social skills [like] interpersonal skills, social responsibility, self-esteem, gullibility, naïveté (i.e., wariness), social problem solving, and the ability to follow rules/obey laws and to avoid being victimized; and practical skills [which include] activities of daily living (personal care), occupational skills, healthcare, travel/transportation, schedules/routines, safety, use of money, use of the telephone" [6].

Given the current global population of 7.3 billion and estimated prevalence of 1% [7], there are about 73 million PWIDs, worldwide. It is critical to not only understand the causes for ID but also understand the types of health services available for PWIDs. Better knowledge about the epidemiology of IDs and available services will help improve the services, conduct research to plug the gaps in knowledge and inform policy-makers to develop strategies to improve the lives of PWIDs. This chapter summarizes the epidemiology of ID and related health services for PWIDs and provides a broad understanding of ID.

2.2 Prevalence of Intellectual Disabilities

2

At the outset, it is important to recognize that it is difficult to compare prevalence studies as they vastly differ in terms of conceptualization of ID, diagnostic criteria followed and the methods adopted to identify ID. King and colleagues [3] while discussing the various factors that tend to influence the prevalence of ID globally observed that definitions used for ID by different surveys determine how ID is identified in the community; age of ascertainment also plays a crucial role as with age adaptive behaviours modify the functional ability of PWIDs; identification of ID also varies according to age based on the specific health condition causing it (with 10 years being a modal age for identification globally); different mortality rates for PWIDs that vary by age. Identification commonly occurs when one starts schooling, so often that is the age when point prevalence shows a peak. Additionally, the prevalence is also determined by the survey instruments used and populations surveyed, such as community/clinical/special institution-based studies.

The prevalence of ID is estimated between 1% and 3%, and the incidence is estimated to be around 1.8% [4, 8]. In developed countries like Finland or the Netherlands, the prevalence of ID is currently less than 1%, while it may rise to 4–5% in more deprived regions of the world and can reach up to 6% in some countries in Eastern Europe [9]. Among the four different severity degrees, 85% have mild ID, 10% moderate, 4% severe and 2% profound [3]. Mild ID being present in 80 to 85% of the world's population [10] could explain why many PWIDs are not identified until they reach school age and start having difficulties acquiring and learning new skills. The prevalence of Borderline Intellectual Functioning (BIF) is estimated to be 12.3%, and Hassiotis and collaborators [11] found that in a sample of 8.450 adults living as part of a family in the United Kingdom, approximately one-eighth had BIF. The prevalence of ID is higher in males than females in both adults and children/adolescents. Among adults, the male-to-female ratio varied between 0.7 and 0.9 [7].

The National Health Interview Survey provides trends in the prevalence of ID among 3–17-year-olds from 1996 to 2008 in the United States. Boyle and colleagues [12] while reporting on the trends found it to be relatively stable around 7/1000 children with the latest round of data from 2006 to 2008 providing an estimate of 6.7/1000 children. However, over the same period the prevalence of learning disorders increased by 5.5% while that of ID reduced marginally, which might be a reflection of administrative data classifying more cases as learning disorders compared to ID, in order to reduce stigma associated with ID. A meta-analysis of 52 community-based studies has observed an overall prevalence of 10.37 ID cases per 1000 population in the world. The prevalence was highest in the low-income countries at 16.41 cases per 1000 population, followed by middle-income countries (15.94 cases per 1000 population) and lowest in high-income countries at 9.21 cases per 1000 population [7]. Highest rates were seen among children/adolescents, those from rural or urban slum populations, and among females. McKenzie and colleagues [13] conducted a systematic review of the prevalence and incidence of intellectual disabilities between 2010 and 2015 and reported a range of prevalence between 0.05% and 1.55%. They offered several reasons for this variation. First, the IQ levels of general population which increases at regular intervals due to environmental factors, a phenomenon known as Flynn effect, are not captured reliably by IQ tests. To overcome the Flynn effect, IQ tests are re-standardized at regular intervals to increase the difficulty level of test items. But a disadvantage is that more people fall below the IQ of 70 [14, 15]. Therefore, IQ scores are not sufficient to diagnose ID. Second, definition of ID has been modified over the numerous revisions of the

standard diagnostic systems which resulted in modifications of the diagnostic criteria of ID. There is still a debate among researchers about whether to include adaptive behaviour capabilities on top of IQ score, or use each of them separately. The American Association of Intellectual and Developmental Disabilities outlines 10 domains of adaptive behaviour and uses both IQ and adaptive behaviours to identify ID and its severity [6]. ID is closely associated with autism spectrum disorder, and trends show that the prevalence of autism spectrum disorder is increasing but prevalence of ID is decreasing because of a diagnostic preference for autism in response to administrative policies of providing services [16–18]. Third, male-to-female ratio is decreasing. The prevalence of autism is higher among males, and it is also believed that between 40% and 60% of individuals with autism spectrum disorder have ID [19, 20]. Fourth, prenatal diagnosis for certain categories of ID, namely, Down's syndrome, Edwards syndrome and Patau syndrome resulting in medical terminations of pregnancies, is also contributing to the decrease in ID prevalence. Additionally, improved public health and risk prevention strategies such as educating about alcohol consumption during pregnancies and reduction in lead-contaminated drinking water may have lowered the risk of ID in population [21]. Fifth, differences in population characteristics, average parental age, increasing maternal age and sex ratio have also been identified as the factors for variations in the prevalence and incidence of ID [13, 22]. King and collaborators [3] found that mild, moderate, severe and profound ID is reported in 85%, 10%, 4% and 2% of the population affected with ID, respectively. A brief summary of more recent studies on prevalence of ID is given in Table 2.1.

The prevalence of ID is estimated between 1% and 3%, and the incidence is estimated to be around 1.8%. Prevalence seems to be higher in children and adolescents, those in low- and middle-income countries, and among females.

2.3 Incidence of Intellectual Disabilities

Compared to prevalence, incidence is a more effective measure of magnitude of ID. However, very few incidence studies have been conducted. A longitudinal study on children with median age of 14 years in Sweden reported cumulative incidence of 0.62% [23], while another study on adults with 50 years of age reported cumulative incidence of 1.58% among males and 0.96% among females [24]. Based upon two cohort studies conducted in Finland in 1985–1986 (n = 9432) and in 1966 (n = 11,965), the cumulative incidence of ID was found 12.6/1000 for ID [8]. However, Heikura and colleagues [8] reported no change in incidence of profound category but a mild shift rate from severe and moderate towards mild ID between 1966 and 1986 cohorts. The cumulative incidence for mild ID was observed to be 7.5/1000 compared to 5/1000 in younger cohort. Katusic and collaborators [25] have reported differences in incidence of ID with reference to gender and degree of ID in the United States. In a cohort of 5919 children born between 1976 and 1980, the cumulative incidence for severe ID was observed more than twice among females than males, and for mild ID it was twice in males than females. For males, cumulative incidence of ID was reported to be 8.3/1000 population and for females 10/1000 population. However, cumulative incidence was found to be 1.7 times greater in males than females [25]. In an epidemiological study of 5070 babies born between 1978 and 1987 in Japan, the incidence of ID was 0.87%. The incidence of ID was 0.51% for mild and 0.36% for severe category [26].

2.4 Mortality in Intellectual Disabilities

Lifespan of people with ID has improved significantly due to advancement in health care, rehabilitation services and personal care. However, worldwide, the mortality is signifi-

Table 2.1 Trends in prevalence of ID

Country	Authors and year	Sample features	Prevalence
Australia	Haider et al. 2013 [160]	Adult population survey	0.1%
	Leonard et al. 2011 [161]	Children/adolescents and adult's population survey	1.3%
Canada	Lin et al. 2013 [162]	Administrative health data used to derive estimates of the prevalence of adult ID	0.1%
China	Zheng et al. 2011 [163]	Nationally representative surveys conducted in 1987 and 2006; age-adjusted prevalence of ID estimated	1.3%
Denmark	Pedersen et al. 2014 [24]	Data of residents who received health services between 2000 to 2012	0.1%
India	Girimaji and Srinath 2010 [146]	2064 children aged 0–16 years were screened for ID on ICD 10 criteria	3%
	Lakhan and Mawson 2016 [22]	Community survey; a total of 8797 tribal population were screened for ID; prevalence of ID among children up to age 18 years was reported	0.6%
Italy	ISTAT 2018 [164]; Salvini F., 2018 [165]	Students with ID	1.9%
USA	Boyle et al. 2011 [12]	Data analysis of National Health Interview Survey (NHIS) datasets 1997–2008; data collected every 3 years from children aged 3–17 years	Rates at each time point 1997, 2000, 2003, and 2006 were 6.8/1000, 7.3/1000, 7.5/1000, and 6.7/1000, respectively
	Braun et al. 2015 [19]	Population-based developmental disabilities surveillance programme data from 1991 to 2010 for 8-year-olds in metropolitan Atlanta	1.6%

cantly higher in ID population compared to their age-matched non-ID peers [27–29]. It appears that the reduction of life expectancy is positively correlated with the severity of ID [30]. In Finland, Patja and colleagues [31] followed a cohort of more than 2400 PWIDs for 35 years and estimated the mortality rate to be 18/1000 person-years, with mortality increasing with severity. Data from Scotland showed that survival rates at 76 years were significantly lower among children with ID [32]. The relative risk of survival reduced to 0.79 and 0.63 for an IQ level that was one and two standard deviations below normal, respectively. Thorpe and colleagues [33] have found a positive relationship between factors such as mood disorder, poor baseline functioning, poor cognitive abilities and psychotropic medication and mortality in PWIDs [33]. Some specific health conditions such as increased prevalence of comorbid Alzheimer's disease and cardiovascular disorders have been associated with ID and also lead to increased mortality [34]. Some of the early work and recent studies on mortality, survival rate and life expectancy are presented in Table 2.2.

Community-based data show that the cumulative incidence of ID was found to be 12.6/1000 for ID. Mortality rate is about 18/1000 person-years, increasing with ID severity. Some syndrome-specific

Table 2.2 Recent estimations of mortality, survival and life expectancy

Country	Authors and year	Sample features	Mortality	Remarks
Australia	Bittles et al. 2002 [166]	Analysed data of 8724 people with ID for their survival rate	The life expectancy was found to be 74 years for mild ID, 67.6 years for moderate ID and 58.6 years for people with severe ID	The strong positive association was found between severity of ID and lower life expectancy rate
England	Tyrer and McGrother 2009 [167]	A cohort of 503 people with ID was followed up	17% of the cohort with moderate and profound ID died within 14 years	The standardized mortality rate was very high for congenital abnormalities (28%), nervous system (5.4%), mental disorders (3.7%) and bronchopneumonia (2.1%)
Finland	Patja et al. 2001 [31]	To investigate cause-specific mortality in ID, a nationally representative sample of 2369 ID cohort was followed up for 35 years	18 per 1000 person-years	The mortality was positively associated with severity of ID. Compared to general population, specific conditions such as cardiovascular and respiratory diseases were found highly associated with mortality in people with ID. But there were no differences in mortality rate with reference to gender
Germany	Dieckmann et al. 2015 [27]	Two sample data of ID population from two different geographical locations in Germany for 2007 to 2009 were analysed and compared with the general population	The life expectancy for males (70.9 years) was higher than females (72.8 years) in Westphalia–Lippe; but lower for males (65.3 years) than the females (69.9 years) in Baden–Wuerttemberg	The life expectancy for male and female ID was found improved, but it was found lower than the general population. The life expectancy of ID population was also found varied in terms of geographical locations
India	Lakhan and Kishore 2016b [29]	Analysed National Sample Survey Organisation data for 2002	The mortality rate in people with ID increases with age in India, particularly after the age of 19 years	This is secondary analysis of the data so it did not provide any information if any specific variable of ID were associated with ID

(continued)

Table 2.2 (continued)

Country	Authors and year	Sample features	Mortality	Remarks
Israel	Merrick 2002 [168]	The data of division for mental retardation of Israel were analysed for 53 residential centres, 1280 persons in community-related residential facilities and about 13,000 persons who participate in day care facilities	A study reported a mortality rate of 10.25 deaths per 1000 population for people with ID living in residential care facilities between 1991 and 1997	It is much higher than the rates reported for their counterparts availing the community day care facilities
Netherland	Maaskant et al. 2002 [28]	Data of 29,290 children with ID aged 5 years, who were registered in the National Case Register of Netherland between 1991 and 1995 were analysed for mortality	The survival age was found to be 41 years for ID and 46 years for ID with Down's syndrome	The mortality rate did not differ with gender
UK	Tyrer et al. 2007 [169]	Adults with ID of age 20 years or over ($N = 2436$), with moderate to profound ID living in Leicestershire and Rutland, UK, between 1993 and 2005 were analysed with the general population of 700,000 people	The cause-specific standardized mortality rate (SMR) was found nine times higher in men (SMR = 883; 95% CI 560–1325) and 17 times higher in women (SMR = 1722; 95% CI = 964–2840) in their 20s compared to the general population of this age	Study found three times higher all-cause and disease-specific mortality rate among ID people compared to the general population, with particular disadvantage for Down's syndrome
USA	Shavelle et al. 2014 [170]	California Department of Developmental Services database of 64,207 people age 5 and older was analysed from 2000 to 2010	The excess death rate increased with age from 0.1 to 6.8/1000 in moderate to mild and 3.4 to 6.7 in profound to severe ID	This study indicates that the mortality rates increase with severity of ID

morbidities such as Alzheimer's disease and cardiovascular disorders also lead to increased mortality.

2.5 Prevalence of Co-Occurring Autism Spectrum Disorder

About 34% of PWIDs have pervasive autistic traits [35–37], while up to 60% of patients with autism have ID [38–44]. In terms of a dual diagnosis (i.e. a developmental disorder such as autistic spectrum disorder (ASD) or ID and psychiatric disorder), there is increased risk of underestimating ASD in PWIDs when schizophrenia is diagnosed [45–47]. About 40% of the items included in diagnostic tools for PWIDs and used to screen for psychosis commonly receive a high score when autism is present [48]. A further consideration giving rise to increased prevalence of ASD may be linked to inaccurate diagnosis and a growing recognition that autistic disorders can be associated with other conditions [49, 50]. In the United States, increase in prevalence was associated with declines in other diagnostic categories, indicating that diagnostic substitution had occurred [51]. A background but key issue in these considerations is to delineate robustly the boundary between ASD and ID. Both ID and ASD are metasyndromic groups to which many different clinical conditions belong [52]. However, many PWIDs have some autistic aspects, as well as many persons with ASD have lower intellectual functioning compared to the general population [20, 53].

About 34% of PWIDs have pervasive autistic traits, while up to 60% of patients with autism have ID. Many PWIDs have some autistic aspects, as well as many persons with ASD have lower intellectual functioning compared to the general population. Both ID and ASD are metasyndromic groups to which many different clinical conditions belong.

2.6 Aetiological Factors and Physical and Psychological Conditions Associated with Intellectual Disabilities

Considering that ID is a disability with implications for life-long consequences for the individual and the family, and necessitates high service provision and social costs, it is necessary to identify the causes in order to take appropriate preventive steps. ID is associated with several biological and psychosocial factors. The biological factors are further divided into genetic and non-genetic factors. The risk factors may act individually or through an interactive effect [54].

In most cases, the aetiology for ID is unknown. Genetic causes are the leading causes among the identifiable causes for ID. The etiological factors could also be antenatal, perinatal, postnatal, brain trauma during delivery, birth asphyxia, intrauterine growth retardation, infections affecting the nervous system, hypothyroidism and iodine deficiency, and lead poisoning [7, 55]. Karam and collaborators [56] have found that the aetiology of ID is 44.4% environmental, 20.5% genetics, 12.6% idiopathic, 13.2% neonatal sequelae and 9.3% other diseases. A study from India found 64.4% genetic, 20.4% perinatal, 12% central nervous system malformation, 3.6% prenatal and 2.4% postnatal causes for ID in India [57]. Vissers and collaborators [58] had reviewed genetic studies in ID and found that with new techniques in genetics research such as genomic microarrays and next-generation sequencing-based technologies, there has been a spurt in genetics-based research in ID though saturation in that area is still far away. There have been attempts to study aetiology from a cultural perspective. One such variable is consanguinity but it did not show strong association with ID [59, 60]. One consistent finding, at least in low- and middle-income countries (LMICs), is that the excess rate of ID is related to preventable aetiological factors such as teratogens,

diet deficiencies, pregnancy and birth-related conditions [61, 62]. However, the cause is unidentified in 60% of PWIDs in LMIC [60]. In general, the causes of ID are unknown for up to 60% of cases [63]; for the rest ID represents a heterogeneous group caused by a different combination of specific causative factors, both genetic and environmental [61]. Known causes are classified by the time they occur in respect to birth, as prenatal, perinatal and postnatal.

2.6.1 Prenatal Causes

2.6.1.1 Genetic Factors

A proportion of cases ranging from 17% to 50% are caused by a genetic disorder [63–66], while non-syndromic ID accounts for 30–50% of cases [67, 68]. Conventionally, genetic forms of ID are divided into two major categories: syndromic ID characterized by associated clinical, radiological, metabolic, or biological features, and non-syndromic forms in which cognitive impairment represents the only manifestation of the disease. Although this distinction remains useful for clinical approach, recent studies and detailed clinical follow-up indicated that distinctions between syndromic and non-syndromic ID are disappearing, and some of the latter could be recognized as syndromic forms [69–71]. Detailed analyses of database and literature searches reveal that more than a thousand of genes can cause ID. Furthermore, more than 290 genes are involved in clinical phenotypes, metabolic and neurological disorders associated with ID [72–74].

Genetic causes are divided into chromosomal (or genomic) mutations and gene (or point) mutations. Trisomy 21 is the chromosome abnormality responsible for over 95% of Down's syndrome, which is the best-known chromosomal cause of ID [63, 75]. Other well-known genomic syndromes are Turner syndrome [76, 77], Klinefelter syndrome [78], and Cri du Chat syndrome [79]. The most prevalent conditions due to gene mutation include Fragile X syndrome [80, 81], galactosemia [82, 83], lipidosis [84], phenylketonuria [85, 86], neurofibromatosis (or von Recklinghausen's disease) [87], Williams's syndrome [88], and Prader–Willi syndrome [89]. ID occurs in other genetic syndromes like tuberous sclerosis [90], Huntington's disease [91, 92], mucopolysaccharidosis [93], alkaptonuria [94], and porphyria [74, 95, 96]. The risk of transmission of recessive genes is greatly increased by consanguineous marriage. For a couple of first cousins, the chance of passing on chromosomal alterations is about five times higher than for couples who are not blood relatives [96]. Idiopathic ID supports the hypothesis that rare de novo point mutations can be significant causal factors of ID [97].

2.6.1.2 Epigenetic Mechanisms

Recent research has shown interest in epigenetic mechanisms, which refer to changes that affect gene activity and expression without changing the DNA sequence or, in a narrower sense, to heritable phenotype changes that do not involve DNA alterations. These two different acceptations imply a different reference to the individual's lifespan, from conception to senescence, or to trans-generational timeframe. Evidence indicates that the fidelity of the transmission of DNA methylation patterns, through which epigenetic modifications are done, is much lower than that of DNA nucleotide sequences and that therefore de novo epimutations can occur more frequently than de novo mutations.

Negative prenatal environmental factors, such as pregnancy distress, exposure to toxic substances (e.g. cannabis, cocaine, ethanol) and viral infections, seem to be able to alter the normal brain development and to contribute to the onset of a neurodevelopmental disorder with mediation of epigenetic mechanisms [98–101]. In animals, the genes most frequently involved in these mechanisms are those that encode the glucocorticoid receptor (Nr3c1) and the brain-derived neurotrophic factor [102]. In mammals, including humans, the most recent studies have focused

on two main mechanisms: epimutations during embryogenesis and epigenetic memory induced by environmental factors, with reference to the effect of pharmacological treatments. It seems to be possible that environment-induced epigenetic modifications can occur throughout an individual's lifespan, even if prenatal development is identified as the period of maximum responsiveness [103]. In this phase, an extensive "epigenetic reprogramming" can take place, that is a pluripotent redefinition of the epigenome. In cell replications that occur from the zygote formation to the blastocyst nesting, even the entire architecture of DNA methylations can undergo a wide cancellation or remodeling [102, 104]. The epigenetic modifications that occur in the last part of the gestation and after birth appear to be much lower, not only in number but also for the type of control exercised on gene expression. These modifications are defined "epigenetic programming", to distinguish it from the aforementioned "reprogramming" and to refer to the changes that guide cell differentiation, from stem cells to various types of neurons and glial cells [105, 106]. In summary, recent insights on epigenetics indicate that the DNA methylation variations determined by environmental factors that can contribute most to the pathogenesis of neurodevelopment disorders or adult psychiatric disorders (or both) are those that occur during the foetal period.

Reprogramming, which allows the zygote to erase the epigenetic markings inherited from the parental gametes, seems to find an exception in parental imprinting. Parents' genome undergoes the effect of specific epigenetic modifications during the meiosis, which is the parents' chromosomes separation to give rise to oocytes or spermatozoa. This process gives a subclass of homologous loci, called "imprinted genes", an exclusive expression of the genetic information inherited from one of the parents. Some of these genes are expressed if inherited from the father, others if inherited from the mother. The other parental allele is, in fact, maintained in a state of repression by DNA methylation. These imprinted genes play a significant role in the brain development, and incorrect imprinting or inappropriate expression is the basis of some syndromes including ID, such as Angelman, Prader–Willi, Beckwith–Wiedemann or Silver–Russell.

Mutations in Methyl CpG-binding protein 2 (MeCP2) and ATP-dependent helicase X-linked protein gene are already well established in Rett syndrome, Down's syndrome, and some X-linked cases [107–110]. However, in most cases such modifications are known to be affected by environmental factors before and after birth [111]. In recent years, a new protein able to recognize epigenetic changes has been identified. This protein, called ZFP57, was also found to contribute to the conservation of these epigenetic changes, from the embryo to the adult, and to enable their transmission to the offspring. Even more recently, the genetic structure of this protein has been defined, which allowed to confirm the hypothesis that also the mechanisms underlying epigenetic modifications have a genetic basis [112, 113].

Among the several relevant implications, epigenetics, as an expression of the complex relationship between genes and environment, may represent a possible explanation of the frequent association between negative life events and psychopathological vulnerability in persons with ID and ASD, an area of research and clinical practice that had always received limited consideration, despite the fact that its importance had been widely documented in the general population.

2.6.1.3 Biological and Environmental Factors

Prenatal causes of ID include congenital infections such as cytomegalovirus, toxoplasmosis, herpes, rubella, influenza and human immunodeficiency virus [114]. The human foetus seems unable to produce an effective immunological response in early pregnancy; the ability of children to produce antibodies increases significantly only between the 6 and

12 months of age. Exposure to radiations; pollutants; heavy metals; harmful medications, such as thalidomide, phenytoin, valproate and warfarin in early pregnancy; and additive substances, such as alcohol, nicotine and cocaine, can also cause ID [67, 115–117]. Other prenatal risk factors are maternal hypoglycaemia, diabetes, hypoxemia and malnutrition [118, 119]. Evidence from experimental studies shows that malnutrition in utero can impact on brain development leading to nervous cells depletion, protein synthesis defect and abnormal electrical activity [120].

2.6.2 Perinatal Causes

Perinatal causes involve complications of labour and delivery, severe prematurity, very low birth weight, birth asphyxia and birth trauma. Furthermore, neonatal complications in the first 4 weeks of life included septicaemia, severe jaundice and hypoglycaemia [121, 122]. Low birth weight at term delivery can be due to genetic causes. In other cases, poor nutritional contribution in uterus associated with placental insufficiency or other damaging agents may occur. These children, born small for gestational age, show retardation in foetal growth and subsequent neurological complications that are different to those related to shorter gestation period. True pre-term births before 26 weeks of gestation and pre-term births after less than 36 weeks of gestation are those at greatest risk of developing neurological damage, which increases in inverse proportion to their degree of maturity and birth weight (<1500 grams) [123, 124]. Other perinatal causes include congenital infections like those listed among prenatal causes, although most infections in newborns are caused by bacteria of the birth canal, especially if it has an active infection.

2.6.3 Postnatal Causes

During the postnatal period, which includes infancy and childhood, brain infections such as encephalitis and bacterial meningitis may damage the brain and cause ID [125]. Furthermore, encephalic traumatism, chronic lead or other toxic exposure, severe and prolonged malnutrition can also lead to ID [81, 126]. Studies report a significant association between ID and exposure to inadequate caregivers, low level of stimulation and social deprivation [127, 128]. Malnutrition and negative socio-environmental conditions are often co-present in the postnatal history of some persons with mild ID.

In most cases, aetiology of ID is unknown. Genetic causes are the most common among identifiable causes. The etiological factors could also be antenatal, perinatal and postnatal. Some of the most common are brain trauma during delivery, birth asphyxia, intrauterine growth retardation, infections affecting the nervous system, hypothyroidism and iodine deficiency, and lead poisoning.

2.7 Psychological and Physical Comorbid Conditions

PWIDs suffer from higher rates of physical and other mental disorders [129, 130] compared to general population. Cooper and colleagues [129] have found that specific physical and mental health problems were significantly higher in adults with ID, with epilepsy being the commonest. Harris [4] has also reported that hearing impairment is present in 10% of cases and epilepsy in 5–30%. Mental health problems are four to five times more common in people with ID [131, 132]. Lundqvist [133] found that about 62% of PWIDs have at least one self-injurious, stereotyped or aggressive/destructive behaviour problem and 18.6% challenging behaviours. Lakhan and Kishore [134] found a higher prevalence of violent and destructive behaviours and misbehaviour with others among moderate and mild ID, and self-injurious, temper-tantrum and stereotype among profound and severe ID. Often physical health problems lead to some form of behaviour problems in PWIDs

[135]. However, it could be understood that the aetiology and comorbid conditions may vary depending on the age targeted and the setting in which the study is carried out.

PWIDs suffer from higher rates of physical and mental disorders compared to the general population, with epilepsy being the commonest (5–30%). It has also reported that hearing impairment is present in 10% of cases. Mental health problems are four to five times more common.

2.8 Mental Health Services for People with Intellectual Disabilities

Despite the existence of national and international policies and legislation, only 39% of countries in the world have policies or programmes related to ID [136] with mental health services being limited by poor availability, accessibility and adequacy [137], apart from few exceptions [130, 138–142]. This lack of services has a relevant impact on epidemiological knowledge, both for ID itself and the co-occurrence of mental disorders. Reversely, the lack of knowledge regarding the substantial epidemiological data on the prevalence of psychopathology in persons with ID represents in many countries a potential barrier to accessing mental health services [143]. In Southeast Asian countries, mental health services show a huge variation of type and range. In Hong Kong, Taiwan and South Korea, there is provision of inpatient, outpatient, day hospital and outreach services, for both children and adults with ID, whereas Vietnam provides a narrower range and greater orientation towards children. In Latin America, South Africa, China, Greece, Asia, India, Taiwan, Serbia and Bulgaria [139, 142–149], services are largely concentrated in secondary and tertiary centres of towns and cities, have a poor connection with other care centres, and are provided by inpatient psychiatric units at district general hospitals and specialized psychiatric hospitals, which are mainly located in big university centres [144]. Even in high-income countries the implementation of mental health policy does not uniformly address the needs of persons with ID. Furthermore, mental health services specialized for ID are uncommon, models of care are generally unclear, and data on service use or mental health outcomes are not systematically collected.

Although persons with ID tend not to refer themselves to mental health services, but rather be referred by family members or other caregivers, a number of barriers relating to the personal (individual) experience of access to services have been investigated and identified, including awareness of their need for care, fear of medical personnel, as well as low expectations of services and a reduced tendency to complain [150]. Some studies identified ethnic variation in the utilization of mental health service [151–155], often related to culturally shaped ideas about ID [156].

Only 39% of countries in the world have policies or programmes related to ID, with mental health services being limited by poor availability, accessibility and adequacy.

Mental health services specialized for ID are uncommon, models of care are generally unclear, and data on service use or mental health outcomes are not systematically collected.

2.9 Gaps in Knowledge and Future Research Needs

Major gaps in the extant literature on ID are in the areas of epidemiology from LMICs. While some studies are available from LMICs the quality of such are often limited by being small clinic-based studies. There are no large cohorts from LMICs which provide rich enough data as other cohort studies such as the Olmstead County study or other cohort studies available in Europe [157]. The absence of such studies hampers the ability to iden-

tify incidence rates, causal factors, trends in prevalence, risk factors amenable to embedded interventions and outcomes, and mortality. There is also a lack of clarity about the effect of mental disorders on behavioural manifestations in PWIDs [158], and it is still to be determined how mental disorders affect behavioural manifestations and to what degree in PWIDs.

Another area of research that is improving but still has some way to go is research related to genetics of ID [58]. While new techniques of exome sequencing and genome sequencing have improved understanding of the genetic sequence for many cases, others are still unknown. Added to this is the fact that few treatments based on genetic research are available, and research needs to be undertaken to understand how treatment based on modifying genetics can be implemented in a cost-effective manner at population level.

Estimates from the United States indicate that the lifetime cost of ID was USD 1.01 million per person in 2003 (CDC), and data from Australia suggest that almost AUD 14.7 billion/year is incurred as cost for managing care for PWIDs and 85% is opportunity cost due to lost time [159]. However, similar research from LMICs is limited. Other consequences are the inadequate consideration of ID within global health issues and the increasing gap between health services for ID and unmet needs. [136].

Tip

A major gap in the extant literature on ID is in the area of epidemiology from LMICs.

While new techniques of exome sequencing and genome sequencing have definitely improved the understanding of the genetic sequence for many cases, others are still unknown.

There is a lack of clarity about the effect of mental disorders on behavioural manifestations in PWIDs.

2.10 Conclusion

The epidemiology of ID has evolved over the decades, and prevalence estimates have tended to be influenced by the changing definitions and diagnostic criteria of ID. Along with it there have been many studies to identify causal factors, and genetic factors are a major identifiable risk factor which has been the focus of research over decades. With recent advances in technology, genetics research has started to evolve too, and new areas of focus are being seen especially in the non-X-linked genetic causes. However, a lot remains to be clarified, and studies from LMICs are particularly few when it comes to understanding longitudinal trends in different parameters, including use of mental health services. Future research needs to plug those gaps in knowledge and identify newer areas of focus.

Key Points

- The prevalence of ID cases is reported as 10.37/1000 population, with higher rates in low- and middle-income countries compared to high-income countries.
- The cumulative incidence is about 12.6 cases/1000 population.
- The lifespan is directly correlated to the severity of ID.
- Though in most cases the aetiology is unknown, genetic causes are the main among identified causes.
- PWIDs suffer from higher rates of physical and mental disorders compared to the general population.
- Knowledge about appropriate mental health services for PWIDs is limited.
- Some major gaps in knowledge are lack of high-quality epidemiological studies from low- and middle-income countries; and few studies on incidence, quality of mental health services and cost-effectiveness.

3

Learning Objectives

- Psychological distress.
- Causes of psychological distress.
- Manifestation of psychological distress.
- Common physical disorders in people with intellectual disabilities (ID).
- Reasons for increasing prevalence of physical disorders.
- Different stages of life for people with ID.

Tip

People with intellectual disabilities are at a higher risk of developing psychological distress as well as physical disorders.

3.1 Psychological Distress

3.1.1 Introduction

Psychological distress describes the experience of an individual discomforting emotional state in response to a specific stressor, threat or harmful situation [1]. A broad range of events may elicit psychological distress. These events include but are not limited to illness, loss of physical function, victimisation, social conflict and economic insecurity. Irrespective of the severity, psychological distress may contribute to the development of a range of physical and mental health disorders in those who are vulnerable, leading to significant public health concerns [2, 3].

3.1.2 High Risk Among Individuals with Intellectual Disabilities

People with intellectual disabilities (ID) experience psychological distress more often and to a higher extent compared to people without ID. Epidemiological evidence is scant because large-scale assessment of subjective distress states is difficult, especially for people with moderate to severe ID. Results for emotional distress based on proxy reports, clinical interviews and self-reports provide divergent answers [4]. However, epidemiological evidence on the rate of stressors points indirectly to high psychological distress. The rate of traumatic experiences and stressful social situations, for example, is heightened among people with ID [5–8].

3.1.3 Causes of Psychological Distress

Abuse and Violence

Individuals with ID experience high rates of violence and all forms of abuse [9]. Intentional harm experienced by individuals with ID is almost always perpetrated by someone they know, such as a family member, and is commonly exhibited as sexual, physical and verbal/emotional abuse [9]. Individuals with ID are vulnerable to even paid caregivers who may be neglectful or abusive. Compared to the general population, people with ID often experience interpersonal violence. A meta-analysis revealed prevalence figures of 21.2% for violence experiences in children and 6.1% in adults with an ID [10, 11]. An earlier study reported abuse and mistreatment of up to 68% for girls and 30% for boys with an ID [12].

Maladaptive Coping Strategies

People with ID may also experience psychological distress to a higher intensity and chronicity due to maladaptive coping with stressors as these occur to people with and without ID alike. According to Lovallo's [13] model, primary appraisal of stressors as threats or non-threats occurs in cognitive subsystems shaped by experience. If a stressor is labelled on the basis of similar experiences as a threat, it is attended to more closely and appraised in relation to one's self-perceived skills and resources. Outcome of this second-

ary appraisal spurs behavioural, cognitive and physiological responses accompanied by emotions. If people experience their skills and resources as deficient in the face of perceived threat, social engagement with others gives way to noxious cognitive and physiological reactivity as a self-preserving fall-back option [14].

Attachment Styles

People learn to appraise stressors and engage other people in addressing threats in the context of attachment relationships [15]. The low rate of secure attachment relationships among children with ID and the high rate of growing up in residential care with less opportunities for the formation of attachment relationships [16], therefore, increase the vulnerability of people with ID for psychological distress. Psychological interventions addressing attachment needs as well as facilitating the communication of distress have been found to improve stress regulation [17], facilitate the training of adaptive behavioural responses to challenging situations [18] and reduce anxiety [19].

Cognitive Biases

Young people with ID show biases in processing social information. Even innocuous interpersonal events are interpreted more often as hostile [20]. These biases increase the likelihood of escalating aggressive conflict, further exacerbating psychological distress. Attributional style and stressors independently predict depressed mood [21].

Stigma

Stigma increases psychological distress in people with ID. People with ID can be more vulnerable to the psychological distress due to stigma [22]. Some researchers have hypothesised that self-reported stigma is positively associated with psychological distress and negatively associated with quality of life, contact with services, and adherence to treatment in people with ID [23]. There is evidence to suggest that stigma and even the perception of stigma may contribute to poor psychological health in people with ID by increasing psychological distress and reducing quality of life [23].

Communication Impairment

Communication impairment and the challenges to express pain [24] and emotions in a clear and direct way are factors that make recognising psychological distress in individuals with ID difficult, making it necessary to then look at the individual's behaviour. Challenging behaviour may also be a person's attempt to get needs met when they experience lower levels of well-being [25]. The vulnerability of individuals with ID to experience traumatic physical experiences and stressful social situations combined with their inability to engage others in dealing with their emotions creates challenges for caregivers and professionals as well as medical staff.

- Individuals with ID are more likely to experience psychological distress compared to their peers without ID.
- Multiple stressful and traumatic life events, maladaptive coping strategies, attachment styles, socio-environmental factors and communication difficulties have been postulated as some of the reasons for the increased psychological distress.

3.1.4 Manifestation of Psychological Distress

Behavioural Manifestations

Manifestation of symptoms with regard to psychological distress might differ between the general and the ID population. In people with ID, symptoms are more prominently expressed on a behavioural and non-verbal level [26]. People with ID might react in states of strong psychological distress, for example, after sexual abuse, with regression, like bedwetting, or complain of diffuse pain and present symptoms of self-injurious behaviour. Mental health symptoms following trauma exposure might include dissociative behaviour, motor agitation, flight reactions and aggression. This often leads to misidentifying psychological distress or posttraumatic stress

disorder (PTSD) symptoms as symptoms of other mental health or behavioural disorders [27]. In this context, the relevance of an elaborate diagnostic protocol appears evident.

3

- **Mental Disorders**

According to Reeve [28], symptoms of psychological distress fall short of meeting the DSM-5 [29] criteria for a clinical diagnosis of anxiety. However, when left unrecognised and untreated, normal anxiety that can contribute to positive effects such as improved attention and performance can become over-learned, habitual or otherwise dysfunctional. This phenomenon can lead to disruptive behaviour, inefficient brain patterns and avoidance of pleasurable experiences, thereby contributing to psychological distress [28]. For instance, Hartley et al. [30] found that adults with ID who sought reassurance for their distress from caregiving staff to an excessive extent, more often experienced rejection and other negative responses from staff, which in turn was associated with elevated rate of depression. Psychological distress should, therefore, have an important place in diagnostic formulation, caregiver education and care planning.

Besides the higher rate to experience a traumatic event or after being exposed to repetitive traumatising incidents, people with ID show a higher vulnerability to develop PTSD. PTSD is a disorder which a person may develop after being involved in or witnessing traumatic events. PTSD may be described differently in some situations: if a person's symptoms emerge more than 6 months after experiencing trauma, this might be called "delayed-onset PTSD". If a person experienced trauma in an early age or it lasted for a long time, you might describe it as "complex PTSD". Not everyone experiencing trauma will develop PTSD. Best known protective factors are a high intelligence level, as well as reliable memory functions. Thus, a lower developmental level in intelligence, typically going along with lower cognitive competences, will raise the incidence of PTSD in people with ID. In addition, the lower levels in verbal expression often limit people with ID to report such complex experiences [31]. People with ID also suffer from painful conditions more often [32]. Improving and preventing psychologically or physically harmful conditions is therefore bound to reduce psychological distress as well [7].

- Psychological distress increases the risk of mental illness such as depressive and anxiety disorders in people with ID.
- Psychological distress can also manifest as behavioural challenges mainly as aggression.

3.1.5 Assessing Psychological Distress

The Bangor Life Events Schedule for Intellectual Disabilities (BLESID) [33] or the Lifestress Inventory (LI) [34] [5] can be used to assess psychological distress in a systematic way. The BLESID, covering a broad range of 24 life events, can be applied both, as a self- and a third-party report instrument. The Lifestress Inventory, a self-report measure, assesses current stressors with 30 items addressing daily situations or life events, with 13 items on negative interpersonal relations. Traumatic events can be assessed via the Trauma Information Form [35], and PTSD can be assessed by the Lancaster and Northgate Trauma Scale (LANTS) [36] or the Impact of Event Scale–Intellectual Disabilities (IES-IDs) [35].

3.1.6 Life Events and Traumatic Experiences

Regarding the contribution of life events (LE) to this vulnerability, evidence is sparse and methodologically limited. Many authors report that people with ID are more frequently exposed to stressful and traumatic environmental conditions than the general population [5, 31, 37–39], and this may impair their resilience to stressors [40, 41]. In particular, children with ID are resulted to be exposed three/four times more than their counterparts with normal intellectual functioning [42].

It has also been suggested that people with ID generally have more complex living

circumstances and less control over their lives [43, 44]. These conditions include the institutionalised living and dependency on caregivers [45–49], isolation, neglect and/or marginalisation [50–52], reduced and impoverished social networks [53, 54], poor housing and lower income [55], reduced access to adequate forms of affective or practical support [56].

Furthermore, the susceptibility to further adverse LE after trauma [57] may be related to dysfunctional coping strategies [58]. Some authors have identified an association between the impairment of cognitive and emotional skills [59], the inadequate levels of social support [54], and all positive and negative LE. People with ID have specific cognitive profiles [60, 61] and less strategies to cope with environmental stressors. Actually, they encounter a number of difficulties in understanding changes and relationships between events [62] as well as in processing and expressing their distress related to the past experiences [47]. Thus, they might act this out behaviourally, displaying functional problems like challenging behaviours [63, 64].

Starting from the childhood, many families and socioeconomic risk factors are associated with emotional/behavioural problems in people with ID, such as poor physical and mental health, challenging behaviour, and hyperactivity. Family and socioeconomic risk factors which have been more frequently reported are bullying, problems of justice, violence and abuse, cohabitation with a single parent, precarious or inadequate housing, parental unemployment, parents with drug addiction, living in a lower socioeconomic community [65].

As suggested by Herman and Evenhuis [66], the risk of psychiatric problems in older people with ID may be increased due to the exposure to more age-related LE than younger adults [66]. In a sample of 988 adults aged over 50, 97% had been subjected to multiple LE during the past year. The most frequently reported LE were the change of staff in setting/day care (85.05%), holiday (65.3%), new residents (55.1%), mild physical illness (47.2%) and change of main professional caregiver (39.5%). Depressive and anxiety symptoms were significantly heightened in individuals who reported more total and negative LE during the preceding year. This association remained significant also after controlling for a depressive or an anxiety disorder.

Surveys conducted in the last two decades of the twentieth century have reported positive correlations between lifetime exposure to LE and the development of physical, somatoform and psychiatric disorders in adulthood [67–79].

Martorell and colleagues [79] surveyed 177 individuals with mild to moderate ID about the impact of LE and traumatic experiences on their mental health. The retrospective survey was performed by a checklist created ad hoc and the Trauma History Screen (THS) [80]. The psychiatric evaluation was carried out through the administration of the PAS-ADD Checklist (Psychiatric Assessment Schedule for Adults with Developmental Disability) [81]. Results showed the presence of at least one traumatic event in the lifetime of 75% of the participants and at least one traumatic event within the 12 months preceding the study in 50% of cases. The statistical analysis also revealed a significant correlation between exposure to traumatic events and – to a lesser extent – LE, and the likelihood of developing a mental disorder, classified according to the ICD-10 criteria [82].

There is evidence that LE during the previous 6 months are significantly predictive of levels of psychological trauma, behavioural changes (both in frequency and severity) [31, 83] and functioning problems in general [84]. Some studies have found that the high prevalence of challenging behaviour in persons with ID is associated with LE and trauma [85, 86], although it has been confirmed for aggressive behaviour, but not for self-injurious or stereotyped behaviours [87].

Owen and colleagues [87] examined the correlations between LE, problems behaviours and mental health in a residential population of adults with ID. On average, each resident had been subjected to 3.5 negative LE in the past 12 months. Changes of staff and residence, conflicts with care staff and other housemates, family relationships and bereavements, and injuries or illnesses were the events most frequently reported by the participants.

Destructive behaviour and heightened risk for depressive/anxiety disorders were more frequently found in residents who had experienced a higher number of LE.

In 2004, Hastings [73] and collaborators evaluated a large sample of more than 1000 individuals living in various arrangements in Northeast England. The authors found a relationship between the exposure to at least one or two LE in the previous year and the pervasiveness of psychiatric symptoms. The disorders, mainly belonging to the affective spectrum, were detected with the PAS-ADD Checklist [81]. The five LE most frequently reported were changes of residence (15.5%), serious illness of relatives or close friends (9%), serious problems with close relatives or friends (8.8%), serious illness or self-injury (8.5%), and death of family members or close relatives (8.3%) [73].

The LE most frequently associated with mental health problems in people with ID is relocation [73, 77, 87], while among traumatising events abuses, especially sexual abuse, and bereavements are more likely [88–90].

Among traumas, abuse has been the most studied. Reiter and colleagues [90] found that students with ID were more frequently abused – physically, sexually and emotionally – than their peers. In addition to the higher incidence of victimisation in this population, it has also been shown that the abuse often goes unreported or, when reported, it tends to be disregarded. Analysing various life histories, some authors have revealed the presence of sexual abuse as a predictor of self-injury, misuse of alcohol and drugs, PTSD, low self-esteem, anger, depression, guilty relationship problems and behavioural problems [91–93].

Other LE and traumatic experiences observed are unemployed/seeking job, problems with police or authority, alcohol problems and major financial crisis, which have also been frequently associated with personality disorders. On the other hand, serious illnesses or injuries, laid off/sacked from work, and retirement from work have been associated with depression [89].

Different studies have highlighted a positive correlation between the exposure to LE/traumas and the presence of PTSD [83, 91, 94, 95], schizophrenia, personality disorders, depression and adjustment reactions [31, 76, 77]. Findings of a recent longitudinal study [49] have shown that LE were related to depressive, anxiety and psychotic symptoms, as well anger and aggression.

Also, dementia appears to be related to exposure to LE [75, 96]. In particular, the speed of cognitive decline has been found to correlate with the type and the number of LE. Relocations, experiences of loss/separation from significant persons and health problems seem to be the more frequent [75]. Recently, the research has focused on the role of trauma also in the aetiology of obesity [31]. Regarding the role of gender, studies have found no statistically significant differences in the type of LE between men and women [89].

In conclusion, current data confirm that the LE and/or traumas often precede psychological problems, and so they could be considered as risk factors. Evidence is still needed for a better understanding of the possible causal role of LE in the aetiology of mental disorders. The effects of negative events seen in the literature on the general population are not necessarily transferable to people with ID [36].

It is difficult to understand what the threshold is to consider identifying an experience as negative or traumatic for persons with ID. However, it is possible to conclude that an event may have a major impact on the person's ability to adapt and to manage life stressors, especially in case of more severe cognitive impairment [58, 97, 98].

Although the understanding of the role of positive and negative LE in the development of psychopathological vulnerability is becoming more and more important, the literature on traumatic experiences across the lifespan and mental health problems in people with ID is limited and not always consistent [49, 62, 73, 74, 76–78, 84, 87, 99], except for abuse [90, 100, 101], personal victimisation, bereavement [102] and PTSD [74, 75].

These difficulties in the clarification of the relationship between LE, ID and mental disorders are due to different aspects: inaccurate research methodologies, non-representative

samples and LE detection tools, which have not adequately adapted from the ones created for the general population. The instruments used often consist of self-report scales whose administration requires good cognitive, emotional and linguistic skills. Furthermore, the content of their items does not cover a wide timeframe but refers only to recent experiences [4, 5, 54, 80, 103–106].

Once these mechanisms are understood, treatment directions could be identified [49], even if the cognitive behaviour therapy and the eye movement desensitisation and reprocessing are already available and effective [31]. Future studies are needed to contribute to the understanding of the impact of LE and trauma by indicating the specific cognitive profiles of participants and by using prospective methodology [107].

3.2 Physical Vulnerability

Vulnerability is a term that is often used with regard to people with ID and other disabilities and has been defined as "…susceptibility to any kind of harm, whether physical, moral or spiritual, at the hands of an agent or agency" [108]. It is related to dynamics of disempowerment and lack of autonomy. There is, therefore, an important relationship in clinical practice between factors associated with vulnerability, and delivery and accessibility of health care through systems and clinicians. A scoping review of the concept of vulnerability and disparities in health care found evidence to support the authors' hypothesis of a direct correlation between co-existing factors of vulnerability and healthcare disparities [109].

People with ID are prone to experience physical disorders more than in the general population for a variety of reasons associated directly with ID and indirectly because of social challenges in maintaining good health [110]. Maintaining good physical health is particularly important for people with ID because of their vulnerability to developing physical health problems that can have an adverse impact on their quality of life and can be associated with significant inequalities in mortality and morbidity. This paragraph is confined to exploring the prevalence of physical disorders in people with ID and describe specific health problems.

3.2.1 Life Expectancy

Over recent decades, there has been a gradual increase in the life expectancy and a sustained reduction in age-standardised mortality rates in people with ID [111]. Life expectancy has increased from 12 years in 1949 to 60 years in 2004 for people with Down syndrome [112]. Studies have reported that people with mild ID may have similar life expectancy to the non-ID population but for people with more severe ID it is lower [113]. The life expectancy of people without a known organic cause for their ID has also gradually increased [114], but people with ID overall still continue to live shorter lives than people without ID in the United Kingdom [115].

Various studies over the last 20 years have reported on premature death in people with ID. A study in South London showed that people with ID are 58 times more likely to die before the age of 50 than the general population [116]. The MENCAP report in the United Kingdom, "Death by Indifference", on six deaths of people with ID described the role of institutional discrimination against people with ID in not providing adequate intervention and support in hospital and primary care [117]. The subsequent Independent Inquiry by Sir Jonathan Michael recommended the establishment of the Learning Disabilities Public Health Observatory in the United Kingdom [118]. A further confidential inquiry into the deaths of people with learning disabilities [119] was undertaken which investigated the known causes of death of people with ID in South West England and reported that men with ID live 13 years less and women live 20 years less than their counterparts without ID. Some of the reasons for premature deaths included significant difficulties or delays in diagnosis, or delays in further investigation, or specialist referral, and problems with their treatment [120].

3.2.2 Causes of Death

The main causes of death in people with ID are respiratory disorders and cardiovascular conditions secondary to congenital heart disease. In contrast, the leading cause of death in the general population is cancer, followed by ischaemic heart disease and cerebrovascular accidents. Cancer as a cause of death was less common compared to people in the general population [121–123]. Tyrer and McGrother [124] found a relatively high cause-specific mortality for deaths caused by congenital abnormalities and diseases of the nervous system in their study of 503 adults with ID who died during a 14-year follow-up period.

3.2.3 Aetiological Factors for Physical Illnesses and Vulnerability

The aetiological factors for physical illness in people with ID are varied and due to not only the presence of physical disorders but also inherited disorders, communication difficulties, behavioural problems, deficits in support and other social determinants of health. People with ID are at a higher risk of specific diseases compared with the non-ID general population [125]. The presence of certain genetic syndromes further increases the risk of physical illness, for example, the prevalence of hypothyroidism is significantly high in people with Down syndrome. Certain neurological conditions such as epilepsy occur more frequently in people with severe ID with underlying genetic syndromes or organic brain damage [126].

The ability to ask for help and access health care is important for physical health conditions to be diagnosed, treated and prevented. An inability to process information, make informed choices and plan to accept help may reduce a person's access to health care. Communication difficulties in describing symptoms may predispose to a lack of awareness by carers of symptoms or their misattribution to behavioural difficulties instead of identifying accurately a physical health cause. Deficits in adaptive behaviour further reduce the ability to seek assessment and treatment for physical conditions. Inability or lack of motivation to engage in activities increases risk factors such as obesity which in turn may lead to the development of physical illnesses. Lack of appropriately adjusted information and processes of identification and access, as well as lack of awareness in individuals, family and carers, also has an impact on engagement with health screening programmes, for example, breast, bowel and cervical cancers [127].

The occurrence of behavioural difficulties in people with ID can further reduce their access to health care leading to reduced opportunities for assessment, accurate diagnosis and effective treatment. People with ID are prescribed medications more than the general population, particularly in attempts to manage behavioural difficulties [128]. Such medications are associated with metabolic effects that can have significant impacts on a person's physical health, causing weight gain and predisposing them to developing diabetes mellitus.

- Individuals with ID are also more likely to experience physical disorders compared to their peers without ID.
- Studies have highlighted reduced life expectancy of people with ID compared to their peers without ID.
- Reasons for increased physical disorders and premature deaths can be associated with the aetiology of ID, communication difficulties, behavioural problems and lack of social support among many other reasons.
- People with ID can struggle to access health care for various reasons.
- Among physical disorders, epilepsy is one of the commonest conditions seen in people with ID.
- Certain physical health conditions are commonly seen among certain groups of people with ID.
- For example, people with Down syndrome and ID are at a higher risk of hypothyroidism.

3.2.4 Common Physical Health Problems

Morbidity

Physical health morbidities are high in people with ID. A large population-based study in Scotland showed that only 32% of people with ID had no other health condition compared with 51.6% without ID and that adults with ID are more likely to have one to four physical health conditions [125]. Epilepsy (OR-31), constipation (OR-11) and visual impairments (OR-7.8) were significantly more prevalent in the ID population. Interestingly, cardiovascular-related conditions such as coronary heart disease, peripheral vascular disease, hypertension and atrial fibrillation had lower prevalence in this study. Authors also reported hearing loss, eczema, dyspepsia, thyroid disorders and Parkinson's disease to be twice as common in people with ID than non-ID population.

Central Nervous System

The commonest neurological condition in people with ID is epilepsy with a prevalence of 1 in 4 that compares with a prevalence rate of 4 to 10 per 1000 in the general population. Prevalence increases with the severity of ID [129, 130]. Epilepsy is a complex disorder that often has familial and genetic influences, as supported by twin studies [131]. This may further explain the higher prevalence of epilepsy in people with more severe ID and complexities associated with the diagnosis and treatment.

People with genetic disorders are more vulnerable to develop seizure disorders where the prevalence can vary according to the specific condition. Landau–Kleffner syndrome, Dravet syndrome, Doose syndrome and Rett syndrome are some of the genetic conditions associated with both epilepsy and ID. Certain genetic syndromes are associated with different types of seizures. Approximately 60% of people with Angelman syndrome experience multiple seizures with atonic, generalised tonic clonic, absence and complex partial seizures [132]. According to Robertson et al. [130], the pooled estimate of the prevalence of epilepsy in people with Down syndrome was lower than in the total ID population at 10–13%. This contrasts with Uppal and collaborators [133] who found a prevalence rate of epilepsy of 20%.

Epilepsy in people with ID has a poor outcome with about 66% of people with ID experiencing seizures despite using antiepileptic medications [129]. A person with epilepsy can die during or following a seizure for no obvious reason known as Sudden Unexpected Death in Epilepsy (SUDEP). Kiani and colleagues [134] report that SUDEP was the second commonest cause of death with a standardised mortality ratio of 37.6 for men and 52 for women in people with ID. Poorly controlled epilepsy is a risk factor for SUDEP, and people with ID who have epilepsy have a high mortality rate [135].

Metabolic Disorders

Inborn errors of metabolisms are a group of rare genetic conditions that can be associated with and/ or lead to ID. Van Karnebeek and Stockler [136], in a systematic literature review, identified a total of 81 treatable forms of inborn errors of metabolisms in which ID was a major feature. Early recognition, identification and treatment can allow initiation of treatments to prevent or minimise brain damage and improve health outcomes, for example, phenylketonuria. More common are the acquired disorders of metabolism. The functional systems of the body or metabolism include eating, sleeping, hunger and temperature control. Disorders of metabolism can affect many systems in the body and over time result in significant and severe effects on multiple organs.

Diabetes is a common metabolic disorder in which there is under-secretion of insulin that regulates the utilisation of sugar and fats by the body. Complications of diabetes include renal damage, cardiovascular events, cerebrovascular events and blindness. The global prevalence of diabetes has increased from 4.7% in 1980 to 8.5% in 2014 [137]. Similar increases can be expected in people with ID, but the prevalence of diabetes in this

population remains unknown [138]. There is evidence to support the assertion that people with ID are at high risk of diabetes, and the risk of diabetes in people with certain genetic syndromes such as Prader–Willi is approximately 25% for non-insulin-dependent diabetes mellitus with the mean age at onset as early as 20 years [139]. The risk of diabetes in people with Down syndrome has been debated on account of the autoimmune nature of diabetes, but the risk is considered high as evidenced in a Dutch study in children where the risk is threefold higher in children with Down syndrome compared to those without the syndrome [140].

Thyroid diseases, especially hypothyroidism, are over-represented in people with ID [141] especially in people with Down syndrome who have a high rate of thyroid disorders primarily of autoimmune origin. The lifetime prevalence of thyroid disease in people with Down syndrome is estimated at 63% with the incidence of primary congenital hypothyroidism in infants with Down syndrome approximately 28 times more than in the general population [142]. Cheung and colleagues [143] have reported a lifetime prevalence of hypocalcaemia of 80% in people with 22q11.2DS which is one of the commonest microdeletions and is typically attributable to hypoparathyroidism in this group.

Respiratory Disorders

Respiratory conditions are higher in people with ID but studies on the prevalence of asthma in people with ID have shown mixed findings. Gale and colleagues [144] reported the prevalence of asthma in people with ID is double that of the general population in the United Kingdom. Similar findings were reported from studies in Scotland [125], while others report no difference in prevalence between ID and the general population [141]. Irrespective of that, a case–control study has shown that people who died as a result of severe asthma following hospital admission were more likely to have ID [145] emphasising the importance of effective treatment of asthma in people with ID.

Even though Chronic Obstructive Pulmonary Disease (COPD) is a common respiratory condition secondary to smoking in the general population, there are no studies on the prevalence of COPD in people with ID. Recurrent chest infections, on the other hand, are commonly seen among children with severe ID [146] that increase morbidity and mortality in people with ID. There are multiple reasons for recurrent chest infections that include aspiration secondary to swallowing difficulties and gastro-oesophageal reflux, decreased cough efficacy due to expiratory muscle dysfunction and/or kyphoscoliosis, and malnutrition leading to respiratory muscle weakness. The presence of cerebral palsy further increases the risk. Almost 50% of people with Prader–Willi syndrome across different age groups reported a history of recurrent respiratory infections [139].

Obstructive Sleep Apnoea (OSA) is another common condition especially affecting certain groups of people with ID. People with Down syndrome are at a higher risk of OSA due to hypotonic upper airway muscles. Obesity itself is a risk factor that further increases the risk of OSA in people with Down syndrome and Prader–Willi syndrome.

Cardiovascular Disorders

Congenital cardiac abnormalities are more prevalent in certain genetic syndromes, especially in Down syndrome. A Swedish cohort study examining cardiovascular diseases showed that 54% of infants with Down syndrome had congenital cardiac defects compared with the risk of congenital heart disease of 1% in the general population. The most common congenital heart conditions in people with Down syndrome are atrioventricular septal defects (42%), ventriculo-septal defects (22%) and atrial septal defects (16%) [147].

Velocardiofacial syndrome or 22q11 Deletion syndrome (22q11DS) is a relatively common microdeletion syndrome, with an incidence estimated to be between 1 in 4000 and 1 in 6000 [148, 149], causing ID with various physical and mental health conditions. Cardiac abnormalities are commonly found

in this syndrome that includes interrupted aortic arch type B, persistent truncus arteriosus, tetralogy of Fallot and isolated ventricular septal defect or transposition [150].

Gastrointestinal Disorders

Dysphagia, or difficulty in swallowing, is highly prevalent in people with ID. Hypertonia or hypotonia of the swallowing muscles along with poor coordination during swallowing are considered to be among potential aetiologies. Dyspepsia and gastro-oesophageal reflux are also common [151]. Constipation is a frequent health condition in people with ID where nearly 70% of institutionalised adults with ID had constipation [152] and in children with severe ID, the prevalence rate is as high as 50%. People with ID are at a higher risk of constipation as a side effect of the various medications they are prescribed (e.g. antipsychotics), reduced mobility and poor fluid intake. Cerebral palsy and Down syndrome are strongly associated with constipation.

Cancers

It was previously thought that people with ID had a lower prevalence of cancers, but more contemporary analysis of data appears to show rates comparable to the general population [153]. There are some differences in the relative frequencies of types of cancer, for example, people with ID are at a much higher risk of gastrointestinal cancer. Rates and patterns of cancers may be changing with increased longevity. A significant challenge in the diagnosis and treatment of cancer is the variability in access to and uptake of screening programmes. Women with ID have a much lower participation rate in cervical and breast screening programmes than women without ID.

In the United Kingdom, figures from the Joint Health and Social Care Self-Assessment Framework demonstrated variability in uptake across three national screening programmes for cervical, breast and bowel cancer. For the bowel screening programme, 41.6% of people with ID were screened compared with 50.4% for the general population. Breast cancer screening was carried out on 39% of women with ID (general population 55.9%) and cervical cancer screening was the lowest with 29% compared with 69.1% [127].

Barriers to uptake of screening include the lack of routine use of accessible materials including invitations to screening, lack of reasonable adjustments to appointment systems, availability of adequate time and adaptations for restrictions in mobility. Professionals cite communication difficulties as a significant barrier and the awareness and attitudes of the professionals themselves have a significant impact. People with ID themselves may have limited knowledge and understanding of cancers and the need and benefits of screening [154].

Sensory Impairment

In a Dutch study of people with ID under the age of 50 years in an institutional setting, nearly 21% had hearing problems and 4% had visual problems. Such prevalence rates are significantly higher compared to the general population. The prevalence rate is higher with increasing severity of ID where 50% of people with severe and profound ID have visual impairments. The prevalence of hearing impairments was significantly high in people with Down syndrome and people with ID over the age of 50 [155]. Some of these conditions are treatable or steps can be taken to reduce the impairment due to sensory deficits, but they are often difficult to detect in people with severe ID.

Nutrition and Weight

Overweight is defined as a Body Mass Index (BMI) ratio of 25–29.9 and obesity BMI > 30 and are currently major health concerns for the general population. Obesity is one of the biggest risk factors for cardiovascular and cerebrovascular events. There has been a marked increase in the number of people with ID with obesity with a higher prevalence than the general population [156–158].

Multiple factors are thought to contribute to overweight and obesity in people with ID, and there is an association with certain genetic syndromes, for example, Down syndrome [158] and Prader–Willi syndrome [139].

Genetic studies have shown that genetic deletions and certain copy number variants are linked to obesity supporting the hypothesis that it is a heritable and highly heterogenous set of conditions [159]. Interestingly, the rate of obesity is lower with increasing severity of ID [158].

Many external factors lead to obesity that include a lack of healthy food choices, the side effects of medications such as antipsychotic drugs, a lack of exercise [156, 160], physical limitations and pain, little motivation and few resources and support to engage in activities. The environment in which a person lives has an impact on maintaining physical activity where people with ID living in less supervised settings are at higher risk of obesity compared to people who live in closely supervised ones [161]. Gender disparity in obesity is an interesting factor in its development. Kanter and Caballero [162] identified socio-cultural factors leading to gender disparity where in developing countries there are more obese women than men and that women with ID are at greater risk of obesity [156, 163, 164]. Such factors are larger body sizes considered as signs of healthiness and happiness alongside sex differences in metabolism and adipose tissue distribution.

- **Musculoskeletal Disorders**

People with ID experience musculoskeletal problems that cause significant functional impairment by reducing mobility and impairing ability to engage in educational and other activities which require fine and gross motor skills. Hypotonia is a common finding in Down syndrome and Prader–Willi syndrome and in people with cerebral palsy. People with ID are at a higher risk of low bone mineral density, osteoporosis and osteopenia often secondary to the use of antiepileptic medication to control seizures that reduces Vitamin D absorption. These factors along with reduced mobility predispose people to bone fractures that may also go unnoticed if they are immobile. Almost 50% of people with ID meet the criteria for screening of osteoporosis and osteopenia [165].

3.2.4.1 Prevention

Primary, secondary and tertiary prevention strategies are important in managing physical health conditions in people with ID. Examples of primary prevention interventions in childhood are screening for visual defects, hearing disorders and musculoskeletal disorders to prevent morbidity and/or to reduce the risk of impairment. Screening every person with ID for common health conditions and specific screening tests in people with congenital disorders is important, for example, testing for hypothyroidism in people with Down syndrome annually as per the guidelines from Down Syndrome Medical Interest Group. Secondary prevention is the detection and treatment of a condition prior to developing complications that involve recognising people at high risk and taking the necessary steps to test and treat. Tertiary prevention is reducing harm from a condition, for example, interventions to prevent a person with cerebral palsy from developing contractures. The biggest challenge with preventative strategies in people with ID is the paucity of research and policies and guidelines on screening and managing health conditions.

- Conditions related to central nervous system, metabolic system, respiratory system, cardiovascular system, gastrointestinal system and musculoskeletal system are commonly seen in people with ID.
- Improving physical health care of people with ID includes early identification and support to access health care.

3.2.5 Improving Health Care and Reducing Physical Vulnerabilities

To reduce health inequalities in people with ID, it is essential to recognise the obstacles in the person and in the system to them receiv-

ing appropriate care. Providing health services for people with ID can be challenging for many reasons not least the multi-morbidity affecting people with ID. In England, General Practitioners have responsibility to offer Annual Health Checks to their patients with ID. Despite various measures to increase uptake of Annual Health Checks only 50% had one [166].

One of the main challenges with improving health care for people with ID is the lack of research often due to multiple barriers such as funding, ethical issues and little interest by researchers in this area. As a result, issues relevant to diagnosis and treatment of physical health issues in people with ID are often not specifically addressed in guidelines with the potential of not identifying health problems as their presentations may be different to people in the general population. In addition, people with ID at high risk may not be recognised as "high risk" or clinicians may not be trained to examine and suspect health issues.

People with ID often express pain or distress through behavioural changes on account of poor communication skills. The behaviour can be perceived as "challenging" to carers and clinicians who may fail to understand the underlying physical cause of the behaviour. This may lead to inadequate assessment and inappropriate treatment. To overcome such difficulties, joint working between mental health clinicians and generalists is recommended. A lack of mental capacity to make decisions about physical health care can be an issue for some people with ID. Legal frameworks to support assessing mental capacity and making best interest decisions are important to support people with ID to access health care [167].

- **Summary**

People with ID are prone to physical health difficulties either directly related to the level of ID or as a consequence of treatments they receive. It is essential that clinicians working with people with ID are alert to unusual presentations, the impact of treatments, and are familiar with the health needs of this population in order to avoid greater morbidity. People with ID are a heterogenous group who experience a range of physical disorders as they grow older including long-term conditions. Skilled interventions by carers and clinicians can help to prevent the onset of physical health problems or to ameliorate their impact through education and support.

3.3 Lifespan and Transitions

3.3.1 Introduction

In the last decade, lifespan issues appear to have received increasing attention. There has been a growth in research and policies. Transition planning and supports for community inclusion, independent living and employment have become key areas of interest. Among many factors that have contributed to this development, a major role has been played by deinstitutionalisation, which created greater access to community-based services and living arrangements. Furthermore, educational advocacy and legislations have facilitated the access to educational opportunities. Provision of behavioural intervention programmes has produced dramatic increases in language, social and practical skills, with many individuals achieving skills necessary to adapt in community living. As of 2012, approximately 50,000 individuals with ID/autism spectrum disorder (ASD) per year turn 18 years old in the United States [168, 169]. Therefore, the challenges of transition to adulthood in ASD are now a significant public health issue [170, 171].

3.3.2 Adolescence

Deterioration in behavioural is seen in approximately one-third to one-fourth of adolescents with ID and ASD [172]. A major causal factor for such deterioration is postulated to be due to hormonal changes and associated sexual desires, especially in the context of limited knowledge and skills around safety and

relationship issues. In females with ID/ASD, this seems to be linked to menarche. The age of onset for menarche is often significantly earlier compared to women in the general population. Adolescence is also marked by various other changes in psychosocial development, educational and life activities, participation to community living and the related safety issues.

3.3.3 Education

Literature shows that adolescents with ID and ASD have lower levels of academic achievement in high school, and the majority of them have post-school services as part of their transition plan [173]. The data in the scientific literature indicate that 40% of individuals with ID/ASD attend college, and a smaller percentage graduate from College, with lower attendance rates among those with more severe symptoms or lack of access to services [168, 174–178]. Those young adults who are attending College or University or trying to pursue professional education may encounter various problems. Living away from home, managing one's daily life and finances, managing the unpredictable stresses of more independent living and navigating the relatively complex social environment of higher education are some of the challenges. However, there are several organisations that provide professional support staff and peer mentoring during College education. Furthermore, there are an increasing number of programmes designed to prepare and support young adults with ID/ASD prior to and during the University studies.

3.3.4 Sexuality

Sexuality encompasses more than just sexual behaviour. It includes self-image, emotions, values, attitudes, beliefs, behaviours and relationships. There are many wrongly held beliefs about ID/ASD individuals, referring to them as sexually immature and sparsely interested in romantic relationships or as asexual [179]. In contrast to these stereotypes, several studies have shown that sexuality is an important part of life for individuals with ASD and that they have general interest in solitary and dyadic sexual behaviours [180]. In fact, people with ID/ASD typically mature physically and sexually according to normal developmental stages. However, a young person with ASD can develop normally in some areas of social and emotional understanding and have difficulties in others. Difficulties in initiating and maintaining relationships appear to be the main difficulty that most people with ID/ASD experience than the lack of interest. The success or failure encountered by young people during their sexual development impacts their ability to effectively transition into adulthood.

Moreover, lack of understanding of rules of dating and romantic relationships, of social skills and also poor social decision-making in adults with ID/ASD may lead these individuals to engage in behaviours that are misinterpreted or get them into trouble, such as "stalking" behaviours [180]. This can have severe consequences, including loss of opportunities for employment, social isolation or even criminal prosecution. Moreover, individuals with ID/ASD report problematic sexual behaviours, including hypersexuality, paraphilic disorders, asexuality and gender-nonconforming feelings [181].

There has been a growing interest in this area recently. Some authors have suggested that specialised sexual education combined with social and communication skills training for adolescents may be beneficial. Such education would focus on improving knowledge so that inappropriate activity can be avoided [182, 183]. However, relatively few interventions and services have been developed and rigorously tested to improve social functioning for late adolescents and adults with ASD.

3.3.5 Adulthood

The transition to adulthood is one of the periods characterised by considerable stress and adjustment for people with ID/ASD and

their families [184]. One of the major difficulties in addressing transition to adulthood adequately is the tremendous heterogeneity of ID/ASD, including heterogeneity of underlying aetiology, clinical manifestations, levels of cognitive and adaptive functioning [185]. This heterogeneity makes essential thorough clinical evaluation and tailored transition plans, services, interventions to the goals and needs of the particular individuals. One of the major challenges is to help individuals, families and schools to plan the transition to adulthood in advance. Transitional issues are numerous and complex and often take time and planning to address these complexities [173].

Transition work should include several issues: helping to find appropriate jobs, providing support to progress in their work placement, considering options for housing, helping to gain more independent living skills and finding appropriate legal and financial counselling for longer term planning regarding financial and healthcare decision-making. Ideally, the individual, parents, teachers and other professionals should all participate in formulating the transition plan. There should be coordination between efforts of school and community agencies [173, 186].

One of the most complex transitions, which generally occur in adulthood, is represented by moving from the parental home to another setting such as independent, shared, supported or residential livings. Many skills are involved in independent living, including managing safety, cooking, cleaning, laundry, dressing and personal finances. In general, teaching and practice of these skills should be part of a transition plan to gain such skills relatively early, so that there is sufficient time for these skills to be acquired. Housing and residential issues are treated in ▶ Chap. 37.

Finding and maintaining a job is a priority during the transition to adulthood as it plays an important role in developing a sense of purpose and well-being, self-esteem, social and mental engagement, and financial independence. The several issues related to vocation and employment are treated in ▶ Chap. 38. Furthermore, young adults have substantial difficulties in meeting the increasing social subtlety of adolescent interactions relative to childhood social interactions.

Most adults with ASD tend to remain socially isolated [187, 188]. Several studies have found that a high percentage of people with ASD have no friendships or have only one friend [189–191]. Another critical transitional issue is the increased risk for periods of aggravation of behavioural symptoms (e.g. aggression, hyperactivity and insistence on sameness), seizures [192, 193] and mental health problems. The psychotropic medication usage tends to increase in individuals with ASD as they enter adolescence and adulthood [194], despite the fact that the evidence base for use of medications in adults with ASD is very limited [26, 195, 196].

The relatively poor outcomes for adults with ASD may be attributable, at least in part, to the relative lack of services for adults. This is further increased by limited research on adults with ASD. In many countries, mandated services and supports for individuals with ASD either disappear or are dramatically reduced after the age of 18–21 years [178, 191, 197]. The transition to adulthood is often a period of considerable stress and adjustment for close family members of persons with ASD\ID [184].

Main difficulties encountered by family members concern the coordination of many types of health, educational and other services. Parents often have longer term concerns about the capacity to move out of the home and to function in post-secondary education, employment and activities of daily living, what will happen to their child when the parents become older, sick or pass away. They have considerable worries about how to address legal issues about guardianship and financial and health decision-making [198]. In addition, these parents tend to experience higher levels of stress, more mental health symptoms, higher divorce rates than parents of typically developing children and higher demands for assistance [199, 200].

When necessary, the transition to adult services must be adequately prepared, not

only through the collaboration of services professionals for the two ages but also by providing young people with the necessary indications about the interventions they will need, where and from whom receive them. It is necessary for the young person and, when appropriate, the parents or caregivers to be involved in the treatment planning. Similar methods should be applied – mutatis mutandis – also to the transition, more gradual but also more subtle, from adulthood to senescence.

3.3.6 Ageing

Life expectancy of people with ID has increased over the last few decades although it is still lower than that of the general population by about 10–15 years. Increase in life expectancy has been linked with an increase in the prevalence of mental and physical ill-health disorders associated with ageing.

- There have been significant changes over the last few decades in the ways people with ID live following deinstitutionalisation and community inclusion.
- As a result, there have been changing expectations from people with ID in different aspects of life.
- Transitioning from one stage of life to another can lead to different challenges for people with ID.

Key Points

- Psychological distress is commonly seen among people with intellectual disabilities (ID)/autism spectrum disorder (ASD).
- Similarly, high rate of physical disorders are seen among people with ID/ASD associated with high mortality.
- People with ID/ASD are further vulnerable due to different stages of transition that they have to go through in their lives.

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_4

Learning Objectives

- To understand prevalence of borderline intellectual functioning (BIF) and associated factors.
- To learn about the ascertainment and diagnosis of BIF.
- To become aware of mental health comorbidities and BIF across the lifespan.
- To understand the issues relating to service delivery and treatment provision to this group.

4.1 Introduction

Intelligence encompasses many different cognitive components that contribute to the ability for abstract thinking, self-realisation, consciousness, moral judgement and a range of adaptive behaviours such as education, employment, forming of relationships and so on. Intelligence is measured by tests that derive IQ scores which are standardised for various population groups. All testing is imperfect and subject to standard error which may be due to cultural or other norms and the construct that each test strives to measure.

In 1961, the American Association on Intellectual and Developmental Disabilities (AAIDD) (formerly American Association on Mental Retardation) suggested a categorisation of mental retardation, as intellectual developmental disorders were then known, which included borderline intellectual functioning (BIF) as the first of five levels of severity. The IQ range was given as 70–85 including people who were on the second to 16th percentile. Subsequently, this categorisation was adopted by the classification manuals of the American Psychiatric Association in DSM-II [1], DSM-III [2] and DSM-IV [3]. This classification tended to overdiagnose people from minority ethnic groups or those in lower social strata as it omitted the additional condition needed for a diagnosis, that of impaired adaptive functioning.

It was then recognised that in order to avoid the likely increase in false positives, that is, people identified as having BIF, the latter became a descriptive V-code rather than a disorder incorrectly, and the IQ upper ceiling for mild intellectual disabilities (ID) was set to 70. An unintended consequence of this change was the de-classifying of people who had reduced cognitive ability but were not deemed to have ID and therefore, were unable to receive services. As this was clearly causing difficulties, clinicians, researchers and policymakers tried to rectify the situation by (1) interpreting needs based on IQ scores flexibly, which is establishing service exemptions so individuals with certain diagnoses may receive services; and (2) raising the ceiling for ID from 70 to 75 given that this is the accepted standard error of IQ measurement. For example, an IQ score of 70 can be as high as 75 or as low as 65. For a full discussion of that debate, see Greenspan [4].

Interest in BIF is international. Wieland [5] argues that BIF is an important element in the onset, treatment and prognosis of mental disorders and the relegation of the concept to a V code "for Conditions Not Attributable to a Mental Disorder that are the Focus of Attention or Treatment" is detrimental to the quality of life of those with BIF and mental or other health comorbidities. In the International Classification of Diseases tenth edition-Clinical Modification (ICD-10-CM) [6], BIF was assigned a "residual code R41.8, other and unspecified symptoms and signs involving cognitive functions and awareness".

Salvador-Carrulla et al. [7] presents the dilemmas that dominate the current understanding of BIF and its classification as veering from the World Psychiatric Association view of BIF being a disorder (or metal condition) that should be included in the international classification of diseases (ICD) to the American Association on Intellectual and Developmental Disorders (AAIDD) view that BIF is a disability and therefore should be included in the International Classification of Functioning (ICF), Health and Disability [8, 9].

Further, Bertelli, Cooper and Salvador-Carulla [10] argue that defining conditions by IQ level is problematical because intellectual developmental disorders are multifactorial and individual abilities and skills may differ between persons at the same IQ level. They propose that assessing specific cognitive

functions may be more fruitful for ascertaining ID but also for combating the associated stigma for the sufferers.

These debates about diagnosis of BIF clearly underscore its high heterogeneity as a condition which is underpinned by both biological and psychosocial factors that increase individual risk for developing it. Consequently, the absence of consensus on what the term BIF should encompass and how it should be classified raises concern that such uncertainties will affect the information on prevalence of the condition and the provision of services to those in need.

4.2 Prevalence

Information about the prevalence of BIF is garnered from a number of sources including clinic populations, country-wide epidemiological surveys or simply estimations based on the population intelligence distributions. Therefore, published literature suggests that prevalence ranges from 13.5% to 18% [7, 11, 12]. These proportions, which all are based on IQ rather than IQ and adaptive behaviour qualification, are close to 14% which is derived by subtracting those with IQ less than 70 (second percentile) from those with an IQ around 85 (16th percentile). Prevalence seems to be relatively higher in males, persons with individual and family problems, negative parent behaviours, low socioeconomic position, and prisoners [13–19]. In the latter, the rate ranges from almost 6–32% [19].

Recent exploratory studies have shown the prevalence of BIF to likely be higher also in mental healthcare populations [12, 20, 21]. Discrepancies in the prevalence rates reported in each study are due to methods of ascertainment, sampling frame and definition/criteria for BIF including whether the additional criterion of adaptive functioning was used.

It is possible that BIF overlaps with the upper end of mild ID but on occasion also with specific learning difficulties, that is, impairment of scholastic ability in one area in the context of normal development and adaptive functioning. Further, given the known impact of severe mental illness, for example, psychosis, bipolar affective disorder, on IQ, it is not surprising that ascertainment of BIF status in adulthood in people with severe mental illness may be contentious in the absence of collateral developmental history.

> The prevalence of BIF ranges from 13.5% to 18% on the basis of the different sources. It seems to be relatively higher in males, persons with individual and family problems, negative parent behaviours, low socioeconomic position, and prisoners.

4.3 BIF and Cognition

Impairment in educational and scholastic achievement has been linked with BIF in school-age children. Underlying processes that have been implicated include information processing [22] measured with event-related potential in the absence of sensory deficits. The findings suggested that the BIF group (mean IQ 81) had deficits in attentional and information processing pathways compared with children of average intelligence mean (IQ 99). Grey matter and brain volume changes may underlie executive or motor function difficulties; they appear to be increased in certain parts of the brain (e.g. right temporal cortex) but decreased in others (e.g. right parahippocampal gyrus) in BIF young persons without other pathology (IQ 80) compared to children of average intelligence (mean IQ 118) [23]. Other studies have replicated such deficits in motor function in up to about 60% of samples drawn from schools for children with special needs (mean IQ 77) [24]. Impulse control may also be affected by BIF as shown by van der Meere et al. [25] in young boys with conduct disorder. They showed that children with BIF and conduct disorder respond faster than the control group, and that their best performances are related to the presence of valid-cue information. This propensity may be perceived as an action-oriented response style that is consistent with the sensation or thrill-seeking characteristics.

There are several genetic conditions with variable effects on IQ which may lack distinguishable characteristics and thus, it may not

be obvious that the sufferers have a number of neurodevelopmental problems that may hinder their academic progress.

The most common conditions associated with variable IQ are autism spectrum disorder [26], attention-deficit/hyperactivity disorder (ADHD) [27], foetal alcohol spectrum disorder [28], Fragile X syndrome premutation carriers [29], velocardiofacial syndrome [30], Prader–Willi syndrome [31] and Williams syndrome [32].

Children with those conditions share specific cognitive profiles but those may not be recognised in classrooms especially where the original genetic abnormality is not known or distinctive facial and other bodily markers may not be prominent and therefore missed. Common problems in the classroom may comprise disturbances in executive function, working memory, remote recall of information, declarative learning and memory, speed of information processing, and temporal sequencing, as well as visuospatial functioning.

Many children and young people with BIF with or without known genetic conditions are also called "slow learners" and may come to the attention of services at the start of primary education. Karande et al. [33] raised the issue of lack of recognition or awareness of BIF in parents of children with BIF who had been referred for assessment due to poor educational attainment.

These children often receive a statement of educational needs which entitles them to support if their difficulties are deemed serious and impede their progress. However, they may leave education without qualifications and therefore, represent a hidden problem. More often than not, those early difficulties have not been subject to remediation or early support and may continue to impact adult life outcomes in a considerable minority. ◘ Table 4.1 presents the main cognitive deficits in comorbid conditions associated with BIF.

BIF has been associated with deficits in attentional and information processing, motor function and impulse control.

4.4 BIF and Health

Analysis of data from the Longitudinal Study of Australian Children [37] showed that 23% of children with BIF were obese by age 7 and were more likely to have been exposed to socioeconomic disadvantage. These children were also rated higher by their parents for total difficulties on the Strengths and Difficulties Questionnaire which implies possible psychiatric morbidity.

Common comorbidities in children include other neurodevelopmental conditions such as ADHD, autism spectrum disorder, conduct disorder and symptoms such as inattention and impulsivity. Other potential presentations of psychiatric disorders may be problem behaviours or somatic complaints.

Van der Meere and colleagues [38] investigated the characteristics of poor impulse control in children with conduct disorder and BIF, comparing them with a control group using the alertness test [39]. They suggested that these children lack an inhibitory response. In their study of disruptive behaviour disorders, Villalobos et al. [40] analysed data from more than 1000 children and found that the presence of BIF considerably increased the amount of disruptive behaviours. Further, the presence of BIF is a poor prognostic factor for the management of children with ADHD.

A narrative review of the literature examining reported psychopathology in people with BIF suggests that the commonest mental conditions found in this population group are personality disorders, posttraumatic stress disorder (PTSD), psychosis, ADHD, bipolar disorder and sleep disorders [41].

Findings from an Israeli study of 173,542 adolescents with BIF screened for military service [42] showed that as a group they were twice as likely to be diagnosed with a psychiatric disorder using the ICD-9 [43], specifically antisocial personality disorder and non-affective psychosis and were more likely to use drugs. The study by Wieland [11] which compared a clinical adult population with and without BIF but with mental disorders with a group of adults with mild ID and

Table 4.1 Cognitive profiles of comorbid conditions associated with BIF

Generalised developmental disorders	*Neurocognitive features*
Autism spectrum disorder	Relative strengths in tasks requiring non-timed abstract reasoning and relative weaknesses in processing speed and comprehension [26]
Attention-deficit/hyperactivity disorder	Deficits in executive function and response inhibition [27]
Specific developmental disorders	
Dyslexia	Phonological deficit [34]
Dyscalculia	Deficient number module [34]
Mathematics learning disorder	Difficulties in multiplication, learning to solve math word problems and automatized memory of basic facts [35]
Non-verbal learning disorder	Poor psychomotor coordination, arithmetic skills and drawing activities. Impaired social judgement and social problem-solving [36]
Other	
Foetal alcohol spectrum disorder	Deficits in executive functioning, particularly in tasks that involve holding and manipulating information in working memory [28]
Fragile X syndrome	Impaired mental status, intelligence, executive functioning, working memory, remote recall of information, declarative learning and memory, information processing speed, and temporal sequencing, visuospatial functioning [29]
Velocardiofacial syndrome	Weaknesses in the areas of visuospatial memory and arithmetic; morphological changes in the frontal cortex [30]
Prader–Willi syndrome	Impaired executive memory, and visuospatial tasks [31]
Williams syndrome	Variable cognitive profile with participants performing better on language and face recognition tasks, compared with visuospatial and number tasks [32]

Adapted from Salvador-Carrulla et al. [7]

mental disorders found lower rates of psychosis and other severe mental disorders in the BIF group, but that the BIF group had higher rates of PTSD. Just over half of the patients with BIF were diagnosed with a personality disorder, most commonly personality disorder not otherwise specified followed by borderline personality disorder [44].

Other studies suggest that limited communication or verbal ability may lead to longer inpatient admissions and more coercive care approaches for those patients [21]. The authors examined records of current psychiatric admissions and of admissions which had taken place in the preceding 5 years to check for evidence of seclusion, other restraint and enforced medication. They found that 44% of the inpatients screened positive for BIF or mild ID and that this group was almost 3 times as likely to have had involuntary admissions currently or in the past 5 years and almost 4 times more likely to have experienced any type of coercive treatment.

Another research found that BIF is likely to remain unidentified in mental health care and substance use services [45], which may hinder necessary treatment adjustments and worse the odds of positive outcome in both the short and long terms [21, 46–48]. Several papers deriving from the Adult Psychiatric Morbidity Surveys [49] in the UK indicate that adults with BIF and mental health issues

are younger, male and of lower socioeconomic status [12]. The BIF group was identified from those responding to the survey who had all completed the National Adult Reading Test (NART) which provides an estimation of current verbal IQ which is highly correlated with overall IQ. The BIF group had higher rates of common mental disorders, substance misuse and personality disorders. Further analyses [50] showed that the BIF group is also more likely to have made suicidal acts though not intending to take their own lives and are least likely to recover from them [51]. This is in accord with findings from epidemiological studies that indicate that low IQ is a risk factor for common mental disorders especially depression [52].

The BIF group is also found to have higher odds for problem gambling [53] and are less happy than their peers without BIF [54]. A recent report on symptoms of psychotic disorders in the BIF group showed that while community-dwelling respondents have twice the rates of psychosis compared to peers without BIF, they are also more likely to report auditory hallucinations but not delusions and that depression is a contributor in the pathway to developing and expressing those symptoms [55].

The most recent Adult Psychiatric Morbidity Survey [56] confirms previous findings and shows that all disorders are increased in the BIF groups compared to their peers of average intelligence. Details are shown in Table 4.2.

One potential reason as to why rates of emotional disorders are higher in this population is the possibility of being chronically frustrated of not meeting expectations set by family, education or the wider society [57]. In adolescents with either BIF or ID, emotional–behavioural difficulties are reported to be worse than for those with neither disability nor BIF [58]. Feelings of unworthiness may be compounded by not being eligible for supports due to arbitrary service cut-offs.

Recently, the relationship between BIF and adult psychiatric morbidity has been found to be partially mediated by exposure to Adverse Childhood Experiences (ACEs) [59].

Persons with BIF show higher rates of all mental disorders, especially depressive disorders, than their peers of average intelligence.

4.5 Social and Legal Aspects of BIF

Most individuals with BIF lead fulfilling lives. However, many face a number of difficulties in lack of prospects or close relationships and may feel that they have not reached their potential. Greenspan [4] argues that BIF is seen "as the poverty disorder" given that many of the individuals labelled as having BIF may also belong to lower socioeconomic and minority ethnic groups which are already vulnerable and discriminated against.

As many individuals will not be detected as suffering from BIF even during their school years, they may end up leaving the education system without skills that will lead to unemployment and possibly being unable to live independently. Many will have supportive families and may be employed in menial jobs without reasonable adjustments in the workplace and may not even know of their rights given that there is no specific statement to mandate input by social or healthcare professionals. This is a significant gap that does not afford people with BIF the same rights as those with disabilities and therefore, may be unable to access services.

Offenders with cognitive limitations should be supported by "appropriate adults". An appropriate adult in English law is a parent, guardian or social worker; or if no person matching this is available, any responsible person over 18. The term was introduced as part of the policing reforms in the Police and Criminal Evidence Act 1984 and applies in England and Wales [60].

People with cognitive limitations are often impulsive and lack social judgement which may also contribute to their criminal behaviour. Rather worryingly, in the USA, given the outlawed application of the death penalty to individuals with intellectual disability, inmates who have committed capital offences may be diagnosed as having BIF so the death penalty could be imposed upon them.

Table 4.2 Psychiatric morbidity by IQ range in a sample of community living adults in England

Predicted verbal IQ [a]						
Mental health conditions [b]	**70**	**71–79**	**80–89**	**90–109**	**110+**	**All**

4.6 Organisational Issues and Service Delivery

Research has shown that people with BIF have a range of difficulties in adaptive functioning and undoubtedly suffer from mental ill-health including a number of mental disorders.

Findings from epidemiological and clinical studies indicate that they receive more medication, have less access to psychological therapies and self-report poorer health [12]. These issues seem to stem from inadequacy of mental health services, which lack the expertise to handle these patients, fail to meet their mental health needs and consequent development of more complex psycho-physical health problems [46].

Study of BIF can support the adaptation or development of treatments to address some of those conditions, for example,

trained staff in mental health services or primary care will ensure that at least BIF status is ascertained and appropriate pathways for assessment, treatment and management are formulated. Public Health initiatives can be inclusive of this population group and ensure that reasonable adjustments are adopted by generic services to improve healthcare and help-seeking behaviour. Researchers in the Netherlands have focused on interventions for substance misuse in this population; Van Duijvenbode and collaborators [61] investigated the standardisation of pictorial materials to address cognitive biases in adults with BIF and alcohol misuse. Van Duijvenbode and colleagues [62] have also examined tests that can be used in clinical practice to aid the detection of cognitive biases in young people and adults with BIF who misuse substances; they suggest that word association tasks are better at identifying high-risk conditions under which alcohol/other substances maybe used.

Education authorities also have a role to play in ensuring that children who are poor academic performers are referred for further assessment and are given the tools to manage their limitations with additional supports. Teachers can also work with families of BIF children to equip parents to support them effectively and seek the right support for the child.

A BIF consensus group from Catalonia, Spain, has posed a number of objectives in improving the lives of people with BIF [7]. This initiative was followed by the creation of an international group of experts (The Borderline Intellectual Functioning Consensus Group) including members of the World Psychiatric Association Section on Intellectual Disability and the Fogarty/NIMH NCD-LIFESPAN Programme, which produced a declaration, named "Girona declaration", with calls for action to promote policies and practices for improving health and quality of life of people with this condition [63].

Those include improvements in early detection based on awareness of warning signs and using appropriate psychometric instruments as well as measures of adaptive functioning in assessment. This process should be instigated as early as possible and no later than the 6 years of life to ensure that early intervention is implemented. Confirming that the individual has a diagnosis of BIF will enable him/her to seek help and be made aware of any rights under disability legislation. Good practice dictates that individualised intervention plans are developed early on with the input from the individual and his/her family carers. The plan should detail any health monitoring required and other provisions to be made regarding periods of transition, reaching adulthood and finding suitable employment.

Box 4.1 Types of Instruments Used in Assessments of Individuals Suspected as Having BIF

Screening assessment with KBIT-2 (Kaufman Brief Intelligence Test-second edition [65]; quick to carry out in routine care; children).

Full psychometric assessment (any established measure of cognitive functioning standardised for the population, e.g. WAIS - Wechsler Adult Intelligence Scale [66]; WISH - Wechsler Intelligence Scale for Children) [67].

Functional assessment and adaptive behaviour (any measure that can provide standardised assessment of abilities and needs, e.g. the Camberwell Assessment of Need for Adults with Developmental and Intellectual Disabilities; CANDID) [68].

Mental ill-health (any validated scales of psychopathology, e.g. Developmental Behaviour Checklist (DBC) [69]-children; Psychiatric Assessment Schedule for Adults with Developmental Disabilities (PAS-ADD)-checklist or mini versions) [70].

Adapted from Recommendations for caring for people with borderline intellectual functioning, Generalitat de Catalunya [64].

As has been mentioned already in the chapter, many of the individuals with BIF face service gaps as well as being turned down by services as they are often found to not be eligible for specialist ID community services but also find generic services difficult to navigate.

Patients with BIF are reported to be underserved by mental health programmes, which are unable to fulfil their mental health needs, leading to the emergence of more complex psycho-physical health issues.

4.7 Concluding Considerations

BIF as a diagnostic entity is highly contested, and current classification approaches are unsatisfactory as they tend to be too narrow in being based on IQ in the main without taking into consideration adaptive functioning. Individuals with BIF across the lifespan have a number of neurocognitive deficits [71] and are likely to also suffer from significant physical and mental health comorbidities for which they receive little targeted support. The mediating risks for further mental ill-health span the environmental and genetic spectrum, which could be the focus of novel research to better understand the biological substrate of intelligence and adaptive functioning but also how education and public (mental) health policies can support disadvantaged communities and children born within those households. BIF also raises important ethical dilemmas in the practice of – dare we say – medicine where forensic aspects are evident, and therefore it merits an overhaul of current conceptual frameworks given that individual lives are at stake.

Tip

The definition of BIF as well as its position within classification systems should be given further thought. A well-defined classification will help patients with BIF be identified more easily and gain access to mental health services, bridging the current gap between high prevalence and low recognition.

Future research and practice should focus more on the mediating risk of BIF for mental ill-health, especially in terms of environmental and genetic factors.

Special attention should also be given to the way through which education, social and mental health policies can adequately support persons with BIF.

Key Points

- There are significant issues in the definition of borderline intellectual functioning which may add to the difficulty of patients accessing support.
- There is little awareness of the complex needs of people with BIF across the lifespan.
- People with BIF have several mental health comorbidities.
- Individuals often fall through services due to artificial constructs about upper IQ limits denoting eligibility for services.

Acknowledgements The content of the chapter has been shaped by discussions developed during the first meeting of the BIF Consensus Group in Girona, Spain 2017 sponsored by the Institut d'Assistència Sanitària, the Government of Catalunya (R Novell, L Verges, J. Cid), and co-sponsored by the NCD-Lifespan (TW98045) and Global RD0C (TW009680) Fogarty/NIMH grants at the Boston Children's Hospital, Harvard Medical School (K. Munir), and the Mental Health Policy Unit, the Centre for Disability Research and Policy Faculty of Health Sciences, University of Sydney (L. Salvador-Carulla, E. Emerson).

Learning Objectives

The primary objective of this chapter is to provide an overview of the peculiarities of presentation of psychopathological symptoms and syndromes in persons with intellectual disability (ID) and/or low-functioning autism spectrum disorder (LF-ASD) as well as the factors that impact on the diagnostic process. Adaptations of ICD and DSM diagnostic criteria to ID/LF-ASD are described. The chapter also provides indication on how to carry out a psychopathological evaluation in an appropriate setting.

5.1 Introduction

Why do we want to conduct mental health assessments? This might seem an obvious question, but in fact the answer is not at all straightforward. In clinical terms, we presumably wish to conduct an assessment in order to help someone, but this is a broad concept which could include multiple different approaches. Making a precise diagnosis can suggest we are getting closer to understanding the person's problems, but this may not necessarily be the case. For instance, there are probably at least 200 different psychiatric diagnoses, but only a small number of possible treatments.

Consider another question: why do people get mentally ill? We can identify at least four fundamental possible reasons:

- The person's biological/physical status.
- Incongruence between the person's hopes, dreams and aspirations, and the realities of their life.
- Psychodynamic issues: bonding, attachment and the complex development of the person's internal world that determines their interactions and relationships for the rest of their life.
- The environments and ecologies in which they live.

Each of these fundamental causes has particular issues for people with ID. Most people with ID have physical issues of one kind or another, including genetic problems, brain damage, hormone imbalances, etc.

The incongruence between a person's hopes and aspirations and the reality of their lives is probably as great in people with ID as any other sector of the population. One need only reflects on the number of people with ID who have seen their brothers and sisters grow up, get boyfriends and girlfriends, good jobs and become independent. Compare that with the lives of most people with ID.

In psychodynamic terms, the development of an individual is an immensely complex process. The relationship between a child and its parents starts even before the child is born; in the later stages of pregnancy, the foetus can hear what is going on, as well as having the other sensory modalities operating. Once the child has been born, the process of bonding is crucial to successful development. Beyond this, the child develops a mental world that is partly a response to do things they experience. Throughout this whole process, it is clear that the presence of ID will have a fundamental impact.

The ecologies of people with ID are typically very limited compared with members of the general population. Most of us have got a wide range of ecological supports that protect us against mental illness. These typically include parents who care for us, partners, friends, meaningful occupation that gives us a sense of self-esteem, and good health. Crucially, our ecologies include a wide range of problem-solving skills that enable us to seek help, and also to adapt our lives to fit our capabilities. Compare this to the ecology of a typical person with ID, who probably has a very small social network, very few opportunities for self-esteem and autonomy and possibly poor physical health. A range of problem-solving skills is typically very impoverished.

5.2 Developing Assessment Protocols

What do these four fundamental dimensions tell us about mental health assessment? Firstly, it will never be possible to find physical

reasons for every mental health problem, simply because they are not entirely generated by physical reasons. Secondly, we need to think carefully about our models of mental health assessment, and what we would like them to achieve. First of all, what should be the focus of our assessment? It is worth noting that we typically have very different emphasis on the assessment of children compared with that of adults. If the patient is a child, it is very often the case that they have been referred because of management problems. One of the first questions that is often asked is whether there are problems in the family. In other words, the context within which the child lives is considered to be a primary focus for evaluation. By the time a person has reached adulthood, it is more likely that a practitioner will say 'he has got agoraphobia or 'she has got a psychotic disorder'. In other words, the perceived locus of the problem has moved from the ecology to some kind of internal pathological state. Logically, there seems no reason for making this shift. Rather it would seem appropriate to view all mental health disorders as probably having contributions from multiple dimensions. Sometimes, the influence of the environment, for example, problems of housing, income, physical health and social disadvantage, can outweigh the impact of any physical causes.

What this means in practical terms is that we need always to assess these four fundamental dimensions whenever considering the mental health needs of an individual. We often talk about multi-disciplinary assessment, but this may actually mean that different professionals continue to work within their own perspectives, rather than coming together around a common framework. It is the latter approach that hold out greater promise for understanding people's needs.

5.3 Differences from the General Population

In persons with ID, especially in the lower part of the severity range and/or LF-ASD the presentation of psychopathological symptoms and syndromes can considerably vary from that of the general population for a number of reasons, including cognitive and communicative impairments, developmental peculiarities and neuroautonomic vulnerability. Also many factors related to carers' and clinicians' consideration of the psychic suffering of these persons can impact on the definition and the identification of psychiatric disorders (PD).

5.4 Cultural Factors

Many clinicians believe that the structural and functional alterations of the central nervous system, detected or hypothesized in many forms of ID and LF-ASD, do not allow the development of a psychic suffering similar to that described by individuals of the general population and upon which the current psychopathological semeiology has been developed. There is, however, no current evidence to support this. Other clinicians and researchers argue that a further problem in the conceptualization of PD in people with ID and LF-ASD consists of the difficulty of ascertaining the impairment of functioning and the degree of subjective distress that they determine, which are fundamental for defining a psychiatric disorder, since in their absence no set of symptoms would have clinical significance. In ID and LF-ASD, these aspects are often already present at a high level for the developmental condition and may impede to identify any increase due to co-occurrent PD. In particular, subjective distress is often higher than in the general population due to the several psychological and relational factors, such as reduced opportunities for participation in community life, greater exposure to traumatic experiences or lower coping skills [1, 2].

This difficulty of distinguishing those manifestations that are a function of the ID or LF-ASD, and those related to additional PD, has been called 'diagnostic over-shadowing' [1] and refers not only to the impairment of functioning and to the subjective distress but also to psychopathological symptoms and the way they cluster into syndromes. A part of such a shadowing seems to be linked to

the above-mentioned clinicians' viewpoint, that severe neurodevelopmental disorders do not allow any further psychic suffering, which depends in turn on the level of specific knowledge and experience in the field. The two pivotal experiments in this regard are those of Reiss and collaborators, in which they showed that groups of randomly selected clinicians tended to formulate fewer psychiatric diagnoses in persons who were known to have an ID compared to those who were known to have IQ within the normal range [3]. Psychiatrists who have not received specific training in ID and LF-ASD also tend to make more diagnosis of psychotic disorder and less diagnosis of mood disorders or anxiety disorders compared to colleagues with higher specific knowledge [4–6].

5.5 Factors Linked to Cognitive and Developmental Peculiarities

In people with ID and/or LF-ASD, the psychiatric symptomatology can be strongly altered by the cognitive, communicative and behavioural characteristics resulting from these conditions, which can make it difficult to disentangle ID from psychiatric problems [7–9]. Sometimes even the nuclear elements of some syndromes, such as anhedonia or delirium, are not identifiable [10], especially in people with pre-verbal communication. Symptoms related to subjective experience are expressed as alterations in basic behaviours or behaviours usually associated with individual well-being [1, 11, 12]. These alterations can be both qualitative and quantitative; for the latter, the expression 'baseline exaggeration' has been proposed [1]. Behavioural problems that already exist at a low rate and low intensity may increase dramatically when a person has stress or mental ill-health.

Other factors that increase the difficulty in the diagnostic process are 'developmental inappropriateness', that is, the mismatch between the level of individual development expected for the chronological age and the level of actual individual development [13]; 'intellectual distortion', which refers to the conditioning that cognitive difficulties may have in understanding and communicating one's own experiences [1, 11, 14, 15]; and 'cognitive disintegration' related to excessively concrete or immature way of coping with emotional stress, as well as cognitive impediment to recognize one's own emotional states [1]. Even the peculiarities in interpersonal, cultural and environmental influences can have a significant impact on the presentation of symptoms, which is called 'psychosocial masking' [1].

Also, neurovegetative vulnerability is common among persons with ID and LF-ASD, it consists of a strong tendency to manifest psychic suffering with dystonias of the autonomic nervous system, somatic symptoms, organic dysfunctions or changes in circadian rhythms [11].

In addition to the aspects treated so far, the identification of psychopathological symptoms is also complicated by problems in communication. As mentioned above, people with ID and/or LF-ASD often have poor verbal expression skills, severe difficulties in understanding what they are experiencing, and a lack of problem-solving skills that could enable them to seek help. Thus, the possibility that they may describe their psychological distress and ask for the necessary treatment is very low.

Even those who are verbally competent and can express their own thoughts and emotions, such as those with mild ID or borderline intellectual functioning, may present many limitations in referring psychopathological symptoms to a clinician. In fact, they can be susceptible, suggestible, prone to acquiescence, they can have a cloak of competence or difficulty in describing lived experience due to attention deficits or space-time disorientation (see also paragraph 5.5) (■ Table 5.1).

In persons with ID and/or LF-ASD, the presentation of psychopathological symptoms and syndromes can considerably vary from that of the general population, for a number of reasons, such as cultural factors, developmental peculiarities and communicative impairments.

Table 5.1 Factors affecting the presentation of psychopathological symptoms in persons with ID and/or LF-ASD

Intellectual distortion	Level of cognitive, communicative, physical and social functioning
Cloak of competence	Problems with self-acceptance
Acquiescence	Problems with being interviewed and receiving questions
Developmental inappropriateness	Individual developmental level
Psychosocial masking	Interpersonal, cultural and environmental influences
Diagnostic overshadowing	Distinction between psychopathological symptoms and expressions of the neurodevelopmental disorder
Atypical or masked presentation	Aggressive behaviour, screams, maladaptive behaviours, etc.
Neurovegetative vulnerability	Somatic symptoms, changes in circadian rhythm and dystonias of the autonomic nervous system
Cognitive disintegration	Coping impairment, low stress threshold and difficulties in recognizing one's own emotional states

5.6 Behavioural Equivalence of Psychopathological Symptoms

In people with ID and/or LF-ASD, problem behaviours (PB) represent one of the factors with the greatest negative impact on the implementation of rehabilitative interventions, on the management of services' costs and on the quality of life of the disabled person and his family [16]. The term PB refer to culturally abnormal behaviours of intensity, frequency and duration such as to put at risk the safety of the person acting on them or others, or behaviour that severely limits or prevents access to the community's ordinary services. The most frequent PB are physical or verbal aggression towards self, other persons or objects, tantrum, escape, oppositional, provocative or impulsive behaviour and screams.

The data in the scientific literature indicate that PB are very frequent in people with ID and/or LF-ASD, even if findings of different studies are extremely variable due to relevant limits and methodological differences, such as inclusion and exclusion criteria, sample characteristics, time interval and evaluation procedures. For example, the reported prevalence of self-injurious behaviour ranges from 1.7% [17] to 41.2% [18], and that of aggression towards others from 7% [19] to 51.8% [20]. Some of the largest studies in this area found that about 25% of people with ID have at least one problem behaviour, 5% show self-injury and 10% show physical outwardly directed aggression, the latter further divided into aggression towards people (6.5%) and objects (3.5%). The verbal aggression is instead acted by 7.5% [21–23]. When considered as a psychopathological category in persons with severe and profound ID, PB account for the 75% of all the diagnoses [24].

The persistence over time of PB also varies consistently in different epidemiological studies. For self-injurious behaviour, in particular, the range of remission rate is very wide, between 3.7% and 96% [25, 26]. However, the surveys conducted at precise time intervals agree on very low remission rates: 79% of PB in general and 65% of stereotypies are still present after 10 years from the onset [25], self-injury disappears only in 38% of cases after 2 years from onset [20] and in 29% after 8 years [17] and outwardly directed aggressive behaviour disappears after 2 years only in 27% [23] and in 30% after 11 years [27]. For many individuals, PB onset in childhood and persist until middle age [28].

It is often difficult to determine whether PB are expression of physical pain, organic problems, drugs, psychological, environmental, socio-relational factors or whether they represent psychiatric symptoms, or even a combination of some of these aspects. The same behaviour can be interpreted in a very different way by the various professionals, even within the same multidisciplinary team,

with consequences that are sometimes relevant for the interventions.

Some PB are very frequent in certain genetic syndromes, such as self-mutilation in Lesch-Nyhan syndrome, hyperphagia in Prader-Willy, introduction of objects into the body orifices in Smith-Magenis, hand rubbing in Rett syndrome or hyperactivity in Fragile X. In these cases, PB are called behavioural phenotypes [29].

Numerous studies have shown a relationship between PB and PD [30–35], especially in persons with low functioning and adaptive skills [31]. Some PB have been identified as symptoms, or groups of symptoms, specific to some PD, taking the name of 'behavioural equivalents' (BE); they are characteristic for onset, development, maintenance and extinction, especially with respect to other concurrent possible symptoms of a PD [36–38]. Other studies have revealed no evidence regarding the possibility that PB can be considered as BE of an underlying psychiatric disorder [39, 40], determining a more aporetic position in a part of the scientific community, for which the PB would be an expression of non-specific emotional stress (see paragraph 5.4).

One of the most recent research in this field focused on the relationship between PB and symptoms of depression, as codified in the DC-LD (Diagnostic Criteria for Learning Disability) [41], and used statistical methods significantly superior to all those used in previous studies. Here, PB were found to be associated more with a dimension of general emotional dysregulation than with a dimension of depression [42]. An in-depth analysis of this research shows that its main value does not concern the level of correspondence between behaviours and symptoms, but the way through which clinical data have to be detected and interpreted in people with ID and/or LF-ASD. A first indication of great utility is the need for specific adaptations for each individual based on the various characteristics, cognitive, communicative, sensorial, adaptive and physical; a second indication is that a dimensional symptomatological model can have a higher predictive validity than a categorical one; a third indication confirms what has already been mentioned about the importance of performing a careful evaluation of the onset, course and above all the co-presence of other symptoms, for every possible BE.

Some behaviours, especially problem behaviours, have been identified as symptoms specific to some psychiatric disorders (PD), taking the name of 'behavioural equivalents' (BE). These BE are characteristic for onset, development, maintenance, extinction and relationship with other symptoms.

5.7 Presentation of Symptoms and Diagnostic Criteria

The complexity and difficulty of the psychopathological evaluation in people with ID and/or LF-ASD also depend on the impossibility of using the diagnostic criteria that define the different psychiatric syndromes in the general population, such as those in the Diagnostic and Statistic Manual of Mental Disorders (DSM) [43] or in the International Classification of Diseases (ICD) [38, 44, 45]. Some authors have suggested that these criteria can be adopted only in case of very mild ID [46], while their validity falls for more severe forms [1, 47]. The reason for this inapplicability is their prevalent reference to the patient's reports, which pre-supposes good communication skills and, albeit to a lesser extent, awareness of intrapsychic experiences. Psychiatric semeiology has always been concerned with the internal mechanisms and the way through which they are expressed, spontaneously or solicited.

As already mentioned, people with ID and LF-ASD often have great difficulties in communication and conceptualization, sometimes they are incapable. Therefore, the evaluation of their psychopathological suffering must be based on the direct observation of behaviours in the context of habitual life as well as on the descriptions made by third parties. Obviously, among the latter, the most relevant are those provided by family members and other persons more closely connected with the person under evaluation.

In addition to not being designed to refer primarily to behaviours and other observable aspects, the diagnostic criteria for the

general population present other important characteristics that make them difficult to use with people with ID/LF-ASD, such as the specifications of quality and duration of symptoms [48].

Some researchers have found that, in respect to schizophrenia, the only first rank symptom which can be detected with a good frequency is auditory hallucination, even in persons with more verbal skills [49]. Symptoms of mania or hypomania are more difficult to detect than depressive symptoms, and in some cases, the latter can mask the former, such as in the presence of irritability [50].

To solve these criticalities, some adaptations of the standard diagnostic criteria have been proposed, for both the DSM system and the ICD. The first attempt dates back to the late 1970s and concerns the Research Diagnostic Criteria (RDC) [51] in the area of schizophrenic spectrum disorders [52], but the most consistent implementations were made in the last 25 years. In the 1990s, an adaptation of the tenth version of the Diagnostic Criteria for Research of the World Health Organization was produced [53] (DCR-10 Modified), with recommendations for clinicians more detailed than those of the RDC but still limited to some major disturbances. The multi-axial approach of these criteria allowed to confirm the communicative and interventional importance of an organized collection of different types of information: acute PD, neurodevelopmental and personality disorders, physical disorders, psychosocial problems, environmental problems and global functioning. The most consistent adaptations for ID were implemented in the criteria for schizophrenia, other psychotic disorders and mood disorders [53, 54]. Interesting data on the presentation of bipolar disorder were produced by Sovner [55], Cain and collaborators [50], Szymanski and King [56], who found a high frequency of BE, such as aggression, self-injurious behaviour, provocation and intrusiveness.

In this period it was also found that psychiatric symptoms could present differently in the various levels of severity of ID. Using a checklist of 30 ICD-10 [45] symptoms associated with depressive disorder (Clinical Behavior Checklist for Persons with Intellectual Disabilities; CBCPID [57]), Marston and collaborators found that the only symptoms common to all people with ID likely to suffer from a depressive disorder were depressed mood and sleep disturbances, all the other symptoms appeared in an almost specific way in the different levels of severity [55, 57] (Table 5.2).

In 1999, the American Academy of Child and Adolescent Psychiatry produced a list of parameters for the adaptation of psychiatric diagnoses for people with ID [56].

As early as the mid-1990s, the scientific community of the field realized that the adaptations produced up to that time were too many and too different from one another to be able to advance knowledge on the presentation and the epidemiology of PD. In fact, the results of the various studies were strongly discordant and the criteria used to obtain them were difficult to compare. Thus, the creation of standard international ICD adaptations was encouraged. The first attempt in this direction was represented by the diagnostic

Table 5.2 Most common depressive symptoms in the different severity levels of ID

ID level	ICD-10 symptoms of depressive disorder
Mild	Crying frequently for no apparent reason
	Significant diurnal mood variation
	Lack of energy
	Loss of interest
	Low self-esteem
Moderate	Social withdrawal
	Self-injurious behaviour (medium intensity and severity)
	Weight loss
Severe and profound	Tendency to scream
	Aggression
	Self-injurious behaviour (high intensity and severity)

Adapted from Marston et al. [57, 55]

criteria Kettering/Leicester [58], for which a group of UK psychiatrists combined their extensive clinical experience with data from all the literature produced up to that point. These criteria showed a good face validity, that is, they were appropriate to the situation, the population and the subject of the investigation and were presented to the Royal College of Psychiatrists as a starting point for the production of that complete and articulated system that would come out 5 years later with the name of Diagnostic Criteria for Psychiatric Disorders for use with Adults with Learning Disabilities [41] (DC-LD).

The DC-LD included different adaptations for the different degrees of severity of ID and used a hierarchical approach in the interpretation of symptoms, so as to support the clinician in the semeiological evaluation of PB, with clear instructions on organic disorders and behavioural phenotypes. Some items were formulated so as to give space to the pathoplastic effect of most severe ID and many symptoms based on the patient's reports, and introspective skills were replaced with observable aspects [59]. Guilt feelings, feelings of unworthiness, loss of anticipation of future positive events or suicidal thoughts were removed in favour of the onset or the increase in maladaptive, self-injurious, withdrawn or oppositional behaviours and physical symptoms. Anhedonia, or the loss of interest and pleasure for most of the activities of daily life, was expressed as a clear reduction in participation in activities, personal skills, collaboration in self-care or an increase in phobic behaviour or seeking reassurance.

A few years before the release of the DC-LD, the Americans of the NADD (National Association for the Dually Diagnosed) have started a process of adaptation of the DSM-IV-TR [60] criteria, with the contribution of an international advisory board. The work was completed in 2007 and was called Diagnostic Manual – Intellectual Disability (DM-ID) [61]. The main authors called it a textbook for the diagnosis of mental disorders in people with ID. In fact, it included a wide introduction on the subject, a detailed description of all the main disorders of DSM-IV-TR and the peculiarities in persons with ID, a summary of the standard criteria and a detailed list of their adaptation to the various degrees of ID. Everything was supported by a careful review of the literature, with an indication of the level of evidence for each conclusion.

The DM-ID also offered easy-to-read tables and clear examples of how the criteria have to be interpreted.

Also, this manual, like the DC-LD, emphasized the need for change compared to what was normally followed in psychiatric semiotics for the general population. A particular recommendation concerned the psychopathological interpretation of the onset or intensification of PB such as aggression, self-injurious behaviour, destructive or severely disturbing behaviours, stereotypies and ritualistic behaviour.

The DM-ID was designed in accordance with an evolutionary perspective that is helping clinicians to identify PD in all ages of life in children as in elderlies, specifying each time the main peculiarities in the presentation of symptoms.

The DM-ID has already been adapted also to DSM-5 [43], with the name of DM-ID 2 [62], again with the participation of an international panel of experts in the field. This latest edition has further detailed the number of possible BE and observable symptoms, for the most severe degrees of ID and LF-ASD, both to improve diagnostic sensitivity and to develop research activity and discussion throughout the international scientific community. However, confirmations of validity and reliability from field trials are limited [63] and many of the symptom adaptations have been proposed as interpretative notes and not as definitive criteria.

The validity of diagnostic criteria refers to their ability to effectively define a given clinical condition, while reliability only indicates the degree to which different operators are able, using them, to formulate the same diagnosis. Validity does not imply reliability and vice versa. It is relatively easy to design a diagnostic system with high reliability, but it is much more difficult to give validity to the proposed diagnoses, especially with respect to ID and ASD, which represent groups of many different syndromes, each of them with

a probable specific way to experience mental suffering and to express it.

The first version of the DM-ID was subjected to a single field study involving 63 clinicians from 11 different countries and around 850 patients. The opinions of the clinicians were positive: 67.9% of those who completed the study indicated that the system was 'easy' or 'very easy' to use, 83.1% that it had allowed to achieve an appropriate diagnosis and 36.5% that this diagnosis was much more valid and precise than that which would have been obtained using DSM-IV-TR [60].

Compared to the previous systems, the DM-ID-2 [62] has substantially increased the reliability of psychiatric diagnoses in people with ID and LF-ASD, while its validity is only partially increased.

Some adaptations to ID/LF-ASD of the diagnostic criteria for the general population have been proposed for both the DSM and the ICD systems. The first attempt, called Research Diagnostic Criteria, dates back to the late 1970s, but the most comprehensive, the DM-ID-2, came out on 2016 with reference to the DSM-5.

5.8 Assessor, Informant and Setting

As mentioned earlier, the psychopathological evaluation of the person with ID and/or LF-ASD implies particular attention, adaptations and abilities. The most important ones related to the evaluation, the information sources and the setting are discussed here.

Assessor

The main difficulty that the assessor may encounter is the obtaining of information directly from the person with ID and/or ASD, who, as already described, may have limitations in their ability to provide information, as well as in understanding and communicating their own suffering. There are persons who neither speak nor understand verbal language; others who would be able to speak but refuse to do it with a stranger and do not do anything more than answering the questions with laconism, sometimes only 'yes' or 'no'; others who need time to answer the questions, sometimes quite a lot of time; others who hide the answers in a stream of stereotyped sentences; others who do not want to be touched or even get close; others who do not interact but are open to any type of manipulation; others who do not accept to maintain a position suitable for the interview; others who want to touch all the objects in the room; others who do not tolerate sensory stimuli that you barely perceive; and others who instead have serious hearing or visual problems.

The difficulties faced by clinicians when interviewing people with ID frequently leads either to a rejection of the case, or an almost total reliance on information from third parties. This can lead to major errors in the evaluation and diagnostic processes (Table 5.3).

It is very important to maintain a welcoming and reassuring attitude, especially in the early stages of the evaluation session. Too formal attitudes should be avoided. People with ASD stay calm and are more willing to cooperate when they are informed precisely about the length of the interview and about the distances (in meters or number of steps) between the room in which they are located and the

Table 5.3 Communication skills in persons with ID

Communication skill		ID level
Preverbal	The person has no cognitive ability to understand words. They can be helped to understand through combinations or sequences of stimuli, tone of voice, objects and images	Severe to profound
Nonverbal	The person has the ability to understand the words but not to use them to express themselves. It uses alternative communication methods, such as gestures or images	Moderate to severe
Verbal	The person has a more or less wide range of comprehension and word-use skills	Mild to moderate

stairs, the elevator, the exit of the building, their car or the bus stop, up to their home. Even the repetition of information often has an anxiolytic effect, especially for people with greater cognitive difficulties; in fact, they often search for it or induce it by asking the same questions for quite a lot of time.

The language has to be simple and much effort has to be made to avoid abstractions, inferences (such as 'what would you do if ...?'), ambiguous expressions, jargon and discrepancies between what is said and the tone of voice, as well as mimicry and gestures.

The assessor should give many examples. A great advantage could also be drawn from the use of expressions known to the person with ID/ASD and a style of making questions that implies the possibility to provide many possible answers.

Box 5.1 Common Causes of Behavioural Alterations in Persons with LF-ASD

- Confusion or fear caused by an extraordinary event or an unfamiliar situation
- Interference with daily routines or repetitive activities
- Difficulty or inability to understand explanations or instructions
- Lack of knowledge on how to behave to be appropriate
- Difficulty or inability to communicate needs and emotions
- Hypersensitivity
- Fear of specific situations or objects
- Pressure to perform tasks that are too difficult

For people with more pronounced linguistic difficulties, the use of images and symbols is quite useful. Also mimicry can help, but be sure to use gestures and actions that the person knows the meaning of.

In detecting the presence of symptoms through the interview, it is useful to consider that some persons with ID attempt to hide their disabilities and adopt a 'cloak of competence' [64], tend to be less forthcoming with respect to self-descriptions, and try to please the interviewer by answering falsely or in a manner that is inaccurate ('acquiescence bias'). Thus, too direct questions can easily condition the answer.

Communicating appropriately represents not only an advantage for the evaluation purposes and for any future therapeutic alliance but also a deontological duty and a legal obligation, aligned with the rights of the person with disability to receive medical acts appropriate to their

Box 5.2 Suggestions for Appropriate Communication

Verbal language

- Active listening
- Check if you understood correctly through frequent summaries of what you heard
- Use easy, straightforward language and short sentences
- Avoid jargon
- Avoid abstractions and complex concepts
- Avoid complex sentence constructions such as conditional tenses
- Articulate clearly with the right tone of voice
- Repeat and rephrase questions
- Check if the person understands
- Use open questions as far as possible

Non-verbal communication

- Look at the person you are communicating with (not your PC monitor or case notes)
- Be smiling and reassuring
- Use intonation, gesture, body language and posture to support the person in their expression
- Use pictorial and symbolized material (e.g. books beyond words series)
- Some people may use signs (individual or standard)
- If necessary, ask for high-tech communication devices, and specialist speech and language therapy support

condition and respectful of their dignity and autonomy (see art. 25 of the UN Convention on the Rights of Persons with Disabilities) [65].
There are some tools that can help the assessor to know the ways in which a non-verbal person with ID/LF-ASD usually expresses distress in response to different factors. One of these is the Disability Distress Assessment Tool (DisDAT) [66].

Being able to guide the informant to reflect on the symptomatology and on the occurrence of behavioural alterations is an operation that requires in-depth training, knowledge of interview techniques and familiarity with the compilation of assessment tools, as well as good interpersonal skills.

It is also necessary to consider the possible discordance between different evaluators, particularly frequent for professionals with different background, who did not receive specific training on mental health of neurodevelopmental disorders or on the use of psychometric tools.

Informant

Family members or other carers represent a valuable source of information in the diagnostic process, especially when the person with ID and/or ASD has serious communication limits or lack of language [67]. Parents and other close relatives can allow to understand how the person developed through their childhood, the adverse experiences he/she encountered, and the achievements and relationships that can have influenced most their current psychological set (see Box 5.3 on usefulness of developmental history). Sometimes, however, emotional involvement and negative attitudes towards assessment services, prejudices or lack of knowledge about co-occurrence of PD can limit the supply of help or even constitute a further obstacle to diagnosis [68, 69]. The false belief that all people with ID and/or ASD have unchangeable abnormal behaviours is widespread [7, 70], as well as the tendency to underestimate or deny the presence of psychiatric symptoms and additional mental health problems.

Healthcare assistants and other professional operators are often subjected to a rapid turnover and, therefore, have a limited time frame of knowledge of the behavioural repertories and relational attitudes of the person with ID/ASD. Thus, they can give wrong information or even be unable to report significant behavioural changes.

The need to obtain accurate information with respect to the entire lifespan requires in some cases the involvement of multiple sources of information.

The reliability of the assessments made through interviews with informants also varies according to the cultural level, the personological characteristics, the nature of the relationship with the person with ID, the level of emotional involvement and effective knowledge of the person under evaluation [71].

In order to maximize the validity of the data collected during the psychopathological evaluation, it is therefore advisable to involve various professionals as evaluators, as well as the participation of different informants. Multi-perspective interdisciplinary assessment, supported by an adequate psychodiagnostic tool, is particularly effective in identifying

Box 5.3 Usefulness of Developmental His tory

- Enables appropriate interpretation of complex epiphenomena with possible psychopathological nature
- Favours the understanding of the pathoplastic effect of ID/LF-ASD on psychopathological features
- Supports (through the identification of usual pattern of behaviours) the distinction between symptoms of mental ill-health from long-standing traits and personological characteristics
- In persons with ID, allows a differential/adjunctive diagnosis for other neurodevelopmental disorders, such as ASD or attention deficit hyperactivity disorder (ADHD)
- Reduces the likelihood of diagnostic overshadowing
- May contribute to understand the aetiology of PB (some behaviours are associated with a specific developmental phase)
- Plans of treatment/interventions/supports need to be designed in a way that is developmentally appropriate

qualitative or quantitative changes in basic behaviours and in determining their character of symptomatological equivalence [72].

Setting

The context of psychopathological evaluation also requires numerous special attention when dealing with a person with ID and/or LF-ASD. First of all, the maximum flexibility should be observed, both in the place, duration and modalities. People with ID and/or ASD are very sensitive to changes and may be frightened by a context that does not include anything familiar.

A standard room of an outpatient clinic can elicit emotional and behavioural alterations, making it very difficult to carry out the psychopathological assessment and increasing the risk of misdiagnosis. It is preferable that the evaluation is performed in one of the places usually attended by the person. If this is not possible, a cosy, silent room with limited sensory stimuli should be preferred. Computer monitors and other screens should be standby or turned off, the room lighting should be soft and the phone silenced, especially in front of persons with probable sense-perception alterations.

Environments that are too 'medicalized' can arouse fear or discomfort, so even when it is unavoidable to carry out the interview in a health clinic, it is better to free it as much as possible from equipment and technical instruments (e.g. syringes, needles, sphygmomanometers and phonendoscopes). For the same reason, it is advisable to avoid wearing a white coat or other typical medical clothing.

> Appropriate setting adaptation represents not only a clinical advantage but also a deontological duty and a legal obligation, aligned with the rights of the person with disability. This includes adequate consideration of family members.

5.9 Focusing on the Individual

Diagnosis and Need

Overall, we need to think carefully about why we are making a diagnosis and what we hope to achieve. One of the problems of diagnoses, particularly those that imply a lifelong condition, is that they tend to become labels attached to the individual. One of the authors of the present chapter (SM) has seen numerous examples where attempts to understand the patient's needs are channelled almost completely by the presence of a diagnosis that someone has made in the past. To illustrate this, one example used in training involves a person in his early 30s with a diagnosis of Asperger's disorder. Without giving specific details (this being a real case), trainees will typically interpret the patient's problems entirely in relation to his diagnosis, rather than the fact that he is now having to live alone, has no friends and has no partner. Even without the diagnosis, the behaviours described in the example could be entirely interpreted in terms of his life circumstances.

To illustrate this even more forcefully, consider two people with symptoms of major depression. Each of them has the same symptoms and severity but one has a biological tendency to get depressed, and this depressed mood has a corresponding impact on the people around them. The other person is depressed *because of* the circumstances in which they live. Each of these people gets the same diagnosis, but the formulation of their problem will be entirely different.

Focusing on the Positive

The above paragraph in no way seeks to minimize the importance of making diagnoses. Diagnoses are an important pathway for clinicians to understand the needs of patients and how they experience the world. They also give important information about the likely time course. At the same time, it can be seen that diagnoses should be one component of a wider investigation. Usually, these investigations tend to focus on the negative factors, for example, the persons symptoms, the impact on their life, the circumstances of their life, etc. At the same time, there is nothing to stop us from focusing on the positive aspects; indeed, this could be a good way to bring

Fig. 5.1 The THRIVE model

together mental health practitioners from a wide range of disciplines.

One thing we can all agree on as professionals is that we want people to *thrive*. We want them to have satisfaction in their lives, and gain the necessary support to help them do this if they have problems. The THRIVE framework (see Fig. 5.1) provides a way of helping people who get away from an 'escalator' model of increasing severity or complexity to one that focuses on a wish to build on individual and community strengths wherever possible. The model was developed by the Anna Freud National Centre for Children & Families and the Tavistock & Portman NHS Foundation Trust [73]. It was designed in the context of mental health services to parents and families, but is applicable to mental health services in general. It aims to talk about mental health and mental health support in a common language that everyone understands.

The framework is needs led. This means that mental health needs are defined by patients and families themselves, alongside professionals, through shared decision-making. Needs are not based on severity, diagnosis or healthcare pathways. The model has the advantage that it also recognizes there are groups of people within society who, though have mental health needs, may not be able to access them for one reason or another. 'Getting risk support' is in this category. Even if we are not in a position to provide services, we should make every effort to monitor the situation.

People with ID typically have multiple problems and needs, many of which are best provided through community resources. Diagnostic issues, seen in this perspective, can perhaps be viewed in a new light, and lead to new ways of working in close collaboration across multiple statutory and voluntary services, as well as with the families themselves.

Tip

Psychopathological evaluation often tends to focus only on negative factors, such as symptoms, their impact on functioning or negative life events. It should also include positive aspects and information from other mental health practitioners instead, in accordance with a person-centred interdisciplinary approach.

Key Points

- In persons with ID and/or LF-ASD, the presentation of psychopathological symptoms and syndromes can considerably vary from that of the general population.
- Factors with a major impact on the identification of psychiatric disorders are diagnostic overshadowing, intellectual distortion, cloak of competence, acquiescence, developmental inappropriateness or psychosocial masking.
- Some behaviours, especially problem behaviours, have been identified as symptoms specific to some psychiatric disorders, taking the name of 'behavioural equivalents'.
- Main adaptations to ID/LF-ASD of the diagnostic criteria for the general population are the DC-LD (Diagnostic Criteria for Psychiatric Disorders for use with Adults with Learning Disabilities) and the DM-ID 2 (Diagnostic Manual – Intellectual Disability, second edition), with reference to the ICD-10 and the DSM-5 respectively.
- Appropriate setting adaptation and adequate consideration of family members represent not only a clinical advantage but also a deontological duty and a legal obligation.

Learning Objectives

Descriptive evaluation of psychopathology and the present state examination represent fundamental phases of the psychiatric assessment of the person with ID and/or ASD, although scarce attention received to date in clinical practice and research. The present chapter describes the three parts into which the human psyche is traditionally divided (cognition, affection, and volition/conation) and addresses all the specific aspects and symptoms to be considered during the present state exam such as availability, accessibility, appearance, behavior and motor activity, speech, cognitive functions, consciousness, insight, judgment skills, orientation, attention, memory, sense perception, mood, anxiety, will, and thought.

Current and future clinical care of individuals with ID/ASD needs a substantial reevaluation and expansion of the psychopathological approach in order to improve professional knowledge, practice, and contact with patients' experience. It is to be hoped that the content of this chapter will be significantly extended and detailed in the forthcoming years.

6.1 Introduction

The term "psychopathology" derives from the Greek ψυχή (psyche) for "soul" or "mind," πάθος (pathos) for "suffering," and λόγος (logos) for "discourse," "reason," or "cause search," and is roughly translated into "the study of the sufferings of the soul." The term was coined by the German psychiatrist Hermann Emminghaus in 1878 [1], but it became a scientific discipline only in 1913, with the publication of Karl Jaspers' book "Allgemeine Psychopathologie," [2] who aimed at describing "the individual as a whole in his illness, as far as it is a mental and psychogenic illness" within the complexity of "the soul of the individual." [3] From that moment on psychopathology had increasingly become "the subject matter of psychiatry" [4] and clinical psychology, successfully guiding clinical and scientific progress.

Currently, the term "psychopathology" is employed in a number of different ways, which are commonly grouped into explanatory and descriptive. The former refers to assumed explanations according to theoretical constructs such as psychodynamics or cognitive behavioral models, while the latter consists only of descriptions of any individual behavior or experience which causes impairment, distress, or disability, with limited absent arguments of causation. In the present chapter, the term psychopathology is used in a descriptive way, with specific reference to defining, understanding, and categorizing symptoms as reported by people with intellectual disability (ID) and/or autism spectrum disorder (ASD) and observed through their behavior.

These groups of people have been excluded from research and clinical approaches based on descriptive psychopathology, mostly because they have been considered unable to provide data rich enough to reflect their experiences, or because of ethical reasons, such as being easily coerced or having low coping with distress factors associated with complex assessment and repeated interviews. Thus, authentic voices of persons with intellectual disabilities and autism are often unheard, their behaviors are inadequately observed, and accommodations to ensure their inclusion are rarely made [5–7]. In fact, descriptive psychopathology is important for persons with ID and ASD as it is to the general population, since it provides the fundamental elements for understanding their condition and suffering, as well as making a psychiatric diagnosis.

People with intellectual disability and/or autism spectrum disorder have been excluded from research and clinical approaches based on descriptive psychopathology, mostly because they have been considered unable to provide data rich enough to reflect their experiences, or because of ethical reasons, such as being easily coerced or having low coping with distress factors associated with complex assessment and repeated interviews.

6.2 General Psychopathology

For 250 years, many psychopathologists took for granted that the study of the mind could be divided into three parts: cognition, affection, and volition/conation [8]. The persistence of these areas of human psyche as major taxonomy references for mental phenomena suggests that there may be a natural utility of this scheme for clinical and research purposes, although various organizational models have been proposed [9], in which some of these areas, especially conation, have been merged or eliminated [10, 11].

6.2.1 Cognition

Traditionally, the term cognition refers to mental processes through which information from the environment is acquired and elaborated as knowledge. Cognition is said to include specific mental functions such as attention, memory, understanding of language, and intelligence. Intelligence is often further broken down into learning, reasoning, problem solving, and decision making.

Intelligence is often defined as the ability to solve problems, whether it is to understand how a toy works, to solve a question of trigonometry, or to guess stock market movements.

The Diagnostic and Statistical Manual's fifth edition of the American Psychiatric association (DSM-5) [12] diagnostic criteria for intellectual disability also includes impairments in reasoning, planning, abstract thinking, making judgments, and learning from both practical experience and from education. Intelligence is often expressed as the intelligence quotient or IQ that compares an individual's test score to the average score of a population. By convention, most, but not every, intelligence test converts raw scores to a distribution with a mean of 100 and a standard deviation of 15. Thus, IQs between 85 and 115 are classified as average. IQs above 130 are unusually high and IQs below 70 are unusually low. IQs between 70 and 85 are below average and sometimes regarded as borderline intellectual functioning. Finally, definitions of ID use IQ scores of below 70 combined with other diagnostic criteria, such as significant deficits in adaptive behavior, age of onset during the developmental period, typically defined as before 18–22 years, exclusion of other explanations, and professional judgment (see ▶ Chap. 1).

DSM-5 definition of adaptive behavior includes four domains: (a) communication, such as conveying information to others and understanding information from others; (b) social skills, such as interacting effectively with others, following social conventions, and responding to nonverbal cues from others; (c) personal independence at home is in the community, including bathing, doing the laundry, and using public transportation; and (d) school or work functioning, such as conforming to social standards, and learning and behaving independently at school or work. Adaptive behavior is usually assessed using appropriately normed psychometric instruments such as the *Vineland Adaptive Behavior Scales* [13] or the *Diagnostic Adaptive Behavior Scale* [14]. The nature of intelligence may be more complicated as it may be better to talk about a complex of correlated but distinct mental functions and abilities. The scientific community is still debating whether these mental functions depend on a single, general intellectual capacity, the so-called *g* for general intelligence as the psychologist Charles Spearman called it in the last century, or by distinguishable individual components or facets of intelligence, such as Howard Gardner's multiple intelligences (e.g., musical-rhythmic, visual-spatial, verbal-linguistic, logical-mathematical, bodily-kinesthetic, interpersonal, and intrapersonal intelligences) that are combined differently from person to person. Other models of intelligence have proposed a hierarchical structure with a generic ability at the apex of a pyramid and more specific skills being progressively differentiated in lower levels of the pyramid model. A common distinction is between crystallized and fluid intelligence. Crystalized intelligence refers to learned knowledge and skills which often increases with age, whereas fluid intelligence refers to the ability to perceive new relationships which is independent of prior experience and is reflected in global capacity to reason

and learn and declines with age. Some have suggested that the evaluation of intelligence according to a unitary model is insufficient. Rather it may be better to describe people's cognitive difficulties and specific disabilities and to understand how cognitive difficulties and specific disabilities are linked to psychopathology [15]. It may also be useful to describe the role of highly specific cognitive functions, such as the orientation of attention, the shift of attention, or some reductions in working memory [16, 17] (see ► Chap. 1).

Traditionally, the term cognition refers to mental processes through which information from the environment is acquired and elaborated as knowledge.

The current model of intelligence, based on IQ, is of limited utility for intellectual disability and autism spectrum disorders, given the wide range and variability of cognitive functions and adaptive capacities.

6.2.2 Affectivity/Affection

Affectivity is the area of human psyche related to the ability to experience moods and affects, such as feelings and emotions. The meaning of everyday terms such as sadness, irritation, joy, etc. may seem self-evident, whereas unusual experiences such as delusions, obsessions, and hallucinations require some careful definition. Yet, this is not the case as feelings and emotions are seemingly obscure and changeable events which are difficult to describe. Affectivity seems to be something that is difficult to define as most people report affect as an internal experience available only to the person who is experiencing it, although observable affective behavior can be identified in people with ID/ASD [18].

The terminology with which problematic feelings is dealt with is often ambiguous and controversial. For some authors feelings are simply excited states due to physiological changes in response to some event [19], while for others they are characterized by conscious perception [20]; affects and mood are terms sometimes used antithetically. For example, Taylor [21] stated that affect is "the emotional tone underlying each behavior," while others have opined that the mood is only a part of an affection of the individual, which is a more global function, when, for most authors, almost the inverse is true [19, 22]. For others, these terms are synonyms [23].

For some, emotions arise from archaic nervous center. Emotions apparently arise, grow, diminish, and disappear without active mental participation so that it may appear that there is a complete disconnection between affective and rational life. Emotions are essential for the adaptation of the organism as they provide the driving force for behavior [24].

An alternative, environmentalist view of emotions as the causes of behavior comes from Skinner [25], who considered emotions to be "an excellent example of the fictional causes to which we commonly attribute behavior" [25]. Rather, emotions refer to predispositions to behave in certain ways and to responses that covary which are under environmental control. Thus, the angry person, in response to their supervisor's criticism, turns red and sweats, takes on a facial expression of anger, slams doors, kicks the cat, and watches fights with unusual interest, suggesting that in response to criticism, observing harm holds this class of behavior together.

The emotional aspect of mental illness is characterized by diffuse and impalpable constellations of fleeting sensations and long-lasting dispositions that are difficult to describe. Contemporary research on emotions suffers from a serious conceptual confusion. The first thing to do is to get a hold on the terminology describing emotions [26]. Two concepts seem to dominate the current debate, namely feelings and emotions. *Feelings* are understood as perceptions of bodily changes and affective states such as, for example, discomfort, pleasure, pain, exaltedness, tiredness and sadness. *Emotions* are mostly considered as intentionally or rationally structured experiences such as anger with somebody, surprise at an event, love of someone, pride in one's own behavior, shame at being caught doing something wrong, guilt about one's previous actions, and so on.

We propose a framework for understanding emotional experience that is grounded in

two key points: (1) the definition of "emotion" as felt motivation to move, (2) the distinction between "affect" and "mood" according to their intentional structure. As for the first point, the word "emotion" derives from the Latin *ex movere*. Emotions are the *lived motivation for movement*. Emotions are kinetic, dynamic forces that drive us in our ongoing interactions with the environment. They are *functional* states which may produce movements and *motivational* conditions that project the person into the future providing a felt readiness for action. The connection between emotion and movement can be illustrated as follows. For instance, in sadness I flow downwards in a slow, sinking manner as things appear to be forlornly sinking and sagging downwards. In joy, I flow upwards in a radiated manner as things around me have an uplifted momentum. In retaliatory anger, I feel driven forward, violently attacking as the object of anger grows larger and occupies the foreground. In love, I flow forward in a gently binding way as the loved person flows forward, toward me. In pride, I go upwards in an inflated rising as things grow smaller compared to me. In humiliation, I flow downwards in a plummeting, quick, and violent drop as persons around me grow larger and look at me. In repugnance, I flow backwards as things flow forward toward me. In awe, I flow backwards and downwards in a shuddering manner as things flow forward and upwards, towering above me. In fear, I move backwards in a shrinking and cringing manner as things flow forward, toward me in a looming and menacing manner. In anxiety, I feel suspended in air in a quavering manner which is felt in a menacing manner. Thus, "emotion" is an umbrella term denoting the multifarious phenomena that make up our emotional experience.

As for the second point, at the opposite ends of our emotional experience we find two very different kinds of experiences: affects and moods. The basic difference lies in the fact that affects are focused and possess an apparently clear intentionality or a specific directedness, are experienced as externally motivated with relatively clear environmental determinants, and thus, are more determined and more articulated than moods. Moods, on the contrary, are characterized by a lack of a clear, if any, intentional structure or goal. They are unfocused, and thus, do not possess a specific directedness and *aboutness*.[1] They are felt as undetermined, and there are no specific identified causes for them. They are more indefinite and indeterminate than affects and are often inarticulate. Moods usually manifest themselves as prolonged constellations of feelings such as vague feelings that permeate the person's whole field of awareness. Examples of affects are fear, grief, joy, anger, and boredom. For example, one is fearful because of the imminent threat of negative social validation when one sees one's boss walking toward oneself with a stormy expression on her face. Examples of moods are anxiety, depression, euphoria, dysphoria, and tedium. For example, anxious mood is shown when over an extended period of time there is a sense of impending threat with no obvious source.

> Affectivity is the area of human psyche related to the ability to experience moods and affects, such as feelings and emotions. Emotions are functional states which may produce movements and motivational states that project a person into the future providing a felt readiness for action. Affects and moods are at the opposite ends of human emotional experience: affects are focused and possess an apparent clear intentionality or a specific directedness, while moods represent prolonged constellations of feelings that permeate a person's whole field of awareness.

6.2.3 Volition/Will

Whether volition can be considered an autonomous psychic function is still under discussion. Contemporary classifications of mental disorders do not include it, considering it a behavioral reduction of affectivity (impulse, desire, and motivation) and to a lesser extent

1 Aboutness is a term used in philosophy of mind, often considered synonymous with intentionality.

of cognition (intention, decision, choice, and control). Yet, until the nineteenth century, volition was the most commonly cited concept to explain the ability to initiate or inhibit behavior. It is still commonly used in the forensic field in the sense of personal responsibility for one's own actions and in social and health policies for people with ID and/or ASD in the sense of self-determination.

In everyday language, volition refers to the ability to choose and carry out behavior to achieve certain aims. Scharfetter [27] defined it as a completed, planned activity based on a motivation or a primary need such as hunger or thirst, or a secondary or acquired need like smoking, reading, etc. With the term "motivation," he referred to a state characterized by emotional and cognitive aspects, often linked to a need. In contrast, Jaspers [28] described volition/will as a function welded to the awareness of a goal, the means to achieve it, and its consequences. In this way, he blurred the boundaries between volition/will and judgment.

Various other terms have been used across time to represent alternative interpretations or specific aspect of volition, including intrinsic motivation, goal orientation, conation, self-direction, self-regulation, and self-determination. From the higher faculty that it was, volition/will has been transformed first into a dark ambiguous force including a multitude of drives, longings, and impulses, and then it has been wiped out and substituted in recent decades by notions such as those of "instinct," "drive," "motivation," and "ability to decide."

Whether Volition can be considered an autonomous psychic function is still under discussion. Contemporary classifications of mental disorders do not include it, considering it a behavioral reduction of affectivity and to a lesser extent of cognition. Various other terms have been used across time to represent alternative interpretations or specific aspect of volition, including intrinsic motivation, goal orientation, conation, self-direction, self-regulation, self-determination, and more recently, instinct, drive, motivation, and ability to decide.

6.3 Present State Examination

The present state examination (PSE) of the person with ID and/or ASD is a fundamental clinical moment in the direct evaluation of psychopathological symptoms. Without it, psychodiagnostic tests and questionnaires are of limited value. Unlike a typical conversation between two people, the PSE has specific techniques and rules, some of which apply to all clinical interviews and concern the professional-patient relationship, and others which are much more specific to the PSE. As already noted, people with ID and/or ASD have many relational, communicative, and expressive characteristics, which the interviewer must take into account. These aspects are treated in the ▶ Chap. 5, the one on assessment of psychopathology.

6.3.1 Availability

The PSE begins with the observation of the availability for evaluation. It is an aspect of primary importance, which is not limited to the reaction to the request for information and private experiences, but extends to the whole interpersonal contact that the person tends to take with the evaluator. In persons with ID and/or ASD, availability is often limited by the individual's cognitive and relational characteristics, but this may not effect more experienced and able clinicians' abilities to detect co-occurrence of psychopathology and ID/ASD. The clinician should record if the individual is sympathetic, cooperative, motivated, appropriate to the situation, and willingly collaborates or if the individual is passive, acquiescent, querulous, ironic, arrogant, oppositional, hostile, aggressive, demanding, or if she/he presents behavioral disturbances that make interaction very difficult.

6.3.2 Accessibility

Accessibility refers to the extent to which the persons under examination let the clinician access their intrapsychic experiences. Compared to availability to which it is often

mistakenly equated, accessibility represents a subsequent moment of the PSE. In fact, a patient may be available to a doctor's examination but unable to communicate his or her mental states. In people with ID and/or ASD, accessibility should be assessed in a less rigid way than in the general population and after collecting information on the usual communication attitude and skill from clinical records and habitual caregivers.

6.3.3 Appearance

This part of the PSE assesses the individual's overall exterior aspect. The individual may show a lively, flamboyant attire, typical of manic states, or be unkempt and poorly treated, as seen in schizophrenic psychoses or major depressive episodes. The interviewer must assess appearance in the light of the characteristics of the person with ID and/or ASD, with particular reference to the usual modes of expression, basic skills, life context, sociocultural background, and motor activity. In addition, the interviewer should be sensitive to whether the individual's appearance reflects caregivers' practices and standards, as much as those of the individual.

6.3.4 Behavior and Motor Activity

Persons with ID and/or ASD may feel more anxious than the general population, especially in unfamiliar contexts. During the PSE, anxiety can manifest itself in many forms of inappropriate or challenging behaviors such as nonresponsiveness, shyness, avoidance, opposition, hyperactivity, stereotypies, or aggression. These behaviors can also be the expression of psychopathological conditions, such as anxiety disorders, manic phases, or alcohol intoxication. In these cases, the interviewer may observe severe crisis of psychomotor agitation or destructive behavior toward everything. Conversely, during depressive episodes, the individual's behavior can be slower and more withdrawn than his/her usual behavior.

6.3.5 Speech

According to traditional psychopathology, the evaluation of speech substantially coincides with that of thought, since thoughts are usually expressed in words; however, since in fact the modes of expression of a thought are not limited to speech and speech cannot be considered a direct expression of thought, this is not necessarily true. Indeed, individuals with ID often have difficulties in expressing their thoughts through speech. When evaluating speech, the interviewer should note the form and content of the individual's speech and nonverbal communication. Evaluation of the form of speech should include both qualitative and quantitative characteristics such as the person being talkative, taciturn, or the speech being articulate, accelerated, mumbled, spontaneous, etc. The most common formal alterations of the speech are represented by poverty or wealth of speech, acceleration, slowing down, fragmentation, or lack of speech.

Speech acceleration is associated with an excess in quantity (logorrea), which may appear sometimes apparently unstoppable and sometimes musical, and may include play on word, puns, and jokes as is frequently seen in hypomania and mania, alcohol intoxication, and psychostimulant usage. In manic episodes, extremely high rates of speech may result in incomplete sentences, incomplete words, word repetition (palilalia), echolalia, repetitive sounds, and quickly switching from one topic to another. Sometimes incoherent speech results in so-called word salad most commonly in psychotic disorders, sometimes referred to as "schizophasia."

Marked increases in rhythm and content can be seen in people with pathological anxiety, although lack of speech, stuttering, and incomplete words may also occur. Individuals with ID/ASD and severe language difficulties including those who are nonverbal may show anxiety through intensification of stereotypic behavior, such as rocking, rubbing, and repetitive hand movements, or self-injurious behavior, such as hitting the face or other body parts, hair pulling (trichotilloma-

nia), or biting nails (onychophagia), cuticles, or the skin of the fingers (dermatophagia). Some individuals may speak coherently, but very slowly which may be an expression of psychomotor retardation as in depressive episodes, disorders of consciousness or memory, and organic brain syndromes.

6.3.6 Cognitive Functions

The assessment of cognitive functions is another key component of the PSE in people with ID or ASD, especially when no precise neuropsychological reports are available. Some researchers assert that cognitive functions can be evaluated through their practical, applicative expression, or executive functions. For example, Miyake et al. [29] have suggested a subdivision into three basic executive processes that, although they have some common elements, must be evaluated through the execution of differentiated tasks. These processes include: (a) *Shifting,* the ability to change, alternate behaviors based on the analysis of the results obtained or predictable; (b) *Updating,* the ability to monitor incoming information, their relevance to a current task, and to update the information content replacing the older or irrelevant information with a more recent relevant information; and (c) *Inhibition,* the ability to consciously inhibit excessive, automatic, or predominant responses.

6.3.6.1 Consciousness

The investigation of the state of consciousness focuses on the awareness of oneself and external, objective world. This is particularly difficult in people with ID/ASD with poor or absent verbal abilities. Consciousness can be altered in a quantitative sense, such as in the clouding of consciousness, as in the twilight state, where awareness is restricted to a limited amount of content, or in the dream-like states where the ability to distinguish between the imaginary and the real is compromised.

In certain psychiatric disorders, such as psychotic episodes due to medical illness or a substance, the alteration of consciousness may be particularly marked and be variously associated with anxiety, agitation, hallucinations, language alteration, insomnia, fever, loss of appetite, neurovegetative symptoms, suicidal thoughts, and impulse dyscontrol. Psychotic episodes due to medical illness or a substance is a rare complication of infectious diseases, intoxications, or brain injuries, although Theodor Hermann Meynert (1833–1892), the German psychiatrist who coined the term, related it to acute episodes of bipolar disorders, catatonic schizophrenia, and dissociative syndromes.

A severe loss of consciousness occurs in delirium, where it is expressed mainly as inability to maintain attention and disorganized thought. Persons with more severe ID/ASD can show significant worsening of their underlying attention difficulties and disorganized behavior. During delirium, disorientation can be observed with respect to places of everyday life, astonishment or perplexity can appear even for most familiar objects and people, and hyperresponsiveness to sensory stimuli can determine impulsive glances in the direction of the source where they came from. More rarely in dementia, there is hyporeactivity, reduced motor activity (hypokinesia), somnolence, and even stupor.

To assess the severity of the inability to maintain attention, the patient can be asked to perform a reordering of objects or data, which he would normally handle easily, for example, by placing the largest or smallest cubes or listing the months of year.

Delirium tremens, a particular form of dementia, can occur in chronic alcoholics after 2–3 days of sudden abstinence. It is characterized by the presence of motor alterations, especially tremor, and visual hallucinations which may sometimes include small animals or objects that move quickly in the room or on their body (microzoopsies). In rare cases of delirium tremens, hyperthermia or epileptic seizures may occur.

Other characteristic reductions of consciousness may occur in parasomnias, such behavioral disturbance of REM sleep, night terrors (*pavor nocturnus*), and somnambulism. Since consciousness is already reduced during sleep, it is difficult characterize them clearly. Parasomnias and sleep-related rhythmic

movement disorders are common in persons with ID/ASD [30–35] (see ▶ Chap. 26). The latter typically involve the head and neck (so-called *jactatio capitis nocturna*), occur at sleep onset, during the Non-REM sleep, and are sustained into light sleep.

6.3.6.2 Insight

The term "insight" refers to the degree of understanding of the impairment of one's psychic functioning and of the factors that determine it.

In persons with ID and/or ASD, the lack of insight in the psychiatric disorders that affect them must be carefully distinguished from underlying cognitive difficulty and atypicality in understanding and judging one's own psychic activity.

6.3.6.3 Judgment Skills

The term "judgment skills" refers to the ability to predict the consequences of one's behavior. This can include both practical and moral consequences. In ID/ASD, it is often reduced, especially due to the co-occurrence of a wide range of other mental disorders.

6.3.6.4 Orientation

The term "orientation" refers to the awareness of one's own being, time, and space. In other words, being oriented means knowing who we are, what day it is, the time of day, and where and in what situation we are at the moment. In persons with ID/ASD, orientation must be evaluated in proportion to premorbid functioning. Some authors also include derealization and depersonalization among the alterations of self-consciousness.

Derealization is an altered perception of the environment, in which the environment appears as unreal, dreamlike, foggy, blurred, or flattened. The person who experience derealization describes him/herself as being far away from the real situation or as seeing everything through a filter. Other persons can be perceived as automatons or robots or otherwise without affective coloring. Derealization can be distinguished from psychotic states for that the person maintains awareness of and insight into the strangeness of the experience. Persons with ID/ASD, who have adequate verbal competence, often use the expression "as if." This phenomenon can occur not only during acute episodes of anxiety and mood disorders, especially depressive ones, but also in those related to substance abuse.

In depersonalization, the feeling of detachment does not concern so much the surrounding environment as in derealization, but rather detachment from one's body or mental states. The person who experiences depersonalization describes herself as an external observer of their own existence. In some cases, these experiences intensify so much that the person believes they are on the verge of insanity. Depersonalization differs from disintegration of the self that occurs in psychotic disorders in that the capacity to discriminate between reality and unreality is maintained [36]. Depersonalization is often triggered by a traumatic or intensely stressful event. It is frequently found in posttraumatic stress disorder; anxiety disorders, particularly during panic attacks; major depressive disorder; substances-related disorders, such as excessive marijuana, cannabis, ketamine, and ecstasy use; seizures; and strokes [37]. Depersonalization seems to represent a negative prognostic factor in mood disorders, since it is often associated with comorbidity, chronicity, and lower response to pharmacological treatments [38]. In the DSM-5, the persistent presence of depersonalization and/or derealization represents the first criterion of a homonymous disorder, which is part of the meta-structure of dissociative disorders [12].

In people with ID/ASD, depersonalization and derealization can be expressed with an acute loss of cognitive abilities, especially attention skills, with chaotic, oppositional, and aggressive behaviors, or more rarely social withdrawal.

6.3.6.5 Attention

Attention is an important cognitive function and should be evaluated carefully. It serves to direct the conscience toward specific contents including the outside world, for example,

toward an image, sound, or the inner world, such as a thought, sensation, or memory. Alcoholic and other substance intoxication, psychosis, obsessive-compulsive disorder, and attention-deficit and hyperactivity disorder include a reduction in attention. Some authors use the term "hypoprosexia" to define an attention reduction associated with narrowing of interests, particularly frequent in depression and dementia. Attentional deficits are common in various syndromes including ID and/or ASD, so the identification of additional qualitative or quantitative dysfunctions due to co-occurrent psychiatric problems requires great experience and competence. Unfortunately, to date, knowledge on attention alterations in ID of different origin is limited, as well as their impact on "higher-order" executive functioning abilities. Deficits of disengaging and set shifting have been identified in Fragile-X syndrome, deficits of selective attention in Williams syndrome, and deficits of attention switching in Prader-Willi syndrome [39, 17].

In individuals with ASD, most frequently reported deficits refer to selective visual attention to social targets and selective visual tactile attention [40–42].

6.3.6.6 Memory

Memory can be evaluated informally with a series of simple questions. For example, for short-term memory, by asking the individual to recall information provided shortly before recall; or, for long-term memory, asking facts related to person history and checking confirmation with documents, family members, or staff.

Memory problems can be divided into qualitative and quantitative problems. Amnesia is obviously the most frequent quantitative memory problem, which can further be characterized by the type and chronology of lost memories. The term "total amnesia" is used when there apparently is no memory, even for one's own identity. The term "partial amnesia" is used when the loss of memory is restricted to only some aspects of their existence. Finally, the term "selective amnesia" is used to refer to specific aspects that are mutually linked. Selective amnesia is further divided into: (a) retrograde amnesia for data related to events preceding the onset of amnesia; (b) anterograde amnesia for data concerning events after the amnesia; (c) amnesic lacunae for data related to a specific period of time; and (d) sense-specific amnesia for data concerning a specific sense organ.

It is also useful to differentiate the causes and prognosis of amnesia. Thus, we speak of: (a) organic amnesia, when physical causes have been identified, such as cranial traumas, cerebral circulation disorders, metabolic disorders, and central nervous system degenerative processes; and (b) psychogenic amnesia in relation to psychological trauma or mental disorders, especially mental disorders such as dissociative, anxious, or depressive disorders. Transient amnesia refers to an amnesia which is limited in duration and may involve a return to premorbid functioning. It may occur in association with a moderate head injury. A stable amnesia occurs when there is no recovery of memory loss. Stable amnesias may occur in association with ischemic damage. Finally, progressive amnesia refers to a gradual worsening of memory. This may occur in some degenerative diseases.

Korsakoff's syndrome is associated with amnesia, impairment in learning, and confabulation (see below) and can occur in alcoholism, vitamin B1 deficiency, and some dementias.

The term hypomnesia refers to a reduction in the memory capacity which can be observed in depression, some psychoses, typical aging, and in some stress-related conditions, such as sleep deprivation. In contrast, the term hypermnesia indicates an increased ability to remember that hinders cognitive performance as it includes memories not useful for the task being performed. It is observed especially in manic excitement and in some twilight states.

The qualitative alterations of the memory are categorized as allomnesies and pseudomnesias. Allomnesias consist of distorted reenactments of actual memories while

pseudomnesias are memories of events that never have been experienced, but which are subjectively considered to be real.

Dejà-vu consists of the sensation of having already previously seen an object, person, or place and déjà-vécu refers to the feeling of having already lived a situation that is actually seen or experienced for the first time. In sporadic and transitory forms, they represent very frequent qualitative changes in memory, both in the general population and in people with ID, without a clear pathological significance. On the other hand, if they are persistent, they may be a symptom of psychiatric and neurological disorders, such as epilepsy, alcoholism, depersonalization, and derealization. In jamais-vu and jamais-vécu, the feeling is the opposite of the previous ones; that is to say, to live a completely new experience while in reality we are faced with a habitual, familiar situation. This is most often seen in temporal epilepsy, some anxiety disorders, and psychoses. These alterations can be confused with ecmnesia, where memories are experienced as actual experiences and more often occur in hallucinogens, intoxications, and in some forms of posttraumatic stress disorder. It is called cryptomnesia when a memory appears to the person as an original creation of his or her own mind.

Many qualitative alterations of memory must be distinguished from the fantastic pseudology (or mythomania or pathological lie), which may occur in people with mild-to-moderate ID and ASD. Here, the person refers as experiences things that he has invented from scratch or that he constantly changes to obtain a material or social advantage, often to increase his self-esteem or protect himself from others' negative judgment. In some cases, especially in older people, the fantastic pseudology requires a further effort to differentiate from confabulation, in which the production of fancy data serves to conceal a memory deficit.

People with ID/ASD may present with various memory problem, although it is challenging to assess as changes must be evaluated relative to baseline functioning, which may be difficult to assess formally. When assessing memory with people with ID/ASD, it is possible to resort to combinations of images or objects related to personal memory; for example, one can verify the ability to connect the image of a familiar car with that of its owner or usual driver. Such idiosyncratic assessments are very simple, but lack normative data and standardization; hence, standardized psychometric tests of intelligence and memory are helpful in determining if a person with ID/ASD has a specific memory problem. Many individuals with ID and ASD also show hypomnesia. This makes it more difficult to identify it as a symptom of a co-occurring psychiatric or neurological disorder.

Studies indicate that memory deficits are not homogeneous across all individuals with ID/ASD, but they are related to the specific etiology of ID and subgroups of ASD. That is, in Down syndrome a widespread deficit in the explicit domain of long-term memory (LTM) compared to the implicit one was demonstrated, while studies on Williams syndrome have showed more mixed results. There is evidence of opposite profiles for the implicit LTM, with individuals with Down syndrome relatively preserved and with Williams syndrome relatively impaired [43].

In persons with ASD memory deficits are related more to retrieval than to encoding and many individuals find it hard to remember information if they need a cognitive organizing strategy to aid recall or if they have to detect such an organizing element in the information itself [44, 45]. Other common memory reductions in ASD concern visuospatial and phonological working memory, especially when tasks impose heavier demands on working memory, attaching context to memories, and information that involves social aspects [46]. Problems with prospective memory, which is the ability to remember to carry out a planned intention at an appropriate moment in the future, can also represent a challenge for people with ASD in everyday life [47].

Some persons with ASD show specific memory skills that are much greater than the general population, as those with savantism, although their nature is still to be defined [48].

Memory problems can be divided into qualitative and quantitative. Amnesia is the most frequent quantitative problem, which can further be characterized by the type and chronology of lost memories. Qualitative alterations are categorized as allomnesies and pseudomnesias.

Differential patterns of memory deficits are documented across different etiological and clinical groups of individuals with ID and/or ASD.

6.3.7 Sense Perception

This expression refers to the neurological organization of sensory experience, that is, to the reaction to internal and external stimuli received by the sense organs. In order to transform them into perceptions, sensations must be integrated with a system of products of central neuropsychological activities, such as memory (e.g., past experiences), emotions (e.g., fear or interest), or volition (e.g., motivation).

Perceptual processing can change sensory information, for example, illusions are contrasting or undefined sensory stimuli which blend with perceptive patterns so tightly that it makes it impossible to distinguish the former from the latter. Illusions can involve all the senses, but the visual illusions are the most characteristic and well known. Pareidolia is the tendency to perceive familiar forms in disordered stimuli, such as seeing faces in the moon or animals in the clouds. This may be reduced in people with ASD, especially when related to social stimuli [49, 50].

The alterations of the sense perception of major clinical interest are hallucinations which are perceptions in absence of an object or an external stimulus to be perceived. They can occur for each of the sensory modalities, including visual, auditory, gustatory, olfactory, and tactile systems. Hallucinations may be coenaesthetic, enteroceptive, and proprioceptive. Coenaesthetic hallucinations are hallucinations related to one's body; they are neurologically and physically impossible, such as perceiving a scratching on the inside of one's skull. Enteroceptive hallucinations stimuli are hallucinations regarding stimuli from inside the body, such as proprioception to detect pressure and internal mechanical stimuli that assist in the correct performance of the neuromotor functions such as standing upright and coordination of movements. Auditory hallucinations are found in psychotic disorders, substance poisoning, and, less frequently, in bipolar and depressive disorders. Visual and olfactory hallucinations are more common in organic disorders.

Simple hallucinations relate to a single sensory modality and do not involve complex cognitive elaborations, for example, whistles, points or bright areolas, and flashes of light or color, whereas complex hallucinations involve more senses and integration by brain areas other than primary sensory ones, for example, seeing a lion and hearing and feeling it roar. In most cases, hallucinations are interpolated or inserted in the typical sense-perceptive context, but rarely involve changes in the whole perceptual field. The most frequent hallucinations are auditory, followed by visual hallucinations.

In people with ID/ASD, who have limited verbal communication skills, hallucinations may be indicated by significant changes in behavior. For example, a person with some visual hallucinations may continue to look at an area of the environment where there does not seem to be any relevant stimuli and another person with auditory hallucinations can show sudden communication gestures or plug their ears. A person with coenaesthetic hallucinations may appear strangely intent on removing something from their skin or inspecting a particular area of their body. But in people with ID, they often experience their own thoughts as real voices. The clinician has to distinguish whether the reported auditory hallucination is experienced by the patient as a real perception of the outside environment or if the patient experiences his/her own thoughts aloud. A list of observable aspects and behaviors with possible hallucinatory equivalents is reported in Table 6.1. These equivalents must be carefully distinguished from certain behaviors typical of ID/ASD, such as speaking in a stereotypical way, speaking to themselves, even asking questions and

Table 6.1 Examples of observable/behavioral equivalents of hallucinations in people with ID/low-functioning ASD

Hallucination (sensorial type)	Behavioral observable equivalents
Visual	Fix an area of the environment, in which there does not seem to be anything particularly to be seen (even considering any attention and special features) Suddenly turn to an area of the environment Nod Make gestures with the hands with apparent reactive or communicative value Move as if he were defending himself or fighting Move as if he were loving Cover the eyes with hands or various bandages Look bad or even angrily at people first appreciated or strangers Avoid or hide from family members or with whom he normally has a good relationship Inspect objects, food, or beverages with exaggerated and unusual intensity
Auditory	Nod Make gestures with the hands with apparent reactive or communicative value Suddenly turn to an area of the environment Cover the ears with hands or fingers, or cover them with various materials
Tactile	Rub or make gestures as if he wanted to take something off his skin
Olfactory	Smell objects, food, or drinks with exaggerated and unusual intensity Curl the nose and grimace as if he perceived unbearable odors Sniff the air as if to check for the presence of gas or other contaminants
Somatosensory Coenesthetic	Make gestures as if he wanted to take something off his body Wear heavy, close-fitting clothing or clothes with many layers of clothing (clothes are interpreted as containers to prevent the escape of parts of the body, perceived as unstable) Bandage the ankles or the wrists with various materials Wear hats, bandanas, or foulards, inadequate to the rest of clothing and context
Multisensorial	Move as if he were loving Move as if he were defending himself or fighting

giving answers or using unusual inflections and tone of voice, shouting or speaking with a loud voice, imitating others, or behaving in ways induced by others. Hallucinations must also be distinguished from hallucinosis, in which the awareness of sense perceptions is not shared by others. In most cases, they are simple changes often in the course of organic pathologies, such as intoxications, neoplasms of the encephalic trunk, angiopathy, cranial trauma, and epilepsy.

6.3.8 Mood

Mood alterations are present in many psychiatric disorders. For example, "low" mood or apathy (from Greek without pathos, i.e., feeling), that is, the lack of emotional resonance, is typical of major depression, but is also found in other disorders, including schizophrenic, bipolar, substance-related, neurocognitive, anxiety, and stress-related disorders. Periods of apathy may also occur in situations of extinction of adaptive behavior, such as losses related to depression, like unemployment, loss of family members and friends, and moving place of living or work. Irritability is sometimes defined as a proneness to anger [51] and excessive responsiveness to stimuli. It is more common in mania, premenstrual dysphoric disorder, borderline personality disorder, and some forms of depression. It is also observed in elevated or

expanded mood which characterizes the hypomanic and manic phases of bipolar disorders, but is also found in substance-related disorders, neurocognitive disorders, and pathological gambling.

A severely altered mood can also be expressed in patients with suicidal ideation and behavior, which are in fact frequently found in depressive and bipolar disorders. Suicidal thoughts and attempts may sometimes have a more complex relationship to psychopathological conditions, as demonstrated by the repeated association with delirium, neurocognitive, dramatic personality disorders, behavioral disturbances, and stress-related disorders. In schizophrenia, paradoxical affective responses may occur such as hilarity when listening to sad topics. In patients with ASD, empathy and emotional reciprocity are lacking (see ▶ Chap. 16). In some dissociative or conversion disorders, emotional detachment may occur, for example, a patient may talk about the severity of his/her own symptoms with absolute coldness (*belle indifférénce*).

During the PSE interview, mood may be observable through the individual's behavior, facial expressions, gestures, speed of movement, response latency to stimuli, and general reactivity to context. Emotional behavior during the PSE may differ in quantity, for example, as it is the case in reduced psychomotor activity, or be too intense. Emotional behavior may also differ in quality, for example, when the person shows detached or paradoxical emotions.

Mood alterations may occur in individuals with ID/ASD in whom it may often replace depressed affect. In the person with ID/ASD, mood changes can also be observed through striking variations in behavior, both in quantitative terms, as reduction or increase in their activities, and qualitative, as an appearance of aggressiveness toward others or to oneself, noncompliance, or provocation (see ◘ Table 6.2). A systematic description of the presentations of emotional changes related to psychiatric disorders in individuals with ID can be found in Vannucchi [52]. It should finally be noted that persons with ID/ASD, due to their insight and language problems, may have serious difficulties in distinguishing bodily feelings related to emotions from other bodily feelings, such as pain, in expressing their emotions, especially their moods, and focusing on the event or situation which has caused them. Sometimes observational measures of mood-related behavior may be helpful [18].

In individuals with ID/ASD, mood alterations may often replace depressed affect. Mood changes can be observed through striking variations in behavior, both in quantitative terms, as reduction or increase in their activities, and qualitative, as an appearance of aggressiveness toward others or to oneself, noncompliance, or provocation.

6.3.9 Anxiety

The term anxiety refers to an unpleasant mood, characterized by strong apprehension, due to uncertainty or expectation of something of great subjective importance which cannot be clearly focused. It is often related to physical or social threats or the possibility of such threats and is often highly adaptive in maintaining the integrity of the organism by avoiding or minimizing harm. In serious cases, it involves an overstimulation of the vegetative nervous system including tachycardia, thoracic constriction, rapid breathing, sweating, and abdominal spasms, which may also exacerbate the emotional response itself. Anxiety also disrupts ongoing adaptive behavior [53] and may imply maladaptive conducts like fight, flight, or freezing (see Kretschmer) [54], so that the anxious person may freeze, does not talks, and no longer engages in adaptive responses to threats such as effective avoidance of the feared stimuli.

Anxiety can also imply sensory-perceptual changes, such as impaired vision (reduced visual fields or objects appearing more distant than they actually are), a feeling of unreality, dying or going insane, and to cognitive problems, such as difficulty in concentration,

Table 6.2 Examples of observable/behavioral equivalents of mood changes in people with ID/low-functioning ASD

Mood alteration	Behavioral/observable equivalent
Deflection	Psychomotor slowdown Reduction of participation in activities or opposition Aggression, both physical and verbal, toward objects or other people Self-harming or self-mutilating behavior Reduction of resistance and/or frequency in carrying out usual activities Reduction of sexual activity or sexually oriented behavior Reduction of a range of emotional responses Pervasive tendency to cry
Elevation or expansion	Psychomotor agitation and/or restlessness Increase in stereotypies Self-harming or self-mutilating behavior Excessive search for interpersonal contact and communication Excessive commitment to activities or occupations Aggression, both physical and verbal, toward other people or objects Excessive increase in sexual activity or sexually oriented behavior Excessive self-esteem and/or behaviors sustained by the feeling of being capable of extraordinary or unrealistic performances Increase in phonation or speech
Irritability	Easy access to anger, even for stimuli and normally well-tolerated situations Aggression, both physical and verbal, toward objects or other people Self-harming or self-mutilating behavior Increase in stereotypies
Lability	Rapid changes in mime and gesture Rapid switches from laughing to crying or vice versa

Hurley [55]; Pary et al. [60]; Charlot et al. [61]; Vannucchi et al. [52]

memory, or hypervigilance. Pathological anxiety is a symptom of anxiety disorders such as panic disorder, agoraphobia, specific phobia, separation anxiety disorder, generalized anxiety disorder, and obsessive-compulsive disorders. It may also occur in delirium, intoxication or substance withdrawal, neurocognitive disorders, somatic symptoms disorder, psychotic disorders, body dysmorphophobia, and stress-related and mood disorders. Sometimes anxiety symptoms occur in response to concerns related to other psychiatric disorders.

In the PSE with individuals with ID/ASD, some anxiety disorders, such as simple phobias, are easily recognized. Other anxiety disorders, such as generalized anxiety disorder, may not be so readily apparent. Some have suggested that anxiety in individuals with ID/ASD may express itself in increased motor activity, intensification of stereotypies, or a tendency to cry [55].

6.3.10 Will

The alterations of the will can be quantitative, such as abulia, hyperbulia, and motor inertia, or may be qualitative like dysbulia, automatism, negativism, and impulse control. Abulia (from the Greek "without will") is expressed by the inability to make decisions independently, take initiative, or to initiate an action,

even if the action is trivial or knowing that it is necessary. Hyperbulia is the opposite of abulia. It manifests itself through an excess of decision-making and initiative, often with negative consequences.

Negativism consists of an energetic and persistent opposition to the movements that one wants to make (passive negativism) or in the execution of actions opposed to those actions that are required (active negativism). The term automatism means acts performed mechanically and without participation of will. Autonomous automatisms are automatic and determined by spontaneous activation of the motor centers. They are automatic but originally were voluntary, yet made subconscious by the great repetition. An example of autochthonous automatism is postepileptic automatisms, consisting of a repetition of complex actions following a seizure and of which the individual does not recall. Abulia is seen in major depressive episodes and some forms of psychoses. Hyperbulia is more common in manic and hypomanic episodes, but it can also occur in mixed-mood episodes and anxiety disorders, and may be associated with hyperkinesis. In some psychotic disorders like schizophrenia, abulia may present as catatonia.

Qualitative alterations in will are also found in disruptive behavior disorders, impulse control disorders, kleptomania, pyromania, antisocial and borderline personality disorders, and some forms of suggestibility, for example, in histrionic or dependent personality disorder, eating disorders, and addiction and substance disorders. Lack of will also characterizes disorders of craving (uncontrollable desire to consume a substance or to behave), loss of control, and underrating of consequences.

Alterations of will may occur in people with ID/ASD without being a symptom of an additional psychiatric disorder. This must, therefore, be carefully defined on the basis of changes from premorbid behavior.

Stereotypies are repetitive behaviors with no immediately apparent purpose. Examples include body rocking, head hitting, and hand flapping. Stereotypies often appear relatively invariant in form. At first glance, they are similar to other repetitive and unchanging behavior, such as compulsions and tics. Compulsions, however, differ in that they typically involve cognitive components, such as fear of contamination or disaster, and typical topographies include hand washing and checking. They mostly serve to get rid of anxiety in response to contamination or an intrusive thought. Whereas stereotypies appear in early development, including the development of typical children, compulsive behaviors rarely appear before the third or fourth year of life and tend to begin in teenage years.

Tics are usually sudden, rapid, ballistic movements and are often topographically simpler movements than stereotypes, although motorically more complex forms of tics exist. Tics usually affect facial muscles of the face (as in blinking, stretching of the mouth, and curling of the nose), vocal apparatus (as in coughing and making noises), and upper body skeletal muscles (shoulders and limbs) and sometimes the trunk. In DSM-5 [12], tic disorders are part of movement disorders together with the disturbance of coordination development and stereotyped movement disorder. Tourette syndrome is characterized by multiple, often more complex and energetic tics associated with the emission of inarticulate sounds, coprolalia (cursing), and behavioral and anxiety disorders. Tourette's syndrome may start as early as 5 years, although many individuals develop related symptoms earlier.

Stereotypies are common in individuals with ID/ASD, especially those with more severe ID. Some individuals with ID/ASD also show tics and Tourettes syndrome that appear broadly similar to these disorders in the general population. Relatively little has been published on this topic.

Alterations of will may occur in people with ID/ASD without being a symptom of an additional psychiatric disorder. This must, therefore, be carefully defined on the basis of changes from premorbid behavior.

6.3.11 Thought

Thought is defined as mental activity that allows us to evaluate reality and formulate judgments through processes of association, correlation, integration, abstraction, and symbolization. Traditionally, for the evaluation of thought, clinicians must refer to both form and content [56]. Quantitative alterations in thinking consist of acceleration and slowing down. Acceleration is characterized by the difficulty in focusing on content, superficial thinking connected with shifting from topic to topic, and consequently constructing associations based on uncommon or idiosyncratic features, sometimes resulting in so-called flight of ideas (idiorrhea). Flight of ideas can be so severe that the patient's spoken words cannot keep up with the rapidly shifting content of his/her thinking such that the outcome can be mutism or motor blocking, which is sometimes seen in very severe manic episodes. In slowing down, thought runs painfully slowly. The patient responds to questions with hesitation and delay (retarded thinking), often laconically. It may be seen in major depression, catatonic schizophrenia, and organic syndromes. A particular type of slowing down is viscous or ponderous thinking, which appears to contribute to alterations in the quality of thought. Viscous thinking is characterized by affirming a concept or acting behavior and failing to abandon it, despite the fact that the context requires it.

Qualitative alterations are much more complex than quantitative ones. Circumstantial thought is characterized by the indirect answers to questions or the conversation's goal. It may include the insertion of irrelevant content, long windedness, or prolixity. Perseveration consists of the continuous repetition of a content of thought, even when it is extraneous to the context. Perseveration can be difficult to distinguish from viscous thinking, which is characterized by the inability to give up a point of view. In perseveration, uncritical use of an idea prevails. Perseveration is often mistakenly equated to intrusive or obsessive thoughts, which instead differ for not being evoked, but rather arising against the person's will who indeed recognizes them as inappropriate.

Perseveration is common in individuals with ID/ASD, while viscosity is more frequent in those with co-occurrence of seizure epileptic disorders and obsessions in those with co-occurrence of obsessive-compulsive disorder.

Dissociation consists of a loss of logical links between individual ideas. It is seen in fragmented and bizarre speech. Frequent derivations of dissociation are represented by fusion, derailment and block (or barrage). Magical thinking consists in the attribution of cause-effect links to stimuli, objects, or situations that did not in fact cause something. In nonpathological forms, beliefs change in the face of criticism. It is widespread in the general population in the form of superstition. Pathological forms are associated with psychoses and obsessive-compulsive disorder with little insight (► Chap. 20).

Primitive or predicate thinking [57] is a form of unlogical thinking which results in illogical conclusions. It equates persons and objects merely on the basis of their predicates or functions, for example, a person who thinks of being a doctor only because he is wearing a white coat or because he is using a stethoscope.

Among the qualitative alterations of thought, qualitative alterations of abstraction deserve special consideration. Abstraction consists of the ability to pass from the particular to the general and to replace with symbols the concrete. It is considered by some to be a cognitive function. Many people with ASD are very concrete thinkers. They tend to misunderstand easily or not understand metaphors, analogies, euphemisms, double meanings, jokes, and puns, and references to emotions and feelings. To support them with this difficulty it may be useful to constantly refer to images, objects, or situations that they have combined with various abstractions. Problems with abstract thinking can occur in the case of co-occurrence of psychotic disorders, severe mood disorders, dementias, and brain lesions of the frontal areas or their connections with other cortical structures. To evaluate abstraction skills, you can informally

ask the individual with ID/ASD to sort sets of objects, blocks, tokens, etc., choosing those that "go well together" or "that have something in common." As a counter-test, you can then ask the person to group the same objects on the basis of a new criterion. The behavior manifested by people in these tests also provides information on the ability to identify different plausible criteria for a task and to flexibly change them.

The most serious and most striking alteration in the quality of thinking is seen in delusions, commonly defined as an error in belief that does not recede to criticism or to the contrary evidence of the facts. Jaspers [28] distinguished primary delusions (or delusions proper) from delusion-like ideas on the basis of their comprehensibility or incomprehensibility. Delusion proper is specific to schizophrenia patients and the most characteristic of them are delusional perceptions in which a person correctly perceives a given worldly object but realizes that the object is there to mean something personal, of extraordinary relevance to him, and typically disconnected from common sense. Jaspers identified the peculiarities of delusion proper in the certainty of the belief, the resistance to influence, and in the absurdity of its content. Delusion-like ideas are those in which any relationship with external circumstances or other psychic alterations is detectable. Holotimic delusions (from Greek involving an overall change in mood) are emblematic, such as delusions of guilt, ruin, and illness. Paradigmatically nihilistic delusions such as the patient is convinced he/she is dead and the world is also dead are linked to serious mood swings. Delusions of grandeur, invention, and wealth are associated with marked euphoria.

In people with ID/ASD and psychotic or mood disorders, delusions tend to be less bizarre and complex than in persons of the general population with the same psychopathological conditions. In those with serious communication difficulties, they must be evaluated through significant variations in the quality of behavior, perhaps through avoidance, anger, or aggression toward objects, environments, people, or situations that were previously well tolerated or even appreciated, sudden refusal of assistance and treatment, and social withdrawal.

> In persons with ID/ASD, delusions tend to be less bizarre and complex than in persons of the general population. In those with serious communication difficulties, the presence of delusion must be evaluated through significant variations in behavior, such as the onset or exaggeration of avoidance, anger, or aggression toward objects, environments, people, or situations that were previously well tolerated or even appreciated, sudden refusal of assistance and treatment, and social withdrawal.

> The present state examination of the person with ID and/or ASD is a fundamental clinical moment in the direct evaluation of psychopathological symptoms. Without it, psychodiagnostic tests and questionnaires are of limited value. It must include the assessment of all the following functions: availability, accessibility, appearance, behavior and motor activity, speech, cognitive functions, consciousness, insight, judgment skills, orientation, attention, memory, sense perception, mood, anxiety, will, and thought.

6.4 Final Considerations and Future Directions

Research and practice has made progress in the assessment of psychopathology as shown by the development of numerous psychometric measures and structured diagnostic interviews, although much is left to be done especially with reference to persons with greater impairment of communication and insight. This has been fostered by social pressure for clinical casualness and health costs containment as well as research investments, which have increasingly focused on neuroimaging, genetic, and neuropsychology. The skill to precisely and carefully assess mental states and symptoms of mental suffering was a core attribute of mental health professionals, but today's curricula pay increasingly less atten-

tion to its training [58], thus, blurring the border between co-occurrence of psychiatric disorders and variants of the underlying neurodevelopmental disorder.

Current and future clinical care of individuals with ID/ASD needs a substantial reevaluation and expansion of the psychopathological approach in order to improve professional knowledge, practice, and contact with patients' experience. It is to be hoped that the ideas of this chapter will be significantly extended and detailed in the forthcoming years. In fact, despite the prophecy from the end of the last century that psychopathology would be doomed by neurobiological parameters, psychiatric diagnosis continues to rely exclusively on psychopathology, even in the very latest classificatory systems, such as DSM-5 [12] and ICD-11 [59], and there is a growing demand for personalized symptom-based approaches and precision psychiatry.

Tip

Current and future clinical care of individuals with ID/ASD needs a substantial reevaluation and expansion of the psychopathological approach in order to improve professional knowledge, practice, and contact with patients' experience. It is to be hoped that the ideas of this chapter will be significantly extended and detailed in the forthcoming years.

Key Points

- The Present State Examination of the person with ID and/or ASD is a fundamental clinical moment in the direct evaluation of psychopathological symptoms. Without it, psychodiagnostic tests and questionnaires are of limited value.
- The Present State Examination must include the assessment of all the following functions: availability, accessibility, appearance, behavior and motor activity, speech, cognitive functions, consciousness, insight, judgment skills, orientation, attention, memory, sense perception, mood, anxiety, will, and thought.
- Differential patterns of memory deficits are documented across different etiological and clinical groups of individuals with ID and/or ASD.
- In individuals with ID/ASD, mood alterations may often replace depressed affect. Mood changes can be observed through striking variations in behavior, both in quantitative terms, as reduction or increase in their activities, and qualitative, as an appearance of aggressiveness to others or to oneself, noncompliance, or provocation.
- Alterations of will may occur in people with ID/ASD without being a symptom of an additional psychiatric disorder. This must, therefore, be carefully defined on the basis of changes from premorbid behavior.
- In persons with ID/ASD, delusions tend to be less bizarre and complex than in persons with other clinical conditions and may manifest through significant variations in behavior, especially in those with serious communication difficulties.
- Current and future clinical care of individuals with ID/ASD needs a substantial reevaluation and expansion of the psychopathological approach in order to improve professional knowledge, practice, and contact with patients' experience.

Problem Behaviour

Shoumitro (Shoumi) Deb, Gemma Unwin, Sally-Ann Cooper, and Johannes Rojahn

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_7

Learning Objectives

- Prevalence of problem behaviour in adults with intellectual disabilities
- Risk factors for problem behaviour
- Assessment of problem behaviour
- Rating Scales for problem behaviour

- A higher proportion of people with intellectual disabilities compared with the general population who do not have intellectual disabilities display problem behaviour.
- Various factors such as age, gender, level of intellectual disabilities, level of communication, co-morbidities such as psychiatric disorder, other neurodevelopmental disorders such as autism spectrum disorder (ASD) and attention deficit hyperactivity disorders (ADHD) may influence the rate and severity of problem behaviour.
- Problem behaviour, in general, and aggression, in particular, poses a major management problem and is a major barrier to social integration, leads to caregiver stress, community placement breakdown and use of restrictive practices.
- A thorough person-centred assessment is vital for a successful management.
- The assessment should take a bio-psycho-social approach by incorporating assessments of the behaviour, the person showing the behaviour, medical, psychiatric/psychological and social/environmental issues.
- A number of instruments are available to rate different types of problem behaviour and assess their impact. Some of these are generic and some are specific to problem behaviour.
- Some functional assessment scales that assess the environmental effect are also available.
- The aetiology of problem behaviour is complex and often is the outcome of an interaction between internal factors within the person and external factors such as the environment.
- Therefore, the management of problem behaviour requires input from a multitude of professionals with relevant and specific skills.
- The ultimate aim of the management of problem behaviours should be to improve the quality of life of the person with intellectual disabilities and their family members.

Tip

Problem behaviour is more prevalent in people with intellectual disabilities than without and is multi-factorial in aetiology.

Therefore, a multi-professional, person-centred, bio-psycho-social approach is needed for a thorough assessment and management of problem behaviours.

7.1 Introduction

Individuals with intellectual disabilities (ID) have an increased risk for the development of problem behaviour (PB) such as aggressive behaviour (AB). AB is common in this population, and it is often targeted for intervention [1, 2]. AB continues to be a major concern for families, caregivers, clinicians and other professionals [3] acting as a major barrier to social integration/inclusion and limiting access to certain residential settings, education, occupational opportunities or social acceptability [4–6]. Furthermore, it has been reported that AB predicts admission to psychiatric inpatient units [7], is the most common reason for referral to mental health services or specialist behavioural support teams [8], is related to use of psychotropic medication [9, 10], is associated with placement breakdowns [11], use of restraint and restrictive practices [12] and higher cost of service provision [13, 14].

7.2 Terminology

Different terminology is currently used in the field to describe PB. The term ‘challenging behaviour’ [15] has received a wide acceptance replacing other terms such as maladaptive, abnormal or aberrant behaviour or

behaviour disorder or behaviour problem. Other terms such as 'behaviour that challenges' or 'behaviour of concern' have also been used recently [16]. Emerson [15] defined challenging behaviour as 'culturally abnormal behaviour(s) of such intensity, frequency or duration that the physical safety of the person or others is likely to be placed in serious jeopardy, or behaviour which is likely to seriously limit use of, or result in the person being denied access to, ordinary community facilities'. The term PB is used by many organisations such as the Royal College of Psychiatrists in the UK [17], and the World Psychiatric Association [18, 19]. PB is seen as a type of behaviour rather than behaviour being a 'problem' as such. PB has been defined as 'socially unacceptable behaviour that causes distress, harm or disadvantage to the persons themselves or to other people, and usually requires some intervention' [19].

The closest categories for PB in the Diagnostic and Statistical Manual-5 (DSM5) are 'Disruptive, Impulse-control, and conduct disorders' and personality disorder [20]. However, given strict criteria for diagnosis, it seems that in a large proportion of people with ID this classification is difficult if not impossible to apply [21]. There are similar problems in categorising PB in ID using the International Classification of Diseases tenth version (ICD-10) criteria [22]. It is not only difficult to define PB, but it is also not clear which behaviours should be classified as PB. For example, the following behaviours may or may not be seen as types of PB; pica, disruptive and oppositional behaviours, hyperactivity, stereotype, social withdrawal, wandering aimlessly, night-time disturbance, inappropriate sexual behaviour (including aggression), antisocial behaviour, screaming/shouting aimlessly (not particularly directed to anyone), scattering objects indiscriminately, socially unacceptable personal habits such as hoarding, smearing faeces and taking others' possessions. However, some of these behaviours could be the manifestation of other pathology. For example, hyperactivity could be part of attention deficit hyperactivity disorder (ADHD) or mania, stereotype could be part of an organic disorder or autism spectrum disorder (ASD) or adverse effects of medication, and social withdrawal could be due to depression or dementia. It is possible that some PB such as antisocial behaviour and aggression are defined as personality disorder when exhibited by people with mild ID [23].

AB is the predominant form of PB [24, 25]. In this chapter, we have presented data interchangeably for both PB and AB. AB can include verbal aggression, physical aggression towards others, property destruction and self-injurious behaviour (SIB; physical aggression towards the self). Outwardly directed aggressive behaviour is often distinguished from SIB as different aetiopathology may be responsible for these two different types of behaviour [26]. For example, outwardly directed aggression is often perceived by many as part of a communication process, whereas SIB has been associated with many organic factors such as genetic syndromes [27]. SIB has also been linked to a dysregulated internal opioid system [26, 28–30]. Some SIB has been shown to be part of an obsessive compulsive disorder or stereotyped behaviour or dysregulation of arousal [26]. The operant model of the development of SIB has received some compelling support in the literature, especially with relation to the strengthening of SIB, however, studies do not support the notion that 'social reinforcement processes are responsible for shaping stereotypy into SIB' [26, 30, 31].

7.3 Prevalence of Problem Behaviour Among People with Intellectual Disabilities

There have been many attempts to determine the rate of PB and AB in people with ID. However, difficulties remain in case detection (finding all people with ID in a representative sample) and case definition (difficulty in defining PB and AB and also use of different methods to record prevalence) [32–34]. Similarly, prevalence rates vary due to differ-

ent populations (e.g. in ages and location of study), time scales and forms of 'prevalence' (e.g. point prevalence, life-time occurrence or time-limited incidence) used in different studies [35]. Epidemiological studies report a very varied rate from 2% to 60% for PB (see Tables 7.1 and 7.2) [5, 33, 36–39]. Prevalence of AB tends to fall somewhere in between and, among all four types of AB reported, verbal aggression tends to be the most common type. Often, adults with ID exhibit multiple forms of AB and other types of PB [6, 40–43]. However, there is little research that has explored the topography of AB in adults with ID in detail, and the field remains dominated by retrospective research lacking detailed descriptions of behaviours in specific settings [44].

7.4 The Impact of the Behaviour

Those who exhibit AB are perceived to be less satisfied with their life situation than those who do not and tend to have a poorer quality of life [45] with a reduction in behaviour being linked with improved quality of life [46, 47]. Presence of AB inevitably increases the risk of injury to the person and those around them. Frequency of AB has been reported to be the best single predictor of restraint-related injury, with one in three emergency restraints resulting in personal injury [48]. Apart from the people with ID, AB also impacts paid caregivers, informal caregivers and family members, including siblings as AB is a common source of stress leading to negative emotions [49, 50]. Paid carers, working in community group homes with residents who exhibit AB, report lower job satisfaction and more anxiety compared with similar workers in homes without such residents [51] and a significant relationship between AB and staff burnout has been reported [52, 53]. In addition, 42% of all caregivers of adults who exhibit physical aggression towards others reported that they felt unable to cope with the behaviour, rising to 58% for family carers of those known to services [54] with fear of assault also relating to emotional exhaustion [55].

7.5 Natural History of Problem Behaviour

PB is commonly considered as a chronic and enduring condition, with aggression during childhood being a major predictor of aggression later in life [56, 57]. Few studies have investigated the age at which such behaviour tends to first emerge, however, available studies suggest that behaviours often appear in childhood [58]. Cross-sectional research reports peak in adolescence/early adulthood and decline from around 30–35 years [25, 33, 54, 59]. The pattern reported in cross-sectional research suggests that remission with age occurs for some individuals. Cooper and colleagues [42, 43] reported 2-year remission rates of 29–38%, and onset of episodes in other individuals, thus, suggested PBs are relapsing-remitting conditions. Other research suggests persistent rates of 50–90% at different time, with rates varying according to type of behaviour and time period studied [60, 61].

7.6 Risk Factors Associated with Problem Behaviour

Epidemiological research has sought to identify factors, both within the person and, less commonly, in the environment, that are associated with PB and AB. Identifying such correlates aids the understanding of the processes involved in a person displaying PB, as well as helping to develop effective management strategies and inform service provision [42, 43, 62]. We presented here an overview of the most commonly studied risk factors for PB. Tables 7.1 and 7.2 present details of community-based studies that have investigated the prevalence of, and factors associated with, AB in adults with ID.

7.6.1 Age

It is difficult to ascertain a true association between age and the rate and type of PB in the absence of any long-term longitudinal cohort study. The current knowledge is based on

Table 7.1 Prevalence of and factors associated with outwardly directed aggressive behaviour in community studies of adults with intellectual disability

Authors	*N*	Population	Assessments	Diagnostic criteria	Findings (% rounded up to closest decimals)
Eyman and Call[a] [127]	5243	Administrative database of service users with ID aged 13 and over, USA	Selected items of the ABS completed by direct-care workers and social workers	The behaviour was rated as occurring frequently or occasionally	13+: [d]28% physically aggressive, 22% destructive and 19% verbally aggressive. People with physical aggression were older, male, of lower ability and institution residents. People with destructiveness were of lower ability, male and institution residents. People with verbal aggression were older, male, of higher ability and institution residents
Jacobson [38]	32,112	Administrative database of service users (children and adults) with ID in one state, USA	42-item questionnaire routinely completed by staff	The general frequency of up to three problem behaviours could be reported	All ages: 11% physically aggressive, 4% destructive and 6% verbally aggressive Aged 22+: 'Psychiatric and developmental disabilities' group: 18% physically aggressive, 7% destructive and 12% verbally aggressive. 'Developmental disabilities only' group: 11% physically aggressive, 4% destructive and 6% verbally aggressive. Adults with physical aggression: 17% profound, 14% severe, 8% moderate and 5% mild ID. Adults with destructiveness: 7% profound, 5% severe, 3% moderate and 2% mild ID. Adults with verbal aggression: 3% profound, 8% severe, 10% moderate and 9% mild ID
Qureshi and Alborz [128] and Emerson et al. [68]	695[b] (4200)	Children and adults using ID services in seven Health Authority areas in England, UK	All ID services were asked to identify people with problem behaviour. Key informants were then asked to return a questionnaire on each person they identified	Interview with staff for each person who had been identified as having aggressive behaviour, on its type, intensity and frequency	All ages: [e,d]11% for all categories, or [f,d]7% for serious/serious but controlled physical aggression, [e,d]9% all categories or [f,d]5% for serious/serious but controlled destructive behaviour
Sigafoos et al. [25]	261	Children and adults using ID services in one state in Australia	Managers were asked to distribute surveys to a senior staff in each service, asking for a questionnaire completed on each person with aggressive behaviour	A two-page questionnaire listed 14 topographies of aggressive behaviour and sought frequency as never (0) through to more than 15 times a day [7]	All ages: 261 people engaged in aggressive behaviour, cited as 11% of 2412 service users; but the non-response rate was unclear

Harris [6]	168[b]	Children and adults using ID services in one health district in England, UK	Staff were asked in writing to identify people with aggressive behaviour; a face-to-face interview was then conducted with the staff of each person so identified	People with serious problems like biting, kicking, scratching, etc. resulting in injury to others, e.g. bruising, bleeding and other tissue damage. Also actions, e.g. shouting/ screaming at others, or violence towards objects, presenting serious management difficulties because of threat of injury	All ages: estimated 18% had aggressive behaviour. The highest prevalence was in the group living in hospital. In day centres, prevalence was higher for men than women, but there was no gender difference in schools or in the hospital population
Borthwick-Duffy [59]	91,164	Administrative database of service users (children and adults) with ID in one state in USA	Routine annual report on adaptive behaviour and diagnoses completed by staff	More than one violent episode causing serious physical injury to others (requiring immediate medical attention) in the past year. Serious property destruction and/or minor property damage on more than six occasions within the past year	All ages: 2% physically aggressive, 7% destructive. 4% of the profound, 3% of severe, 2% of moderate and 1% of the mild ID showed aggression; 1% of females and 3% of males; 3% of non-verbal and 2% with verbal skills showed aggression. Persons destructive to property were 15% of the profound, 10% of severe, 7% of moderate and 4% of mild ID; 5% of females and 8% of males; 7% of non-verbal and 8% with verbal skills 21+: 3% were aggressive and 8% destructive
Smith et al.[a] [37]	2202	Adults (aged 20 years and over) included in an ID register for one county in England	Face-to-face interview with each person supported by their carer	Items from the DAS (aggressive behaviour rated as absent, severe and frequent {more than 3 times a week}, less severe but frequent, severe but less frequent or lesser management problem)	[d]22% physically aggressive and 17% destructive. Both aggressive behaviours were individually associated with more severe disabilities. The strength of other associations was not reported

Table 7.1 (continued)

Authors	*N*	Population	Assessments	Diagnostic criteria	Findings (% rounded up to closest decimals)
Emerson et al. [68]	264[b] (2189)	Children and adults with ID in two Health Authority areas in England	All services supporting people with ID were asked to identify people with problem behaviour. Key informants were then asked to return a questionnaire on each person so identified	Individual schedule incorporating a measure of aggressive behaviour (serious, serious but controlled, moderate, lesser or none)	All ages: [d]7% physically aggressive
Deb et al.[a] [33]	101	Random sample of 16- to 64-year-olds with ID known to a social services department in Wales, UK	Face-to-face interview with each person supported by their carer	Items from the DAS (aggressive and destructive behaviour rated as absent, severe and frequent {more than 3 times a week}, less severe but frequent, severe but less frequent)	23% physically aggressive, 12% destructive and 29% screaming/shouting behaviour. Physical aggression: 65% were female; 22% severe, 39% moderate and 39% mild ID [30% of women and 16% of men were physically aggressive; 45% with severe, 22% with moderate and 19% with mild ID were physically aggressive]. Only taking psychotropic drugs was associated with physical aggression
Tyrer et al.[c] [54]	3065	Adults (aged 20 years and over) on an ID register in one county in England	Face-to-face interview with each person supported by their carer	Questions from the DAS. Carer report of frequency (more than 3 times per week) and/or severe physical aggression towards others	14% physically aggressive. Higher prevalence for men, younger adults, more severe ID and in institutional settings; lower prevalence for people with Down syndrome. No relationship with epilepsy or autistic symptoms
Crocker et al.[a] [5]	3165	Adults (aged 18 years and over) receiving ID services in Canada	Educators in participating agencies were sent a survey form to fill in about aggressive behaviour over the past 12 months	MOAS. verbal and/or motor behaviour towards oneself, environment or others, directly or indirectly and more or less planned. Could potentially cause physical/psychological harm to others, and may have management difficulties {0 = no behaviour, 4 = highest score of such behaviour}	52% aggressive in the previous 12 months. 24% physically aggressive, 24% aggressive to property and 38% verbally aggressive. No gender difference for physical or verbal aggression; men more aggressive to property (Mann-Whitney U). Mild/moderate ID more verbally aggressive (41% vs. 29%). Profound/severe ID more physically aggressive (32% vs. 21%) and aggressive to property. Age was negatively correlated with physical and property aggression (Spearman correlation) for men, but not women. Highest in group homes. Physical, property and verbal aggression were highly correlated

Lowe et al. [41]	901[b]; 705 adults +196 children (5395)	Children (aged 5 years or over) or adults with ID using services in a defined area, Wales	All services supporting people with ID were asked to identify people with problem behaviour. A face-to-face interview was then conducted with the primary carer of identified persons	Individual schedule incorporating a measure of aggressive behaviour (serious, serious but controlled, moderate, lesser or none)	All ages: [d]4% had serious, 2% serious but controlled, 5% moderate, 3% lesser and 86% no physical aggression; 2% had serious, 1% serious but controlled, 4% moderate, 3% lesser and 90% no destructive behaviour
Jones et al. [77] and Cooper et al.[c] [43]	1023	Adults (aged 16 years or over) receiving social care, specialist health services or known to GPs in a defined area in Scotland in UK	All identified adults with ID invited to participate. Face-to-face interviews with specialist nurse. Those potentially with problem behaviour, mental illness or ASD further assessed by a specialist psychiatrist	C21st Health check to screen for aggressive behaviour. Operationalised DC-LD definition of aggressive behaviour (excluded problem behaviour with a known cause such as ASD, mental illness or physical illness). Risk factors assessed: personal factors, lifestyle and supports, health and disabilities	[g]Point prevalence: 23% with problem behaviour (including SIB; psychiatrist's opinion); 18.7% with problem behaviour (including SIB; DC-LD). [g]7% verbally aggressive, 3% property destruction and 6% physically aggressive to others. [h]10% with outwardly directed aggression. [g]Higher prevalence of problem behaviour (including SIB) for females, lower ability level, living in a congregate care setting, or with paid carer support (rather than living with a family carer), having ADHD, urinary incontinence, visual impairment, not having Down syndrome and not having severe physical disabilities. [h]Higher prevalence of outwardly directed aggression for men, more severe ID, not living with family, presence of ADHD, absence of Down syndrome and presence of urinary incontinence
Lundqvist et al.[c] [36]	915	Adults (aged 18 years and over) receiving care from Local Health Authorities in a county in Sweden	Staff members judged to be in a good position to provide information about each participant were interviewed by country council workers, specialising in working with adults with ID and BPs using an inventory. Data collection took place at daily activity centres and community homes	BPI to determine presence and severity of aggressive destructive behaviour. Risk factors assessed: Personal factors, disability/disorder, body functions, social activity/participation and services/treatment factors	62% with problem behaviour (including SIB); 18.7% identified as having challenging behaviour (with at least one behaviour rated as severe). 30.4% with aggressive destructive behaviour and 11.9% with severe aggressive destructive behaviour. Higher prevalence for women, older ages, presence of autism, longer night sleep duration (negative correlation), presence of auditory hypersensitivity, using signs to communicate, absence of group functioning, presence of initiation of social interaction and in contact with psychiatry. These variables accounted for 23% of the variance in aggressive destructive behaviour

Table 7.2 Prevalence of and factors associated with SIB in community studies of adults with ID

Authors	*N*	Population	Assessments	Diagnostic criteria	Findings (% rounded up to close decimals)
Eyman and Call[a] [127]	5243	Administrative database of service users with ID aged 13 and over, USA	Selected items of the ABS were completed by direct-care workers and social workers	SIB rated as occurring frequently or occasionally	13+: [d]24% had SIB, ranging from 5% of mild-moderate ID living with relatives to 47% of profound ID in hospitals. People with SIB were older, Caucasian rather than Mexican American, of lower ability and in institutions. Equal gender distribution
Jacobson [38]	32,112	Administrative database of service users (children and adults) with ID in one state, USA	42-item questionnaire routinely completed by staff	The general frequency of up to three problem behaviours could be reported	All ages: 8% had SIB Aged 22+: 11% with 'psychiatric and developmental disabilities' had SIB and 9% with developmental disabilities only had SIB. Of adults with SIB, 18% profound, 6% severe, 3% moderate and 3% mild ID
Kebbon and Windahl [129]	28,215	Services for people with ID in 22 of 25 counties, Sweden	Staff completed a structured questionnaire	SIB including an overt motor component, such as head hitting, head banging, hitting other parts of the body, hair pulling and scratching; at frequency of daily, weekly, monthly or once or twice in 3 months	All ages: 4% had SIB; 11% in institutions, 2% in integrated accommodation. People with SIB were 46% female [compared with 44% female for whole ID population], 40% profound, 48% severe, 12% moderate and 1% mild ID [13% with profound, 7% severe, 1% moderate and 1% mild ID have SIB]. Highest frequency of SIB at ages 22–51
Rojahn [130]	431[b] (25,872)	Children and adults with ID using 294 services (excluding hospitals), in Germany	Postal survey for staff to complete on persons with SIB; second postal survey completed on three users of the same service who did not have SIB	SIB that causes (or potentially causes) damage; 15 topographies, with 3-point severity scale and 4-point frequency scale	All ages: 2% had SIB; 7% in schools/training centres, 2% in sheltered workshops and 8% in group homes. Of people with SIB, 48% female, 16% profound, 43% severe, 28% moderate and 13% mild ID

Authors	*N*	Population	Assessments	Diagnostic criteria	Findings (% rounded up to close decimals)
Oliver et al. [131]	596[b] (not reported)	All service users (children and adults) with ID in one health region, England	Staff/carers were asked in writing to identify people with SIB; a face-to-face screening interview was then conducted with the staff of each identified person	Repeated, self-inflicted, non-accidental injury, producing bruising/bleeding/other tissue damage + such SIB prevented by protective measures/interventions	All ages: People with SIB were 42% female; 40% profound, 49% severe and 12% mild ID Adults: 3% who used a social education centre had SIB; 12% in a long-stay hospital had SIB
Qureshi and Alborz [128], Emerson et al. [68]	695[b] (4200)	Children and adults using ID services, in seven Health Authority areas, England	All services supporting people with ID were asked to identify people with challenging behaviour. Key informants were then asked to return a questionnaire on each person they had so identified	Interview with staff for each person who had been identified as having challenging behaviour, on its type, intensity and frequency	All ages: [e,d]8% had SIB, or [f,d]4% had serious/serious but controlled SIB
Borthwick-Duffy [59]	91,164	Administrative database of service users (children and adults) with ID in one state, USA	Routine annual report on adaptive behaviour and diagnoses completed by staff	Client Development Evaluation Report (1. severe SIB requiring medical attention once per month and/or minor SIB requiring first aid weekly, or 2. weekly SIB)	All ages: 2% had type 1 SIB and 9% had type 2 SIB. Of persons with SIB, 25% profound, 15% severe, 7% moderate and 3% mild ID; 9% females and 10% males; 17% non-verbal and 9% with verbal skills had frequent SIB
Hillery and Mulcahy[a] [132]	429	IQ < 50, living in a single community care area (children and adults), Ireland	Carers completed a record sheet daily for 4 weeks, indicating whether or not SIB had occurred	Self-injurious and non-accidental behaviour, producing bruising, bleeding or other tissue damage, + such SIB prevented by protective devices or restraints	All ages: 62 (14%) have SIB; of whom 42% female (NS); 5% profound, 53% severe and 42% moderate ID; no association between age and SIB (t-test) or accommodation type and SIB

Collacott et al.[c] [75]	2101	Adults (aged 20 years and over) with ID in a defined geographical area, England	Face-to-face interview with each person supported by their carer	Items from the DAS (SIB rated as absent, severe and frequent {more than 3 times a week}, less severe but frequent, severe but less frequent or lesser management problem)	17% had SIB + 3% with past history of SIB in remission; SIB was severe and frequent for 2%, frequent but less severe for 3%, severe but less frequent for 3% and lesser management problem for 9%. Lower age, lower ability, impaired hearing, impaired mobility and 'number of autistic symptoms' were independently associated with SIB, but epilepsy, gender and impaired vision were not
Emerson et al. [68]	264[b] (2189)	Children and adults with ID in two Health Authority areas, England	All services supporting people with ID were asked to identify people with challenging behaviour. Key informants were then asked to return a questionnaire on each person they had so identified	Individual schedule incorporating a measure of SIB (SIB defined as serious, serious but controlled, moderate, lesser or none)	All ages: [d]3% had SIB
Deb et al.[a] [33]	101	Random sample of 16–64-year olds with ID known to a social services department, Wales	Face-to-face interview with each person supported by their carer	Items from the DAS (SIB rated as absent, severe and frequent {more than 3 times a week}, less severe but frequent and severe but less frequent. 'Lesser management problem' was omitted)	24% have SIB; of whom 67% were female; 33% severe, 33% moderate, 33% mild ID [36% of women and 12% of men have severe and/or frequent SIB; 73% of sample with severe, 19% with moderate and 17% with mild ID have SIB]. Female gender, more severe ID, impaired communication skills and psychotropic drugs were associated with SIB
Lowe et al. [41]	901[b]; 705 adults +196 children (5395)	Children (aged 5 years or over) or adults with ID using services in a defined area, Wales	All services supporting people with ID were asked to identify people with challenging behaviour. A face-to-face interview was then conducted with the primary carer of each identified person	Individual schedule incorporating a measure of SIB previously designed by Alborz et al. [64] (SIB defined as serious, serious but controlled, moderate, lesser or none)	All ages: [d]3% have serious, 1% serious but controlled, 4% moderate, 3% lesser, 90% no SIB

cross-sectional or retrospective case studies. AB is commonly considered to increase with age until mid-adulthood [65]; however, studies have reported mixed results in terms of an overall relationship with age [34, 66]. Some studies did not find any associations with age, most consistently with SIB [36, 42, 43, 67]. The difference among studies may be explained by a shift in topography with age. For example, the severity of verbal aggression towards others increased in the study by Tsiouris and colleagues [24], whereas all other types decreased with age. Tyrer and colleagues [54] reported a decreased prevalence of physical aggression towards others with age. Lundqvist [36] reported decreasing prevalence with age for outwardly directed aggression with a second peak among those aged 70 or older.

7.6.2 Gender

It is a commonly held assertion that AB is associated with the male gender [68], although some studies have reported SIB to be more common in females [5, 33]. Crocker and colleagues [5] highlight from their study of individual associations that SIB was also more severe in those with more severe ID and more females have a severe ID [21, 66] which could act as a confounder, accentuating the actual gender difference. This highlights the importance of controlling for other variables through multivariate analyses. Three studies did not locate any gender associations with SIB, however, females were more likely to exhibit outwardly directed aggression (including verbal aggression) [36, 42, 43]. Drieschner and colleagues [67] report more severe total and individual types of aggression in females in inpatient treatment facilities. This is in contrast to other studies that have reported more severe/prevalent aggression in males, including a meta-analysis [5, 6, 24, 54, 59, 62].

7.6.3 Severity of Intellectual Impairment

Increasing severity of ID has commonly been associated with PB [5, 33, 59]. Tsiouris and colleagues [24] reported increased frequency of AB associated with increased severity of ID for two types of AB, namely physical aggression towards others (Tyrer and colleagues also reported this relationship [54]) and SIB, whereas verbal aggression and property destruction demonstrated the opposite effect. Cooper and colleagues [42, 43] also found SIB and outwardly directed aggression to be more common among those with more severe ID. Lundqvist [36] reported the same in relation to SIB only. Aman and colleagues [69] did not find any relationship with severity of overall aggression. However, Emerson and colleagues [68] reported an association between mild ID and verbal aggression, meanness and cruelty, and between severe ID and physical aggression and temper tantrums.

7.6.4 Verbal Communication

Lower levels of language skill have been associated with a higher prevalence and severity of aggressive behaviours, especially SIB [5, 33, 41, 66, 70, 71]. A meta-analysis and systematic review also assert that SIB is associated with lower levels of expressive or receptive verbal communication [26, 62], with no association with aggression towards others [62]. However, other studies have failed to locate individual associations when accounting for potentially confounding variables [42, 43].

7.6.5 Physical Health

Increased prevalence of PB has been linked to various physical conditions, although they remain rarely studied. An early study found that individuals with ID and poor physical health were more likely to exhibit PB than those with better health, regardless of health issue [72]. A systematic review synthesised evidence published between 1990 and 2008 on the relationship between physical health problems and challenging behaviour in people with ID [73]. Eleven well-conducted studies were reviewed that reported significant and independent associations between pain related to cerebral palsy, chronic sleep problems, uri-

nary incontinence and visual impairment. Results were also suggestive of associations with gastrointestinal problems, menstrual cycle and sub-types of epilepsy. However, the authors commented that for some physical health conditions, no articles were identified. Furthermore, as the majority of studies were cross-sectional or retrospective, the authors specified a need for further longitudinal research that can delineate cause and effect. Other authors have reported few associations with physical health conditions [33, 42, 43, 74]. Some have reported associations with visual or hearing impairments [6, 42, 75], immobility [76] and urinary incontinence [43] and found mobility problems to be associated with the presence of SIB [68, 71, 74]. On the other hand, it seems that PB is less common in those with physical disability [77].

PB could be associated with pain, which is often under-recognised in people with ID, largely due to communication difficulties and diagnostic overshadowing [78, 79]. This, along with the increased prevalence of health conditions [73, 78, 80], may indicate that PB is the manifestation of an uncomfortable/aberrant internal state, with pain reducing the capacity for adaptive behaviour [81]. Chronic pain and behavioural expressions of pain have been linked to increased levels of AB in adults with ID [79, 82]. Furthermore, some authors have suggested that pain regulation may be disturbed in some people with ID [3]. For example, ASD, which has a high co-morbidity with ID [83], has been associated with sensory processing abnormalities, including hypersensitivity and hyposensitivity to pain [84].

7.6.6 Psychiatric Disorders

The extent of overlap between mental health problems and PB has been a matter of ongoing debate. There have been many studies showing that psychiatric morbidity including anxiety disorders, psychotic disorders and mood disorders among people with ID is associated with higher levels of PB [85, 86, 87]. Conversely, other studies have not found any such association [41, 66, 88]. It is now accepted by the majority that mental health and PB interplay in complex ways and that there are multiple reasons for PB with mental illness being only one of many possible causes or outcomes. It is likely that mental health problems, when defined as diagnosable mental disorders from standard classification systems, do not play a major role in the vast majority of PB. However, it is worth keeping in mind that in many prevalence studies PB is classified as a psychiatric disorder. The previous labelling of PB as the so-called behavioural 'equivalents' of psychiatric symptoms is not supported by the evidence [88–91]. Perhaps it would be better to describe PB as sometimes being behavioural 'correlates' of psychiatric symptoms in people with ID [34, 66, 89, 92] (for further description of the concept of behavioural equivalence and the cases in which it can be considered as such refers to ▶ Chap. 5).

There are obvious difficulties in diagnosing psychiatric disorders in people with ID, especially those with severe and profound ID, limited communication skills and co-morbid ASD [21, 33, 66], which may lead to both under-diagnosis and over-diagnosis of psychiatric illness in people with ID, in general, and ID and PB, in particular. The under-diagnosis may happen because of the so-called 'diagnostic/behavioural overshadowing', whereby the behaviour is perceived as part of the developmental disability repertoire rather than a symptom of an underlying psychiatric illness [33, 66, 93]. Over-diagnosis may also occur, influenced by co-morbid physical health problems, lack of knowledge of carers, medication adverse effects [33, 66], health insurance systems or used as a justification for psychotropic medication prescription. This has led to wide-ranging prevalence estimates [94] and difficulties in consistently identifying psychiatric risk factors. For example, some people with ID may look as if they are hallucinating when they speak to themselves, speak or look at an imaginary person, speak to an object such as a tree or a table or talk about an imaginary world/friend, whereas, in fact, these are manifestations of neurodevelopmental disorders such as ASD and/or ID.

Among studies using multiple regression analyses, varied results relating to psychiatric conditions were reported. Cooper and colleagues [42, 43] did not locate any association other than with ADHD. Similarly, Drieschner and colleagues [67] only reported an association between ADHD/disruptive behaviour disorder and frequency of aggression, while Lundqvist [36] and Tyrer and colleagues [54] reported no independent associations. Conversely, Tsiouris and colleagues [24] who specifically studied the relationships between aggressive behaviour and psychiatric conditions reported independent associations for all psychiatric conditions under investigation.

Melville and colleagues [95] argued that identifying dimensions of psychopathology has a greater validity than diagnoses of psychiatric disorder using a categorical classification system in the general population. In a subsequent paper, Melville and colleagues [88] using an exploratory and confirmatory factor analysis of psychopathology in two large samples of adults with ID identified PB within an emotion dysregulation problem behaviour dimension that was distinct from the depressive, anxiety, organic and psychosis dimensions. The authors found that the dimensional model had better predictive validity than a categorical diagnosis.

7.6.7 Neurodevelopmental Disorders (ASD and ADHD)

Both ASD and ADHD are common comorbidities of ID [83, 96–99] and both ASD and ADHD have commonly been implicated as a risk factor for PB [100, 101]. Tsiouris and colleagues [24] report independent associations between diagnosis of autism, and physical aggression against others and property destruction. Conversely, others have reported no relationships with outwardly directed aggression [36, 43, 54, 67]. Coe and Matson [102, 103] found a higher rate of some PB in children with ADHD and ID when compared with children with ID who did not have ADHD. Similarly, Melville and colleagues [98] found a higher rate of PB in people with ID and autism compared with those who have just ID but no autism. However, this difference no longer existed once the groups were individually matched.

7.6.8 Epilepsy

Mental health symptoms could be observed in the pre-ictal, ictal, post-ictal and inter-ictal phases. In certain types of seizures, particularly associated with complex partial seizures, certain psychological and behavioural symptoms could be manifested during the 'ictal' phase. The inter-ictal psychopathology is the subject of research over many years and the findings in this area to some extent still remain controversial [104]. There have been six controlled studies of PB and psychopathology among adults with ID and with and without epilepsy [66, 105]. Overall, no significant difference is observed in the rate of PB between epilepsy and the non-epilepsy group. Further, non-controlled studies have supported these findings [66, 105]. Deb and Hunter [106] reported a significantly higher rate of PB among the subgroups of individuals with epilepsy who showed generalised epileptiform EEG changes, who received one anti-epileptic drug at a time and those who received carbamazepine. Some studies have shown an increased rate of psychopathology, in general, but not necessarily PB among children with epilepsy in the general population and also with ID [107, 108]. However, some have shown that PB started in children before the onset of epilepsy [109].

A recent systematic review and meta-analysis has found no association between epilepsy and PB in adults with ID, and hypothesised that although multi-factorial in eatiology, the underlying brain damage in the case of severe ID and psychosocial advantages in the case of mild ID are the stronger determinants of parapsychology in this population than the epilepsy *per se* [110, 111].

Factors that affect behaviour in the presence of epilepsy are related to (a) an underlying brain damage such as the location and severity of any deformity or space occupying lesion or abnormal electrical discharge in the brain; (b) epilepsy-related factors such as certain epileptic syndromes are prone to develop more PB; (c) seizure-related factors such as the severity,

type and frequency of seizures; (d) anti-epileptic–related factors such as the adverse effects of certain anti-epileptic medicine such as topiramate, levetiracetam and perampanel and (e) psychosocial factors such as loss of occupation, financial problems, lack of support, locus of control being outside the person so the person does not have any control over when the seizure is going to occur, etc. [105]

7.6.9 Life Events

In a systematic review, Wigham and colleagues [112] summarised findings from 15 studies. There is also a further publication from the same authors on this subject [113]. The majority of studies reported an association between life events and PB. The types of life events described in the summarised studies included sexual and other abuses, bereavement, and other life events. The description of PB included aggression, SIB, irritability, 'acting out', hyperactivity, destructive behaviour, conduct disorders, adjustment disorders, stereotypical behaviour and inappropriate speech.

7.7 Environmental/Contextual Risk Factors for Problem Behaviour

Carr [114] categorised functions of PB in terms of social positive reinforcement, social negative reinforcement and sensory (i.e. automatic) reinforcement. Environmental factors for PB have most commonly been studied through functional assessment [115], which seeks to identify relationships between antecedents and reinforcing consequences [116] and to identify contextual variables and events that elicit PB [117]. Emerson and Einfeld [3] included these features in their operant model for PB (see Figs. 7.1 and 7.2). Researchers have suggested that people with ID and subsequent limited communication skills 'rely primarily on expressive behaviour to communicate their wants and needs…these limited skills can lead to communication in the form of… behaviour' [1, 16, 114].

7.8 Behavioural Phenotypes

Certain genetic syndromes that cause ID are also shown to be strongly associated with certain features of PB and SIB [118, 119]. For example, Cri du Chat, Cornelia de Lange, Angelman, Fragile X, Prader-Willi, Lowe, Smith Magenis, Lesch-Nyhan, Rett and Brachmann de-Lange syndromes are known to carry a higher risk for certain types of behaviours such as physical aggression and SIB [27, 119, 120]. Conversely, research has demonstrated that those with Down syndrome are less likely to exhibit physically aggressive behaviour [54, 76]. In Table 7.3, we have presented both physical and behavioural phenotypes of some of the relevant syndromes.

7.9 Assessment of Problem Behaviour

In this section, we present a bio-psycho-social assessment model for PB. Important aspects include an assessment of the (a) behaviour, (b) person showing the behaviour, (c) cause(s) of the behaviour, (d) reaction to and consequences of the behaviour and (e) environment and the risks involved with the behaviour (see Comprehensive Assessment of Triggers for behaviours of concern Scale; [121] ▶ https://spectrom.wixsite.com/project).

Using this model, the assessment may be carried out under four broad headings, namely *B*ehaviour, *M*edical, the Person, *P*sychological/Psychiatric and *S*ocial (*BMPPS*) (see Table 7.4). The importance of this schema is that it informs the intervention plan to reduce the PB, and to treat other conditions that might be presenting as PBs but actually need specific treatments to correct or ameliorate them.

An important area of assessment of PB includes the assessment of the individual themselves. This should include an assessment of (a) their strengths and abilities, opportunities and resources available to them; (b) their mental and physical health needs, educational/vocational needs and impact of disabilities, service and resource gaps in their lives; (c) their likes, dislikes and preferences and how they express these; (d) their history such as social, developmental, psy-

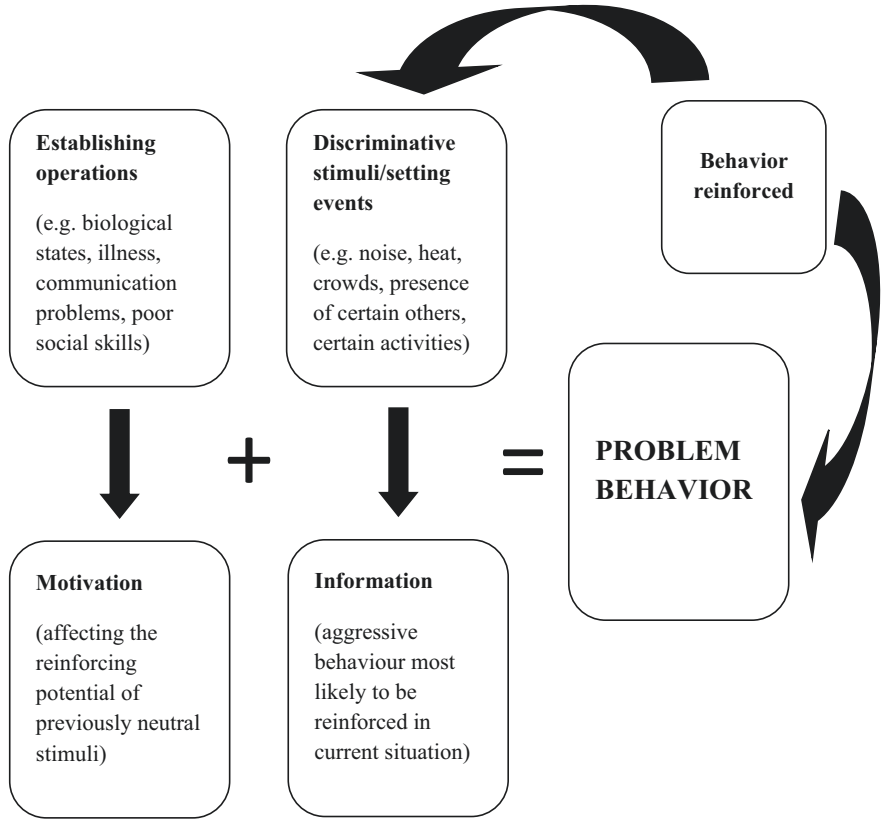

Fig. 7.1 Schematic representation of the Operant model of aggressive behaviour. (Adapted from Emerson and Einfeld [3])

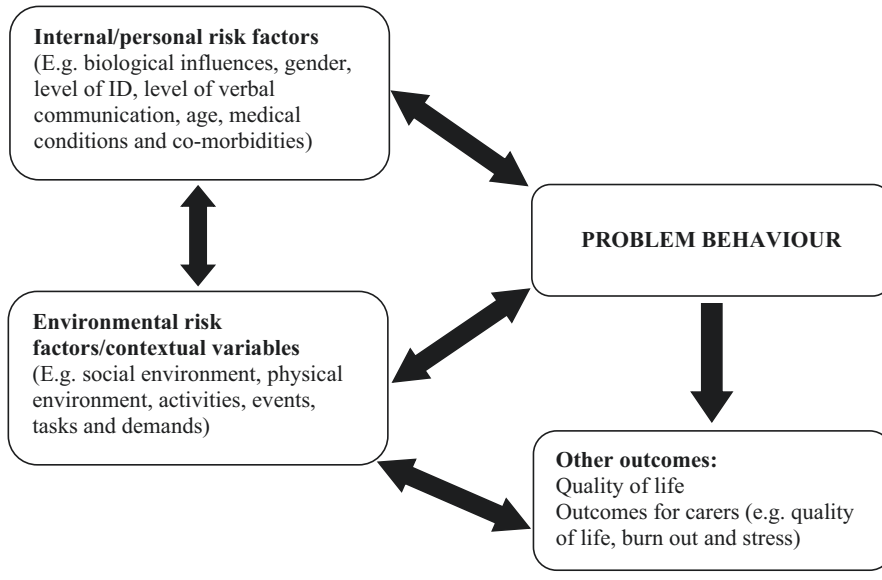

Fig. 7.2 Schema for problem behaviour in intellectual disabilities

Table 7.3 Physical and behavioural phenotypes of common genetic syndrome associated with intellectual disabilities [118]

Name of the syndrome	Genetic phenotype	Physical phenotype	Behavioural phenotype
Down's syndrome	Trisomy 21 (95%); Translocation (4%); Mosaic (1%); 1:600–1000 live births (average incidence); 1:1500 (maternal age <30); 1:800 (maternal age 30–34) and 1:100 (maternal age 40–44)	Short stature; small head; brachycephaly; high arched palate; eyes: upward, outward slant and epicanthic fold; protruded tongue; eyes: nystagmus, cataract and Brushfield spots; simian (single palmar) crease; fingers: syndactyly and toes: sandal gap	Moderate learning disability; usually of friendly nature but some may show problem behaviour; dementia is very common with early age of onset
Fragile X/ ataxia syndrome (FRAXT) (also FRAXA and FRAXE)	1 in 4000 men; 1 in 6000 women; Xq27.3; CGG repeat (up to 50 is normal; 43–200: carrier); CGG trinucleotide expansion; (>200: Fragile X syndrome) (90%); Fragile X Mental Retardation-1 (FMR-1 gene); absent/ low FMR protein (FMRP)	Subtle physical features and usually do not appear before adulthood; macro-orchidism (large testes); long face; long ear; prominent jaw; connective tissue disorders; epilepsy (25%; usually appears in adolescence) and cardiac abnormalities (mitral valve prolapse, post-ductal coarctation, aortic hypoplasia and dilatation)	Mild-to-moderate ID (30% severe ID); delay/abnormal language development; dysfunction in social play; verbal communication (speech volume, word/ phrase perseveration); non-verbal communication (gaze aversion); repetitive motor behaviour (hand flapping, hand biting and rocking); ADHD and ASD features; poor mathematical skills; abnormal sensitivity to external stimulus; mouthing/ smelling of objects; aggression (20–30%); hyperarousal and over activity
Foetal alcohol spectrum disorder (FASD)	0.2–3 per 100 live births; 10–20% mild ID; 8 or > drinks per day; bingeing/ poly drug use; newborn babies show features of alcohol withdrawal; microcephaly and epicanthic fold	Short palpebral fissure; optic nerve hypoplasia with poor visual acuity; hearing loss; ventricular septal defect (VSD), renal hypoplasia and bladder diverticula	Hyperactivity; sleep disturbance and language impairment
Rett syndrome	1 in 10,000–15,000; only girls are affected; gene at Xq28 (MECP2)	Develop normally up to age 18 months to 2 years; starts showing deterioration; epilepsy (59–72%); limb spasticity from age 5; a few years plateauing, further deterioration, increased spasticity/rigidity lower limb; poor balance, tremor and wide-based gait	Severe and profound ID; abnormal motor movement (hand flapping/wringing) and autistic features

(continued)

Table 7.3 (continued)

Name of the syndrome	Genetic phenotype	Physical phenotype	Behavioural phenotype
Prader-Willi syndrome	1.2–1.3 per 10,000; boy: girl:1.6:1.2; deletion of chromosome 15 (q11q13) of paternal origin (50–70% cases); FISH test; maternal disomy in chromosome 15; (some cases)	Obesity; diabetes; cryptorchidism; hypogenitalism and duodenal ulcer/ renal stone	Moderate ID; hyperphagia (excessive eating); sleep disturbances (excessive daytime sleepiness); psychotic features and skin picking
Lesch-Nyhan syndrome	X-linked recessive condition (Xq26q27); 1 in 10,000–380,000; inborn error of xanthine metabolism	Poor prognosis; spasticity and epilepsy	Severe/ profound ID; severe self-injurious behaviour common
Phenylketonuria	1 in 5000–10,000 live births; autosomal recessive (gene 12q22–24); detected by routine heel prick test of newborn babies and dietary treatment from infancy	Fair skin, blonde hair and blue eyes; seizure, eczema; tremor and musty odour urine (untreated cases)	Poor attention, hyperactive and aggression (untreated cases)
Velocardiofacial syndrome	Also known as Shprintzen/ Di George/ Cayler/ Takao/ 22q11-deletion/ CATCH 22 syndromes; autosomal dominant; 1 in 5000; majority microdeletion at 22q11.2	Cleft palate; cardiac abnormalities (ventricular septal defect); pulmonary stenosis; facial dysmorphology; seizures; hypocalcaemia	Common in late life: psychoses (schizophrenia); bipolar disorder; social withdrawal; anxiety
Angelman syndrome	Also known as happy puppet syndrome; 1:20–30,000; deletion of chromosome 15 (of maternal origin; as opposed to Prader-Willi syndrome, which is of paternal origin); 15q11-q13 (60–75% cases)	Severe epilepsy (86%); microcephaly (small skull); characteristic EEG pattern; blue eyes and blonde hair in two-thirds of cases; waddling gait (ataxia); prognathism	Severe ID; characteristic laughter; typically sociable and affectionate; over excitability; over activity and short attention span; get better with age
Williams syndrome	1 in 15,000 infants; autosomal dominant; elastin gene at 7q11.3	Idiopathic infantile hypercalcaemia; treat with a low-calcium diet and vitamin D restriction; 'Elfin-like' face (prominent cheeks, wide mouth and flat nasal bridge); kidney and heart lesions (supravalvular aortic stenosis and peripheral pulmonary artery stenosis); growth is usually retarded; life expectancy is related to metabolic and heart abnormalities; abnormally sensitive hearing	Moderate or severe ID; social disinhibition with abnormal friendliness to strangers; over activity; poor concentration; eating and sleeping abnormalities; abnormal anxiety; poor peer relationships; aggression (5–10% children) gets better with age

Table 7.3 (continued)

Name of the syndrome	Genetic phenotype	Physical phenotype	Behavioural phenotype
Rubenstein-Taybi syndrome	1 in 125,000; microdeletions at 16p13.3 (in some)	Short stature; small head; beaked or straight nose; downward slanting eyes; stiff gait; congenital heart defects; urinary tract abnormalities; severe constipation	Moderate ID; reduced attention span; rocking; spinning; hand flapping; friendly disposition; self-stimulatory activities such as rocking; intolerance of loud noises
Smith-Magenis syndrome	1 in 50,000; deletions at 17p11.2	Flattened mid-face; abnormally shaped upper lip; short hands and feet; single transverse palmar crease; abnormally shaped or placed ears and sometimes a high arched palate or protruding tongue; coarse facial features; otitis media and squint; speech delay is more pronounced than delay in motor achievement	Moderate ID is common; self-hugging and mid-line hand clapping; sleep disorders are common with some children waking repeatedly in a state of agitation; absence of rapid eye movement (REM) sleep
Smith-Lemli-Opitz syndrome	1 in 30,000; mildly affected people may be undiagnosed; one of the commonest autosomal recessive conditions; gene located at 11q12–13; deficiency of the enzyme 7-dehydrocholesterol reductase results in elevated levels of a cholesterol precursor	Small head; drooping eyelids; squint; forward-facing nostrils; small lower jaw; finger abnormalities such as extra fingers (polydactyly) and syndactyly (webbed fingers)	Intelligence varies from normal to severe ID; aggressive and self-injurious behaviours and autistic spectrum disorders
Tuberous Sclerosis Complex (TSC)	Autosomal dominant; 1 in 7000 newborns; chromosome 9 (9q34-TSC1): 50%; Chromosome 16 (16p13-TSC2): 50%; TSC2 is close to the gene for the adult polycystic kidney disorder (APKD-1)	Multi-system disorder; hamartomas in brain, retina, heart, lungs and kidney (skull X-ray will show calcified tubers); subependymal nodules in the brain (shown in MRI); adenoma sebaceum (angiofibroma and facial butterfly rash); depigmented skin area (hypomelanic macules) (best seen under the UV light); other skin lesions (Shagreen patches); 65–80% epilepsy; periungual fibroma; polycystic kidney in some	Learning disability (50%); language delay; restlessness; aggression; self-injurious behaviour; ASD/ADHD (up to 50%); also, unipolar or bipolar depression; anxiety

(continued)

Table 7.3 (continued)

Name of the syndrome	Genetic phenotype	Physical phenotype	Behavioural phenotype
Cornelia de Lange syndrome	1 in 60,000 live births; Nipped B-like or NIPBL gene (chromosome 5) (40%)	Growth retardation; distinctive facial features consisting of well-defined arched eyebrows which meet in the middle; long curled eyelashes; small nose with forward-facing nostrils and down-turned mouth with thin lips; limb abnormalities such as small or shortened limbs, especially arms; hearing impairments; gut malformations; congenital heart defects; early mortality is high because of feeding problems with regurgitation and vomiting leading to aspiration pneumonia in some cases	The degree of ID is usually severe, and speech is often very limited; however, some affected people have IQs within the normal range; self-injury, autistic features and pleasurable responses to vestibular stimulation, e.g. spinning in a chair have been reported as part of the behavioural repertoire; compulsive behaviour; self-injurious behaviour (not supported by recent studies)
XO (Turner's syndrome)	1 in 10,000 live female births; 45X karyotype (in some)	Short stature; ovarian failure; puberty does not usually occur naturally; webbed neck; low hairline; widely spaced nipples; multiple pigmented naevi; coarctation of the aorta or a ventricular septal defect (12%)	Usually of normal intelligence; hyperactivity and distractibility are common in childhood; poor social skills, with immature social relationships and low self-esteem in adolescence; specific cognitive abnormalities including deficits in spatial perception, visual motor integration, affect recognition, visual memory and attention
XYY syndrome	1 in 1000 live male births; 10% have mosaic 46, XY/47, XYY	Most are over 10 cm taller than their fathers as adults; sexual development and fertility are unaffected	Lower mean intelligence scores (with a large overlap with the normal range); poor social adaptation; distractibility; hyperactivity; temper tantrums; speech and language problems; little evidence to suggest a significant link with seriously aggressive criminal conduct in adult life

Table 7.4 Bio-psycho-social (*BMPPS*) model of assessment of problem behaviour in people with intellectual disability

Behaviour (*B*)	See list in ► Sect. 7.9.1
Medical and organic factors (*M*) (See also ► Sect. 7.9.2)	Physical symptoms (toothache, tummy ache, heartburn, headache, etc.) Medical conditions (cardiovascular, respiratory, endocrine, gastrointestinal, musculoskeletal, dental, skin and genito-urinary) Physical disabilities Problem with sleep, appetite, weight, bowel and bladder Epilepsy and other neurological conditions (spasticity, movement disorders, multiple sclerosis, brain tumour, etc.) Genetic conditions (Lesch-Nyhan syndrome, Prader-Willi syndrome, Fragile X syndrome, Smith-Magenis syndrome, etc.) Sensory impairment Communication/speech problems Drug- and alcohol-related factors Current medication, previous medication, polypharmacy and high-dose medication use and adverse effects including anti-cholinergic burden
Relevant histories (*Person*)	Developmental, social, family, occupational and relationship Current accommodation, daytime occupation, leisure activities family circumstances Patient's interests, strengths-abilities, likes, dislikes and preferences and how they express these opportunities, impact of disabilities, needs (including mental and physical health) and service and resource gaps Daily/weekly diary
Psychological/ psychiatric factors (*P*) (See also ► Sect. 7.9.3)	Psychiatric disorders: psychoses, bipolar disorders, dementia, depressive disorders, anxiety-related disorders, etc. Psychological symptoms: depression, anxiety, etc. Personality traits Dysregulated arousal and affect
Social/environmental factors (*S*) (See also ► Sect. 7.9.4)	Crowded/noisy/uncomfortable environment Demanding activities, lack of interesting activities, too many changes in the activities, etc. Personalities of other people/staff Change in the environment, activities of daily living at home (e.g. washing and cleaning), activities of daily living outside home (e.g. shopping), relationships, occupation and activities including leisure activities and financial situation and therapeutic interventions Changes required in the level of supervision and support, and major life events including abuse Adequate support for patients and also their caregivers (both family caregivers and paid care staff)

chological and history of use of services and (d) difficulties in developing fulfilling relationships, etc. Therefore, the formulation for the management of PB should be person centred. In this context, it is helpful to have a description of the individual's current and past weekly routine.

7.9.1 Behaviour

Assessment of the actual behaviour should include (a) past history of PB; (b) baseline behaviour prior to the onset of current PB; (c) the onset of the behaviour(s) to describe whether they appeared gradually over time or relatively abruptly perhaps precipitated by an acute event; (d) the frequency, severity and duration of the behaviour(s); (e) nature, content and the context of the behaviour as some behaviours may occur in certain circumstances/settings but not in others; (f) associated behaviours and (g) the impact of the behaviour(s) on the person's life, other's life and the environment. As for the consequences

of PB, the behaviour(s) may lead to (a) reduced quality of life for the individual and her/his caregivers; (b) reduced access to services including education, day service and employment opportunity and may lead to a threatened or actual loss of placement in a residential setting or day placement and (c) reduced social activities including leisure activities, access to friends, etc. In severe cases, the individual may end up being physically restrained, medicated or taken to a hospital or police station. All these scenarios may subsequently have their impact on the individuals, their behaviour and their caregivers. For example, some of these consequences may work as perpetuating factors for the ongoing behaviour(s). Some negative consequences of the behaviour such as physical restraint and use of medication may be seen as inappropriate or excessive and the individuals or their caregivers may perceive them as punishments.

Assessment of risks, including (a) risk to others, (b) risk to the individual, (c) risk to the environment and (d) other risks, forms an important part of the formulation. Clinicians should use the right methods of risk assessment, take note of previous risk assessment and review risks on a regular basis and (e) review the measures taken to reduce risks to assess their effectiveness.

The behaviour must be described in terms that are as follows: (a) clear, specific and unambiguous, (b) measurable (by observation or self-report or observer rating) and (c) capable of future replication.

7.9.2 Medical and Organic Factors

A full review of all bodily systems is essential, as both acute-onset and chronic conditions can present with PB. Assessment of medical and organic factors is an important part of both the differential diagnosis and assessment of contributory factors, and should include history taking, examination and investigations as indicted for:

(a) Chronic physical conditions such as headaches, toothaches, pain in other parts of the body and constipation may manifest as PB. It is important to assess individual's pain threshold as, for example, some individuals with ID, particularly those with autistic features, may have an impaired response to pain (either hypersensitive or hyposensitive) [84]. Gastro-oesophageal reflux disorder is common in people with ID and can present as PB, as can recurrent chest infection, heart/lungs/abdominal/GU/endocrine disease, etc.

(b) Epilepsy and other neurological conditions such as limb spasticity in cerebral palsy [105].

(c) Genetic conditions, such as Lesch-Nyhan syndrome, Fragile X syndrome, Prader-Willi syndrome and Smith Magenis syndrome, are associated with a higher prevalence of PB, particularly SIB [27].

(d) Sensory impairment such as hearing and visual impairment which may lead to PB through frustration but impairment in sensory processing as is known to affect individuals with ASD and ID may also lead to PB, particularly if caregivers are not aware of these difficulties.

(e) Communication problems as in some cases people with ID may communicate their distress through PB. However other forms of communication difficulties such as a discrepancy between expressive and comprehensive speech skills, and impaired social communication skills may also cause confusion and/or frustration leading to PB.

(f) Physical disabilities such as paralysis may cause frustration and lead to PB.

(g) Illicit drug and alcohol-related factors, although this is not known to be a major problem in individuals with ID, could affect a number of individuals with borderline intelligence.

(h) Some prescribed drugs can cause adverse events, which may lead to PB, and there are risks of PBs associated with polypharmacy and with excess anti-cholinergic burden due to polypharmacy, which is common for people with ID.

7.9.3 Psychological/Psychiatric Factors

This should include an assessment of psychiatric disorders as well as neuropsychological and other psychological factors. Psychiatric disorders such as depression, bipolar disorder, schizophrenia and other psychoses and anxiety-related disorders may lead to PB among individuals with ID [21, 66]. However, one has to be mindful about the common problems encountered in making a diagnosis of psychiatric disorders in this population [34]. As ASD and ADHD are common co-morbidities of ID, their influence on the manifestation of PB has to be assessed carefully. Therefore, it is important to investigate for these conditions because the management of PB may vary depending on the presence or absence of any psychiatric disorder. Additionally, clinicians should look for evidence of persistent enduring abnormalities of personality that are contributing to difficulties in interpersonal, occupational and social domains (e.g. paranoid and psychopathic). However, clinicians should be careful in using a diagnosis such as a personality disorder, which may simply be a way of describing PB in people with mild-to-moderate ID, whereas the same behaviour among individuals with severe and profound ID may not attract a diagnosis of a personality disorder.

Clinicians should also look for other contributory psychological and emotional factors such as (a) bereavement; (b) psychological trauma; (c) physical, sexual and emotional abuse; (d) new, ongoing or recurrent stress and life events and (e) relationship difficulty leading to loss of self-esteem and isolation that may perpetuate PB. There are important neuropsychological factors such as (a) impaired intelligence, (b) impaired memory, (c) impaired or abnormal communication skills, (d) impaired executive function, (e) impaired frontal lobe function such as lack of initiative and apathy and (f) lower threshold of stress tolerance, etc., which all should be considered when clinicians are assessing PB to formulate a management plan.

Impairment in executive function may take the form of a lack of planning ability, ability to think in abstract terms, multi-tasking abilities and sense of judgment. A lack or impairment of these functions is likely to cause stress and inability to address problems in day-to-day life and, as a result, may lead to PB. Many people with ID are likely to show impairment in their executive function. This impairment may remain subtle and undetected, and indeed there are practical difficulties in reliably assessing these aspects of cognitive function in most people with ID [122]. However, in the absence of an understanding of this process, the potential for PB may increase.

Some people with ID may appear to their caregivers as unwilling to take part in activities, and more and more demands may be placed on them in order to rectify this behaviour. However, the caregivers may not realise that this behaviour is caused by the impaired function of the pre-frontal cortex and the individual may not, therefore, have any control over their behaviour. This simple understanding on the part of the caregiver may help immensely in the management of such PB.

Individuals with ID may have a lowered tolerance of stress, and this may lead to PB. The lower threshold could be caused by many factors including (a) the cognitive factors that are discussed above, (b) lack of social support, (c) lack of self-esteem, (d) poor self-image, (e) learned maladaptive behaviour from the past, (f) lack of psychological and social reserve including the inability to use advanced psychological defences as opposed to using more primitive psychological defences and (g) an inability to think in abstract terms. All these areas need careful consideration in the assessment.

7.9.4 Social Factors

Assessment of environmental factors including a description of daily activities, educational activities, occupational and leisure activities, relationship and friendship with

others including family members and authority figures and change in the environment are all important factors for consideration in the formulation of management of PB. Such factors may play a major role in predisposing to, precipitating and perpetuating PB. Some individuals may perceive their environment as too demanding. For example, an individual may not want to carry out certain activities that are required of them and are seen as necessary for their personal welfare by the care staff. Similarly, some individuals may find the lack of space around them, other people around them and lots of activities/noise around them overwhelming and stressful. It is important to keep in mind that certain activities that may not seem demanding to a person who does not have ID may be perceived as demanding by some individuals with ID. Similarly, some individuals may perceive their environment as under-stimulating and lacking in appropriate activities. Both under- and over-stimulation in the environment may lead to PB. Structure and routine are also important for some people and lack of these can lead to misunderstandings, anxieties, confusion and so PBs.

Personalities of other people around the individual including those of care staff are likely to affect the individual's behaviour. Similarly, the way others interact with an individual with ID may also impact on her/his behaviour. Lack of respect for the individual with ID may be evident and can lead to PB. The lack of support from others including caregivers and other residents in a house may lead to PB. Similarly, a confrontational attitude on the part of the care staff may perpetuate PB. Although these are important causes for PB and must be considered during the assessment, these issues have to be handled with sensitivity and caution to avoid any conflict with the caregivers or the individual with ID.

Clinicians should also assess whether the individual has experienced any significant life events in the recent or distant past (e.g. loss and change). This should include a history of ongoing or past sexual, emotional and physical abuse. The individual may not feel part of an inclusive service or wider community or may experience stigmatisation and discrimination. He or she may also lack appropriate social exposure and support. All these should be considered carefully. A functional assessment of the behaviour is likely to include all the above elements including an assessment of antecedents and consequences of the behaviour.

An important area to assess is whether the caregivers are adequately supported (including having had adequate training) and whether they are fully involved in the formulation and provision of care. The need for support for stress and fatigue among caregivers should be assessed carefully. The absence of these supports may help perpetuate PB by creating a vicious cycle.

Other important areas to assess are the organisational settings, systems and processes in place to support the individual with ID and her/his caregivers, and the need to address the possible absence of adequate support.

Another useful schema (*H.E.L.P*) for assessment of PB in people with ID has been proposed by Bradley and colleagues (see ◘ Fig. 7.3) [16].

7.10 Assessment Methods/Tools

There is a large and growing number of behaviour rating instruments and it exceeds the scope of a book chapter like this to provide a comprehensive presentation and critical appraisal of all the available instruments. We have presented here some of the more prominent instruments (see ◘ Table 7.5). We have not presented scales that assess only psychiatric disorders or stereotyped behaviour. Further information on assessment scales is available from other sources including the UK NICE Guideline [123] and the European Guideline [124, 34].

7.11 Functional Assessment

The hallmark of behavioural interventions is to develop well-founded hypotheses about the contingencies of reinforcement of a given target behaviour in order to guide the development of rational customised behavioural

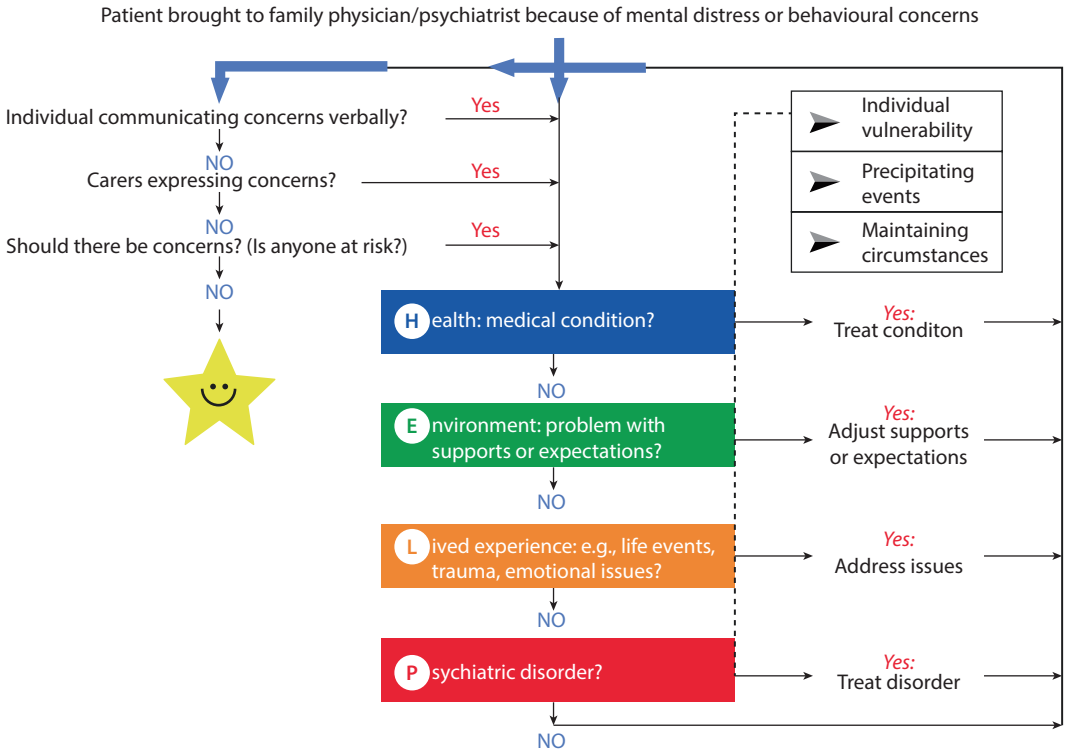

Fig. 7.3 H.E.L.P. diagram

interventions. Functional assessment can include interviews, naturalistic contingency observations and rating scales. In Table 7.4, we present some commonly used functional assessment rating scales. Various methods for functional and contextual assessments have been proposed with associated benefits and drawbacks [125]. Experimental manipulation of variables allows for the inference of causality; however, this method is time consuming, requires a high level of expertise and artificially producing AB using potentially aversive stimuli is unethical [125, 126]. Direct observation is also potentially an intensive resource, especially if behaviours are not exhibited frequently [125, 126]. In response, the use of interviews and checklists with informants are the most preferred and widely used methods for functional assessment [127] to provide a simple, quick, accessible assessment and requiring less expertise on the part of the clinician [125, 126].

7.12 Conclusion

PB, in general, and AB, in particular, is a complex phenomenon that involves a multitude of factors and is the outcome of an interaction between the person and her/his environment. It is difficult to define and classify PB using any standard psychiatric classification system such as the DSM-5 (disruptive, impulse control and conduct disorder) [21]. One reason is that by definition these disorders assume that the person is behaving with intent, which is difficult to determine in most cases of PB in ID. The other difficulty is to determine the criterion that these behaviours are inappropriate for their age as in ID the chronological age does not correspond to the developmental age. Also, a diagnosis of the intermittent explosive disorder cannot be made before 6 years of age or equivalent developmental level according to DSM-5 criteria, which makes this diagnosis impossible for individuals with severe and pro-

Table 7.5 Some rating scales used for the assessment of problem behaviour in people with intellectual disability

Instrument title Author(s) and year of publication	Description and target population	Items and subscales
Combined scales for assessment of behavioural and psychiatric problems		
Developmental Behaviour Checklist (DBC) (Einfeld and Tonge, 1994) [133]	Parent or teacher rated; children and adolescents Standardised and normed assessment of emotional and behavioural problems	96 items (parent version), 93 items (teacher version); 5 subscales: disruptive/antisocial, self-absorbed, communication disturbance, anxiety and social relating
Adaptive Behavior Scale (ABS) and ABS Residential and Community: 2nd Edition (ABS-RC:2) (Nihira et al., 1975) [134]	Informant rated; ABS-RC:2: all ages Measures personal independence and social skills divided into two parts: first measures individual responsibility and functioning or social adaptation; second part measures social maladaptation and can be used to measure problem behaviour Three types of score are available: domain, factor and comparison Adequate psychometric properties, however, has low inter-rater reliability for part 2	356 items, divided into two parts Second part has seven subscales: social behaviour, conformity, trustworthiness, stereotyped and hyperactive behaviour, self-abusive behaviour and social engagement
Diagnostic Assessment of the Severely Handicapped-II (DASH-II) (Matson, 1995) [135]	Informant rated; all ages; severe and profound ID only Developed to reflect DSM categories that are most commonly diagnosed in people with ID Six behavioural factors: emotional lability, aggressive behaviour/conduct disorder, language disorder/verbal aggressive behaviour, social withdrawal/stereotyped behaviour, eating disorder and sleep disorder Measures severity, frequency and duration of behaviours Good psychometric properties have been reported	84 items; Eight subscales: impulse control, organic syndromes, anxiety, mood/depression, mania, pervasive developmental disorder/autism, schizophrenia and stereotypies/tics
Matson Evaluation of Social Skills for Individuals with Severe Retardation (MESSIER) (Matson et al., 1998) [136]	Informant rated; all ages; severe and profound ID only Assesses social strengths and weaknesses including providing a profile of social skills both positive and negative and maladaptive behaviours. Good reliability data have been published by the authors of the instrument	85 items Six subscales: positive verbal, positive non-verbal, general positive, negative verbal, negative non-verbal and general negative

Table 7.5 (continued)

Instrument title Author(s) and year of publication	Description and target population	Items and subscales
Nisonger Child Behavior Rating Form (NCBRF) (Aman et al., 1996) [137]	Parent or teacher rated; children Social competence and problem behaviour subsections Adequate psychometric properties are reported The NCBRF has age- and gender-based norms on a restricted sample of children and adolescents	66 items in the problem behaviours subsection
Reiss Screen for Maladaptive Behavior (RSMB) (Reiss, 1997) [138]	Informant rated, all ages Psychopathology screening instrument (not a diagnostic tool) Clinically and factorially derived subscales Factor structure and good concurrent validity replicated	36 items; Eight subscales: aggressive behaviour, autism, psychosis, paranoia, depression (behavioural signs), depression (physical signs), dependent personality disorder and avoidant personality disorder
Scales of Independent Behavior-Revised (SIB-R) (Bruininks et al., 1996) [139]	Informant rated, all ages with developmental disabilities and other populations with needs for special assistance Designed to measure adaptive and maladaptive behaviour and to determine the type and amount of special assistance required Normed scores are available	Four clusters of independent behaviour and three clusters of problem behaviour: internalised, externalised and social
Vineland Adaptive Behavior Scales, second Edition (VABS) (Sparrow et al., 2005) [140]	Self-, parent- and teacher rated, all ages Measures adaptive and maladaptive behaviours among people with ID, ASD, ADHD, post-traumatic brain injury, hearing impairment and dementia One of the most widely used standardised assessment instruments. Survey and expanded interview version available	49-item optional maladaptive behaviour section: 10 internalising behaviours 10 externalising behaviours 15 'other' behaviour problems 14 'critical' items

(continued)

Table 7.5 (continued)

Instrument title Author(s) and year of publication	Description and target population	Items and subscales
Specific behaviour problem scales		
Aberrant Behavior Checklist (ABC) (Aman et al., 1995) [69], later *ABC-Community (ABC-C)* and *Aberrant Behavior Checklist, 2nd Edition (ABC-2)* (Aman and Singh, 2017) [141]	Informant rated; all ages Assessment of a broad range of problem behaviour Scale empirically developed and subscales determined by factor analysis. ABC-C developed to assess behaviour among community-residing individuals with ID Favourable psychometric properties; has been widely used and evaluated	58 items Five subscales: irritability, social withdrawal, stereotypic behaviour, hyperactivity/noncompliance and inappropriate speech Subscale scores should only be used; total score is not a valid measure [141]
Adult Scale of Hostility and Aggression: Reactivel Proactive (A-SHARP) (Matlock and Aman, 2014) [142] also Children's-SHARP (C-SHARP) (Farmer and Aman, 2009) [143]	Informant rated, adult and children's version Empirically developed measure of severity and/or frequency of interpersonal aggression among people with aggressive behaviour and ID Captures reactive and proactive aggression Factors derived from factor analysis	52 items; Five factors: verbal aggression, physical aggression, hostile affect, covert aggression and bullying
Behavior Problems Inventory (BPI-01) (Rojahn et al., 2001) [144] and the short version (*BPI-S*) (Rojahn et al., 2012) [145]	Informant rated, all ages Measures maladaptive behaviour in terms of frequency and seriousness Regularly used for clinical and research purposes Empirically derived factor structure Fair-to-excellent psychometric properties have been reported by the authors of the scale	BPI-01: 52 items; and BPI-S: 30 items. Three subtypes of behaviour: SIB, stereotyped behaviour and aggressive/destructive behaviour
Challenging Behavior Interview (CBI) (Oliver et al., 2003) [146]	Informant rated, all ages Assesses the severity of challenging behaviour Adequate psychometric properties reported by the authors of the scale	Five behaviours first rated for presence: Self-injury, physical aggression, verbal aggression, disruption of the environment and inappropriate vocalisation 14 questions to establish the severity of each behaviour rated as present
Checklist of Challenging Behavior (CCB) (Harris et al., 1994) [147]	Informant rated, all ages Developed to determine prevalence of challenging behaviour among people with ID Little validation data are available	Two parts: 14 items relating to aggression/physical contact with others or self 18 items relating to other problem behaviours including stereotypical behaviour and property destruction

Table 7.5 (continued)

Instrument title Author(s) and year of publication	Description and target population	Items and subscales
Modified-Overt Aggression Scale (MOAS) (Ratey and Gutheil, 1991) [148]	Informant rated, all ages Provides scores for the past week. Was not developed for use with people with ID but has been successfully used with people with ID and has established reliability [149]	16 items; Four categories of behaviour: verbal aggression, physical aggression against objects, physical aggression against the self and physical aggression against others
Repetitive Behavior Scale-Revised (RBS-R) (Bodfish et al., 2000) [150]	Informant rated, all ages Assesses the severity of abnormal and repetitive behaviours Empirically derived scale with good reported psychometric properties	43 items; Six subscales: stereotyped behaviour, self-injurious behaviour, compulsive behaviour, ritualistic behaviour, sameness behaviour and restricted behaviour
Problem Behaviour Checklist (PBCL) (Tyrer et al., 2016) [151]	Informant rated, all ages Based on factor analysis of the original 37-item scale; has good inter-rater reliability and convergence with MAS (Tyrer et al. [152])	28 items; Seven subscales: personal and property violence, self-harm, sexually inappropriate behaviour, contrary behaviour, demanding and difficult behaviour and wandering
Functional assessment		
Functional Assessment for Multiple Causality (FACT) (Matson et al., 2003) [153]	Informant rated, developed using a sample of adults Developed to assess problem behaviour that may be maintained by multiple functions. Uses forced choice questions Empirically derived with factors derived from factor analysis Limited data on psychometric properties; initial evaluation indicates good validity and reliability [153]	35 items; Five subscales: tangible (target behaviour has a history of producing tangible items), physical (behaviour is exhibited during physical discomfort), attention (behaviour attracts attention from others), escape (behaviour is used to escape disagreeable situations) and non-social
Functional Analysis Screening Tool (FAST) (Iwata and DeLeon, 1995) [154]	Informant rated, all ages Should be used as part of a comprehensive functional assessment Moderate psychometric properties reported	16 items; Four subscales: social/attention/preferred items, social escape, automatic sensory stimulation and automatic pain attenuation
Motivation Assessment Scales (MAS) (Durand and Crimmins, 1988) [155], (Spreat and Connelly, 1986) [156]	Informant rated, all ages Clinically derived subscales Relatively weak psychometric properties reported	16 items; Four subscales: sensory, escape, attention and tangible

(continued)

Table 7.5 (continued)

Instrument title Author(s) and year of publication	Description and target population	Items and subscales
Questions About Behavior Function (QABF) (Singh et al., 2009) [157]	Informant rated, all ages Clinically derived subscales, acceptable good psychometric properties have been reported	25 items; Five subscales: attention, escape, non-social, physical and tangible These subscales are cross-referenced against nine behaviours: physical aggression, verbal aggression, self-injury, tantrums, disruptive behaviours, stereotypes, inappropriate verbal behaviour and non-compliance
Contextual Assessment Inventory for Problem Behaviour (CAIPB) (Carr et al., 2008) [125], (McAtee et al., 2004) [126]	Informant rated; developed using a sample of adults For the assessment of contextual factors. Has adequate convergent and predictive validity and test-retest reliability but questionable inter-rater reliability	93 items; Four categories, each with two or three subcategories: social/cultural (including negative interactions and disappointments), tasks/activity (including factors related to tasks and daily routines), physical environment (including uncomfortable environment and changes in the environment) and biological (including medication and illness)
Setting Event Checklist (SEC) (Gardner et al., 1986) [158]	Informant rated; all ages Identifies motivational conditions or setting events. Limited psychometric evaluation	Over 78 setting events; Organised into nine categories: physical setting, time of day, day of week, weather conditions, activities, presence of particular clients, presence of particular staff, social context and personal context
Setting Event Inventory (SEI) (Tustin et al., 1997) [159]	Informant rated; all ages Identifies setting events for problem behaviour The authors report good inter-rater reliability and internal consistency	155 items; 19 scales, 6 of which measure preceding behaviours of individuals and 13 relate to the environment (including carer attention, instruction and touch; criticism or correcting; peer agitation or encroachment; possessions; task difficulty and organised activity; noise; change and disappointment)

found ID and also for most with less severe ID. Another major problem in defining PB is that almost inevitably PB is reported by someone else rather than the person exhibiting the behaviour. Therefore, the same behaviour which appears problematic to some may not appear so to others. Having said that, there are some severe behaviours, for example, SIB related to Lesch-Nyhan syndrome will almost universally appear as a PB. As a result, a dimensional approach to define psychopathology associated with PB in people with ID is the best approach in dealing with this behaviour instead of trying to categorise them according to any standard psychiatric classification system.

The management of PB will require a thorough assessment of causes and effects of the individual's behaviour. Therefore, we recommend that a formulation based on the bio-psycho-social causes and the effects of PB must be established first before initiating any

intervention. In assessing PB, the types of PB should be described along with severity ratings (mild, moderate and severe) and a frequency rating (low, medium and high). As the definition of severity and frequency would vary depending on many factors such as the type of behaviour and perception of the person reporting the behaviour, etc., neither 'severity' nor 'frequency' is defined here and is left with the clinicians to define under each specific circumstance.

AB remains a major management challenge and causes immense distress to people showing the behaviour and others around them. AB may lead to unnecessary hospitalisation and use of medication, exclusion from many social opportunities and is a source of stress for family and friends. Both neurobiological and environmental factors play a large role in predisposing to, precipitating and maintaining AB, and must be taken into account during the assessment (*B.M.P.P.S.*) (see Table 7.3). In addition, co-morbidities of physical and psychiatric disorders can contribute. A suggested schema (*H.E.L.P.*) (see Fig. 7.3) can be used to do this assessment, including a bank of specific tests of cognitive and executive function, medical investigations to investigate organic causes and consideration of psychosocial and environmental factors. This will ensure a holistic and optimum approach to successful management of aggression. In essence, as aggression is multi-factorial, its management has to be multi-faceted with multi-professional input in an integrated fashion with the ultimate goal to improve the people with ID and their carers' quality of life.

For pharmacological and nonpharmacological management of PB and intervention refer to ▶ Chaps. 11 and 12, respectively.

Key Points

- Problem behaviour is more prevalent in people with intellectual disabilities than those who do not have intellectual disabilities.
- Problem behaviour is multi-factorial in aetiology including internal factors like genetic disorders and external factors such as the environment and other psychosocial issues.
- Therefore, a multi-professional, person-centred, bio-psycho-social approach is needed for a thorough assessment of problem behaviour.
- Both pharmacological and non-pharmacological interventions are implemented for its treatment but their role remains limited, making this a major management problem.

Learning Objectives

The issues discussed in this chapter do no focus on a specific area of mental health, but they are pivotal to the whole field of mental health assessment, certainly in people with ID and LF-ASD, but probably also across the whole population. The basic questions we are asking is 'how should we be doing assessment, and who should be collecting the information?'. In many service contexts, it is assumed that psychiatrists and psychologists will work mainly on the basis of their clinical knowledge and expertise, while other staff are the ones likely to use structured instruments. For patients with ID and LF-ASD, the problems of language often lead to a great emphasis on the completion of structured assessments by informants. Very often, a patient will receive multiple assessments by a variety of health professionals, but then someone has the task of synthesizing this into a meaningful formulation. Many questions arise by this scenario. For example, should all the clinicians use structured methods? What type of assessments should be used? How should we bring all this information together? Should we actually be structuring the whole assessment process, including the final formulation? This chapter's main aim is to offer some practical and theoretical guidance on the incorporation of structured assessments into clinical services working with people who have ID and/or LF-ASD.

8.1 Introduction

The broad aims of this chapter are to offer some guidance on the use of structured assessment methods with people who have intellectual disability (ID) and/or low-functioning autism spectrum disorder (LF-ASD), and to give a review of the main tools available as well as some examples of their use.

In order to consider the potential contribution of using structured methods, it is necessary to look closely at the fundamental issues relating to the whole process of mental health assessment. There are many reasons why someone might wish to employ a structured method, and there are likely to be differing viewpoints of the potential users of such assessments. An informed decision about the use of, and choice of, structured assessment inevitably needs a close look at some difficult questions; the answers to which may not always be clear cut. If structured assessments are to be used in a clinical service, this may be to measure changes in response to treatment, or as part of the diagnostic process. In either case, it is desirable to examine the quality of information they generate, how this information will be used, whether it aids communication between different professionals and how much confidence clinicians have in the information. Potentially, the adoption of structured methods can significantly improve the overall quality of assessment and monitoring, but in order to do this there needs to be agreement among the clinical team about what methods are to be used and when to use them.

8.2 Why Use a Structured Assessment?

These are some of the numerous reasons why one may wish to use a structured assessment:

- To improve the quality of one's own clinical assessment
- To draw on the knowledge of other staff who may not have a formal training in psychiatry psychology, but who knows the patient better than yourself
- To free up expert clinical time by getting lesser-paid people to collect information
- To get the patient's own perspective by asking them to complete their own answers
- To enable a common assessment framework across professionals within the service
- To enable the use of a potentially 'free' resource, that is, the person themselves and their family

Many clinical services employ questionnaires and checklists to collect part of their information. However, the choice and selection of assessments are not always done with a coher-

ent assessment policy in mind. Broadly speaking, psychiatrists and psychologists are much less likely to use structured methods than other staff, as they rely too much and too often on clinical impression. Whether it is desirable for the senior clinicians also to include structure in their assessments is something we will also consider.

8.3 Structured Assessments and Developmental Level

The fact that many people with ID have very poor language, or no language at all, sometimes leads to the suggestion that structured assessments are more important with people who have ID than with the general population. Certainly, if the person has very poor language, we become highly reliant on third-party reports, and these reports are often aided by checklists and questionnaires. If the person is of a developmental level sufficient to have good language, and their disorder does not lead to a lack of insight, then assessment relies largely on what the patient says. This does, however, lead to a fundamental question: why do we often use structured methods to collect information from third parties, but rarely structure the clinical interview itself? Interviewing is a highly volatile process, open to influence by numerous factors that will be discussed shortly.

8.4 Fundamental Dimensions of Structured Assessments

There are a great many published assessments, making it sometimes difficult to decide which ones to employ. The following notes hopefully give some guidance on the main differences between them.

8.4.1 Different Models of Mental Disorder

This is probably the most fundamental dimension that determines how we assess, and what structured tools we might employ in the process. Within this dimension, one of the biggest problems that faces any designer of assessments is how to reconcile psychiatric and behavioural approaches.

8.4.1.1 The Psychiatric Approach

Over the hundred or so years that psychiatry has existed as a discipline, it has been observed that symptoms cluster together. For example, a person who is depressed is also highly likely to have lost interest in things, feel low in energy and perhaps feel hopeless about the future. Through these observations, the classic diagnostic constellations or syndromes have gradually been identified and clarified (see ► Chap. 5). One of the main focuses of psychiatric assessment is, thus, to collect the information necessary to decide on which of these clusters the person's symptoms belong.

8.4.1.2 The Behavioural Approach

A behavioural analysis does not seek to identify pathologies, but rather looks at the relationships between antecedent conditions and behavioural consequences. This is often done with the aim of changing antecedent conditions to reduce undesirable behaviours. Behavioural assessments may, therefore, simply collect information about various behaviours, and may additionally provide some form of scoring which is often based on factor analysis. Behavioural analysis and interventions are widely used when working with people who have ID.

8.4.1.3 Reconciling These Two Approaches

What is the difference between a 'symptom' and a 'behaviour'? In a sense, all symptoms manifest of course in observed behaviours. However, the behaviours identified in behavioural analysis are usually ones that are considered of major concern in their own right; for example, aggression or self-injury. In comparison, symptoms like depressed mood or anxiety are probably better described as *indicators* of a general condition that may be manifested in many other ways beyond the actual listed symptoms in ICD-10 or DSM-5.

A real problem of reconciling behavioural and psychiatric approaches arises with symptoms/behaviours that can be viewed in radically different ways, for example:

- Worry about being abandoned
- Chaotic relationships
- Impulsiveness
- Self-harm
- Splitting
- Anger

From a behavioural/ecological perspective, such symptoms may be regarded primarily as a response to long-term history, including early childhood development, bonding and attachment, and ecological factors. These are, however, also symptoms for *borderline personality disorder*. These two different views require two different assessment approaches. If one is seeking primarily to determine whether the person meets the criteria for this disorder, then the chosen assessment tool would need to focus closely on severity and duration of the symptoms. If one is wishing to conduct a behavioural analysis, then the relationship between the behaviours and the person's wider ecology would need to be assessed. Each of these approaches would require a different assessment tool.

For people with ID/LF-ASD, a particular issue arises in relation to *challenging behaviour*. Challenging behaviours are highly prevalent in people with ID (see ▶ Chaps. 5 and 7), and it is notable that the term 'challenging' has been introduced in preference to the term 'problem behaviours'. What is the difference between a 'challenging behaviour' and a 'problem behaviour'? Many people with ID, particularly those with most severe cognitive impairment, can exhibit aggressive or destructive behaviours, but probably do not fully understand their impact or social significance. The term 'challenging' implies that the person with ID is not really in control of these behaviours, and that we, as service providers, have a responsibility to help the person. Diagnoses such as conduct disorder and personality disorder, on the other hand, imply that the person *does* understand the consequences of his/her action but nevertheless does it (or even enjoys doing it in the knowledge that it will cause upset to others).

The more severe the level of ID, the more difficult it becomes to judge whether the person understands the consequences of the action. While these judgements are very difficult, structured approaches to assessment can be helpful if they present the assessor with a formal framework that includes points to consider and appropriate choices to make. For instance, the Child and Adolescent Psychiatric Assessment Schedule (ChA-PAS) [1] section on Conduct Disorder offers the following four rating categories: *Staying out against parental/carer wishes*

1. Not present/not rated
2. [P] Has frequently stayed out at night against parental/carer wishes, but at least one of the following applies:
   (i) Does not fully understand the effect it has on others
   (ii) Behaviour appears to be driven by frustration, or an emotional reaction to life circumstances
   (iii) Gets genuinely upset by the resulting distress to carers
3. [P] Has frequently stayed out, and is more or less indifferent to the distress it causes to carers, despite being aware of the effect it is having
4. [P] Stays out repeatedly against carers' wishes, fully understands the effect it has, but responds in at least one of the following ways:
   (i) Takes pleasure in the upset it causes
   (ii) Makes up glib excuses that are clearly lies
   (iii) Expresses glib feelings of guilt and remorse that are clearly not genuine

Only levels 2 and 3 contribute to a diagnosis of conduct disorder. Level 1 scores as zero because of the extenuating circumstances that indicate it is not a symptom of this disorder.

8.4.1.4 The Statistical Approach

Some assessments do not start with the ICD-10 [2] or DSM-5 [3] rules, but instead take a purely statistical approach to the identification

problems. For instance, the Developmental Behaviour Checklist [4] was developed by starting with a very large number of behaviours, which were then subsequently rendered down into a number of factors using factor analysis. The advantage of such an approach is that it achieves a very wide coverage of all the behaviours of concern. The shortcoming is that the resulting factors may not be easy to interpret in terms of clinical practice or interventions.

8.5 The Coverage of the Assessment

This to some extent relates to the discussion of models of mental illness in the section above. However, it is important to distinguish broad-spectrum assessments from those that are for a specific area, such as autism, depression, and ADHD. When choosing a specific area assessment, it is important to consider whether the use of this tool might bias the final outcome in favour of the area covered. For instance, consider a clinic that specializes in ADHD, and routinely uses an ADHD-specific tool to collect the data. Unless adequate safeguards are in place, there is a risk that other potential explanations for person's problems, for example, bipolar disorder, will receive less consideration than they merit.

> Potentially, the adoption of structured assessment methods can significantly improve the overall quality of clinical assessment and monitoring, especially with reference to patients with lower levels of communication or cognitive ability. The selection of structured assessments, both informant based and self-rated, needs careful matching to the characteristics of the patient. If the assessment has a specific focus, for example, ADHD, it is important to consider whether that choice might bias the outcome in favour of the area covered.

8.5.1 The Level of Structure, Detail, Precision, Guidance and Analysis

The relationships between these five characteristics mentioned in the title are probably the most central aspects that distinguish between the various assessments that are available. To think about the interaction between these aspects, it is important to start with the desired outcome of using structured tools. There are actually many ways in which their use can be of benefit [5], but here we will consider four of the main reasons:

1. To screen for potential cases who will subsequently receive an in-depth assessment
2. To predict what an expert clinician would probably conclude if a full assessment was undertaken
3. To collect information that will form part of a subsequent diagnosis or formulation
4. To make actual diagnoses or formulations

Reasons 1 and 2 above have in common that no expert clinician is involved in the process: they both imply that the person competing it may not have a background in psychopathology. Screening tools are often highly structured, with little precision needed in categorizing the answers, and little guidance given beyond the wordings of the items themselves. Analysis takes the form of a built-in scoring system that renders an answer to the question, 'should this person receive a more in-depth assessment?'. Screening tools do, to some extent, predict what an expert would conclude, but research studies wishing to make more accurate predictions will often use a more complex assessment, probably requiring training. In either case, the psychometric properties of the assessment are very important. In the case of screening, the most important psychometric aspect is probably that no genuine cases are missed. To make more accurate predictions of expert opinion, the assessment must be reliable and valid. This is discussed in more detail shortly.

A very different form of structure is present in ICD-10 [2] and DSM-5 [3]. They are themselves structured assessments, in that they provide rules to determine what symptoms are associated with the various diagnoses, along with information relating to time course, etc. They have a high degree of general clinical guidance and distil the knowledge of a great many experts about, for example, the relationships between physical and mental disorders. They are, however, *low* in precision because they give relatively little guidance on how to identify different manifestations of the same symptom. This is particularly important in relation to people with ID because they very often show symptoms in a different way, particularly if their level of ID is severe. ICD-10 [2] and DSM-5 [3] also have low precision in terms of guidance on symptom severity. How severe should a symptom be before one includes it as present; how would a mild example of the symptom and a severe example differ?

The clinical interview is often one of the principal avenue by which these diagnostic decisions are made. Clinical interviewing is frequently conducted without a formal structure. In this next section, we will consider whether structuring such interviews could be beneficial.

Screening for cases to undergo in-depth assessment, predicting clinician conclusion, collecting information of clinical utility and making actual diagnoses or formulations represent the four main ways in which the use of assessment tools can be of benefit. It is important to know from the beginning the desired result of using structured instruments during the assessment, considering that the clinical interview is often the principal avenue by which the diagnostic decisions are made.

8.6 Clinical Interviewing

Interviewing patients and informants is one of the primary methods for collecting information on mental status. Generally speaking, nothing can replace the validity of the patient's own report; for which reason, clinical interviewing is often used to make pivotal decisions. Surprisingly, training in the process of interviewing is often neglected, and the use of structured formats is rarely employed. To illustrate the advantages of a structured approach, consider one of the core symptoms of depression, low mood itself. If a patient is showing evidence of this symptom, how should we decide if the symptom is strong enough to say it is present?

The Present State Examination, the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) [6] and the Psychiatric Assessment Schedule for Adults with Developmental Disability (PAS-ADD) [7] assessments all take the view that it should be possible to rate a symptom as present, but that it is *below the threshold for clinical significance*. This is a very important point. Many of us experience symptoms of low mood or anxiety from time to time, but mostly these would not be considered pathological. The provision of a subclinical category also flags up the presence of a symptom that might subsequently become more significant in the future.

In order for the assessment of symptom severity to be workable and reliable, some rules need to be applied to each symptom. The Present State Examination relied mainly on use of the terms: *not present, mild, moderate* and *severe* as the rating categories. The limitation of this is that the terms mean different things to different people. The PAS-ADD [7] system has developed and evolved over about 25 years at the time this was written. Much of that evolution was in terms of the refinement of severity definitions. The current definitions for low mood (in the Mini PAS-ADD [8] Version 3) are as follows:

Item 7: Depressed mood

1. Not present or not rated.
2. Episodes of depressed mood occur most days, but [P] is sometimes more cheerful or can very often be cheered up by the intervention of others.
3. Depressed mood is a significant problem on most days, but attempts to cheer [P] will sometimes be successful.
4. The depressed mood is persistent and unresponsive to attempts to cheer [P] up.

When scoring, rating level 1 actually produces a score of 0. In other words, depressed mood is there, but it is considered to be sub-clinical.

The other dimension of structured interviewing is the wording of questions. It has been observed by one of us (SM) that it is easy to get involved in a lengthy discussion of a symptom with the patient or informant, yet still not have the information to tie down the symptom severity. The evolution of the PAS-ADD system has also resulted in question forms that are designed to determine symptom presence and severity as efficiently as possible. The question for low mood in the Mini PAS-ADD Version 3 (interview for informants) is as follows:

- **Item 7**
  - How is [P]'s mood?
  - Is [P] happy?
  - Does [P] feel depressed/low?
  - How does s/he show it? What does s/he do?
- **If Evidence of Depression:**
  - Is there anything you can do to cheer him/ her up when s/he is like this?
  - During {rating period}, has [P] been depressed all the time?
- **If not all the time:**
  - Are there some days when s/he is happier? Or just periods during the day?

Note how the wordings enable each of the severity categories to be evaluated.

8.7 Interviewing People with ID

A sizeable proportion of people with ID *can* respond meaningfully to a clinical interview, but the questions need to be carefully formulated and sensitively asked. Using the PAS-ADD 10, Patel, Goldberg and Moss [9] showed the following ratings of interview adequacy by the interviewer (who was an experienced psychiatrist).

Rating of subject's account of symptoms	Adequacy (%)
Subject responds adequately	36
Account somewhat inadequate but interview can proceed	13
Account seriously inadequate but interview proceeds in an attempt to rate some subjective responses	12
Impossible to continue with interview	38

Thus, nearly half the adults who were interviewed were able to give a useful contribution to a clinical interview. Given the unique validity of the patient's own report, it is highly desirable that any way of improving the quality of patient interviewing in people with ID is worth the effort. Good structured assessments, designed specifically for people with ID, can help in this respect, partly because they can provide ways of asking questions that have been tried and tested over a period of time. Also, the structure provides a way of helping the interviewer probe other possible problem areas that may not be clearly visible at the beginning, and hence, may have been omitted.

Training in the process of interviewing is often inappropriately neglected, and the use of structured formats is rarely employed.

Specifically designed, structured assessment can improve the quality of patient interviewing in people with ID/LF-ASD for many reasons, including the provision of questions that have been tried and tested over time and the possibility to probe problem areas that could be omitted.

8.8 Psychometric Properties

It is not proposed to have a lengthy discussion of psychometric issues here; they are well described elsewhere [10]. However, it might be helpful to offer some thoughts regarding the interpretation of psychometric data.

8.8.1 Reliability

First of all, nobody doubts the desirability of making assessments reliably. Any assessment, structured or otherwise, that produces different results from the same case presentation is of questionable value. The problem is that reliability in structured assessments is a result of various factors:

- The number of items
- The number of rating categories
- The tightness with which the ratings are defined
- The amount of training the users receive
- Whether the user retain their training or drift away from it

In choosing a structured assessment on grounds of reliability, an appropriate balance must, therefore, be struck. Does it cover the information you need, at the level of detail you require? If training is required, are you able to ensure the users get adequately trained? Using an assessment designed for trained raters which is being used by *non-trained* raters runs the risk of producing results that look highly informative but may simply be wrong.

8.8.2 Validity

The issue of validity is far more complex than that of reliability, and there is one main reason why this is the case. Consider the process of diagnosis in physical medicine. Over hundreds of years, the relationships between symptoms and their causes have become more and more precisely clarified. The validity of a physical diagnosis can be measured by the extent to which it correctly identifies the pathology. Nowadays, thousands of different procedures are used to identify pathologies, and the diagnosis is made in the light of that evidence. In comparison, we are making diagnoses of mental health problems, usually *in the absence* of clear evidence of physical causes. This lack of relationship between cause and effect makes the process of diagnosis fundamentally different. Diagnoses of mental health are, generally speaking, clinical judgements. This does not mean they have no utility, but it is vital to recognize this fact when considering issues of validity.

How, then, do we estimate the validity of a mental health assessment? Bearing in mind that ICD-10 and DSM-5 are themselves structured assessments, how could we estimate their validity? One answer would be that they are of course valid because they represent the distilled knowledge of clinical experts, collected over a very long period of time. As such, they can be considered a *gold standard*. However, the fact that they are not precise means that the validity of an assessment as measured by its conformity to ICD-10 or DSM-5 is not a very useful measure. A more common gold standard is that of clinical expertise. How far does the assessment predict what a clinical expert would say about the case? This approach has merit, but the limitation is that people completing the assessments are often in a very different situation from the clinical experts whose opinion is sought. The clinical expert may indeed have greater expertise to sift and judge clinical material, but may not be in such a good position to actually know the client.

Linking the knowledge and expertise of the various stakeholders in the case, from families through to all the health and social service professionals who may be involved, is something that structured assessments can potentially enhance.

8.8.3 Factor Structure

From a psychometric perspective, structured assessments are often considered to be better if their underlying factor structure shows a meaningful relationship to the concepts being

measured. For instance, items purporting to assess obsessive compulsive disorder should be closely correlated together, and less correlated with items in another section, such as depression. To some extent this is undoubtedly true. The person who is low in mood is often someone who has lost energy, feels hopeless for the future, etc. However, there is another consideration to be borne in mind. Both DSM-5 and ICD-10 take a *polydiagnostic* approach to diagnosis, that is, two different people can have widely differing symptoms yet still receive the same diagnosis. Also, it is well recognized that some symptoms overlap different diagnostic constellations, for instance, there are clear overlaps between ADHD and bipolar disorder, and between obsessive compulsive disorder and autism.

These considerations mean that an assessment that conforms very closely to the rules of ICD-10 and DSM-5, and is, hence, clinically very useful, may actually perform more poorly in terms of factor structure than an assessment that was designed primarily using a statistical approach.

> In choosing a structured assessment, an appropriate balance must be struck between psychometric properties (reliability, validity and factor structure) and contextual clinical utility. When necessary, users have to be adequately trained.

8.9 Some Examples of Structured Assessments

This chapter does not attempt a comprehensive review of structured assessments. Rather, we offer a sample of these, showing how they differ in terms of the various fundamental dimensions:

- Area covered
- Sophistication of rating and questioning
- The method of collecting information
- The primary aim of the assessment
- Who are the likely users

8.9.1 Fully Diagnostic Interview

8.9.1.1 The PAS-ADD Clinical Interview

The PAS-ADD Clinical Interview [7] is the most complex of the PAS-ADD assessments. It generates ICD-10 and DSM-5 diagnoses on a criterion-by-criterion basis, allowing the user to see clearly the extent to which individual criteria have been fulfilled. It covers all the principal axis I psychiatric disorders in detail, and additionally has an informant interview for ADHD and a screen for autism. There is a strong emphasis on final interpretation and diagnosis by the users themselves. There are no restrictions placed on who may use the interview, although it is clear that a background in psychiatry psychology is highly desirable in terms of interpreting results.

The PAS-ADD Clinical Interview was derived originally from the Present State Examination [11]. The original version, the PAS-ADD 10, was subsequently revised more than 20 years later in the light of information derived from training users over that period. During that time, many changes in question wording and definitions of rating severity were made.

The PAS-ADD clinical interview can be used with anyone who has sufficient language and cognitive development to be able to participate in a clinical interview. This includes children as well as adults, both with and without intellectual disability. The interview can also be used with an informant only.

Information is gathered through patient and/or informant interviewing, for whom there are separate sets of questions. Symptoms are rated on a 4-point scale of severity, the use of which enables a lot of precision to be built into the fulfilment of the diagnostic criteria. As with all the PAS-ADD assessments, the PAS-ADD clinical interview is equally valid for the general population, in which case questioning of the patient can use the informant questions. The PAS-ADD assessments are now also available in digital versions,

available via a website which can also be used off-line for conducting interviews where no Internet is available.

The refinement of the scoring system is illustrated by its approach to psychosis. Psychotic symptoms are notoriously difficult to identify reliably. In the PAS-ADD clinical interview, scores can only get the top severity rating if they are based on the patient's own account of symptoms rather than on an informant report. As such, diagnoses based on informant interviewing alone usually result in 'query' diagnoses for psychosis. The relationship between mood and psychotic symptoms undergoes a complex analysis to determine the final diagnosis.

Field trials investigated the validity of PAS-ADD in relation to the clinical opinion of referring psychiatrists [12, 13]. Inter-rater reliability of the PAS-ADD 10 [2] gave a mean Kappa of 0.65 for individual item codes of, and Kappa 0.7 for agreement on index of definition (clinical significance of the symptoms) [14]. The relationships between respondent (patient) and informant reports of symptoms, and the implications of deriving diagnoses solely from informant interviews, are discussed in Moss and colleagues [15]. The issues of using care staff as informants are discussed in Moss and Patel [16].

8.9.2 Other Structured Interviews

There are various structured assessments using an interview format that produce what would be better referred to as diagnostic 'indications'. These are not screening tools because they potentially provide enough information to actually make a diagnosis. They do not, however, provide a detailed criterion-by-criterion analysis that directly maps onto ICD-10 or DSM-5 criteria.

8.9.2.1 The PIMRA

The Psychopathology Instrument for Mentally Retarded Adults (PIMRA) [17–19] was designed for the use with adults who have mild-to-moderate levels of intellectual disability, and was originally derived from DSM III [20]. It is available in an informant interview version, and also for self-report (meaning self-completion by the informant). Questions have to be answered by yes or no. The PIMRA is designed to assess psychiatric disorder and psychopathology. It has eight sub-scales, scores from which measure seven diagnostic categories: schizophrenia, depression, psychosexual disorders, adaptation disorders, anxiety, somatoform disorders and personality disorders.

Many research studies have been conducted on the PIMRA, producing mixed conclusions about its psychometric properties. Thus, while the authors showed good internal consistency and acceptable test-retest reliability [18], others have shown lower reliability [21–25]. The construct validity was examined for the schizophrenia sub-scale first by Linaker and Helle [26] and then by Swiezy and collaborators [27], for the psychosexual sub-scales by Matson and Russell [28]. The construct validity of the remaining five sub-scales has not yet been rigorously evaluated. The factorial analysis of PIMRA was carried out first by Balboni and collaborators [29] and then by Sturmey and Ley [21]. The investigations did not produce clear and consistent results: only four main factors were identified and not all the eight sub-scales of the instrument were referred to independent constructs. The results of other researches indicate that the PIMRA is useful above all for research purposes, and therapeutic planning and outcome evaluation [27].

8.9.2.2 The DASH

The Diagnostic Assessment for the Severely Handicapped (DASH) [30, 31] assesses the presence of psychiatric disorders in people with severe and very severe ID. It consists of 84 items and organized in the following sub-scales based on the diagnostic criteria of DSM-III-R [32]: control of impulses, organic disorders, anxiety disorders, mood disorders, mania, pervasive developmental disorders, autism, schizophrenia, stereotyped behaviour, self-injurious behaviour, elimination disorders, nutrition disorders, sleep disorders and sexual disorders. The assessment is an informant interview, where each item is scored on a 3-point Likert scale for frequency, duration

and severity. The psychometric characteristics of the instrument have been well established, especially for the sub-scales of depression, mania and autism [33–37]. Overall, these confirm the reliability of the instrument, although further research is needed to prove the construct validity of many sub-scales.

The two-factor analysis conducted across time [31, 38] identified six and five factors, respectively, of which only the following three were in common: emotional lability, language disorders and sleep disorders.

DASH-II has been used in numerous clinical and epidemiological studies, including those referred to adolescence or early adulthood [39] and senescence [40].

8.9.2.3 Mini PAS-ADD and ChA-PAS

The Mini PAS-ADD [8] and the Child and Adolescent Psychiatric Assessment Schedule (ChA-PAS) are for completion by informant interview, and are widely used in Europe and Australia. They adopt the same four-point rating structure as in the PAS-ADD Clinical Interview, and similarly cover the principal axis I psychiatric disorders. Both include the autism screen, and the ChA-PAS [1] additionally covers ADHD and conduct disorder. In most cases, the scoring conforms exactly to the rating criteria laid down in ICD-10 [2] or DSM-5 [3]. However, there are some minor departures to enable a single score to be generated for each of the diagnostic constellations. For instance, the requirement for specific core symptoms of depression (low mood, loss of interest and loss of energy) is not specifically required.

The Mini PAS-ADD was conceived as an assessment that could provide an in-depth investigation of symptoms, but could be completed by people who did not necessarily have a background in psychology or psychiatry. The ChA-PAS follows this format, and was produced in response to requests for an assessment whose symptom definitions and questions were more appropriately directed towards younger people. These two assessments include a lot of guidance on how to recognize the various symptoms, and provide a semi-structured interview structure to help guide the way in which questions are formulated.

Psychometric properties of the Mini PAS-ADD can be found in Prosser et al. [41]. Results of a major study on the Dutch version of the Mini PAS-ADD have also been reported [42].

8.9.2.4 The CIS

The Clinical Interview Schedule (CIS) – mental handicap [43] – was created originally for the general population and adapted subsequently for the use of persons with ID. The version for the general population [44] was designed to be used by experienced psychiatrists, following a specific training, as a support in the formulation of ICD diagnosis. It is divided into four parts: one with the pathological anamnesis, both remote and near; one with a structured interview including ten groups of symptoms; one with additional information on the family and personal history and the last with a detail of anomalies communicated during the interview. This last part is the one that has undergone multiple changes in the adaptation to use with the ID, with seven additional items. It is also the one that, in the adapted version, presents the lowest inter-rater reliability. In general, the few data available on the psychometric characteristics of this scale are not encouraging and the terminology maintained in the various items seems to be less usable by most people with ID [45].

8.9.3 Full-Spectrum Questionnaires

These are wide-spectrum assessment, but are primarily checklists rather than interviews.

8.9.3.1 The P-AID

The Psychopathology Checklists for Adults with Intellectual Disability (P-AID) [46] is a battery of checklists to be used with informants, and is able to identify 10 different psychiatric disorders and 8 types of problem behaviours according to the Diagnostic Criteria for psychiatric disorders for use with adults with Learning Disabilities/mental retardation (DC-LD) [47]. It shows internal consistency, reliability and acceptable inter-rater, 8 units orthogonal to factor analysis,

while sensitivity and specificity are still to be explored [46].

8.9.3.2 The DBC

The Developmental Behaviour Checklist (DBC) [4] is an excellent example of an assessment whose development started from a primarily statistical standpoint. A large number of different kinds of behaviour in children were investigated in a large population of children with emotional or behavioural difficulties. From the scores, factor analysis derived a number of factors, and subsequently a smaller, refined set of items. The parent/carer version has 96 items in five different sub-scales. The items are scored on a 4-point Likert scale. The six factors identified by factor analysis are as follows: disruptive behaviour, self-absorbed behaviour, communication disturbance, anxiety, autistic-relating behaviour and antisocial behaviour.

The version for adults (DBC-A) [48, 49] includes 107 items, which are completed by family members, paid carers or someone else who know the person with ID well, reporting problems over a 6-month period. Each descriptive item of behavioural and emotional disturbance is scored on a 3-point Likert scale, from 'not true' to 'very true'. The DBC-A can be scored at three levels: (1) the overall measure, total behaviour problem score or alternatively the mean item score (MIS), the proportion of items checked (PIC) and the intensity index (II); (2) sub-scale scores measure disturbance in six dimensions, which may also be scored as total scores or as MIS with PIC and II and (3) scores on individual items.

Because it was derived from a statistical viewpoint, its psychometric properties are very good [50–54]. As such, it is very useful for epidemiological studies, but the factor scores may relate less to routine psychiatric practice.

8.9.3.3 The BSI

The Brief Symptom Inventory (BSI) [55] is an instrument of self-evaluation of psychological distress, developed for the general adult population, which essentially represents the brief form of the Symptom Checklist-90-R (SCL-90-R) [56]. It evaluates a wide range of symptoms through 53 items organized in the following nine sub-scales: somatization, obsession compulsion, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation and psychoticism. It also allows to obtain three global indices of psychopathology: general gravity, symptom distress and general symptomatological positivity. The BSI has been judged to be a valid tool for the self-assessment of psychological symptoms in people with mild ID or borderline intellectual functioning, although internal consistency and reliability were found to be rather low for all sub-scales [57–59]. The validity of the construct was verified by comparing sub-scales' average scores of three different groups of persons: persons living in the community attending a specialized clinical unit for assessment of ID severity (community group), persons under evaluation for co-occurrent psychiatric disorders (clinical group) and persons convicted of a crime (forensic group). The three groups presented significant differences in eight of the nine sub-scales and in two of the three global indices. The community group showed the lowest number of symptoms, followed by the forensic group and the clinician [58].

8.9.3.4 The PPS-LD

The Present Psychiatric State – Learning Disabilities (PPS-LD) [60] is an adaptation of the Present State Examination [61] and supports the psychiatric diagnosis according to the Diagnostic Criteria for Research-10 [62]. It contains 116 items and complements the information gathered by the evaluator and his closest assistants.

8.9.4 Screening Checklists

Screening assessments do not claim to provide comprehensive assessment on which a formulation or diagnosis can be made. Rather, they aim to make a statistical prediction of what an in-depth assessment would conclude, were to be undertaken, in the same way that a cancer screening gives an estimate of the probably presence of the disease. Very often, this simply takes the form of a yes/no conclusion, that is, 'yes', the person probably has a problem that

needs further assessment, or 'no', they probably do not have a mental health problem. Of course, the scores generated by screening assessments can also be valuable in their own right, giving an indication of the kinds of areas where problems might exist.

Two of the most important statistical characteristics of screening assessments are *sensitivity* and *specificity*. An assessment that is sensitive will be good at identifying all potential cases. An assessment that is specific will be good at distinguishing between non-cases and cases. Of course, one cannot get something for nothing. Checklists, when used by non-trained users, are very unreliable, and hence, not very specific. In order to increase sensitivity, it is inevitable that one has to lower the threshold score for identifying 'caseness', and this in turn increases the number of false-positive results (i.e. people who appear to have a problem when they actually do not).

In choosing a screening assessment, these points need to be considered carefully. If one wishes to definitely identify all possible cases, and then follow them up, a very sensitive assessment would be the choice. The disadvantage is that there will be many false positives, that is, people who triggered the screen but do not actually have a disorder. If resources for full assessment are limited, it may be appropriate to choose an assessment with higher specificity, on the assumption that all the severe cases would be identified. One would have to accept that some cases would be missed, but they would hopefully be the more mild ones.

8.9.4.1 The PAS-ADD Checklist

The PAS-ADD Checklist is a 25-item questionnaire, written in everyday language, designed for use primarily by care staff and families, the people who have the most immediate perception of changes in the behaviour of the people for whom they care. The Checklist aims to help staff and carers decide whether further assessment of an individual's mental health may be helpful. It can be used to screen whole groups of individuals, or as part of a regular monitoring of people who are considered to be at risk of mental illness. It is designed to record the presence of a range of problems, all of which may be part of a psychiatric condition. The scoring system includes threshold scores which, if exceeded, indicate the presence of a potential psychiatric problem, which may then be more fully assessed.

The PAS-ADD Checklist produces three scores, relating to:

1. Affective or neurotic disorder
2. Possible organic condition (including dementia)
3. Psychotic disorder

It also has a checklist for life events.

Factor analysis of the checklist completed on a community sample of 201 individuals yielded eight factors, of which seven were readily interpretable in diagnostic terms. Internal consistency of the scales was generally acceptable. Inter-rater reliability in terms of case identification, the main purpose of the checklist was quite good, 83% of the decisions being in agreement with expert clinical opinion. Validity in relation to clinical opinion was also satisfactory; case detection rising appropriately with the clinically judged severity of disorder [63]. Subsequent independent studies have further investigated the Checklist's psychometric properties [64], and established norms for an adult sample [65].

8.9.4.2 The ADD

The Assessment of Dual Diagnosis (ADD) [66] was developed to evaluate the full range of psychiatric disorders in adults with mild or moderate ID. To overcome any verbal capacity limits of the proband, the instrument can be administered to someone who knows the person to be evaluated well, such as a caregiver or family members. The scale consists of 79 items and 13 sub-scales organized according to the DSM-IV diagnoses: mania, depression, anxiety, post-traumatic stress disorder, substance abuse, somatoform disorders, dementia, conduct disorder, developmental pervasive disorder, schizophrenia, personality disorders, eating disorders and sexual disorders. Authors found good psychometric characteristics [66]. One study examined the correlations between the ADD sub-scales and a short version of the MMPI-168 (168-item Minnesota Multiphasic Personality

Inventory), adapted for use with people with ID [67]. The sub-scales of the two instruments, which measured similar psychological constructs, resulted not to correlate with each other, suggesting that ADD may have problems of construct and convergent validity.

8.9.4.3 The RSMB

The Reiss Screen for Maladaptive Behavior (RSMB) [68, 69] is one of the older and well-established scales evaluating psychopathology in individuals with ID through an interview to their caregiver or family member. It includes 38 items accompanied by a definition and some examples. The tool provides scores for the following eight dimensions: aggressive behaviour, autism, psychosis, paranoia, behavioural signs of depression, physical signs of depression, dependent personality disorder and avoidant disorder. The score assigned to each item is chosen on a 3-point scale based on symptom severity, that is, the impact of symptoms on the person's functioning during the last 2 months. A high score at one or more of the tools dimensions indicates a need for referral for more detailed evaluation.

The RSMB showed good psychometric properties across the range of ID, although some uncertainties on its factorial structure were pointed out as well as a higher sensitivity to depression than to other areas of psychopathology [68, 70–75].

8.9.4.4 The ABCL

The Adult Behavior Checklist (ABCL) [76] was not specifically designed for ID or LF-ASD. In fact it is an adaptation of the Young Adult Behavior checklist (YABCL) [77], created to support the clinician in the assessment of psychopathological symptoms in young adults of the general population. The ABCL includes 118 items to be self-rated by a proxy of the person with ID through a 3-point Likert scale ('not true', 'a little bit true' or 'sometimes true' and 'quite true') and in reference to the last 3 months. When used with persons with ID, the ABCL confirmed the good psychometric characteristics showed with use with the general population, including high concordance with clinical diagnoses based on DSM-IV criteria [78, 79]. The factor analysis identified eight syndromic subgroups: anxiety/depression, social withdrawal, somatic complaints, altered thinking, problems of attention, aggressive behaviour, transgressive behaviour and intrusiveness. Furthermore, two broad groups were also identified and defined as 'internalizing' and 'externalizing' disorders. The former showed the strongest correlations with the sub-scales of social withdrawal, somatic complaints and anxiety/depression, the latter with the sub-scales of transgressive and aggressive behaviour. In addition, the ABCL showed good predictive abilities of individual functioning, as measured by the Global Assessment of Functioning (GAF) [79], the Social Functioning Scale for the Mentally Retarded (SRZ-P) [80] and the Best Status Index (Best) [78, 81]. An equivalent of the ABCL for the developmental age, the Child Behavior Checklist (CBCL) [82], has also been repeatedly studied in children and adolescents with mild ID, with as many results of validity [83–85].

8.9.4.5 The SPAIDD-G

The Systematic Psychopathological Assessment for persons with Intellectual and Developmental Disabilities – General screening (SPAIDD-G) [86, 87] is part of a wide tools system to support professionals working with persons with ID and LF-ASD in the identification of psychopathological symptoms and syndromes. It includes 56 items, which represent descriptions of the most frequent observable and behavioural aspects of all the symptoms that appear in the various DSM-5 diagnostic categories. These items were developed to be rated by a mental health professional through the information gathered by interviewing a family member of the person with ID/LF-ASD or any other proxy who have a good perception of changes in the behaviour of the people for whom they care.

Raters do not have to attribute or rate the severity of any score, they only have to indicate the presence or absence of an item by ticking the appropriate box.

The SPAIDD-G evaluates the following syndromic groupings, consistent with those included in the DSM-5: nutrition/feeding disorders, psychotic disorders, mood disorder –

depression, mood disorder – mania, anxiety disorders, side effects of drugs, delirium, dementia, substance-related disorders, odd personality disorder, dramatic personality disorder, anxiety personality disorder, impulse control disorder, autism spectrum disorder, dissociative identity disorder, somatic symptom disorder, sexuality disorder and obsessive compulsive disorder.

The SPAIDD-G showed very good psychometric characteristics. To date it is available only in Italian, although validations of the English, German and French translations are already underway.

8.9.5 Assessments Focusing on a Specific Area

Most of the assessment tools for specific psychopathological areas are adaptations of tools originally created for the general population. Their validity for use with persons with ID/LF-ASD is uncertain, especially with reference to those with greater difficulties of communication and psychological insight.

The vast majority of tools for specific psychopathology concern mood and anxiety disorders. In recent years, there has been an increasing focus of research on both autism spectrum disorder (in persons with ID) and dementia. This interest is likely to result in the development of further assessments in the future.

8.9.5.1 Mood Disorders

In the area of mood disorders, the literature includes significant reports for all the following tools: Affective Rating Scale [88], Hamilton Depression Scale – Mental Handicap Version [89], Beck Depression Inventory (BDI) [90], Mental Retardation Depression Scale (MRDS) [91, 92], Self-Report Depression Questionnaire (SRDQ) [93], Zung Self-Rating Depression Inventory: Mental Handicap Version [94–96], Intellectual Disability Mood Scale [97], the Anxiety, Depression and Mood Scale (ADAMS) [98], Mood, Interest and Pleasure Questionnaire (MIPQ) [99], Glasgow Depression Scale for people with a Learning Disability (GDS-LD) [100], Mood and Anxiety Semi-Structured Interview (MASS) [101] and interRAI Intellectual Disability Assessment System (InterRAI ID) [102].

8.9.5.2 The SRDQ

The Self-Report Depression Questionnaire (SRDQ) [93] is not, as the name suggests, for completion by the patients themselves. Rather, it is a series of questions posed *to* the individual themselves. There is a pre-test to determine whether the person is able to respond meaningfully to the questions. The items are rated on a 3-point scale.

The SRDQ has good psychometric properties [103, 104] and is probably helpful in clinical work around depression in this population [105–107].

8.9.5.3 The IDMS

The Intellectual Disability Mood Scale (IDMS) also showed good psychometric characteristics [97]. However, it has been studied almost exclusively with persons with mild ID. It is articulated in six dimensions: anger, confusion, depression, fatigue, tension and vigour. Given the possible difficulties of employing self-report measures with people who have intellectual disabilities, numerous extra procedures were used, including pictures of buckets filled to various levels and marked to represent the five points of the response scales.

8.9.5.4 The ADAMS

The Anxiety, Depression and Mood Scale (ADAMS) [98] is an informant interview and can be used for all levels of ID severity. It is composed of 28 items organized into five sub-scales: manic/hyperactive behaviour, depressed mood, social avoidance, generalized anxiety and compulsive behaviour.

8.9.5.5 The MIPQ

The Mood, Interest and Pleasure Questionnaire (MIPQ) [99] includes 25 items grouped into two sub-scales (mood and interest/pleasure). It is an informant interview with Likert scale scores and for use with reference to every person with ID or LF-ASD, regardless of communication and insight impairments. It showed good psychometric properties, including high concurrent validity with the Aberrant Behavior Checklist (ABC) [108].

8.9.5.6 The GDS-LD

The Glasgow Depression Scale for people with a Learning Disability (GDS-LD) [100] integrates the information collected by interviewing the person with ID (mild-to-moderate degree) with that provided by their usual carer. For this purpose the instrument is divided into two parts containing 20 and 16 items.

8.9.5.7 The MASS

The Mood and Anxiety Semi-Structured Interview (MASS) [101] is a standardized diagnostic interview specific for anxiety and mood disorders, as indicated by its name. It has been designed to be used with the usual caregivers of the person with ID and is composed of 35 items corresponding to as many symptoms of DSM, whose presence or absence has to be indicated by the rater with respect to the month before the compilation. MASS showed good sensitivity and specificity, with high concordance rates both with clinical diagnoses and with the scores of the Hamilton Depression Rating Scale (HDRS) [109]. As mentioned above (see ▶ Sect. 6.1), about 10 years ago a diagnostic interview was also published for mood and anxiety disorders, called Mood and Anxiety Semi-Structured Interview (MASS) [101].

8.9.5.8 The InterRAI ID

The interRAI Intellectual Disability Assessment System (InterRAI ID) is a comprehensive, standardized instrument for evaluating the needs, strengths and preferences of adults with intellectual or developmental disabilities. It includes two sub-scales to assess depression and aggression. The InterRAI ID is in turn part of a wide tool battery developed in 2007 to promote social and community engagement by identifying persons who may benefit from additional supports or services in specific areas [102].

The concurrent validity of the InterRAI ID sub-scales for depression and aggression was evaluated through comparison with the RSMB and showed statistical significance [102].

Anxiety Disorders

In the area of anxiety disorders and obsessive compulsive disorder, the following tools have all been valued in the scientific literature across time: Zung Anxiety Rating Scale: Adults Mental Handicap Version [110, 111], Glasgow Anxiety Scale for people with an Intellectual Disability (GAS-ID) [112], Fear Survey for Adults with Mental Retardation (FSAMR) [113] and Yale-Brown Obsessive Compulsive Scale (Y-BOCS) [114, 115].

The GAS-ID consists of 27 items referring to physical symptoms and single phobic aspects, while the FSAMR is much more complex, including 85 items. Both instruments are designed to be used with people with mild-to-moderate ID or borderline intellectual functioning, but the GAS-ID shows the advantage of requiring a lower attention span.

Autism Spectrum Disorders

Tools to screen for ASD in adults with ID have to be chosen on the basis of their suitability with different levels of conceptual and communication impairments. The 10-item Autism Spectrum Quotient (AQ-10) [116] is one of the most common for use with borderline intellectual functioning and mild ID, while the Diagnostic Behavioral Assessment for Autism Spectrum Disorder – Revised (DiBAS-R) [117] and the Pervasive Developmental Disorder in Mental Retardation Scale (PDD-MRS) [118] seem to be more appropriate for moderate ID. In most severe cases, the Systematic Psychopathological Assessment for persons with Intellectual and Developmental Disabilities – Autism Spectrum Disorder (SPAIDD-ASD) [119] or the Autism Spectrum Disorder – Diagnosis Scale for Intellectually Disabled Adults (ASD-DA) [120] should be preferred.

To support clinicians in the refinement of the diagnosis, the Autism Diagnostic Observation Schedule (ADOS; ADOS-II) [121, 122] and the Autism Diagnostic Interview – Revised (ADI-R) [123] are widely employed, although they have shown to present some problems of sensitivity and validity

when used with adults with ID, especially in highest degrees of severity and in the presence of other psychiatric disorders [124]. The Gilliam Autism Rating Scale – Second Edition (GARS-2) [125] seems to show greater discriminative capacity, even if research evidence is limited.

The Diagnostic Interview for Social and Communication Disorders (DISCO) [126] also offers a comprehensive evaluation of the ASD across the range of ID, allowing to subtype on the basis of overall functioning [127] and supporting the differential diagnosis between ASD, ID and schizophrenia spectrum disorders [128].

Recently, the Social Communication Questionnaire (SCQ) [129] has been adapted for use with adults with ID of various severity (SCQ-AID) [130] and can be used as a screening tool. However, it still has major specificity problems: the high scores often do not derive from the presence of many DSA nuclear symptoms but from that of CP, co-occurring psychiatric disorders or undesirable effects of psychoactive drugs.

More information on diagnostic instrumental assessment of ASD in persons with ID is provided in ► Chap. 16.

Dementia

In the area of dementia and other major neurocognitive disorders, three well-known and widely studied tools are the Dementia Scale for Down Syndrome (DSDS) [131], the Dementia Questionnaire for Mentally Retarded persons (DMR) [132] and the Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID) [133]. For persons with mild ID and good introspective and communicative skills, some adaptations of instruments widely used in the general population are also available, such as the Shultz Mini-Mental State Exam [134] and the Cambridge Examination for Mental Disorders of Older People with Down Syndrome and Others with Intellectual Disabilities (CAMDEX-DS) [135].

The DSDS includes 60 items organized into three categories, one for each of the stages in which the progression of the disorder is normally divided. The DMR instead has two categories, in which it orders 50 items and 8 sub-scales: the first category concerns cognitive functions, such as memory and orientation, while the second refers to social-emotional skills, such as mood, interests, speech, practical skills and problem behaviour. Although DMR has been designed to be used with persons with ID of any degree of severity, its sensitivity has been shown to decrease in those with highest cognitive impairment [132].

Another instrument of interest is the Multidimensional Observation Scale for Elderly Subjects (MOSES) [136], which is also centred on the detection of significant changes in behaviour through the reports of reliable informants. Its structure is based on three behavioural factors: adaptive, maladaptive externalizing and maladaptive internalizing [137].

The Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID) [133] was designed with the aim of overcoming the main limits of previous instruments. It focuses only on recent behavioural changes and shows very good psychometric characteristics. For these reasons it was included, with some adaptations, in the evaluation package of the National Task Group on Intellectual Disabilities and Dementia Practices (NTG), called NTG-Early Detection Screen for Dementia (NTG-EDSD) [138], and recently translated and validated into various languages.

A comprehensive review of measures used in the screening, assessment and diagnosis of dementia in persons with ID has been recently published by McKenzie and collaborators [139].

Personality Disorders

In the area of personality disorders, two relevant tools are the Standardized Assessment of Personality (SAP) [140, 141] and the Minnesota Multiphasic Personality Inventory 168(L) [MMPI-168(L)] [142].

Although initial studies using the SAP were limited to people with mild and moderate ID [141, 143], subsequently it has been used across the whole range of severity, showing good psychometric properties [144–147]. The SAP is a semi-structured diagnostic

interview which relies on having an informant who knows the patient well from at least 5 years.

The MMPI-168(L) [142] represents a modified version of the MMPI-168 [148], which is in turn a reduced version of the well-known Minnesota Multiphasic Personality Inventory. The MMPI-168(L) [142] was produced for use with persons with mild ID and includes simplified questions that can be answered yes or no, rather than true or false. A group of L (Lie) items was also added to increase validity. It provides scores for three validity scales and ten personality scales. The MMPI-168(L) has been shown in empirical studies to possess good psychometric characteristics, particularly towards odd cluster personality disorders [67, 149–151].

8.9.6 Structuring the Whole Case Formulation

Little attention has been given to the idea of actually providing structure to the way the whole case is formulated, but such an approach deserves consideration. It is very clear that most people's mental health problems are a complex mixture of fundamental factors: biological, developmental, psychodynamic and ecological. As such, it is rare that a single person provides all the information necessary to understand fully why the person is experiencing the problems that they have. Multidisciplinary assessment is normally used, but with it comes the problem that different professionals have different ways of thinking, and are often in very differing relationships with the patient. Family members know the person best, but rarely have professional knowledge of psychopathology. Senior clinicians have the best ability to synthesize clinical information, but are often not in the position to collect it themselves. In a large organization, different professional groups sometimes work so independently that it is difficult to bring together all the relevant information pertaining to the specific case.

It is often true in case formulation that a given set of observations and symptoms can be accounted for by a number of different hypotheses. Given all the information, how do we decide which hypothesis is true?

8.9.6.1 The PAS-ADD Clinical Interview: Formulation Section

The score form for the PAS-ADD clinical interview provides an opportunity to bring together all these disparate pieces of information in one place; essentially, to make a dossier of the information necessary to make diagnostic decisions. The last part of the score form provides a way of identifying the key elements of the case in relation to various fundamental dimensions: psychiatric assessment, birth history and developmental factors, problem behaviours, physical health status, intellectual adaptive and language functioning, current ecology and 'contingencies'. This last item refers to the pivotal evidence that can arise when something suddenly changes in the person's behaviour that relates to something that has happened in their life. Such contingencies can often give unique insight into what is actually happening.

The key to completing this section of the score form is that the various items are rated according to their judged relevance to *understanding the case*, rather than to their severity. For instance, someone may have a severe self-injurious behaviour, but it always happens in the same way and at the same level. This, in itself, does not tell us much about what is going on. In comparison, someone's self-injurious behaviour that fluctuates markedly in response to what is happening around them, or started after a major life event, can tell us a lot more.

This part of the form has not been tested in any study; indeed, it would be very difficult to mount such a study. However, clinicians have reported that the completion of this section by a small group of professionals over a short period of time can often highlight hypotheses for why the person is suffering the problems, and can also identify further key pieces of information that would be desirable to collect. This is of course the same process that goes on in many case discussions. As with

other structured assessments, however, the provision of a structure can sometimes help the team consider all the pieces of evidence in a more impartial way.

8.9.6.2 The SPAIDD: An Integrated System of Tools

As mentioned above, the Systematic Psychopathological Assessment for persons with Intellectual and Developmental Disabilities (SPAIDD) [87] is an example of a comprehensive set of tools for all the different practical needs related to psychopathological assessment and monitoring, to be used by mental health professional and the whole multidisciplinary team working with people with ID and LF-ASD. In fact, it includes tools for every phase of the clinical intervention, such as general psychopathological screening, diagnostic categorical specification, dimensional diagnosis and symptoms monitoring.

The items of the SPAIDD system have been kept unchanged across all the battery tools since they represent observable and behavioural aspects of cross-categorical symptoms.

In designing and implementing this system, authors tried to overcome also the other main limits of previous tools, such as the impossibility of being used for all the degrees of intellectual and communication impairment, the misalignment with the DSM or the ICD, the lack of some main symptoms or syndromes, the lack of chronological criteria, the long times of administration and the scarce interdisciplinary usability [152].

To date, the SPAIDD system includes tools for general screening, follow-up, autism spectrum disorder, mood disorders, anxiety disorders and psychotic disorders, which are available only in Italian, although validations of the English, German and French translations are underway.

8.9.7 Other Structured Assessments

The above sections covered only a small proportion of the numerous structured assessments that are available for use with people who have ID/LF-ASD. Hopefully, the ones we have highlighted give some insight into the dimensions that need to be considered when selecting appropriate ones. Useful sources of further information are represented by the reviews by Flynn and collaborators [153], Hermans [154] and Tyrer and collaborators [155].

Assessment tools can be distinguished on the basis of their fundamental dimensions, we can count: (a) fully diagnostic interviews such as PAS-ADD; (b) other structured diagnostic interviews like PIMRA, DASH, mini PAS-ADD, ChA-PAS and CIS; (c) checklists such as P-AID, DBC, BSI and PPS-LD; (d) screening checklists like PAS-ADD Checklist, ADD, RSMB, ABCL and SPAIDD-G; assessment focusing on a specific area, especially mood and anxiety disorder and dementia. New comprehensive sets of tools for all the different practical needs related to psychopathological assessment and monitoring are being developed for interdisciplinary use by mental health professional and the whole multidisciplinary team.

8.10 Choosing a Structured Assessment

The appropriate choice of assessment(s) for a research project may be very different from those needed for a clinical service. In either case, however, the choice should be guided by a consideration of the desired outcome of the assessment.

8.10.1 Measuring Change

One of the most straightforward uses of structured assessments is probably for the measurement of change, either in response to treatment or over a period of time. For this purpose, issues of validity become less significant. *Reliability* is the central requirement. One needs to have faith in the ability of the assessment to reproduce the same results in

the same set of circumstances. A change in these results, therefore, indicates a change in the person's mental status. Although most structured assessments give estimates of reliability, it is important to bear in mind that this often depends on the training of users. In a research study, it is relatively easy to obtain good reliability through rigorous training of the users. Some structured assessments suggest, or require, some form of training. If the particular assessment is to be used, therefore, it must be accepted that resources are allocated for that training. Even after training, however, it is possible that users will drift away from the correct procedure. Indeed, Havercamp and Reiss [24] indicated that problems of reproducibility of PIMRA results by different evaluators seemed to arise because professionals in different areas recorded differently, or had not received specific training in the use of the tool. In a real-life clinical setting, it would certainly be desirable to monitor and update the training of users from time to time.

8.10.2 Diagnosis and Formulation

Clinicians such as psychiatrists and psychologists often do not use structured methods. One possible reason is that they feel it would be more time consuming. Another is that they may feel their clinical training is sufficient that a structured approach is not necessary. The numerous studies of the reliability of clinical interviewing indicate that the latter reason is questionable. Diagnostic reliability tends to be low [156–158], but this is certainly not due to a lack of clinical skills. Rather, it is an indication of the multiple sources of information that tend to influence outcome, for example, reason for referral, or bias in the people who know the individual.

It would not be sensible to suggest that everybody always should use a formal structured assessment in every case. Rather, structured tools should be like any other tools, that is, to be used where appropriate. More broadly, it is very useful to learn how to use some of these methods so that even routine clinical interviewing can be conducted with a more rigorous structure in mind. This can help overcome sources of influence and bias and can also give the opportunity for other possible diagnoses and formulations to be given consideration.

Ultimately, the various assessments are probably best judged by their *usefulness*; do they help to achieve the desired outcome? In clinical work, structured assessments can contribute to the quality of the patient's clinical information, and any issues of reliability and validity can be handled at the level of case discussion. For instance, a structured interview may statistically be reliable and valid, but the clinical team knows that the informants are not giving a true picture, either because they have their own agenda or they are unable to be objective. In an extreme example, someone with psychopathy may *deliberately* mislead the assessors. Such things can only be judged in the context of the case, and lie outside the confines of the assessment's statistical properties.

8.11 Structured Assessments as Part of a Protocol

Finally, it is important to mention that the use of structured assessments in clinical work is much more beneficial if it is part of an overall policy or protocol on assessment in the service. Unfortunately, this often does not happen. It is sometimes perceived, for instance, that one professional group should receive training in a particular assessment, but the rest of the health professionals are unaware of this. As a result, the information from these assessments may be considered by other clinicians to be of questionable validity.

It is only by getting health professionals together to learn about and discuss the assessments that they can become part of the flow of information, leading hopefully to better case formulations in the future.

One of the most straightforward uses of structured assessment is probably the measurement of change, either in response to treatment or over a period of time. To this purpose, reliability is a central

requirement and consequently specific and updated training of users. More broadly, it is very useful to learn how to use some assessment tools so that even routine clinical interviewing can be conducted with a more rigorous structure in mind. This can help overcome sources of influence and bias and give the opportunity for other possible diagnoses and formulations to be given consideration.

Tip

The use of structured assessments in clinical work is much more beneficial if it is part of an overall policy or protocol on interdisciplinary assessment in the service.

The instrumental assessment of psychiatric disorders in persons with lower communication and cognitive skills needs substantial improvement and it is probable that this will be brought in the next years. Thus, constant update is suggested.

Key Points

- Interviewing is a highly volatile process, open to influence by numerous factors that can be very difficult for people with ID associated with a very poor language, or even no language at all. This sometimes leads to the suggestion that structured assessments can be more important with people who have ID than with the general population.
- When choosing to use a structured approach, however, it is important to distinguish broad-spectrum assessments from those involving a specific area with the aim of not influencing the final diagnostic outcome and determining the presence and severity of symptoms as efficiently as possible.
- An assessment tool should have good psychometric properties, in particular, reliability and validity associated with a factorial structure in significant relationship with the measured concepts. Reliability seems to be the central requirement so that a change in the results indicates a change in the person's mental state and is important to bear in mind that this often depends on the training of users.
- The ideal is a tool that allows both to synthesize all the information obtained from the patient himself, from third parties close to the patient or from other colleagues who have previously examined him or, at the same time, in the case of a multidisciplinary work group, and to evaluate the various symptoms significant for diagnosis. This is even more true in the case of mental health professionals who work with people with ID and LF-ASD.

Learning Objectives

This chapter is devoted to the epidemiology of psychiatric disorders in people with intellectual disabilities (ID). It starts by considering the types of psychiatric disorders that people with ID experience, within the context of diagnostic overshadowing and the multi-morbidity that typically occurs in people with ID, and the implications when conducting assessments. It then considers the reported prevalence of psychiatric disorders across the life-course and compares this with the prevalence in the general population, and also for people with co-occurring ID and autism spectrum disorder. Relevant aspects of aetiology are then considered, followed by information on the course of psychiatric disorders in this population.

1. To understand how commonly psychiatric disorders are experienced by children, young people, and adults with ID
2. To understand variation in the prevalence of psychiatric disorders in people with ID compared with the general population
3. To understand the influence of co-occurring autism spectrum disorder with ID on the prevalence of psychiatric disorders
4. To understand the course of psychiatric disorders in people with ID

9.1 Introduction

People with ID can experience all types of psychiatric disorders that occur in the general population. Some disorders occur more frequently in people with ID than in the general population, and some common disorders, in particular problem behaviours, are not often seen in the general population. Psychiatric disorders are common in people with ID, which is perhaps not surprising, given the complex mix of biological factors, psychological and social disadvantages, and additional developmental factors that people with ID have and are exposed to.

Psychiatric disorders are commonly overlooked in people with ID for a number of reasons including diagnostic overshadowing, complexity and multi-morbidity, reliance on carer reports, and differing presentations (see ▶ Chap. 5). A previously undiagnosed psychiatric disorder can be found in around 30% of adults, especially in those with more severe ID [1]. The term 'diagnostic overshadowing', which is commonly used, describes how the additional problems experienced by a person with ID tend to be misattributed as due to their ID rather than correctly attributed to co-occurring disorders [2]. Failure to identify additional disorders results in failure to offer interventions and care and so is a very important problem.

Psychiatric assessments are complex in people with ID, as psychiatric disorders tend not to occur in isolation. Psychiatric disorders can occur on top of existing long standing neurodevelopmental disorders such as autism spectrum disorder (ASD) or attention-deficit-hyperactivity disorder (ADHD) and co-occur together with physical disorders, impairments, and disabilities. Indeed, multi-morbidity is the norm for people with ID; assessments reveal that almost all adults with ID have multi-morbidity (two or more disorders as well as their ID) [3]. Other studies have found that even when the conditions were restricted to a limited number of physical and psychiatric disorders receiving input from general practitioners (i.e. already identified), the majority with ID had multi-morbidity, and the extent of multi-morbidity in young 20 years old adults with ID was similar to that in the 50- to 54-year-old general population [4, 5]. Additionally, a range of neurodevelopmental conditions tend to co-occur, for which the term ESSENCE has been coined (Early Symptomatic Syndromes Eliciting Neurodevelopmental Clinical Examination) [6]. ESSENCE includes major problems in: motor skills, general development, speech and language, social interaction and communication, behaviour, hyperactivity or impulsivity, hypoactivity, inattention, sleep or feeding difficulties [6]; genetic data also increasingly supports the ESSENCE clustering of neuro-developmental (including epilepsy) and psychiatric disorders [7]. The identification of co-occurring psychiatric disorders in persons with ID or ID

and co-occurring ASD requires specific clinical skills and specific tools, particularly to differentiate between psychopathological symptoms and behavioural changes due to other factors, such as physical pain, response to trauma, or overwhelmed neuro-autonomic, flight, or freeze reactions to environmental stressors (see ▶ Chap. 5).

Psychiatric disorders, physical disorders, and drug side-effects can mimic each other, so given the high levels of multi-morbidity, psychiatric disorders should not be considered in isolation. Some physical disorders relate to the persons underlying cause of ID, but lifestyle and environmental factors, sub-optimal support, and healthcare are also important contributors [8]. Multi-morbidity also results in polypharmacy and potential problems with disease-disease, disease-drug, and drug-drug interactions. People with ID may not be able to self-report drug side effects and are reliant on others observing these, so pharmacovigilance is essential. Anticholinergic burden can also be an issue due to polypharmacy and the strong anticholinergic effects of many psychotropic drugs. This has potential negative side effects such as further impairments of cognition [9, 10].

As well as multi-morbidity, assessments are complicated further by limitations in reciprocal communication and understanding, and decision-making capacity, visual and hearing impairments, and reliance on carer observations and reports, sometimes several carers/teams of carers. Together, this means that differential diagnosis is not only crucial but also complex, in order to establish the best treatment and care plan for the individual.

People with ID experience the full range and high rates of psychiatric disorders. These are often overlooked or misattributed to the persons' ID, causing unnecessary suffering. Psychiatric assessments are complex as, in addition to having ID, multi-morbidity is typical. Interventions need to be tailored to each individual's needs, taking account of physical health as well as the psychiatric disorders.

9.2 Prevalence of Psychiatric Disorders

The prevalence of problem behaviours will not be further considered within this chapter, as it is considered in depth in ▶ Chap. 7.

Studies differ in the prevalence of psychiatric disorders they report, due to the methods they use. In particular, differences in reported rates relate to the disorders included as psychiatric disorders, for example, whether or not problem behaviours and ASD are included along-side other psychiatric disorders, and also how representative the studied population with ID is. Given that the boundary between mild ID and the general population merges, particularly in adulthood, some studies report rates separately for people with mild ID from people with moderate-profound ID. Rates vary also by the age ranges included in the studies. Study results also vary for other reasons, such as the types of assessments completed and diagnostic criteria used, or whether information has been taken from existing records such as general practitioner health records, which are likely to underreport the extent of psychiatric disorders. Studies also vary in the size of the populations studied, therefore limiting conclusions that can be drawn, particularly for less common conditions. Some studies report point prevalence of psychiatric disorders, some report period prevalence, or lifetime prevalence, and some do not provide precise distinction between these, which also impacts on reported rates, contributes to variation in rates, and limits the validity of comparing rates between studies. Some authors have attempted to synthesise information on studies of prevalence of psychiatric disorders in children and young people [11] and in adults [12, 13], but these syntheses have inherent limitations in view of all the reasons given above, as the authors acknowledge. As one would expect, recent meta-analysis found that pooled prevalence is lower in population-based studies than in non-population-based studies, and in low overall risk-of-bias studies as compared to the moderate overall risk-of-bias studies [13].

Reported point prevalence rates of psychiatric disorders in children and young people with ID range from 30% [14, 15] to 50% [16], though it should be noted that these rates include problem behaviours. A study examining robust data from UK private household surveys reported a prevalence of 36% in 641 children and young people (aged 5–16 years) with ID [15]. This study was only of children/youth living in private households, and in view of the general population sampling frame, the individuals with ID had predominantly mild ID. A representative sample of US adolescents found that 65.1% has a lifetime prevalence for a psychiatric disorder [17].

For adults with ID, reported prevalence ranges from 14.5% (excluding problem behaviours, ADHD, ASD, dementia, and personality disorder, people aged 65 and over, and people with severe ID) [16] to 43.8% (adults with moderate to profound ID only) [18], depending on the conditions included and the quality assessment applied [16–21]. The largest adult population-based prevalence study in which each person (aged 16 years and over) was individually assessed included 1023 adults with ID [19]. Using robust methods, it reported a point prevalence of psychiatric disorders of 28.3% (or 40.9% if problem behaviours are also included). It reported rates separately for adults with mild ID at 25.4% and for adults with moderate to profound ID at 30.2% [19].

The effect of severity of ID on prevalence of psychiatric disorders is controversial, with some findings indicating higher rates in persons with severe/profound ID [22–24] and some others indicating the opposite [13, 25]. Some differences are accounted for by whether or not problem behaviours and/or ASD were included within the definition of psychiatric disorders, as they occur more commonly in people with more severe ID.

The effect of sex on prevalence of psychiatric disorders of any type is also currently not clearly understood. Most studies found no differences [13, 17, 26, 27], but some have identified a significantly higher prevalence among males than females [28]. Some of these discrepancies may be explained by whether or not the definition of psychiatric disorders included problem behaviours and/or ASD.

To date there is a lack of prevalence estimates of co-occurring psychiatric disorders identified using the new Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) [29] (and proposed International and Statistical Classification of Diseases and Related Health Problems 11th revision: ICD-11) definition of ID/disorders of intellectual development (see new ICD-11 term) [30], and differentiated by severity levels of adaptive functioning and specific (not general IQ) cognitive functioning [31]. Platt and collaborators found low adaptive behaviour to be associated with a higher rate of psychiatric disorders than low IQ, although results of their study have to be interpreted in light of several limitations [17].

Reported point prevalence rates of psychiatric disorders in persons with ID range from 30% to 50% in children and adolescents and from 14.5% to 43.8% in adults. Several factors account for the different rates reported, especially the specific types of conditions included in the definition of psychiatric disorder (e.g. whether ASD and problem behaviours are included), the type of sample, and the assessments used.

9.3 Prevalence of Psychiatric Disorders Compared with General Population

Presentation of psychiatric disorders can differ from that seen in the general population, and so the categories of psychiatric disorders as described in the standard psychiatric diagnostic manuals, the International and Statistical Classification of Diseases and Related Health Problems tenth revision (ICD-10) [32], and the DSM-5 [29] are not always easy for generalists to apply. For this reason, the manuals have been interpreted for use with people with ID, with the publication of DC-LD (Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning Disabilities/Mental Retardation) [33], com-

plementary to ICD-10, and The Diagnostic Manual-Intellectual Disability 2 (DM-ID-2) [34], complementary to DSM-5. DC-LD is currently being revised into a second edition, in keeping with the publication of ICD-11. Whilst these differences pose challenges when comparing prevalence of types of psychiatric disorders between the population with ID and the general population (i.e. comparing like with like), work does suggest that similar broad categories of conditions do occur, with the addition of problem behaviours. For example, a study using exploratory and confirmatory factor analyses on two large datasets of psychopathology in adults with mild-profound ID ($n = 457$; $n = 274$) extracted a model of psychopathology with five factors: depressive, anxiety, cognitive decline, psychosis, and affect dysregulation-problem behaviour [35, 36]. The affect dysregulation-problem behaviour factor had good discriminate validity, face validity, and predictive validity over a 5-year follow-up period. This study provides a conceptualisation of problem behaviours within the broad over-arching family of psychiatric disorders, whilst being distinct from the other categories of depression, anxiety, cognitive decline, and psychosis, all of which resonate with the broad categories seen within the general population.

The study of 641 children and young people described above [15] reported a prevalence of psychiatric disorders including problem behaviours/conduct disorder of 36% in 641 children and young people aged 5–16 years with ID, compared with 8% of 17,774 children without ID [15]. Hence in this study, the children and young people with ID accounted for 14% of all children with psychiatric disorders, and their prevalence of psychiatric disorders was higher than for other children and young people for 27 out of 28 ICD-10 categories [15].

A recent study has drawn direct comparison between children/young people with ID and the child/youth general population, using the same methods for both, and appears to be unique in including a whole country sample, so is large, includes people of all ability levels, and is representative [37]. The study used data from Scotland's Census, 2011, which had an estimated 94% coverage of the whole country, and systematically enquired for everyone whether they had ID (and distinguished this from specific learning disabilities and from autism spectrum disorder) and whether they had a mental health condition. It included 5234 aged 0–15 years with ID and 911,097 without ID. Of the children/young people with ID, 12.8% had mental health conditions compared with only 0.3% of the children/youth without ID. Mental health conditions were significantly more prevalent at all age groups, children, youth, and adults; indeed ID (all ages) had an odds ratio of 7.1 in predicted mental health conditions. The disparity between the people with ID and those without was apparent at all age groups, but more so for the children and young people than for adults. Mental health conditions were also related to poorer general health status [37].

The study using Scotland's Census, 2011 described above, also reported on adults, drawing direct comparison between adults with ID and the adult general population, using the same methods for both [37]. It included 18,660 adults aged 16–64 years with ID compared with 3,470,078 without ID and 2455 adults aged 65 years and over with ID compared with 887,879 without ID. Of the adults with ID, 23.4% of the adults and 27.2% of the older adults had mental health conditions compared with 5.3% and 4.5% of the general population, respectively. Mental health conditions were significantly and substantially more prevalent at all age groups. Mental health conditions were also related to poorer general health status. Contrary to the general population, males rather than females were more likely to have mental health conditions [37].

A Swedish prevalence study specifically concerning older people had a large cohort of people with ID ($n = 7936$), aged 55 years or more and an age, and sex-matched cohort from the general population [25]. Information regarding psychiatric diagnoses was collected from the National Patient Register during 2002–2012. Seventeen per cent of persons with ID had at least one psychiatric diagnosis versus 10% of the general population cohort (OR 1.84). Most common diagnoses in the ID

cohort were 'other' psychiatric diagnoses (i.e. not included in any of the diagnostic groups) (10%) and affective disorders (7%), whilst the general population cohort was most often diagnosed with affective disorders (4%) and alcohol/substance-abuse-related disorders (4%). The highest odds for ID were found for psychotic disorder (10.4), ADHD (3.81), dementia (2.71), personality disorder (as a unique group) (2.67), affective disorder (1.74), and anxiety disorder (1.36) [25].

Despite the problems in comparing like for like between the population with ID and the general population, there is considerable evidence to show that most psychiatric disorders are more common in adults with ID than in the general population [23]. This includes schizophrenia [38, 39], bipolar disorder and mania [17, 40, 41], dementia (particularly in adults with Down syndrome [42, 43], but also in people with ID not due to Down syndrome [44, 45]), ASD [15, 46, 47], and ADHD [15].

Unipolar depression and anxiety are common in people with ID. Some research suggests they are more common than in the general population [17], whilst other studies do not [40, 48, 49]. It is perhaps surprising that unipolar depression and anxiety are common, given the high levels of mood stabilising drugs prescribed for people with ID: About 25% of people with ID have epilepsy [3] and so are prescribed anti-epileptic drugs, and whilst mood-stabilisation is not the purpose for their prescription in this situation (epilepsy), most do also have mood-stabilising properties. Epilepsy is much less common in the general population, at about 1% of the population, so the use of these drugs is much less prevalent. Longitudinal studies suggest that depression and anxiety may be more enduring conditions in people with ID than in the general population, although there are small numbers of people with ID within these longitudinal studies, and of those, almost all have mild ID, so are not representative of all people with ID [50–52].

There is considerable evidence to show that some psychiatric disorders are more common in children and adults with ID than in the general population, including autism spectrum disorder, ADHD, bipolar disorder, dementia, and schizophrenia. Depression and anxiety are also common; it is disputed whether or not they occur more commonly than in the general population, but given the high rate of usage of mood stabilising drugs (for epilepsy), it is notable that they have not been reported to be less common than in the general population.

9.4 Prevalence of Psychiatric Disorders in Persons with Co-occurring Intellectual Disabilities and Autism Spectrum Disorder

Persons with both ID and ASD may present several symptoms and deficits which are not seen in those with ID or ASD alone, and a different frequency of co-occurrent disorders [53], some of which may be accounted for by differing population characteristics such as a higher proportion of males and higher proportion with more severe ID.

As above mentioned, in persons with ID and ASD, one of the main issues in diagnosing co-occurrent psychiatric disorders is represented by the difficulty to distinguish between behavioural changes associated to psychopathological symptoms and those that can be attributed to physical, psychological, or environmental factors. In other words, behavioural responses to pain (including pain associated with sensory hypersensitivities), traumatic life events and life stressors (such as change and loss, both of which are frequent in the lives of people with ID and ASD), overlap with behaviours and symptoms that constitute criteria for psychiatric diagnoses. An essential part of diagnostic practice therefore working with people with ID and ASD is to include assessment of the support environment (e.g. for sensory triggers in ASD, whether expectations are appropriate or overwhelming), as well as examining the lived experience of the individual for past or present trauma circumstances that may be triggering intense emotional responses. In the absence of recog-

nising such life events, other psychiatric disorders (e.g. mood and anxiety disorders) may be diagnosed in error. Epidemiological studies of psychiatric disorders in ID and ASD have not routinely included trauma and adjustment-related diagnoses; the high prevalence of anxiety and mood disorders in this population may relate in part to these diagnostic errors [54].

Investigations on which types of instruments used to support direct clinical assessments are the most valid have been carried out, in particular with regard to screening tools and semi structured interviews (see ▶ Chap. 8). This point should be considered also whilst reviewing evidence produced so far. Instruments that do not consider the context of the individuals lived experience (e.g. screening instruments considering only behaviours and symptoms in the absence of considering what may have triggered these) will not be able to differentiate between psychopathology associated with unrecognised medical conditions, trauma, and adjustment-related conditions from other major psychiatric disorders.

Research shows an inverse relationship between IQ and severity of ASD, with rate of problem behaviours in ASD being lower at higher IQ [55–58]. Conversely, severity of ASD symptoms – and not that of ID – is directly associated with the rates of stereotypies [59, 60].

Although still limited and controversial, literature on the prevalence of psychiatric disorders in persons with both ID and ASD may indicate a higher rate of the full range of psychiatric disorders in comparison with those with ID or ASD alone [61–63]. Conversely, a study of adults with ASD compared rates with controls with ID matched for age, gender, ability-level, and Down syndrome [64]. They found that although the adults with ASD had a higher point prevalence of problem behaviours compared with the whole adult population with ID, there was no difference in prevalence, or incidence of either problem behaviours or other psychiatric disorders when compared with their matched controls [64]. They concluded that the differences in rates of psychiatric disorders were accounted for by other factors, including ability level and Down syndrome. The adults with ASD who had problem behaviours were, however, less likely to recover over a 2-year period than were their matched controls [64]. Greater agreement has been identified on higher rates of problem behaviours, stereotypies and rituals, communication difficulties, and social impairment in comparison to ID alone [57, 58, 65–67]. Nevertheless, specific investigation on causes and triggers is lacking and current prevalence might present some overlap issues with behavioural changes of non-psychopathological origin.

Furthermore, the co-occurrence of ASD with ID has been associated with a higher probability to be hospitalised and to receive a psychopharmacological treatment [68–70]. Lunsky and collaborators found that more than half of adults with ID and ASD have a co-occurring psychiatric disorder (26.1% mood disorder, 26.1% psychotic disorder, and 4.3% personality disorder), although they did not include trauma nor adjustment disorder. However, when compared with those with only ID, they did not show statistically significant differences except for the probability of the diagnosis of a psychotic disorder being lower in the co-occurring ID and ASD group [71]. In addition, individuals with problem behaviours and ASD were less likely to receive a diagnosis of schizophrenia, whereas the latter increased if problem behaviours were absent [66]. In all cases, the presence of problem behaviours had a negative impact on overall functioning and quality of life [61, 66, 69, 72–77].

The presence of ID in persons with ASD seems to negatively impact on the possibility of having an adjunctive diagnosis of psychiatric disorder. In a 10-year longitudinal study, Selten and collaborators found that the co-occurrence of ID in persons with ASD reversed the trend of a higher rate of diagnoses of bipolar and psychotic disorders than the general population [78]. Individuals with ASD who have greater cognitive abilities have been reported to have higher rates of depression than those with co-occurrent ID, which has simplistically been explained with a greater awareness of their difficulties [79–82].

Specific diagnostic procedure and tools seem to represent a significant determinant for the reliability of prevalence findings in persons with ID and ASD. These often include too many subjective symptoms which are not easy to identify in this group of patients and should be substituted by behavioural and observable equivalents (see ▶ Chap. 5). Different studies have found an increasing prevalence of psychiatric disorders as long as the specificity of their assessment tools rose. By using the Psychiatric Assessment Schedules for Adults with Developmental Disabilities (PAS-ADD), Thalen found an overall rate of 69.6% vs 8.6% in persons with ID alone [83], and through the Diagnostic Assessment for the Severely Handicapped-II (DASH-II), Matson and Cervantes found statistically significant differences in 8 out of the 12 subscales of the tools, on anxiety, mania, schizophrenia, stereotypies/tics, self-injurious behaviour, eating disorders, sexual disorders, and impulse control [63]. Nevertheless, the sensitivity for psychopathological features of some tools, such as the DASH, has not definitively been ascertained and high score reports may express mental distress due to other causes, including adaptive response to overwhelming stress.

Among specific psychiatric disorders, mood disorders [62, 83], anxiety disorders [26, 73, 83], somatic symptoms disorder, and impulse control disorders [61, 84–86] have been reported as the most frequent. Nevertheless, most of these study findings could be hampered by issues of multimorbidity and differential diagnosis.

Higher rates of inattention, hyperactivity, and impulsive behaviours have been observed in teens with both ASD and ID in comparison with those without ASD [87]. In addition, people with both conditions resulted to be more vulnerable to sleep problems, organic syndrome, stereotypies, and tics, although the psychopathological nature of this difference has not been confirmed [61].

The co-occurrence of psychiatric disorders has been found to be higher in males, in youth, and in persons with mild-to-moderate ID [66, 69, 71]. Thalen found psychoses and anxiety disorder to trend inversely to the severity of ID more than other disorders [83].

Some high rates of psychiatric disorders in persons with ID and ASD, such as that of bipolar disorder, seem to be related to behavioural dysregulation, as expressed by restlessness, agitation, or distraction, and may reflect the symptom overlap between psychopathological features, autism, and ID rather than a true co-occurrence of psychiatric disorders [26]. A subgroup of persons with ID and ASD, which shows adjunctive symptoms that cross diagnostic boundaries and include psychotic symptoms, excessive anxiety, mood lability, and information-processing deficits, seems to identify a complex neurodevelopmental disorder deserving a new diagnostic category [88]. Multiple complex developmental disorder (MCDD), multiplex developmental disorder (MDD) [89], and multidimensionally impaired disorder [90] are the terms and underlying models proposed for this category.

For psychotic disorders, most prevalence studies did not include adequate methods of assessment that distinguished from autistic features, psychotic-like symptoms, and symptoms of other psychiatric disorders, especially psychotic features of a post-traumatic stress disorder [91]. Psychotic-like behaviour such as talking to one's self, regression, and particular postures can be a common response of person with ID (with or without ASD) to stressful and other negative events [10], whilst bizarre expression or fantastic thinking can represent normal ways of experiencing the world of many persons with ASD. The link between Adverse Childhood Experiences and later psychosis increasingly identified in the general population during the last 20 years [92, 93] is being shown to occur also, or even more, in persons with borderline intellectual functioning, ID, and ASD [94–97].

Compared with the general population, people with co-occurring ID and ASD are markedly more likely to report a mental health condition. A whole population study included 5709 children and adults with co-occurring ID and ASD compared with 5,289,694 other children and adults in the general population [98]. After adjusting for age and sex, the odds ratio for a mental health condition was 25.6 or 130.8 when the interaction between age

co-occurring ID and ASD was also adjusted for [98]. Further study with the same data set reported on the relative independence of ID and ASD in contributing to the high odds ratio for a mental health condition compared with the general population [99]. It reported that 9396 of the 1,548,819 children had ID, 25,063 of the 1,548,819 children had autism, 16,953 of the 3,746,584 adults had ID, and 6649 of the 3,746,584 adults had autism. In the children, both ID (odds ratio of 7.0) and autism (odds ratio of 23.1) independently predicted mental health conditions. Also in adults, ID (odds ratio of 3.5) and autism (odds ratio of 5.3) both independently predicted mental health conditions [99].

Although still limited and controversial, the literature on the prevalence of psychiatric disorders in persons with both ID and ASD indicates a higher rate in comparison with those with ID or ASD alone.

9.5 Aetiology of Psychiatric Disorders

The aetiology of psychiatric disorders in people with ID is typically multi-factorial. Some specific causes of ID are associated with specific types of psychiatric disorders ('behavioural phenotypes'), for example, Down syndrome and dementia; other factors can also influence presentations of behavioural phenotypes. Multi-factorial aetiology can be considered on biological, psychological, social, and developmental dimensions and in terms of predisposing, precipitating, and maintaining factors. Aetiology has been represented graphically across the life-course, in detail, by Accessible Cause-Outcome Representation and Notation System (ACORNS) [100]. This shows that some of the multiple, interacting aetiologies are transactional; and linear cause and effect directions cannot usually be inferred. Considering aetiology is helpful in finding ways to prevent or reduce psychiatric disorders, or to aid recovery.

There are both similarities and additional complexity in aetiology of psychiatric disorders in people with ID compared with the general population. Similarities include that some psychiatric disorders have a degree of heritability so the person may have acquired the disorder even without having ID. Neurological disorders such as epilepsy are considered to increase the risk of psychiatric disorders in the general population, and whilst the ID literature is a bit mixed on this point, epilepsy is about 25 times more common in people with ID compared with the general population [101]. The addition of the developmental dimension adds complexity, including parental bonding and development of attachments at early age, impairments in attentional control, and communication limitations [102–104]. There are transactional effects of the person with ID and carers; psychiatric disorder in the person with ID affecting the carer-person with ID interaction, and carer stress and health, in turn further affecting the mental health of the person with ID; a spiralling vicious circle can be established [105]. Being dependent upon others in daily tasks can be restrictive upon what one can achieve and aspire to, which may also impact upon health.

Further complexity stems from people with ID having greater burden in all of the dimensions, such as the behavioural phenotypes of some causes of ID; additional physical disorders and disabilities; psychological factors associated with ID; and multiple social disadvantages. Abuse, neglect, or exploitation have been shown to predict psychiatric disorders in adults with ID [106]. Life events are more common for people with ID, and when they do occur, they tend to be multiple, for example, the death of a parent-carer leading to multiple changes in the person's life and care, move of home, and dislocation from former environment, family friends, and occupations [15, 19, 48, 107–109]. Lone parent family, poor family functioning, lack of parental educational qualifications, income poverty, and households with no paid employment have been shown to be associated with psychiatric disorders in children and young people with ID [15, 110]. Social disadvantages experienced by people with ID also include lack of paid employment, poverty of environment and recreational opportunities, social exclusion, and

experience of bullying, harassment, stigma, and hate crimes [111–114]. Aetiology of specific psychiatric disorders is considered in greater detail in the relevant chapters.

The aetiology of psychiatric disorders in people with ID is typically multi-factorial, with biological, psychological, social, and developmental dimensions and in terms of predisposing, precipitating, and maintaining factors. Some specific causes of ID are associated with specific types of psychiatric disorders.

9.6 Incidence and Course of Psychiatric Disorders

There has been less research conducted on the incidence and course of psychiatric disorders in people with ID, compared with prevalence studies. ► Chapter 7 considers the course of problem behaviours. The few studies on other psychiatric disorders suggest a more enduring pattern for psychiatric disorders than one might expect from studies with the general population, albeit with episodes of remission along the way. It is not clear if this pattern is due to greater severity of psychiatric disorders in people with ID, or poorer interventions/access to interventions, compared with the general population.

Regarding children and young people, a study followed a cohort of Australian children and young people with ID, aged 4–19.5 years, over 14 years. Hyperactivity was more prominent at younger ages and persisted for longer in the children and young people with more severe ID. Emotional disorders emerged later in childhood [115–117]. Similar findings have been reported from longitudinal studies with children in the Netherlands [118, 119].

Regarding adults, the incidence of mental disorders, excluding problem behaviours, has been reported to be 12.6% over a 2-year period, 8.3% for affective disorders, 1.7% for anxiety disorders, and 1.4% for psychotic disorders [39, 106]. Despite high mood stabiliser use (22.4%), 2-year incident mania has been reported to be 1.1% which is much higher than the general population, with a standardised incident ratio of 41.5 for first episode (or 52.7 excluding Down syndrome) [41]. Full remission of psychosis after 2 years was reported to be only 14.3% [39], poorer than it is for aggression or self-injury [120, 121]. At age 65 years or older, the standardised incidence ratio for dementia is reported to be 4.98 [122], showing it is much higher in adults with ID – it is even higher in adults with Down syndrome. These findings show that incidence is higher than that found in the general population for psychosis, bipolar disorder, and dementia, whilst much of the current high prevalence of common psychiatric disorders is due to enduring disorders, rather than new episodes. The evidence-base is, however, limited in quantity.

The few available studies on the course of psychiatric disorders in persons with ID suggest a more enduring pattern than in the general population.

9.7 Conclusion

In conclusion, psychiatric disorders are common in people with ID across the whole life-course. Point prevalence (excluding problem behaviours) is about 30% and may be higher in people who have co-occurring ID and ASD. Psychiatric disorders appear to be more enduring than in the general population, but there have been few longitudinal studies investigating the course of psychiatric disorders. Many factors contribute to the high rates. Given the extensive multi-morbidity that people with ID experience, and the added developmental dimension, assessments are complex, but important to get right, so that the most appropriate interventions can be offered to improve the person's quality of life.

Key Points

- Psychiatric disorders are common across the whole life-course, and much more so than in the general population.
- The point prevalence of psychiatric disorders (excluding problem behaviours) is about 30%; having ID increases the odds of psychiatric disorders by about 7 times compared with the general population.
- Schizophrenia, bipolar disorder, dementia, autism, and ADHD all occur more commonly than in the general population.
- The co-occurrence of ID and autism may be associated with a higher rate of the full range of psychiatric disorders in comparison with those with ID or autism alone.
- Aetiology is multi-factorial, due to a range of biological, psychological, social, and developmental factors.
- Psychiatric disorders may be more enduring than in the general population, but there are few studies on the course of psychiatric disorders.
- Psychiatric disorders typically coexist with other physical disorders and impairments, and assessments are therefore complex.

Learning Objectives

- To understand the biological, psychological and social risk factors for the development of mental illness in individuals with an intellectual disability
- To understand how the diagnosis of mental illness in people with intellectual disability can be overshadowed, especially when there are comorbid conditions such as autism, ADHD, epilepsy and cerebral palsy

10.1 Introduction

Intellectual disability (ID) is defined as a developmental condition that affects both intellectual and adaptive functioning in conceptual, practical and social domains [1]. ID affects approximately 1% of the population [2]. ID is often classified into mild, moderate, severe and profound based largely on the results of IQ testing, with corresponding differences in life skills and the need for support. The majority of people with an ID have a mild ID [1]. There are multi-faceted explanations for ID and autism, from medical to cultural and spiritual. The cause of mild ID is most often unknown. Conversely, there is often a demonstrable cause for moderate to severe ID [3], for example, a chromosomal abnormality or perinatal complication [4]. It is expected that with increased uptake of genetic testing and increased resolution of genetic testing, previously unknown causes will be shown to have a genetic basis.

Language of the disorder has changed over the last 50 years, from mental retardation to learning disability and now increasingly intellectual disability, reflecting a change in wider societal attitudes towards, and understanding of, ID. In the relatively recent past, people labelled with 'mental retardation' were housed in institutions and were not believed to have the capacity to develop mental illness. Our knowledge and conceptualisation of ID and psychiatric illness is ever expanding. People with ID are not a homogenous group and an individual's risk of mental illness will vary based on constitutional and environmental factors. The reported prevalence of mental illness in people with ID differs owing to different methods of sampling and case ascertainment. The recognition and diagnosis of mental illness in people with ID can be complicated by atypical presentations and communication limitations. It is now understood that people with ID across the lifespan are at least as likely to experience mental health conditions as the general population [5–7], with certain groups being at particular risk [6, 7]. People with more severe ID or with lower ability levels have been found to have an even higher prevalence of mental ill health [6]. In addition, challenging behaviours that are unrelated to mental illness are present in a significant proportion of individuals with ID [8]. The impact of these behaviours can be significant, for example, increasing the need for costly support packages, potential exclusion from social activities and substantial caregiver burden.

The aim of this chapter is to discuss the factors that contribute to the development and maintenance of mental illness in ID and their interplay. We have followed a conventional bio-psycho-social approach.

10.2 Biological Factors

There are a plethora of biological risk factors for the development of a mental illness in an individual with ID, ranging from genetic predisposition to complications that occur in utero or around the time of birth. Significant perinatal complications which have led to an admission to a special baby care unit or neonatal intensive care have been implicated in the aetiology of ID [9]. Pregnancy and birth complications, as well as sometimes being a cause of ID, have also been associated with later development of mental illness, particularly schizophrenia, in people with ID [10].

As with the general population, certain mental illnesses can occur in multiple members of one family due to shared genetic and environmental risk factors [11]. A number of genetic syndromes are associated with ID, physical and mental illness, for example, Down syndrome. Chronic physical illness in itself can predispose an individual to certain

mental health conditions such as depression or anxiety [12]. For example, a meta-analysis performed by Anderson et al. [13] showed that the presence of diabetes doubled the odds of comorbid depression. In addition, certain physical health conditions can be mistaken for mental illness. For example, individuals with Down syndrome are at greater risk of developing thyroid disease [14] which can mimic affective disorder. This underscores the importance of accurate history taking and physical examination with appropriate investigations in people with Down syndrome.

Advances in genetic research have spawned interest in behavioural phenotypes, which are a particular cluster of cognitive, linguistic and behavioural profiles associated with specific genetic syndromes [15]. In addition, several genetic conditions are associated with specific mental illnesses. This information can allow us to predict and closely monitor for the development of particular psychiatric illnesses [15], although the nature of the link is not always clear (i.e. the mechanisms from genotype to phenotype have not been well defined). Examples of well-known associations are as follows:

1. *Prader-Willi syndrome (PWS) and psychotic disorder:* The most striking feature of PWS is insatiable appetite and food-seeking behaviour; individuals with the disorder may also have increased propensity to develop psychotic disorder. The additional risk seems to be confined to those with maternal uniparental disomy (accounting for approximately 25% [16] of cases) and the onset of the psychotic symptoms is in early adult life [17].
2. *Velo-cardio-facial (DiGeorge) syndrome and schizophrenia:* Associated features of velo-cardio-facial syndrome include palatal anomalies, cardiac anomalies and dysmorphic facial features. Psychotic disorders (most commonly schizophrenia and schizoaffective disorders) are far more common in children, adolescents and young adults than in populations without velo-cardio-facial syndrome that have been matched for IQ [18]. Schizophreniform disorders develop in up to 41% [19] of people with the syndrome.
3. *Down syndrome (DS)/trisomy 21 and Alzheimer's dementia (AD):* In addition to characteristic facial features, people with DS have associated physical health conditions such as cardiac defects, increased risk for leukaemia, autoimmune disorders, and by 50 years old, up to 55% [20] of those with DS have clinical features of dementia. Evidence suggests common pathogenic pathways between DS and AD, including the over-expression of the Amyloid Precursor Protein (APP) gene coded for on chromosome 21 which is important in the neurodevelopment of AD [21].
4. *Williams syndrome (WS) and anxiety:* Individuals with WS are known to appear as being hyper-social, outgoing and friendly. Despite this, they experience greater levels of anxiety than both individuals without ID and those with ID due to another cause [22] (■ Table 10.1).

In addition to our current understanding of genetic syndromes and their specific behavioural phenotypes, developments in molecular genetics have made it possible to study rare chromosomal copy-number variations (CNVs). CNVs have been implicated in the development of a broad range of complex conditions including ID, severe mental illness and autism [23]. As the resolution of genetic testing improves, it should one day be possible to test for CNVs in routine clinical practice leading to further discoveries. Wolfe et al. [23] found that up to 11% of new genetic diagnosis could be uncovered if chromosome microarray analysis was performed routinely. This is still a new and expanding field but with further research, geneticists should be able to uncover new genetic diagnoses with characteristic psychiatric phenotypes with potential implications for management. Overlap in the genetic risk markers (CNVs) for classically neurodevelopmental disorders (including Attention-Deficit/Hyperactivity Disorder (ADHD), Autism Spectrum Disorder (ASD) and ID) and those that had previously been considered neurodegenerative disorders (namely adult-onset schizophrenia and bipolar affective disorder) challenge existing psychiatric nosology and suggest shared pathways

Table 10.1 Examples of different syndromes with associated symptoms/behavioural phenotypes and associated psychiatric illness

Genetic syndrome	Psychiatric symptoms and behavioural phenotypes associated with syndrome	Psychiatric illness associated with syndrome
Prader-Willi syndrome – Chromosome 15 abnormality (paternal deletion, maternal uniparental disomy or imprinting defect)	Hyperphagia, skin picking, temper tantrums, aggression, hoarding, obsessional traits Sleep disturbance Stubbornness	Affective disorders often with psychosis Obsessive-Compulsive Disorder
Velo-cardio-facial (DiGeorge) syndrome – Deletion of genetic material from chromosome 22	Shy, withdrawn Problems in social relationships Concrete thinking Mood fluctuations	Schizophrenia spectrum disorders ADHD
Down syndrome – trisomy 21	Self-talk Particular deficits in working memory Sociable nature Age-related cognitive decline Aggression Stubbornness	Alzheimer's type dementia, atypical psychotic features, Obsessive-Compulsive Disorder, anxiety Depression
Williams syndrome – deletion of genetic material from chromosome 7	Autistic traits Overly friendly/gregarious Loquacious/'cocktail party speech' Hyperactivity	Generalised and social anxiety disorder Phobias/fears Obsessive-Compulsive Disorder

and the development of what had previously been considered discrete disorders [24]. How and why the same genetic variation is expressed differently remains undetermined but is an exciting area of research [11, 24, 25].

The development of mental illness in a person with ID is multi-factorial. Despite DNA sequencing technology being available and evidence of a strong inherited component to many psychiatric diagnosis, researchers have not been able to find clear genetic causes for most of these conditions [26]. Research into the way in which our environment can influence the development of mental illness and modulate the expression of genetic predisposition to disorders is helping us to gain new insights into the aetiology of mental illness in those with and without ID. Epigenetics describes the modification of gene expression (epigenome) that arises without altering the genetic code due to non-genetic influences, such as physical or emotional events [27]. Epigenetic mechanisms of gene regulation are composed of a complex, interconnected and plastic network comprising DNA methylation, post-translational modification of histones and non-coding RNAs [28]. Recent research on transcriptional activity at the molecular level has identified higher-order layers of regulation, including three-dimensional chromosome organisation, chromatin accessibility and RNA epigenetic modifications (epitranscriptome) [29–31]. Depending on the immediacy between an individual's life and the occurrence of changes in his/her epigenome, two main types of epigenetics are distinguished, *direct* and *indirect*. *Direct* epigenetics refers to changes that occur in the lifespan of an individual, due to direct experiences with his environment, while *indirect* epigenetics concerns changes that occur inside of the womb, due to events during gestation, or changes that affect the individual's predecessors, due to events that occur even long before conception and that are transmitted across generations [32–34]. Intrauterine epigenetic changes, called *foetal programming* (or *re-programming* in reference to the very

first weeks after conception), are hypothesised to constitute the most numerous and most important epigenetic changes for an individual's life and to represent a form of adaptive response to environmental stimuli, as to prepare an organism to tolerate negative external factors that may be encountered after birth [32, 35–38]. Intrauterine epigenetic changes can mark germinal cells and be transmitted to the offspring (imprinted genes) [35]. If, however, offspring's environmental conditions are markedly different than predecessors' ones, the offspring would be epigenetically mismatched and have a phenotype not appropriate for that environment. This could explain why highly stressful life circumstances or certain compounds such as alcohol or environmental toxicants, which profoundly alter the epigenetic make-up, could exert undesirable transgenerational effects and determine vulnerability to neurodevelopmental and psychiatric disorders [32, 39]. Likewise, the alteration of partial (alleles from both parents are differently expressed) and complete (complete suppression of one parent's allele) genomic imprinting of certain genes seem to influence the physiology of neural circuits and affect mental functioning and behavioural phenotypes [40].

Also foetal programming has been shown to link maternal pregnancy stress, exposure to toxic substances and viral infections with brain development and emotional reactivity of the offspring [35, 37, 41–43].

However, the epigenetic load accumulated over the course of an individual's lifetime might also bring risk factors for disease, as some direct epigenetic changes have been associated with predisposition to psychiatric disorders [26, 44–47]. The epigenetic relationship between stressful early life adversity and anxiety and depressive disorders has been extensively studied, with particular regard to the brain-derived neurotrophic factor (BDNF), hypothalamic–pituitary–adrenal (HPA) axis, serotonin transporter and FKBP5 (a critical regulator of the HPA cortisol response) genes [48]. Interestingly, variants in genes encoding for epigenetic modifiers have also been reported on [49].

In the last decades, the availability of high-throughput technologies has facilitated the generation of vast amounts of public epigenome-wide datasets that enable less biased and more integrative views on how the epigenetic regulation works in health and disease. The hope is that once we understand more about the interaction between genetics and psycho-social risk factors in influencing the susceptibility of mental illness, we will be able to think about new options for prevention and treatment of mental illness [50].

Several genetic syndromes show particular behavioural, cognitive and linguistic profiles related to specific mental illnesses. Epigenetics modification has also been associated with predisposition to psychiatric disorders, in both direct (during the person's life span) and indirect (during gestation or before the conception and transmitted across generations) ways. Epigenetic foetal programming links maternal pregnancy stress, exposure to toxic substances and viral infections with brain development and emotional reactivity of the offspring. Perinatal complications, chronic physical illnesses, sensory impairments, comorbidities and related medication can also contribute to mental health problems.

10.3 Psychological Factors

Vulnerability to the development of mental illness could be related to an individual's early life experiences and relationships. Attachment theory describes the notion that human beings are motivated to seek proximity to 'attachment figures', typically the primary caregiver [51]. An inconsistent and insecure relationship with such a figure could lead to the development of emotional problems and in some cases mental disorders due to reduced resilience in coping with stressful life events [52]. This theory has been influential in shaping our understanding regarding the psychological factors leading to the possible development of a mental illness, but research into

how the attachment theory could affect the mental health of people with ID has been relatively limited. The available research suggests that although attachment behaviours are generally similar to those without ID, they may be delayed or blunted in people with ID [53]. Another hypothesis is that the ID in itself could be experienced as a trauma, for both the parents at diagnosis and the child when they become cognitively aware of their diagnosis, and therefore affects the bond between a child and their attachment figure [54]. Reactive attachment disorder symptoms (unusual social behaviours including being withdrawn, disinhibited or overfriendly) has been found to be present in individuals with ID that suffered early childhood adversity, although symptoms seem to diminish with age [55].

The diathesis-stress model proposed by Abramson and colleagues [56] outlines the concept that psychological distress or the development of mental illness arises from the interaction between pre-existing (genetic) vulnerability to mental illness and stressful life events. Studies have supported the theory that stress is associated with the development of depressed mood in both the general and ID populations [57].

Individuals with ID are more likely to experience adverse life events such as stigma and discrimination, social exclusion, reduced employment and vocational opportunities and poverty [58]. Individuals with ID are also more likely to experience all types of abuse due to their vulnerability. A review of the limited available evidence into adverse life events in people with ID, performed by Martorell and colleagues [59], highlighted the importance of understanding and identifying the role of life events and traumatic experiences as predictors of psychopathology in people with ID. Adverse life events and psychosocial disadvantage have been linked to the development of psychiatric morbidity in young people and adults with ID [60]. Ali and colleagues [61] showed that higher rates of self-reported stigma were associated with higher psychological distress and service use. People that have experienced adverse life events may later go onto develop difficulties with processing their emotions which can manifest as interpersonal difficulties, presenting in some cases as emotionally unstable personality disorder or depression [62, 63]. Certain experiences which may not seem particularly traumatic to the general population could induce a post-traumatic reaction in a person with ID. For example, moving home may be experienced as a traumatic event for a person with ID as they may have no control over any aspect of the move and no choice about where they move to or who they will be living with. These experiences may be expressed in individuals with ID by an apparent increase in 'challenging behaviour' which in a person without an ID would be interpreted as anger or avoidance associated with Post-Traumatic Stress Disorder (PTSD) [59].

People with ID, specifically those with moderate ID [64], often feel that they have been discriminated against due to their ID. Ali and colleagues [65] described how this can result in barriers to accessing health care for several reasons, including poor communication. For example, a person can feel discriminated against if their health practitioner does not modify their communication in accordance with their needs, making it impossible for them to understand the salient points of the consultation [66]. Such discrimination can lead to feeling stigmatised, which impacts negatively on an individual with ID psychological wellbeing and can cause psychological distress [66].

The persistent exposure to uncontrollable, stressful situations can contribute to 'learned helplessness', that is, that a person 'learns' that he/she is helpless in many situations and does not attempt to try and change them, even when change is possible [67]. Learned helplessness can increase a person's risk of depression [68]. Although this can be a universal condition, those with ID are much more vulnerable [69, 70] since the tendency to overestimate their performance due to a lack of ability to recognise their deficits, difficulty in connecting their performance to internal causes (external locus of control[1]) and effectively judging their ability, and difficulty in

1 A belief that life is controlled by outside factors which the person cannot influence.

identifying the cognitive exhaustion state symptoms [69, 71].

Another vulnerability factor, conceptually associated and partially overlapped to external locus of control and learned helplessness, is represented by low environmental mastery. Environmental mastery refers to the ability to autonomously access and modify the surrounding context as well as being able to control events [72]. People with ID often receive excessive long-term support for all activities of daily living, which strongly limits the opportunities of successful experiences and the development of a sense of self-efficacy.

Psychological factors associated with psychopathological co-occurrences in persons with ID are also described within ▶ Chap. 3.

Adverse life events, including some experiences that may not seem overly traumatic to the general population, psychosocial disadvantage, poor coping skills, communication problems and issues with understanding and expressing emotions, have been linked to the development of psychiatric comorbidity in young people and adults with ID. Other psychological factors commonly associated with psychopathological causality are represented by the perception of being different and inferior to others or dependent on the support of others, poor self-esteem, negative self-image, low environmental mastery and learned helplessness.

10.4 Social Factors

Involvement in meaningful activities and living in a supportive environment is important for everyone, particularly those that have an ID, yet they may have more difficulty than those in the general population in achieving this [73]. Individuals with ID may have poor coping skills related to difficulties with problem solving and therefore require good support networks. Despite the increased levels of support that individuals with ID require, the subjective feeling of loneliness is a widespread problem in people with ID with reported prevalence rates of up to 45% [74]. A person with ID will often be socially isolated (only 6% of people with ID are in paid employment) [75], meaning they often only have a small social network mainly consisting of other service users, paid carers and family members [76]. There is a probable bi-directional relationship between loneliness in an individual with ID and physical and mental health problems [74]. Currently there is only limited evidence to suggest that loneliness in itself directly leads to the development of mental illness in the ID population, although there is some evidence to suggest that loneliness can contribute to a person with ID's existing predisposition toward mental illness [77]. Research in the general population indicates that loneliness, along with a psychological sense of belonging, can affect the experience of depression (biological, affective, behavioural and cognitive symptoms) more than the actual social support available [78].

Social factors associated with psychopathological co-occurrences in persons with ID are also described within ▶ Chap. 3 (■ Table 10.2).

People with ID are often socially isolated and discriminated or have a small social network which does not protect them from feelings of loneliness. Experiences of financial disadvantage are also frequent.

They may not be aware of their rights and be exposed to all kinds of abuse, for which they have to rely on the support of others. Their access to healthcare is often difficult and limited, and they have no control over any aspect of their living environment and no choice as to where they move or who they live with. This affects the possibility of self-determination and making decisions for one's life and health.

Table 10.2 Factors contributing to the development and maintenance of mental illness in persons with ID/ASD

Biological	Psychological	Social
Pregnancy and birth complications Pregnancy and birth complications, as well as sometimes being a cause of ID, have also been associated with brain damage and/or later development of mental illness, particularly schizophrenia	*Attachment factors* Inconsistent and insecure relationships with parental figures	*Social isolation* Social isolation, small social network (mainly consisting of other service users, paid carers and family members) and feeling of loneliness
Genetic factors Several genetic conditions show well-known behavioural phenotypes, associated with specific mental illnesses (e.g. Prader-Willi syndrome, Williams syndrome, Down syndrome, DiGeorge syndrome)	*Adverse life events* Adverse life events have been linked to the development of psychiatric morbidity in young people and adults with ID/ASD	*Economic disadvantage* Unemployment and economic disadvantage are common among people with ID/ASD, with all its consequences on mental health vulnerability
Epigenetic factors Direct (during the person's life span) and indirect (during gestation or before the conception and transmitted across generations) epigenetic changes have been associated with mental health issues	*Traumatic experiences* Proneness to be traumatised by life experiences is higher in persons with ID/ASD with higher impact on mental health. Life experiences that may not seem overly traumatic to the general population could induce a post-traumatic reaction in persons with ID/ASD	*Discrimination and stigmatisation* Discrimination by society can lead to stigmatisation in people with ID and affect their self-esteem and self-image
Physical illness Some physical illnesses, especially chronic physical illness, can predispose to certain mental health conditions such as depression or anxiety, or can determine various symptoms of mental disorders	*Difficulty to express emotions* People with ID/ASD often have difficulty to process and express their emotions, which cause in turn further psychological and relational issues	*Abuse* Individuals with ID/ASD are likely to experience all types of abuse They may not be aware of their rights and have to rely on the support of others to be advocates for their needs
Sensory impairment Sensory impairment can increase psychopathological vulnerability through a negative impact on many psychological and relational aspects	*Poor coping mechanisms* Individuals with ID/ASD may have poor coping skills related to difficulties with problem solving, managing frustration, anger and the consequences of their own behaviours	*Access to physical and mental health care* Persons with ID/ASD may face issues in accessing health care services for several reasons, including communication failure, setting inadequacy and lack of specific knowledge of the medical staff. This may negatively impact on self-determination and making decisions for their own health. This can also hinder early diagnosis and early intervention

Table 10.2 (continued)

Biological	Psychological	Social
Medication Side effects of psychotropic and non-psychotropic drugs can negatively impact on mental functioning, especially in case of polypharmacy and/or long-lasting treatments	*Self-worth* The aspects of life that society values (e.g. high social status, independence, employment, relationships and family) are those in which people with ID/ASD may have greatest difficulties, which can affect their self-esteem	*Living in inappropriate environment* Living in a pleasant and supportive environment is important for everyone, but persons with ID/ASD may have more difficulty than those in the general population in achieving this. They often have no control over any aspect of the living environment and no choice about where they move to or who they live with
	Self-image ID and ASD themselves may be experienced as a trauma, both by the person with the condition and their family. Persons with ID/ASD may feel different, inferior to others or dependent on the support of others and develop a poor or negative self-image that can contribute to mental health problems	
	Learned helplessness The persistent exposure to uncontrollable stressful and negative situations, which characterises the life of many persons with ID/ASD, can significantly reduce the individual's belief in their innate ability to achieve goals	
	Low environmental mastery Persons with ID/ASD often need and receive considerable and long-lasting support for many activities, including daily living activities. This limits the development of a sense of self-efficacy and internal locus of control	

10.5 Comorbidities

Diagnostic overshadowing occurs when the symptoms or signs of a physical or mental illness are incorrectly attributed to an individual's diagnosis of ID and hence potentially treatable causes for the presentation are neglected [79]. Overshadowing is even more likely when a person suffers from an ID and a comorbid condition, and this can further complicate the clinical picture. For this reason, it is important to be aware of common comorbidities and their association with mental illness to avoid delayed diagnosis or treatment. Psychopathological co-occurrences are the main object of the whole textbook the present chapter is included in. Heredown some short paragraphs are reported in reference to main co-occurring developmental disorders and neurological conditions.

10.5.1 Autism

Autism spectrum disorder (ASD) are a group of conditions that are characterised by a combination of social communication deficits, restricted interests and repetitive behaviours [1] (see ► Chap. 16). The prevalence of autism in those with ID is reportedly as high as 35% (in comparison to 1% in the general population) and is found to be higher in those with a lower verbal IQ or more severe disability [80]. Conversely, an IQ below 70 is found in at least

half of all people with autism [81]. There is therefore significant aetiological and diagnostic overlap between ID and ASD, leading to challenges in clearly distinguishing between the two conditions [82]. Owen et al. [24] proposed that ID, ASD and schizophrenia are connected and are part of the same neurodevelopmental disorder. He goes on to suggest that researchers need to reconsider the way in which they use diagnostic categories and focus on the developmental context of pathogenesis of certain syndromes, which could result in changes in the way in which psychiatric services are delivered.

Comprehension deficits experienced by an individual with ID may exacerbate the deficits in communication that an individual with ASD has, leading to even more challenges in diagnosing mental illness in this group. Buck et al. [83] describe how the presence of an ID makes identifying subjective symptoms of psychiatric disorders in people with ASD even more challenging due to limited expressive language resulting in those with comorbid ID and ASD being less likely to receive a diagnosis of anxiety or depression than those with ASD alone. An increased prevalence of physical aggression has been found to be associated with individuals with comorbid ID and autism [84], specifically self-injurious behaviour [85].

There is a large variation in mental illness prevalence rates in people with ASD, which may be due to difficulties in distinguishing between psychiatric illness and ASD clinically due to the conceptual overlap between the two conditions [86]. Depressive symptoms can also be misattributed to autism as symptoms such as flattened affect and social withdrawal occur in both conditions [87]. It can be difficult to distinguish the restricted and repetitive behaviours associated with ASD with the same symptoms present in obsessive compulsive disorder [88], again leading to diagnostic confusion and uncertainty. Similarly, the lack of conformity to social convention in people with ASD can be misinterpreted as mental illness. Other factors that contribute to difficulties in diagnosis of psychiatric illness in individuals with ASD include atypical psychiatric presentation in those with ASD, lack of validated instruments and lack of experienced clinical staff [89]. This emphasises the importance of taking a thorough developmental history and gathering collateral history.

Despite the variation in prevalence rates, psychiatric disorders have been found to occur frequently in adults with ASD. Mouridsen et al. [90] found rates of comorbid schizophrenia spectrum disorders to be as high as 35% in individuals with atypical autism. Conversely autistic-like traits and rates of ASD are higher in people with a diagnosis of psychosis than in the general population [91]. Recent studies suggest there are shared risk pathways between ASD and psychosis including a common genetic mechanism [92]. Anxiety is known to occur frequently in individuals with ASD [93]. Hyper- or hyporeactivity to sensory information is a known feature of ASD occurring in up to 96% of children with ASD [94]. This sensory over responsivity has been found to predict later development of anxiety disorders [95].

10.5.2 ADHD

Attention-deficit/hyperactivity-disorder (ADHD) is characterised by symptoms of inattention, hyperactivity and sometimes impulsive behaviours which interfere with functioning [1] (see ▶ Chap. 17). Pooled prevalence rates of ADHD indicate rates of 2.5% in adults without intellectual disability but higher rates in those with ID [96, 97].

Higher rates of a range of psychiatric illnesses have been found in people with ADHD [98]. The most frequent comorbid conditions are mood disorders, anxiety disorders, substance misuse disorders and personality disorder [99]. There are specific challenges in diagnosis of these comorbidities, for example, the emotional dysregulation present in ADHD could lead to misdiagnosis of a mood disorder or be labelled as challenging behaviour [100]. Equally an anxiety or mood disorder could be misattributed to ADHD symptoms. For this reason, rates of comorbid conditions vary widely in the available literature and this is an area which requires further research.

10.5.3 Epilepsy

Population-based studies of adult ID populations have found a prevalence of comorbid epilepsy to be in the region of 25% [101]. The prevalence increases with the severity of ID, occurring in 45% of those with severe ID in comparison to 15% with mild ID [102] (see ▶ Chap. 29). Up to 50% of people with comorbid ID and epilepsy have psychiatric or behavioural problems [103]. There is a complex relationship between the presence of behaviour that challenges and epilepsy in a person with ID. Although a link may exist, Blickwedel and colleagues [104] postulated that it is unlikely that epilepsy alone is the cause of challenging behaviour.

Epilepsy is associated with a range of psychiatric conditions in the general population including depression, anxiety, psychosis and personality disorders [105]. These illnesses are associated with the severity and chronicity of the epilepsy as well as type of epilepsy (increased in temporal lobe or refractory epilepsy) and adverse medication side effects.

10.5.4 Cerebral Palsy

More than 40% of children with cerebral palsy have a co-existing ID [106]. It is estimated that half of children with hemiplegia have a problem with behaviour, emotions or relationships including irritability, hyperactivity and anxiety, which has been associated with the underlying brain damage [107].

The risks of diagnostic overshadowing and misinterpretation of signs and symptoms increase along with the number and complexity of physical or mental illness that co-occur with ID/ASD. Mental health professionals must be aware of common comorbidities (i.e. ADHD, epilepsy and cerebral palsy) and their association with mental illness to limit the risk of diagnostic overshadowing and consequent delays in diagnosis or treatments.

Summary

In this chapter, we have discussed in detail the causes of mental illness in ID and their interaction. A conventional biopsychosocial framework was used to outline the causes and consequences of mental illness in people with intellectual disability. We have also discussed the challenges of diagnosing mental illness in individuals with ID and common comorbidities such as autism, ADHD and epilepsy.

Tip

Neurodevelopmental disorders frequently co-occur with other mental health problems to the point that some of them have been proposed to be part of the same neurodevelopmental disorder. Future research and clinical attention needs to reconsider the way in which diagnostic categories are used and focus on developmental context in the pathogenesis of mental illness.

Key Points

- Aetiology and pathogenesis of mental illness in ID is multi-factorial.
- There are biological, psychological and social risk factors for development of mental illness which combine to predispose an individual with ID to mental illness.
- There are several comorbid conditions which are associated with mental illness. One must be aware of overshadowing and consider assessment for mental illness.

Psychopharmacology

Shoumitro (Shoumi) Deb, Marco O. Bertelli, and Michele Rossi

Contents

M. O. Bertelli et al. (eds.), *Textbook of Psychiatry for Intellectual Disability and Autism Spectrum Disorder*, https://doi.org/10.1007/978-3-319-95720-3_11

Learning Objectives

- Rate of psychotropic use among adults with intellectual disabilities
- RCT-based evidence for individual psychotropic medications
- Polypharmacy
- High dose psychotropic use
- Adverse events of psychotropics
- Withdrawal studies of anti-psychotics

- A high proportion of people with intellectual disabilities receive medication for both physical and mental health problems.
- A high proportion receive off-label psychotropic medication for the management of problem behaviour in the absence of any psychiatric disorder.
- The evidence for the effectiveness of psychotropic medication to treat problem behaviour per se in people with intellectual disabilities is poor.
- On the basis of current evidence, the use of psychotropic medication could neither be supported nor refuted in this context.
- Non-pharmacological interventions should always be considered first or along with medication.
- A thorough assessment (including appropriate examination and investigations) of the causes and effects of problem behaviour followed by an appropriate formulation is a pre-requisite for using medication.
- People with intellectual disabilities and their carers should be involved in the decision-making process all along.
- Where appropriate other relevant professionals should be involved.
- Start with a low dose and increase the dose slowly modulating one medication at a time and avoid polypharmacy.
- Monitor effectiveness and adverse events associated with the intervention, and quality of life of the person with intellectual disabilities.
- At all subsequent follow-up assessments, consider withdrawal of medication and alternative non-medication-based management options.

Tip

Psychotropic medications are used commonly to treat problem behaviour in people with intellectual disabilities.

The evidence in support of their effectiveness is poor.

Non-pharmacological interventions should always be considered first for the management of problem behaviour in people with intellectual disabilities.

11.1 Introduction

11.1.1 Frequent Use, Polypharmacy and High Dose

Psychotropic medications such as anti-psychotics, anti-depressants, mood stabilisers including anti-epileptic medications and lithium, anti-anxiety medications including benzodiazepines, psychostimulants, beta-adrenergic blockers, opioid antagonists are used widely among people with intellectual disabilities (ID) [1]. The reported rate of use of these medications among people with ID varies between 32% and 85%; some of these studies have reported the rate of anti-psychotic use alone [2–11]. These medications are used in addition to existing high use of medication for physical problems (see ► Case Study 1) [12]. These medications are used for both mental illness and also problem behaviour (PB) for which they are not licenced [13]. A recent analysis of pooled data from the UK primary care (General Practice) database showed that of the 33,016 adults with ID, 49% (n = 16,242) received psychotropic medication between 1999 and 2013, and only 21% (n = 7065) had a diagnosis of mental illness but 25% (n = 8300) also had a diagnosis of PB [14]. In a previous study, Clarke and colleagues (1990) found that 36% of those who received psychotropic medication did not have a psychiatric diagnosis [15]. However, it is worth remembering that diagnosing both mental illness [16] and PB could be difficult in many people with ID [17].

Case Study 1: Frequent Use of Psychotropic Medication in People with Intellectual Disabilities

- Risperidone 2.5 mgs
- Carbamazepine 2000 mgs
- Sodium Valproate 2700 mgs
- Lamotrigine 400 mgs
- Lithium Carbonate 1200 mgs
- Methylphenidate 5 mgs
- Procyclidine 15 mgs
- Ferrous Fumarate + Vitamins + Lactulose + cod liver oil + various skin ointments
- PRN (as required medication): Clobazam + Lorazepam
- Rectal diazepam + buccal midazolam as rescue medication for status epilepticus.

The above is a list of a daily dose of medications for an adult with intellectual disabilities. This is not atypical for many people with ID. Notice the polypharmacy of psychotropic medication here (anti-psychotic + anti-epileptic + lithium + stimulant) and also the combination of three anti-epileptic medications at a high dose. Both sodium valproate and carbamazepine are used at a higher than recommended dose. If used simultaneously with sodium valproate, the dose of lamotrigine should be lower. If risperidone and anti-epileptics are already used, why is lithium needed to be added to control behaviour? Also, why a psychostimulant is used if already a number of psychotropics are used to control behaviour. If this is used for ADHD, why are the other psychotropics used for behaviour control? It seems that a number of psychotropic medications have been combined here in desperation without a proper formulation/rationale for this drug regime. Also, note that regular use of procyclidine with anti-psychotics can precipitate tardive dyskinesia in a person with an underlying brain damage. Also, note the prescription of a large number of medications here for medical conditions over and above the psychotropic use.

The rate of use of different psychotropic medications may vary from country to country. For example, in a recent community psychiatric clinic-based study of psychotropic medication use for management of PB in 100 adults with ID in the UK, 48% received new generation of anti-psychotics, 41% anti-epileptic medications (although in a high proportion of these participants, they were used for epilepsy treatment rather than any mental health problem and epilepsy can affect up to 25% of adults with ID [18]), 29% new generation anti-depressants, 27% old generation anti-psychotics, 9% anti-anxiety medications, 8% beta-blockers, 5% older generation anti-depressants, 4% psychostimulants and 3% lithium [19]. However, among Dutch population of 2373 adults with ID, de Kuijper and colleagues (2010) [9] found 32% received anti-psychotics (of these 65% received old generation and 23% new generation anti-psychotics), 58% of them received these medications for PB, 22.5% for psychoses (11.7% of them were diagnosed using DSM-IV criteria) [20], and in 18.5% of cases no reason was described in the patient records. In the same population, 17% also received anti-depressants and 20% benzodiazepines. Therefore, it appears that compared with the UK population, a higher proportion of participants received older generation of anti-psychotics and anti-anxiety medications such as benzodiazepine, but a lower proportion received anti-depressants in the Dutch population. However, the profile of psychotropic medication prescription found in these studies [9, 19, 21, 22] is similar to what was reported in a consensus survey in which the UK psychiatrists were asked to rank order their preference of use of psychotropic medication for the management of PB in people with ID, although most psychiatrists preferred to use a non-medication-based approach first [23]. Aman and colleagues' (2000) [24] international consensus study found a similar trend which preferred valproic acid and carbamazepine among the mood stabilisers/anti-epileptics. In the UK, it seems that the use of lithium as a mood stabiliser medication as well as for the management of PB is falling out of favour.

Reilly and colleagues (2014) [25] reported among individuals with ID in the UK and in Ireland that of four neurogenetic syndromes, psychostimulants were used among 21% of individuals with Fragile X syndrome (FXS), 3% with Prader-Willi syndrome (PWS), 4% with Williams syndrome (WS) and none with Velo-cardio-facial syndrome (VCFS). Risperidone was used among 7% of FRX, 6% of PWS and none of WS or VCFS individuals. SSRIs were used for 1% of FRX, 4% of PWS and none of WS or VCFS individuals. On the other hand, melatonin was used among 9% of FRX, 3% of PWS, 15% of WS and 8% of VCFS individuals.

The expectation that the use of psychotropic medication will decrease considerably once people with ID move out of long-stay institutions into the community has never materialised. All studies on this have found that the rate of psychotropic use has remained the same after discharge from institutions, some showing a decrease in anti-psychotic use at the expense of increased anti-depressant use, although overall there is an increase in the use of new generation than old generation anti-psychotics [26–29].

11.1.1.1 Polypharmacy

Despite the widespread condemnation of and lack of evidence for the use of polypharmacy (simultaneous use of more than one) of anti-psychotic medications, this practice remains widespread [30]. On the other hand, the merits and demerits of combining an anti-psychotic with another group of psychotropic medication specifically for the management of PB in adults with ID are currently unknown [31]. In Deb and colleagues' (2014) [19] study, however, the rate of polypharmacy of anti-psychotics alone is relatively low (10%), although the use of polypharmacy of all types of psychotropics remains relatively high (45%). Branford (1996) [32] showed that with an active programme, polypharmacy of anti-psychotics alone could be reduced, and in some cases, anti-psychotics could be withdrawn altogether or their dose reduced without any adverse consequences. However, most places lack such active programme for anti-psychotic withdrawal. However, it is worth keeping in mind that in a number of individuals where two anti-psychotics were prescribed simultaneously, the clinicians may be in the process of switching over from one to another.

11.1.1.2 High-Dose Anti-psychotics

Deb and colleagues' (2014) [19] study has also highlighted a trend towards the use of high-dose anti-psychotic medications in a number of adults with ID. According to the British National Formulary (BNF) (► bnf.org.uk), the usual maintenance dose of chlorpromazine for the treatment of psychoses is up to 300 mg a day, although a maximum dose of 1000 mgs has been recommended for exceptional cases. In Deb and colleagues' (2014) [19] study 23% of adults with ID received daily chlorpromazine-equivalent anti-psychotics dose of more than 300 mgs. Interestingly, these proportions are very similar to what was described in Branford's (1996) [3] study 13 years prior to Deb and colleague's (2014) [19], which reported the rate of anti-psychotic medication use in a population-based sample of adults with ID in the UK. In Branford's (1996) [3] study of the 198 patients who received anti-psychotic medication, 56 (28%) received at a daily dose over 300 mgs.

In Deb and colleagues' (2014) [19] study, the dose used for both risperidone and olanzapine was very low. However, the recommended daily dose suggested in the BNF is for the licenced indication for the treatment of psychosis. Therefore, it is anticipated that dosage will perhaps be lower when used for the management of PB. It is possible that in the case of anti-psychotics, clinicians feel that a lower dose acts as an anti-anxiety/anti-arousal medication rather than an anti-psychotic, with the primary intention of the behavioural management being to decrease the underlying anxiety/arousal.

11.1.2 Quality of Evidence

La Malfa and colleagues' (2006) [33] review on the use of anti-psychotic medications in people with ID identified 195 studies of which 127 were of type V, 44 of type IV, 9 of type III, 21 of type II and 4 of type I evidence.

One hundred and seventeen studies included old generation anti-psychotics and 78 new generation. Randomised controlled trials (RCTs) are seen as the gold standard for evidence in medicine and there are major challenges in involving people with ID in RCTs [34]. Mulhall and colleagues (2018) [35] in their recent systematic review summarised the main challenges as (a) difficulties recruiting, (b) obtaining consent, (c) resistance to the use of control groups (placebo), (d) engaging with carers, staff and stakeholders, (e) the need to adapt interventions and resources to be disability-accessible and (f) staff turnover. The authors felt that with reasonable adjustments, most of these barriers could be overcome. Another problem is with defining the clinical phenomenology of PB in order to be specific about the therapeutic objectives. The lack of RCT means that people with ID are deprived of receiving evidence-based intervention and as a result, clinicians' bias is rife in the day to day practice. Only 11% of the population in 100 RCTs of anti-psychotics for the treatment of PB included people with ID [36] as often disability in general and ID, in particular, is an exclusion criterion in pharmacological studies.

Therefore, the evidence presented in this chapter on the effectiveness of psychotropic medications has to be interpreted with caution. Most studies in this field are case reports on a small number of participants. It is known that studies with positive findings are more likely to be published than studies with negative findings. This is likely to create a reporting bias for the published case reports. There are only a few RCTs, but they often used a small cohort size, resulting in insufficient statistical power to draw firm conclusions. The outcome measures used are often not appropriate or validated. The method of selection of the control group and the experimental group is not always clear or appropriate, and outcome data are often not presented in an appropriate manner. For example, most studies neither quote the 'number needed to treat' (NNT) nor use analysis based on the 'intention to treat' (ITT). Most studies do not distinguish symptoms of psychiatric illness from those of PBs, and often researchers do not take into account the effect of co-morbid ASD and ADHD on PB symptoms. Also in many studies, participants with co-morbid psychiatric disorders were not excluded. It, therefore, remains unclear whether the psychotropic medications used in these studies treated the underlying psychiatric condition or the PB per se.

PBs are usually long standing; therefore, short follow-up periods used in most studies meant that it is not possible to know whether patients would derive any benefit in the long term. Only long-term follow-up will determine the effect of many confounding factors such as environmental changes, etc., that are concomitant with the use of psychotropic medications. Most studies do not take into account the confounding effect of concomitant non-medication-based management of behaviour, which may have a profound effect on the behaviour (although an adequately powered RCT should balance out these confounders in both groups). Similarly, in most studies, the anti-psychotics were used as add-on therapy, which made it difficult to tease apart the confounding effect of concomitant medications. For example, the use of anti-epileptic medications is common among adults with ID [37] and these medications may have an effect on the behaviour [38, 39]. However, an RCT design should take care of some of these confounding factors.

Another problem of interpreting the case report-based data is that many patients who showed improvement on a particular medication may have had an unsuccessful trial of other medications that have been shown to be effective in other case studies. Therefore, the individualised response to specific medication is always going to be difficult to determine. An individual's genetic make-up is likely to influence her/his response to a particular medication. There may be many causes of PBs among individuals with ID and many factors including medical, psychological and social may influence behaviour (see ▶ Chap. 7 on problem behaviour) (also see https://spectrom.wixsite.com/project). It is, therefore, imperative to carry out a detailed assessment of the causes and consequences of PBs before an intervention is implemented. However, none of the studies provides any detail of behaviour analysis. This sort of issue could be addressed by

including an overall quality of life (QoL) outcome measure. However, up until Unwin and Deb's (2014) [40] publication of Caregiver's Concern-Quality of Life Scale (CC-QoLS), no health-related QoL (HRQoL) existed for individuals with ID who manifest aggressive behaviour. Future studies should also assess the effect of interventions on family carers' burden and cost effectiveness [41, 42].

11.1.3 Indication

Although these cannot be seen as indications, psychiatrists usually consider psychotropic medications for the management of PB in individuals with ID under following circumstances: (a) failure of non-medication-based interventions, (b) risk/evidence of harm to others, property and self, (c) high frequency and severity of problem behaviours, (d) to treat an underlying psychiatric disorder or anxiety, (e) to help with the implementation of non-medication-based interventions such as positive behavioural support (with concurrent use of medication), (f) risk of breakdown of the individual's community placement, (g) lack of adequate or available non-medication-based interventions (although this should not be used as a rationale for using medication), (h) good response to medication in the past and (i) patient/ caregiver choice.

There is public concern regarding the use of psychotropic medication in individuals with ID for the management of PB in the absence of a diagnosed psychiatric disorder (see ► Case Study 2). Some of the reasons for this concern are: (a) perceived excessive use of medication (polypharmacy, use of higher than recommended dose of anti-psychotics) [43], (b) long-term use without reviews [13], (c) worry about adverse effects which could be difficult to assess, and inappropriate concomitant use of drugs to counteract adverse effects [19], (d) overall lack of evidence to support the effectiveness of psychotropic medications to manage PB [44–51], (e) out of licence use of psychotropic medications [52], (g) use of medication without explicit patient consent which often occurs in ID, (f) difficulty in assessing adverse effects in many individuals with ID, (g) difficulty in obtaining necessary investigations such as serum lithium level or blood tests for other adverse effects [53] and (h) difficulty in securing explicit informed consent in many cases [13, 53].

Case Study 2: Inappropriate Use of Psychotropic Medication.

A proprietor of a group home brought a 63-year-old gentleman with moderate ID to a psychiatric clinic asking for psychotropic medication to control his non-co-operative and anxious behaviour. Further examination revealed that the gentleman did not want to go to the day centre and became disturbed when he was forced to do so. When asked the proprietor of the group home told the clinician that they do not have a contract with social services department for payment of this gentleman's day care within the group home, therefore, they do not have a choice but to send him to the day centre. The clinician refused to prescribe psychotropic medication and asked the proprietor to sort out the contract issue with the social services department.

The general principles for using psychotropic medications for different psychiatric disorders among individuals with ID are similar to those used for the general population who do not have ID. As no specific evidence base exists to recommend specific medications for psychiatric disorders among adults with ID, the readers are directed to some of the generic guidelines on pharmacological management of common psychiatric disorders such as schizophrenia, depressive disorders, etc., such as the NICE guidelines (► www.nice.org.uk) and the Maudsley guide in the UK [54], the Frith Prescribing Guidelines in the UK [55] and others for specific application to individuals with ID [1, 56, 57]. However, the primary aim of this chapter is to discuss issues related to the use of psychotropic medications for the management of PB among people with ID.

11.1.4 Off-Label Use

When psychotropic medications are used for PB in the absence of a psychiatric disorder, they become the off-label or unlicenced use of a licenced medication. It may, therefore, be necessary to use a lower dose than what it is licenced for as the drugs may produce excessive adverse effects. For example, European legislation requires a Paediatric Investigational Plan (PIP) for all drugs that are marketed with indications for adults or the elderly. In Italy and in many other countries, off-label use is regulated by laws. The Italian Drug Agency (AIFA) specifies that 'if carried out in an appropriate manner, off-label use adds important therapeutic tools, especially for what concerns the therapy of rare diseases or involving population groups not normally included in common clinical trials'. When using medication out of its licenced indication, it is important to consider the following: (a) assess the risk of the medication in the ID population, (b) ensure that the medication has been shown to be safe for use in the ID population, (c) ensure that the evidence of efficacy is established in other population or in the ID population for other indications, (d) if necessary ask for a second opinion from a colleague who has experience of using the medication in the ID population, (e) involve as much as possible the person with ID, her/his family and other carers and professionals involved in the care, (f) make it explicit to relevant people that the medication is used outside its licenced indication and explain the rationale for its use and any potential risk involved and (g) make sure that the procedure for appropriate monitoring and follow-up is in place and adhered to.

11.1.5 Safety and Tolerability

The issue of safety and tolerability is of paramount importance in case of people with ID as they may have a different metabolism than the general population that may create different pharmacokinetics and pharmacodynamics. As a result, they may be vulnerable to develop more adverse effects than usual and also communication difficulties may make detection of adverse effects difficult. There is very little evidence available to guide clinicians on the safety and tolerability of psychotropic medication in the ID population. Therefore, the therapeutic drug monitoring remains an effective way to minimise the risk of adverse effects or toxicity. Some of the common and important adverse effects related to psychotropic prescribing in the ID population are listed below.

(a) Hyperactivity, restlessness, irritability and aggression are often observed with treatments with selective serotonin reuptake inhibitors (SSRIs) and sometimes benzodiazepines.
(b) Serotonin syndrome is a rare but serious adverse effect usually associated with the use of SSRI (particularly more than one SSRI). Symptoms include tachycardia, sweating, raised blood pressure and body temperature, dilated pupils, myoclonus, leading to shock. Treatment is symptomatic and immediate withdrawal of SSRI and if necessary, use of serotonin antagonist such as cyproheptadine.
(c) SSRI withdrawal may cause withdrawal symptoms in the form of increased restlessness and agitation. Therefore, it is necessary to start with a low dose and increase dose gradually. If necessary, restart slowly or use a different SSRI.
(d) New generation anti-psychotics can lead to obesity, metabolic syndrome and diabetes. These adverse effects, if not promptly treated, may bring on a significant increase in the risk of premature death.
(e) Disorders of the extrapyramidal system such as akathisia (often confused with agitation and improperly treated as such), oculogyric crises and Parkinsonian motor symptoms appear primarily during treatment with old generation anti-psychotics but may also occur from risperidone and other new generation anti-psychotics. These

symptoms may be misinterpreted as part of ID phenotype.

(f) Neuroleptic malignant syndrome (NMS) a rare but life-threatening adverse effect is associated with anti-psychotic treatment. Symptoms include raised body temperature, fluctuating blood pressure, muscle stiffness, sweating and other evidence of autonomic dysregulation. Muscle CPK is raised and treatment is symptomatic and immediate withdrawal of anti-psychotics.

(g) Constipation, if neglected, can cause severe distress (e.g. headache, depression, abdominal pain) which, in people with ID, may be expressed as sleep disorders, loss of appetite, agitation and aggression. This is mainly associated with treatments with tricyclic anti-depressants and some anti-psychotics.

(h) Anti-cholinergic syndrome, associated with the use of tricyclic anti-depressants and some anti-psychotics, may lead to agitation, motor restlessness, dysarthria, disorientation, hallucinations and convulsions. More severe symptoms include severe constipation, urinary retention, dry mouth, fever and tachycardia.

(i) Sedation, drowsiness and lethargy are associated with many psychotropic medications use.

11.1.6 Types and Rate of Anti-psychotic Adverse Effects

Mahan and colleagues (2010) [58] showed that among 80 individuals with ID in the USA, polypharmacy of psychotropic medication from different classes increased the likelihood of developing adverse effects. A number of measures have been used either in their original form or in adapted versions in order to assess adverse effects of psychotropic medications in individuals with ID. Some of these are Udvalg for Kliniske Undersøgelser (UKU) scale [59], Abnormal Involuntary Movement Scale (AIMS) [60], the Dyskinesia Identification System Condensed User Scale (DISCUS) [61], and Barnes Akathisia Rating Scale-Revised [62]. Some scales were specifically designed for use among individuals with ID such as the Matson Evaluation of the Drug Side Effects (MEDS) [63], CLAMPS [64], Monitoring of Side Effects Scale (MOSES) [65].

One recent Dutch study found that 84.4% of 103 adults with ID and PB had at least one adverse event and 45.6% had over three adverse events. Presence of adverse events had a significantly negative influence on the person's quality of life. Respectively 13% of the patients who did not receive psychotropic drugs (23% of all participants) and 61% of the patients treated with more than two psychotropic drugs had more than three adverse events [66]. Matson and Mahan (2010) [67] reviewed the studies on adverse effects due to psychotropic medication use among individuals with ID, and Matson and Hess (2011) [68] did the same for individuals with ASD. As expected, most studies are on adverse effects of anti-psychotic medications as they are the most widely used psychotropic medication for individuals with ID. Most studies reported adverse effects associated with old generation anti-psychotic medications such as haloperidol, chlorpromazine, etc. For the old generation anti-psychotic medications, extrapyramidal adverse effects such as Parkinsonism, akathisia and tardive dyskinesia are reported in most studies. One recent Dutch study of 99 individuals with ID who were treated with anti-psychotics found extrapyramidal symptoms in 53%, overweight or obesity in 46% and the metabolic syndrome in 11% of participants. In addition, hyperprolactinaemia was present in 17% and the evidence of abnormal bone metabolism in 25% of participants. Increasing age and more severe ID were associated with dyskinesia and a higher dosage of the anti-psychotic medication was associated with Parkinsonism. Less severe ID was related to higher Body Mass Index and the use of atypical anti-psychotics was also associated with a higher diastolic blood pressure [69].

Anti-psychotic-treated people with ID reported to have a significantly higher incidence of movement adverse effects particu-

larly Parkinsonism and akathisia (and possibly the rare NMS) when compared with the anti-psychotic-treated non-ID general population [70]. It is not always clear whether some of these abnormal movements are caused by the underlying brain damage or the medication or the combination of the two as studies show that individuals with ID are more prone to develop these symptoms [58, 66, 71]. However, within the ID population, the rate of these symptoms is higher among those who are treated with anti-psychotic medications than those who are not. For example, in Mahan and colleagues' study of 80 in-patients with ID in the USA, abnormal involuntary movements were recorded among 30% of those who did not take any psychotropic medication compared with 86.7% of those who took those medications [58]. In Ganesh and colleagues' (1989) [72] study among 66 in-patient adults with ID in the UK who were treated with anti-psychotic medication, five (7.6%) developed akathisia and 18 (27%) developed tardive dyskinesia. However, it is also reported that severity of ID is a risk factor for tardive dyskinesia [71], perhaps indirectly implying the role of underlying brain damage in the causation of these symptoms. A similar argument exists as to whether schizophrenia itself rather than the anti-psychotic medications per se is a risk factor for some of these adverse effects, particularly glucose intolerance.

There is also debate as to whether the new generation of anti-psychotic medications are less prone to cause adverse effects in general but extrapyramidal symptoms in particular when compared with the old generation anti-psychotic medications. In general, it has been shown that the new generation anti-psychotic medications produce less adverse effects particularly extrapyramidal symptoms than the old generation medications, although these adverse effects have also been reported among individuals with ID who have been treated with risperidone and also olanzapine. There are also anecdotal reports of risperidone causing serious adverse effects such as neuroleptic malignant syndrome (NMS) in individuals with ID. However, for the new generation anti-psychotic medications, the metabolic syndrome including weight gain, diabetes mellitus, change in lipid profile and hyperprolactinaemia are the most commonly described adverse effects. Only a handful of studies have assessed these symptoms in individuals with ID (see next section). However, interestingly a number of studies have reported dyskinesia and other extrapyramidal symptoms upon withdrawal of anti-psychotic medication in a high proportion of individuals with ID [73, 74] (60% in one study) [67, 75] (see ► Case Study 3). This phenomenon may suggest that these symptoms may sometimes have been suppressed by the use of anti-psychotic medications.

Case Study 3: Appearance of Dyskinesia After Withdrawal of Anti-psychotic Medication.

A 54-year-old lady with mild ID who has a long history of paranoid ideas and crying behaviour became confused and developed oro-facial dyskinesia after withdrawal of long-standing risperidone. These symptoms improved after re-instating risperidone.

There is also concern whether anti-psychotic medications have an effect on cognition, particularly among children. Aman and colleagues (2009) [76] have reviewed this subject. At least one RCT [77] did not find any effect of risperidone on cognition of children with ID when compared with the effect of placebo. On the other hand, Stratta and colleagues' (2013) [78] review has shown that in the non-ID general population, administering anti-psychotic medication in an individually optimised manner seems to have the potential of improving the cognitive aspect of schizophrenia, regardless of the kind of anti-psychotic medication used. Similar findings were reported for children with ID who were treated with risperidone for PB [76].

The main concern of using the new generation anti-psychotic medications is the adverse effect of metabolic syndrome. Zuddas and colleagues (2011) [79] reviewed the adverse effects of newer anti-psychotic medication including metabolic indices among children

and adolescents including those with ASD but not necessary with ID. Based on the review of RCTs, the authors showed that adverse effect of weight gain is worst with treatment with olanzapine and best with aripiprazole with intermediate effect from risperidone and quetiapine. Indeed, Deb and colleagues' (2014) [51] systematic review on aripiprazole has shown that adverse effects such as hyperprolactinaemia had improved in a number of individuals with ID when switched from other anti-psychotics such as risperidone to aripiprazole. A number of studies assessed the adverse effects of metabolic syndrome/disorders associated with newer anti-psychotic medications in individuals with ID [80–86]. Frighi and colleagues (2011) [86] observed the rate of metabolic syndrome among 138 anti-psychotic-treated and 64 anti-psychotic naïve individuals with ID and compared that with a non-ID general population that was treated with anti-psychotic medication. Among individuals with ID, 48% received risperidone, 18% olanzapine, 10% thioxanthenes, and 24% other anti-psychotic medication. Ninety-five percent of individuals with ID received monotherapy of average duration of 8 years and of an average chlorpromazine equivalent daily dose of 108 mgs (range 16–667 mgs). Metabolic indices were the same or more favourable in individuals with ID compared with the non-ID general population. However, overweight/obesity and type 2 diabetes were more prevalent among women with ID than the non-ID control group. There were no statistical or clinical differences in the metabolic indices between the anti-psychotic-treated versus anti-psychotic naïve individuals with ID. However, there was a non-significant trend towards a higher rate of type 2 diabetes in the group that received anti-psychotic medication.

It is not clear whether individuals with ID are more prone to develop metabolic syndrome compared with the non-ID general population irrespective of anti-psychotic treatment. Among Taiwanese population, Chang and colleagues (2012) [87] reported that metabolic syndrome and obesity are common in adults with ID. de Winter and colleagues (2011) [88] reported that among 412 elderly Dutch population with ID over age 50 years, a weighted prevalence of metabolic syndrome was significantly higher (25.1%) than the non-ID population (15.7%) of the same age, with a significantly higher risk for individuals with mild ID. On the contrary, Hsu and colleagues (2012) [89] reported a lower rate of metabolic syndrome among 164 institutionalised (overall rate of 11.6, with 8% in males and 17.2% in females) individuals with ID compared with the non-ID general Taiwanese population. The authors defined metabolic syndrome on the basis of the presence of three or more of the following; (a) central obesity, (b) elevated blood pressure, (c) elevated fasting glucose level, (d) elevated triglycerides and (e) reduced high-density lipoprotein (National Institute of Health, USA, 2002) [90].

11.1.7 Withdrawal Studies

A recent systematic review showed that withdrawal particularly of anti-psychotic medication is possible in a proportion of people with ID (4–74%) (*see* ▶ Case Study 4) [91]. However, most of the studies included in this systematic review are from the USA that included patients from long-stay institutions [32, 92–94]. We have found that there were two studies in the UK [32, 95] and one recent one from the Netherlands [96] where a concerted structured effort was made to withdraw anti-psychotic medication. In Branford's (1996) [32] study, 25% (31/123) achieved a total withdrawal, and in 42% (52/123) of cases, an attempt to withdraw or reduce dose-precipitated problem behaviour that led to reinstatement of anti-psychotics. In Ahmed and colleagues' study, 33% (12/36) [95] achieved complete withdrawal, and another 19% (7/36) achieved at least a 50% reduction in dose. In de Kuijper and colleagues' (2014) [96] study, 44% (43/98) achieved a complete withdrawal, but in 16% (7/43) of cases anti-psychotics were reinstated at 12 weeks follow-up, so 37% (36/98) remained off anti-psychotics at 12 weeks.

There is another recent open label discontinuation study from the Netherlands [97]. In this study, of 129 participants, 61% had completely discontinued anti-psychotics at 16 weeks, 46% at 28 weeks and 40% at 40 weeks. In 49% of participants, behaviour deteriorated at 16 weeks follow-up leading to re-instatement of medication. In our recent study in Cornwall in England, we have managed to withdraw anti-psychotics totally among 46.5% (33/71) and reduced dosage by at least 50% in another 11.3% (8/71) of adults with ID. At 12 weeks follow-up, no one required hospital admission or change in placement [98].

Case Study 4: Successful Withdrawal of Anti-psychotic Medication

A 19-year-old young man with moderate ID and ASD became aggressive towards his parents who asked for psychotropic medication. He was prescribed risperidone at 0.25 mg daily oral dose which was increased to 0.25 mgs twice daily dose with good effect on the behaviour. However, further assessment revealed this young man's obsession with water and fear of noise. After a few months of behaviour modification, his behaviour improved when his risperidone was gradually withdrawn without any deterioration in behaviour.

11.1.7.1 Withdrawal Symptoms

Some studies showed either no change in behaviour or improvement after withdrawal of anti-psychotics in the majority of cases [91, 94–96] but others showed worsening of behaviour in a higher proportion of cases [32, 99]. A number of studies showed that withdrawal of anti-psychotics (particularly the old generation ones like chlorpromazine, haloperidol, thioridazine) may precipitate extrapyramidal symptoms (mostly demonstrated by increase in DISCUS score), particularly dyskinesia and akathisia [75, 91, 95, 100–102]. These symptoms might be misinterpreted as recurrence of the original problem behaviour [103]. Rebound akathisia might appear within the first few days, whereas rebound parkinsonism usually emerges after a week and rebound dyskinesia might only become apparent within a month [104, 105]. However, most studies show that DISCUS score tends to come back to baseline after a few weeks and months and dyskinesia improves at a follow-up [96, 106]. This is an indicator for the clinicians who are considering withdrawal of anti-psychotics that instead of re-instating anti-psychotics straight away because of the resurgence of PB after withdrawal of anti-psychotics, they should wait (if necessary with the help of as necessary PRN prescription) until the behaviour improves (Deb et al., 2009, WP) [107] (see ▶ Case Study 5 and 6) (see ◘ Fig. 11.1).

However, other possibilities also need to be considered. For example, behaviour may deteriorate for reasons that are not at all related to the withdrawal process, so one should not automatically relate deterioration of behaviour to the dose reduction or withdrawal. Instead a thorough assessment of behaviour should be carried out (see ▶ Chap. 7). Sometimes an underlying psychiatric disorder may be unmasked upon withdrawal of medication or dose reduction, particularly if the medication has been used for a long time. A careful assessment of mental state will be necessary in that case as making a diagnosis of a psychiatric disorder in a person with ID could be difficult (see ▶ Chap. 7). In some cases, previous behaviour may return upon dose reduction or withdrawal. In these circumstances, a full functional assessment of the behaviour will be necessary including the assessment of pre-disposing, precipitating and perpetuating factors (see ▶ Chap. 7).

It is worth keeping in mind the so-called 'placebo' or 'nocebo' effect in this context. For example, some people with ID or their carers may have severe anxieties about the withdrawal process as they are fearful that upon withdrawal of medication, the person's behaviour may deteriorate and they do not want to upset the *status quo*. Because of this effect, some carers may have an exaggerated perception of the severity of the emergent problem behaviour.

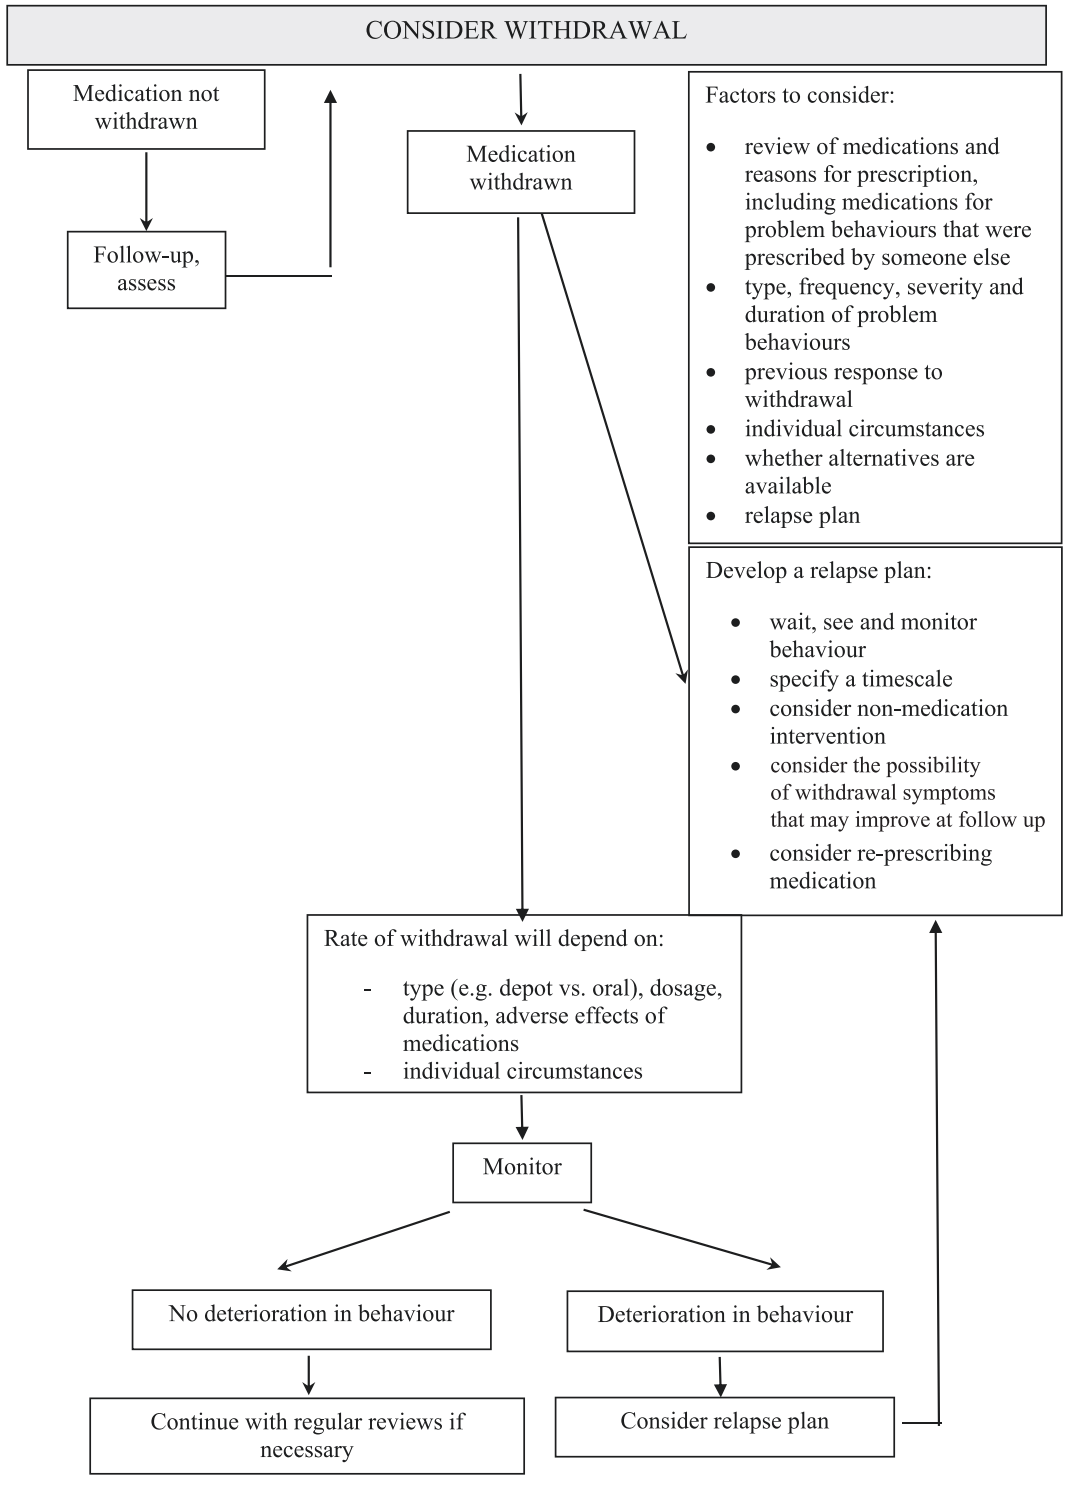

Fig. 11.1 Flow chart for considering withdrawal of medication. (Adapted from Deb et al., 2009; ▶ http://www.ld-medication.bham.ac.uk)

Case Study 5: Unsuccessful Withdrawal of Anti-psychotic Medication

A 68-year-old gentleman with mild ID who developed dementia was treated with risperidone for many years because of history of aggressive behaviour. After 3 months of gradual withdrawal of risperidone, the man became physically aggressive on one occasion in an evening club. The care staff panicked, and local police were called out at night, which led to re-instating of risperidone by an emergency doctor.

Case Study 6: Successful Withdrawal of Anti-psychotic Medication

A 26-year-old man with severe ID who had no speech became disturbed when his risperidone, which he received for many years, was gradually withdrawn. The care staff became very anxious and there was pressure on the clinician through his general practitioner for re-instating risperidone. However, the clinician explained to the care staff that sometimes after years of use, drug withdrawal may produce rebound PB, sometimes caused by withdrawal dyskinesia. The man was treated with PRN (as required) medication over the next 3 months and his behaviour gradually settled without requiring any regular medication.

11.1.7.2 Factors Affecting Withdrawal

A number of factors have shown to affect withdrawal. For example, Branford (1996) [32] found that a lower dose of anti-psychotics, minimal psychopathology, lack of aggression, stereotype and hyperactivity at baseline helped with the successful withdrawal. Ahmed and colleagues (2000) [95] on the other hand highlighted the environmental and organisational factors. For example, they suggested that experienced and full-time staff in regular employment, low staff turnover, staff training, courses for managing problem behaviour, less reliance on environmental restrictions are likely to facilitate the withdrawal process. de Kuijper and colleagues (2018) [97] found that female gender, a lower rate of baseline problem behaviours and lower baseline dosage are in favour, and the presence of severe behaviour and autonomic and extrapyramidal symptoms at baseline are factors against a successful withdrawal. de Kuipjer and colleagues (2018) [97] also found that the presence of co-morbid autism, a higher dose of anti-psychotic drug, higher behaviour rating and akathisia scores, and more-frequent worsening of health during discontinuation were associated with a lower incidence of complete discontinuation. These factors also affect re-instatement rate. For example, Janowsky and colleagues (2006) [99] found within a large population in an American residential institution, 66.3% (55/83) of individuals remained anti-psychotic-free almost 10 years after withdrawal. However, in a subsequent study, Janowsky and colleagues (2008) [100] demonstrated that unfortunately, it becomes difficult to withdraw anti-psychotic medications altogether in a very high proportion of those who showed worsening of behaviour after one or two attempts of withdrawal.

A number of authors have highlighted the influence of staff perception on withdrawal studies (see ► Case Study 7) [101, 102, 106, 108]. Greater restriction and lesser scope of adaptation within the living environment, poor staff training and organisational policies and both clinicians and care staff's lack of confidence in dealing with transient behaviour change upon withdrawal of medication are also some of the important factors [95]. Proper training and support for care staff is thus of paramount importance for a success with an withdrawal programme. Deb and colleagues have recently developed an online staff training programme called SPECTROM (Short term PsychoEducation for carers to Reduce Overmedication of people with intellectual disabilities) to help with the reduction of overmedication of adults with ID [109, 110].

Case Study 7: Carer Attitude Influencing Psychotropic Prescribing

A proprietor of a community group home brought a 32-year-old man with moderate ID, who does not speak, to the psychiatric clinic. The person has been on multiple psychotropic medications for several years including a number of anti-psychotics at a high dose along with a regular dose of procyclidine. Examination revealed that the man had severe tremor and dyskinetic body movements including movements in facial muscles. When the clinician proposed a reduction in the number of psychotropic medications, the proprietor became very anxious, suggesting that the man has a history of very difficult behaviour and he needs all his medication otherwise he would become very aggressive. It was also suggested that the movement disorders were nothing new, therefore, indirectly suggesting that they could not be harmful and may be part of his intellectual disabilities. However, the clinician eventually went ahead with the reduction in the medication and told the proprietor that medicines regulatory bodies will raise concern if medication reduction is not tried and the license for the group home may be at stake.

11.1.7.3 Need for a Structured Pathway

It is clear that in order to succeed with the withdrawal of anti-psychotics, it is imperative to follow a structured pathway, which includes a withdrawal plan presented in ◘ Fig. 11.1 and proper consideration of initiation of medicinal treatment as per the International Guideline (see ◘ Table 11.1) recommendations [107]. Furthermore, the clinicians need to consider complex factors involved in prescribing which will affect the withdrawal process such as variables related to patients, treatment modalities, type and dosage of medication, environment which may not be appropriate for the person, and other resources, including appropriate psychosocial support structure around the person as well as their caregivers. In the process of withdrawal, clinicians also need to consider factors mentioned earlier in the text that may influence successful withdrawal, including carer training and organisational support structure. Apart from our recent paper on anti-psychotic withdrawal [98], no other study so far described a structured pathway for withdrawal.

11.1.8 Outcome Measures

The outcome measure is part of a quality assessment system that also includes structural and process indicators. In addition, the comparative assessment of the efficiency of health interventions is a fundamental strategy to promote quality and equity of care. A myriad of factors influences the outcome and its measures in the treatment of mental health in people with ID. For example, the level of abilities, communication skills, level of support may all affect outcome measurement. Outcome measures may involve an assessment of rate and severity of target symptom/behaviour, adverse events, the burden of care, patients and their family's quality of life, patient-related outcome and process outcome. As the intervention must be person-centred so an assessment of the quality of life (QoL) is of paramount importance. For example, an intervention may improve symptom but producing harmful effect may reduce rather than improve the patient's quality of life. The term effectiveness describes the combined effect of the efficacy of an intervention with its safety/tolerability and adherence to the intervention. The mental health services for people with ID overlap among health care and social care, general and specialised health care, services for children and adults. Therefore, adoption of a holistic, multidimensional, bio-psycho-social approach to health care when it comes to treatment of mental health in people with ID is an ideal option. Among the person-centred outcome measures, the QoL measures are gathering momentum in the individualised planning of the interventions, in the implementation of

Table 11.1 Recommendations for good practice prescribing for PB for people with ID [170]

The prescriber needs to ensure that a thorough assessment using a bio-psycho-social approach has been conducted and recorded prior to initiating treatment	The prescriber should provide the person and/or their family or carers a written treatment plan at the time of prescribing
The prescriber should ensure that an appropriate formulation is carried out and a treatment plan drawn, prior to instigating any intervention	The method and timing of the assessment of treatment outcome should be set at the beginning of the treatment
The prescriber needs to ensure that appropriate physical examinations and investigations have been carried out	As far as possible, there should be an objective way to assess outcomes (the use of standardised scales is recommended)
The prescriber is responsible for assessing the person's capacity to consent to treatment	The prescriber should ensure that follow-up assessments have taken place
The prescriber should discuss the formulation and treatment plan with the person and/ or their family or carers	As far as possible, one medication should be prescribed at a time
The prescriber should allow the person and/or their family or carers to influence the decisions that are made and included in the treatment plan	Start with a low dose and increase the dose gradually until improvement or appearance of the adverse effect
The prescriber should clarify to the person and/or their family or carers if the medication is prescribed outside their licenced indication. If this is the case, they should be told about the type and quality of evidence that is available to demonstrate its effectiveness	As a general rule, the medication should be used within the recommended dose range
Where possible, and when necessary, the prescriber should discuss the formulation and treatment plan with other relevant professionals	Consideration for withdrawing medication and exploring non-medication management options should be on-going
The treatment plan should be part of a broader care plan that takes a person-centred approach	The prescriber should remember that medication might be used at the same time with non-medication management
The treatment plan must comply with the country's legal framework, including the relevant Mental Health and Capacity Act	The prescriber should document all appropriate information and share it with appropriate individuals when necessary
The formulation and treatment plan should be shared with all the relevant parties, including GPs, as soon as possible	The prescriber should discuss with the person and/ or their family, carer or key person common and serious adverse events related to the treatment (where possible, they should provide accessible information in writing)
The prescriber should identify a key person who will ensure that medication is administered appropriately and communicate all changes to the relevant parties	The prescriber should advise what action to take if a serious adverse event takes place
The consultation should take into account the communication needs of the person	When 'as required' medication is prescribed, the prescriber is responsible for providing as much information as possible about why and when the medication may be used and should monitor this regularly

clinical trials and in the organisation of services [40, 108, 111]. A list of commonly used outcome measures for PB in ID is provided in ▶ Chap. 7 on Problem Behaviour.

11.1.9 Ethical Issues

When treating people with ID, informed consent and compliance are two important aspects of both research and clinical practice. These involve issues such as personal freedom, confidentiality, and understanding on their part, particularly in the context of cognitive impairment. Very rarely people with ID are involved in the decision-making process. Similarly, taking consent through deception or misleading information or by use of physical force, of any type of coercion may not only be unethical but may be illegal. Similar ethical concern applies regarding the covert use of medication, particularly concealed in food. Compliance with psychological and behavioural therapies is also often low, especially for the use of concomitant psychotropic medication. One of the main reasons seems to be the prejudice and stigma associated with ID, and as a result, people with ID are either marginalised or patronised. This is reflected in the common practice whereby the professionals and clinicians ignore the person with ID in front of them and speak about them with their caregivers. One key problem is gathering informed consent from a person with a severe cognitive impairment. It is necessary to use accessible information or pictures in order to facilitate communication with many people with ID. Professionals involved in the care of a person with ID should always document the assessment of capacity and ability to provide informed consent to the proposed intervention. In the absence of this capacity, a consensus should be gathered as close as possible between the multidisciplinary team, the legal representative of the person with ID, the family and other significant figures of relationship. The decision should be made in the best interests of the person with ID.

One practical example of this is the use of lithium, which when started is very difficult to withdraw. Lithium also has a narrow therapeutic window leading to toxicity easily for which regular monitoring of blood tests is necessary, which is often not possible in many people with severe/profound ID thus raising an ethical issue. However, in the absence of capacity, it is a difficult decision to implement this intervention, particularly where other alternative medications such as anti-epileptic mood stabilisers are available.

11.2 Pharmacological Classes

11.2.1 Anti-psychotic Medications

11.2.1.1 Old-Generation Anti-psychotics

There are a number of old controlled trials involving old generation anti-psychotics [33, 112]. Some of them have been summarised here. Wardell and colleagues' (1958) [113] 3-month RCT on 41 adults with ID showed a marginally worse response on chlorpromazine (average dose 400–600 mgs/day) when compared with the placebo. Weir and colleagues' (1968) [114] 12 weeks study of randomisation of 45 in-patients with ID into pericyazine vs. chlorpromazine vs. placebo (doses are unknown) did not show any intergroup significant difference in PB outcome. Vaisanen and colleagues (1975) [115] used sulpiride (150–300 mgs/day) vs. chlorpromazine (25–50 mgs/day) vs. placebo in 60 in-patients with ID in a cross-over trial for 4 weeks. Behaviour was changed towards a more positive direction when sulpiride replaced placebo as per the global assessment scale only ($p < 0.05$). Sulpiride was found to be as effective as chlorpromazine ($p < 0.1$). Elie and colleagues' (1980) [116] study of 51 adults with ID showed placebo was superior to thioridazine in improving PB. Aman and colleagues (1989) [117] randomised 20 children and adults in institutions in a cross-over trial to receive either haloperidol high dose (daily 0.05 mg per kg body weight) or low dose (daily 0.025 mg per kg body weight) or placebo for 3 weeks. Haloperidol was found to be marginally better than placebo in high dose. Malt and colleagues (1995) [118] in a cross-over trial among 31 adults with ID showed

that zuclopenthixol (5.5 mgs/day) was better than haloperidol (1.5 mgs/day). Singh and Owino (1992) [119] showed efficacy of zuclopenthixol tablets in a double-blind study of a small number of in-patients with ID and PB.

11.2.1.2 New-Generation Anti-psychotics

Risperidone

There are three RCTs of risperidone among adults with ID [43, 120, 121]. Two of these studies showed that risperidone was significantly better than placebo in improving PB but Tyrer and colleagues' study [43] did not find a significant difference in outcome among groups treated with risperidone, haloperidol and placebo. There are six RCTs among children with ID with or without ASD [77, 122–126]. RUPP study (2002) [125] and Shea and colleagues (2004) [126] primarily included children with ASD, some of whom also had ID, whereas Aman and colleagues (2002) [124] and Snyder and colleagues (2002) [77] primarily included children with ID but excluded those who had ASD. Of these four studies, only the RUPP study (2002) [125] was not sponsored by a pharmaceutical company. McDougle and colleagues (1998) [127] in an RCT showed that some core symptoms of ASD improved significantly in the risperidone group compared with the placebo group. Many of these children also had ID and some showed PB such as aggression as well. All these studies showed a significant improvement in PB in the risperidone group compared with the placebo group.

There was a significant reduction in scores for the risperidone compared with the placebo group on the Clinical Global Impression-Improvement (CGI-I) scale [60], Aberrant Behaviour Checklist (ABC) [128, 129] and Visual Analogue Scale (VAS) to rate the most troublesome target behaviour ($p < 0.05$). A total of 109 (54.5%) participants were rated as 'much improved' or 'very much improved' at endpoint on the CGI-I in the risperidone treated groups ($n = 200$) and 24 (11%) in the placebo groups ($n = 218$). Our meta-analysis showed that the overall Number Needed to Treat (NNT) to achieve a rating of 'much' or 'very much improved' on the CGI over a period of 4–8 weeks of treatment with risperidone versus placebo is 3 with a range between 2 and 5 [47]. However, main concern about using risperidone is its adverse effects such as somnolence and weight gain (not much evidence is available from the RCTs on other adverse effects such as metabolic and cardiac).

Three of the RCTs involving children were continued for many weeks using open label designs [82, 83, 130]. These studies showed that the efficacy of risperidone had been maintained over 52 weeks and medication adverse effects were by and large tolerable. Croonenberghs and colleagues' (2005) [131] open-label one-year follow-up study of 504 risperidone-treated children with ID reported long-term efficacy and tolerability. Seventy-three percent of the children completed the study with a mean dose of 1.6 mgs/ day risperidone. The most common adverse events were somnolence (30%), rhinitis (27%), headache (22%) and weight increase (17.3%). Overall 91.7% had shown some adverse events. The incidence of movement disorders was low, and no clinically significant changes in mean laboratory values were noted, except for a transient increase in serum prolactin levels. Improvement in behaviour which was first observed within the first week of treatment initiation was maintained at the follow-up and significant improvements were also noted in positive social behaviour.

Aripiprazole

Deb and colleagues' (2014) [51] systematic review on the efficacy of aripiprazole in the management of PB among individuals with ID and with or without ASD reported two RCTs that included 75 and 218 children, respectively (age 6–17 years), with ASD and with and without ID in a parallel design RCT over 8 weeks period [132, 133]. Both these studies have been carried out by the pharmaceutical company that produces aripiprazole, and it is not clear whether there is any overlap among the participants in these two studies. In both studies, the diagnosis of ASD was confirmed by the Autism Interview-Revised (ADI-R) [134] assessment and both studies included children with the ABC-I score [129] of >=18 and CGI-S >=4 [60]. Both studies excluded children with a diagnosis of Fragile

X syndrome and any other major psychiatric disorder such as schizophrenia, depression and bipolar disorder. The first RCT gave flexible doses of aripiprazole with the average daily dose being 10 mgs [132]. There was a significant improvement in the ABC-I score (score change at follow-up: −12.9 in the risperidone group vs. -5 in the placebo group) and a significant mean improvement in CGI-I score (2.2 or much improved in the risperidone vs. 3.6 or no change in the placebo group). The second study used fixed doses of aripiprazole [133]. According to the ABC-I score, the aripiprazole groups showed significant improvement compared with the placebo group (score change at follow-up: −12.4 for 5 mg, −13.2 for 10 mg, −14.4 for 15 mg aripiprazole, respectively, compared with −8.4 for the placebo group). CGI-I showed statistically significant improvement for all the aripiprazole groups compared with the placebo group. Most studies reported adverse effects from aripiprazole in the form of weight gain, increased appetite, sedation, tiredness, drooling and tremor. However, aripiprazole improved serum prolactin level in some participants and overall did not show any adverse effect on QTc interval. There was an open label extension of one study [135] following the RCT that included 330 children, which showed that the improvement shown in the aripiprazole group during the RCT lasted for 52 weeks and the adverse effects were tolerable [136]. Deb and colleagues (2014) [51] have also found another 17 studies of either prospective or retrospective case reports that reported improvement in most people with ID treated with aripiprazole. However, there is a need for more carefully designed RCTs into the use of aripiprazole in the management of PB in individuals with ID and/or ASD conducted independent of pharmaceutical companies.

Other Newer Anti-psychotic Medications

Singh and colleagues (2010) [137] reviewed studies on clozapine for the management of PB in individuals with ID. They included 13 small studies, of which only three seem to be controlled studies with a very small number of participants of one, two and three, respectively. However, Boachie and McGinnity's (1997) [138] study was not included in this review, who examined case notes and medication charts of 17 individuals with ID who received clozapine 200–900 mgs/day with an average range of treatment for 32.1 months. According to Singh and colleagues' (2010) [137] review, the dose range of clozapine in different studies varied from 10 to 900/day, the average being 300–400 mgs. Most studies are retrospective case notes review that included a small number of participants. All studies reported improvement according to subjective measures such as CGI and about one third of those who used rating scales have shown improvement according to a rating scale although most studies did not use any rating scale. Adverse events reported included extrapyramidal symptoms, vomiting, drowsiness, weight gain, hypersalivation, tachycardia, hypotension as well as hypertension, urinary incontinence, leukopenia (reported in one study) and seizures (reported in one study that used 10–300 mgs daily dose).

Janowsky and colleagues (2003) [139] reported a retrospective study on 18- to 55-year-old individuals with ID (45% were male), the majority of whom had severe to profound ID. Olanzapine 2.5–22.5 mgs/day (mean dose 9.1 mgs/day) was used as an add-on for up to 6 months. Aggression reduced in 93% ($p < 0.01$) and SIB in 86% ($p < 0.044$) of 14 participants. Adverse effects were sedation (20%), constipation (10%), gait problem (5%) and weight gain. No increase in serum glucose levels was seen. McDonough and colleagues (2000) [140] reported that olanzapine reduced the stereotyped form of chronic SIB in four of seven individuals with ID. Williams and colleagues (2000) [141] treated 12 adults with mild to moderate ID who had a variety of reasons for giving olanzapine, including psychosis, PB, adverse effects of other medications and inadequate treatment responses. The authors found that 58.3% of the participants 'greatly improved', a proportion essentially same as for those who improved on risperidone treatment.

La Malfa and colleagues (2003) [142] in a prospective case series on the use of quetiapine 300–1200 mgs/day for 6 months on 15

individuals with ID (age 25 to 47 years; 66.7% male) reported significant improvement, particularly among those who had mild to moderate ID.

Cohen and colleagues (2003) [143] have reported adverse effects from ziprasidone (145 mgs/day) among 40 individuals with ID who received other anti-psychotic treatment previously. There was a reduction in behaviour frequency after ziprasidone treatment among 19 individuals who showed mild to moderate frequency of PB, whereas six individuals who showed a high frequency of PB did not show much change after ziprasidone treatment. However, ziprasidone treatment was associated with a significant weight loss of 3.6 kg as well as significant reduction in total cholesterol and triglycerides ($P <= 0.5$). This drug is withdrawn from the UK market for its serious cardiac adverse effects.

There is only one small retrospective chart study of asenapine on PB in people with ID who had psychiatric disorders [144].

11.2.2 Anti-depressants

The evidence on the use of anti-depressants for the management of PB in adults with ID is scant. One RCT on clomipramine showed beneficial effects but the cohort size was very small (n = 10) [145]. However, the response to the SSRIs has been varied whereby some studies reported clear favourable results [146–150], some showed negative effects [150–152], and other studies demonstrated both positive and negative outcomes [153, 154]. King and colleagues (2009) [155] did not find any significant difference in efficacy between citalopram and placebo in a large sample of children with ASD and a high level of repetitive behaviour. This discrepancy in findings, therefore, makes it difficult to draw any definite conclusion regarding the effectiveness of anti-depressants in this context [156].

Improvements were largely reported in SIB and perseverative/compulsive behaviours. It may, therefore, be the case that medications were in effect treating underlying behaviours that are part of the obsessive-compulsive disorder (OCD) spectrum for which SSRIs are indicated anyway. Not surprisingly the anti-depressants were most effective in the management of PB when depression or anxiety was present in the background. In a number of cases, deterioration in behaviour is reported, which may have been caused by the adverse effects of some of the anti-depressants. In general, the majority of the evidence based on open label trials and case series studies is fraught with methodological concerns. The small sample sizes meant that the studies were statistically underpowered and often control groups were not recruited. There was a dearth of validated outcome measures utilised, and where more than one assessor conducted the outcome measurements, inter-rater reliability was not contemplated.

The efficacy of anti-depressants certainly deserves more attention in research, as there is evidence to suggest that these medications are used commonly in the management of PB in individuals with ID [19]. This review does not suggest that they are ineffective but that there is not enough good quality evidence for their efficacy at present.

11.2.3 Mood Stabilisers (Lithium and Anti-epileptic Medications)

Deb and colleagues' (2008) [46] systematic review revealed three small primarily cross-over RCTs of lithium of which only two were published in a peer-reviewed journal [157, 158] and the other one was published as a book chapter [159]. As the participants in these studies were all in-patients, it is difficult to generalise these findings for individuals with ID who live in community settings. Although all these studies showed that a proportion of participants treated with lithium improved, it was not clear whether this improvement was significant compared with the placebo group and also the outcome measures used were not validated and standardised. Also, some studies showed the effectiveness of lithium on PBs but not on others. Therefore, it is difficult to draw any definitive conclusion on the efficacy of lithium for the treatment of PB in people

with ID. There are other concerns regarding the use of lithium such as the need to carry out regular blood tests, which may not be possible for a number of people with ID, narrow therapeutic range between effective and toxic serum level, lithium toxicity and a high chance of relapse if lithium is withdrawn. There is little evidence of the use of lithium by the UK psychiatrists for the ID population [3, 19, 23].

Among other mood stabilisers such as antiepileptics, only a small RCT involving 10 clients is available on the use of carbamazepine [160] and the rest of the studies are case series. There are a small number of small RCTs and non-controlled studies [161, 162] of sodium valproate primarily on children and adolescents with ASD, some of whom also had ID showing some effect on behaviour but nothing is conclusive at the moment [163]. Although there has been anecdotal evidence suggesting that lamotrigine may make behaviour worse in people with ID, a small RCT did not show any change in PB in participants with ASD who were treated with lamotrigine [164] (see also a recent systematic review and meta-analysis by Hirota and colleagues, and Limbu and colleagues [165, 166]). Similarly anecdotal concern about levetiracetam making behaviour worse in people with ID was not always supported [167]. There are no RCTs to support the use of topiramate in people with ID/ASD and PB [168, 169]. Although there is no RCT-based evidence in support of mood stabilisers, that does not mean that these medications are ineffective. As mood stabilisers such as carbamazepine and sodium valproate are used regularly to treat PB in people with ID [23, 53], there is an urgent need to carry out properly designed RCTs involving these drugs notwithstanding the practical difficulties of carrying out RCTs in this population [34, 35].

11.2.4 Opioid Antagonists

The opioid antagonist drug naltrexone has been used to treat PB in children with ASD with or without ID. A systematic review by Roy and colleagues (2014) [49] has found 10 studies that used an RCT design. Two studies used a parallel design ($n = 59$) and the rest of the studies used a cross-over design. The number of children included in these studies ranged from 4 to 20. Less than half of the studies showed a statistically significant improvement in irritability and hyperactivity in the naltrexone group compared with the placebo group, but none has shown any significant effect on the core symptoms of ASD. Most studies either did not observe any adverse effects or report any. Adverse effects included sedation, loss of appetite, vomiting and stereotyped behaviour and in some cases paradoxical increase in aggression.

Roy and colleagues (2014) [50] in another systematic review included 10 cross-over trials of naltrexone for the treatment of primarily SIB in adults with ASD with or without ID. The number of participants included ranged from 4 to 24 and the study period ranged from 4 to 17 weeks. Only two studies found a significant improvement in the naltrexone group compared with the placebo. The dose of naltrexone varied from 50 mgs to 150 mgs per day or 0.5 mg to 2 mgs per kg body weight. Eleven (9%) out of overall 124 participants included in these 10 studies reported minor adverse effects. Adverse effects included weight loss, loss of appetite, mild liver function abnormalities, sleep problems, etc.

There are only a handful of RCTs on naltrexone that included a small number of participants over a relatively short period of follow-up using different doses and crossover design, which has its drawbacks. The findings are equivocal in that some showed a beneficial effect from naltrexone and the others did not. One study showed differential effect depending on the dose, particularly the higher dose being effective and lower dose being non-effective. Therefore, it is difficult to draw any definitive conclusion about the efficacy of naltrexone in the treatment of SIB and other PB among adults with ASD and/or ID.

11.2.5 Anti-anxiety Medications

Findings from a small number ($n = 3$) of small scale uncontrolled studies of buspirone for treatment of PB in adults with ID are mixed [163]. King and Davanzo's (1996) [170] pro-

spective uncontrolled study of 26 adults with ID (age 25–63 years; 46% male) on the effect of buspirone 25–60 mgs/day (average 52 mgs/day) on aggression and/or SIB in people with ID did not show any improvement from buspirone. A recent systematic review and meta-analysis has found two RCTs on buspirone showing some equivocal results on the ASD symptoms of children [156]. There is little evidence currently to recommend any anti-anxiety medication for the long-term management of PB including aggression in people with ID. The benzodiazepine group of medications carries the risk of tolerance and dependence in the long run. In some cases, benzodiazepines may paradoxically increase aggression. The evidence for the effectiveness of buspirone is currently poor, therefore, cannot be recommended. However, for the general population, some SSRIs, selective noradrenaline reuptake inhibitors (SNRIs), an anti-epileptic medication pregabalin and an anti-psychotic quetiapine are now recommended treatment for anxiety-related disorders [171]. In the field of ID, some anti-psychotics are prescribed in a smaller than anti-psychotic dose to manage PB with the assumption that at a lower dose anti-psychotics may work as anti-anxiety medications, although the evidence to support this assumption currently is not available from the literature.

11.2.6 Beta-Blockers

Ward and colleagues (2013) [48] have published a systematic review on the use of beta-blocker medications such as propranolol, nadolol, acebutolol, metoprolol and oxprenolol for the treatment of PB in individuals with ID. They found 14 studies (nine prospective studies and five retrospective chart reviews) primarily on propranolol, dose ranging up to 340 mgs a day, which included between one and 19 participants. The target symptoms included aggression, SIB, irritability, hyperactivity, impulsive behaviour, etc., and in one case anxiety, and in another case somnolence. Target behaviour improved in a number of cases, in some cases the improvement was moderate, and in some cases, there was no improvement, and in a minority of cases, behaviour deteriorated. Not all studies mentioned the proportion of patients reporting adverse effects. Common adverse effects included bradycardia, hypotension, vomiting, sedation as well as insomnia. No study reported any severe adverse effects. However, as none of these studies are RCTs, it is difficult to draw any definitive conclusion on the efficacy of beta-blocker medications in the treatment of PB among people with ID.

11.2.7 Psychostimulants

Psychostimulants' effects on people with ID and ADHD are not well established. Among the psychostimulants, methylphenidate (MPH) is most widely used. A recent systematic review [172] of all the RCTs involving people with ID that assessed effectiveness of MPH on the core ADHD symptoms did not find any RCT on adults with ID. Fifteen papers from 13 studies on children and adolescents with ID were included (315 participants were on MPH and the same number on placebo), 12 of which used a cross over design, and one used a parallel design. On average around 40–50% responded to MPH in the ID group, whereas around 70–80% response rate is reported among the non-ID children. It also seems that overall the effect size of MPH's effectiveness in ID children (average around 0.5) is lower than that in the non-ID children (average around 0.8–1.3). Significant adverse effects included sleep difficulties and poor appetite along with weight loss. Other important adverse effects included irritability, social withdrawal and increased motor activities including tic. The type and rate of adverse effects among ID children seem similar to those in the non-ID children (average around 12–24%). Similarly, the placebo effect seen among ID children seems to be similar to that in the non-ID children (average around 12.5%).

Among the non-ID children, studies have shown MPH's efficacy on overt and covert aggression when associated with ADHD [173]. In Aman and colleagues' pooled data from their three previous studies (n = 90), they reported a significant improvement in the MPH group compared with the placebo group

in (a) Teacher's ABC-Irritability subscale score and (b) Parent's Revised Behaviour Problem Checklist (RBPC) conduct problem subscale rating [174]. However, some other small scale studies did not find any significant difference in problem behaviour between ADHD and non-ADHD children with ID. In practice it is not always easy to tease apart symptom of aggression or other similar problem behaviour in people with ADHD particularly in the presence of ID because of symptom overlap among these conditions [17].

11.2.8 Vitamins and Others

The only study available on the effectiveness of diet (zinc supplement) on the management of PB (pica) did not include a proper placebo control group [175]. Therefore, it is difficult to draw any conclusion from this study on the effectiveness of the diet. Apart from zinc, the other vitamins and supplements that showed some effects in various psychiatric disorders but not specifically in ID are folic acid, S-adenosyl-methionine (SAMe), omega-3 fatty acids, L-tryptophan, methylfolate and Vitamin C and D [176, 177]. Several endocrinal agents such as oxytocin, growth hormone and thyroxin have been used in small scale controlled and uncontrolled studies showing equivocal results on cognition and behaviour in people with ID, particularly with Fragile X syndrome and Prader Willi syndrome [169]. Glutamatergic and γ-aminobutyric acidergic (GABAergic) agents have been investigated in people with ID associated with genetic syndromes with disappointing results [169]. Acetylcholinesterase inhibitors such as donepezil and also other cholinergic agents such as L-carnitine/L-acetylcarnitine returned equivocal results in people with Down's syndrome [169]. Clonidine, a centrally acting α2 adrenergic agonist, has been used in the context of ASD and ADHD showing some early moderate effects [169]. Melatonin has been shown to be effective in regulating sleep disturbance, particularly in the context of ASD [178]. Regularising sleep pattern seems to help to improve behaviour in people with ASD/ID [164]. Other melatonergic agents such as agomelatine are at their very early stage of exploration in people with ASD/ID [164].

11.3 Conclusion

On the basis of the evidence available, it is difficult to either recommend or refute the use of psychotropic medications for the management of PB in people with ID. Furthermore, there is no evidence to show the effectiveness of particular psychotropic medication for a particular type of PB. However, there is now moderate quality RCT-based evidence available on the efficacy of risperidone and some preliminary evidence for the efficacy of aripiprazole particularly for children with ASD but also with ID. In the absence of gold standard evidence, guidelines have been developed in order to provide advice to clinicians when using psychotropic medications for the management of PB in individuals with ID [108, 179–183]. These guides advise that a thorough assessment of the causes and effects of the PB including organic/medical, psychiatric, psychological and social factors should be carried out before a medication is prescribed (see also ▶ Chap. 7 on Problem Behaviour) (see ▶ Case Study 8 and 9). See ◘ Table 11.1 and ◘ Fig. 11.2 for main recommendations.

Case Study 8: The Role of Medical Problem in Causing Problem Behaviour

A 65-year-old lady with severe ID suffered from a stroke that led to paralysis of the right side of her body. She started screaming and shouting regularly and the care staff asked for psychotropic medication to manage her behaviour. However, close examination revealed that the lady developed spasticity in her right hand and she was constantly getting frustrated by not being able to stretch fingers of her right hand, which led to screaming. Instead of psychotropic medication, baclofen was prescribed as a muscle relaxant and the lady's behaviour improved.

Case Study 9: A Medical Symptom Leading to Problem Behaviour

A 75-year-old gentleman with moderate ID and limited communication skills developed symptoms of dementia. He started screaming and head banging. His sister who is his primary carer asked for psychotropic medication but the clinician prescribed paracetamol on a regular dose assuming that the behaviour may have been precipitated by headaches. This has produced a good result and the gentleman stopped screaming and head banging.

Non-medication-based intervention should always be considered first (see ▶ Case Study 10). However, medication may sometimes be used to facilitate non-medication-based intervention. Individuals with ID and their caregivers as well as the multidisciplinary team should be fully involved in the decision-making process from the outset (see ▶ Case Study 11) [184]. There are accessible versions of information leaflets (with audio versions) on psychotropic medications freely available for downloading from the web (▶ www.ld-medication.bham.ac.uk; https://spectrom.wixsite.com/project) [185]. These should be handed over to patients and their carers where appropriate.

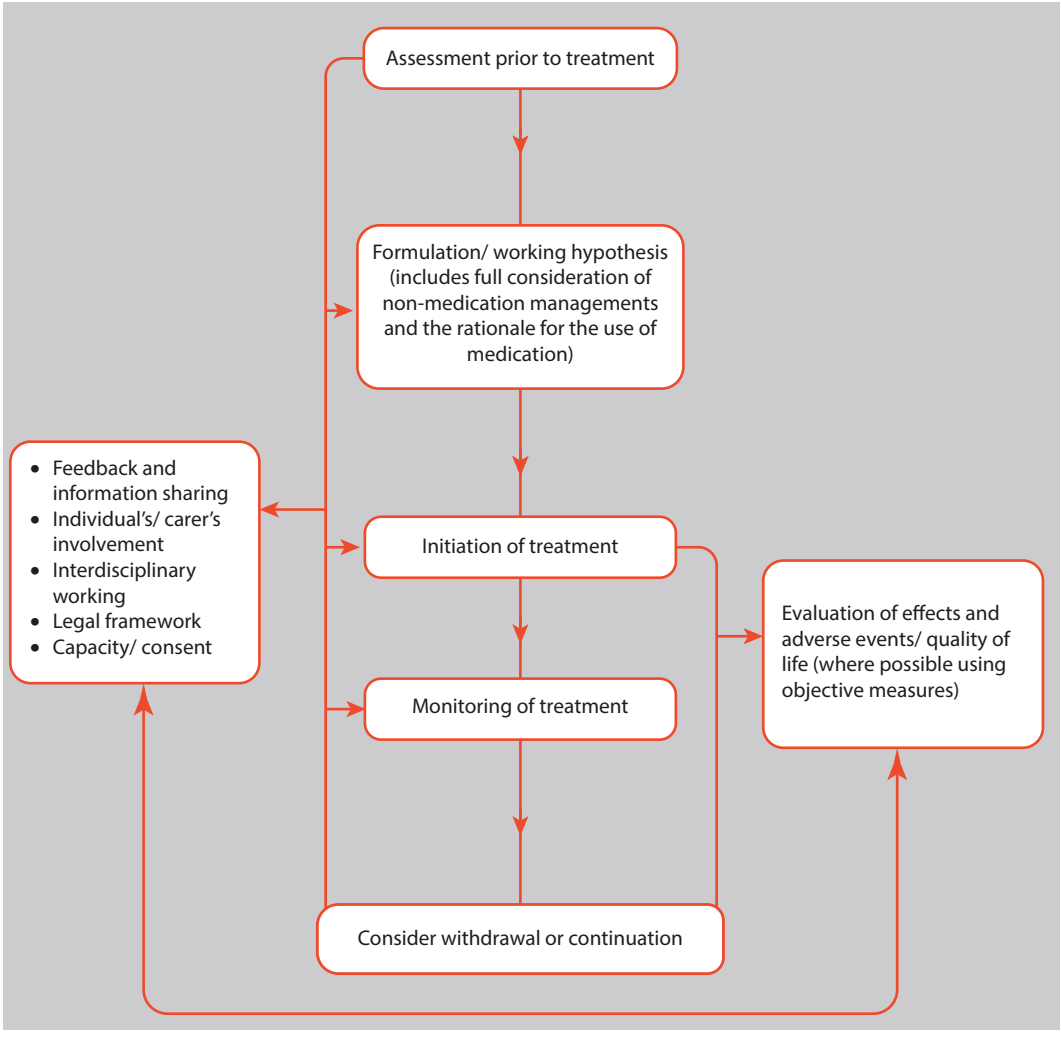

Fig. 11.2 Key processes associated with using medication to manage PB in adults with ID [107]

Case Study 10: The Role of Non-medication Intervention in Problem Behaviour Management

Care staff in a community group home wanted psychotropic medication for a 27-year-old man with severe ID and no speech because of his PB. Further assessment revealed that the person becomes agitated when he is not allowed to go out for a car ride which he enjoys. A Speech and Language Therapy assessment revealed that when the care staff was telling the person, 'you can't go out in a car' and the moment the person heard the word 'car', he thought he was going out and became very frustrated and disturbed as he was not allowed to go out. The Speech Therapist devised a picture board with 'a picture of a car crossed out', which the care staff showed when the person was not allowed to go out and kept him engaged with alternative activities within the house that he enjoys. This strategy was successful, and his behaviour improved without the need of any psychotropic medication.

Case Study 11: The Benefit of Multi-disciplinary Involvement in the Management Programme

Care staff asked for psychotropic medication to control PB in a 36-year-old lady with moderate ID who has no speech. Further assessment by a Speech Therapist revealed that the care staff usually ask the lady what she wants for her dinner and give her two or three choices. She always opts for the last option but when the food is served, she refuses to eat them and becomes disturbed. Speech Therapist suggested that instead of giving her choice verbally, the care staff should show pictures of different meals and will also involve her in the preparation of her meals. This strategy was successful, and her behaviour improved without any psychotropic medication.

Both the impact of the intervention on the behaviour and the adverse events should be assessed as objectively as possible if necessary, using validated instruments (see ► Chap. 7 on Problem behaviour for a list of assessment tools). At each follow-up, the original formulation should be reassessed, and non-medication-based interventions should be considered along with the possibility of withdrawing medication. It is important to recognise the difficulty of monitoring treatment because of difficulty in carrying out necessary investigations (see ► Case Study 12). It is worth keeping in mind that it is possible to successfully withdraw anti-psychotic medications after long-term use in a high proportion of individuals with ID. If medication is withdrawn, a relapse plan should be in place and the possibility of withdrawal symptoms in the form of PB should be considered before taking a decision to reinstate any psychotropic medication. The ultimate aim of the management should be symptom reduction as well as to improve the quality of life of the individual with ID and their caregivers.

Case Study 12: Difficulty in Monitoring Treatment Effect and Carry Out Necessary Investigations

A 33-year-old man with moderate ID and no speech showed PB periodically and the carers raised the issue whether this is part of a bipolar disorder. However, the clinician was not certain as there were no other symptoms to support the diagnosis of bipolar disorder apart from the periodic nature of the behaviour. A small dose of risperidone was used with good effect. The clinician was reluctant to use lithium as another patient in the same clinic developed PB 6 months after withdrawal of lithium after a long-time use. Monitoring of lithium level and other investigations were difficult to carry out in these cases.

Whether medication should be continued will depend on the relationship between efficacy and the undesirable effects, keeping also in mind the potential for contraindications and compliance. Use any medication that was successful in the past and caused no or least harm. Monitor undesirable effects of intervention and interaction with other medication and substances regularly. Discontinue therapy or at least reduce the dose if it does not produce beneficial effects or produces unacceptable adverse effects.

Family history may provide clues to the current problem in the person with ID. The treatment has to be cost-effective. When using more than one medication, evaluate and modify one at a time, assessing the contribution of each individual medication to the observed benefits or adverse effects. Communicate with the person with ID clearly if necessary, using accessible information and other methods such as the use of pictures [185, 186]. It is always prudent to check at the outset patient's and family's expectations from the treatment. For example, some patients may prefer oral over intramuscular therapy or liquid form, perhaps dissolved in their preferred drink. Others may like tablets, perhaps of a certain colour. Assess and document patient's capacity to give an informed consent. If the person cannot consent, then consider involving the legal representative and the family. Any decision taken has to be in the patient's best interests. Re-evaluate the dosage frequently, with the intent of using the lowest possible dose for the shortest possible time, but also for as long as necessary. Adherence to treatment must also be monitored carefully. There are many factors that can influence compliance, such as the expectations of the person with ID and their families and carers or the dynamics involving family members. It is important to communicate with a stable and reliable informant. If no significant beneficial effects have been observed after a period of three to four months after reaching the optimum desirable dose, treatment should be discontinued. Intervention should be an integral part of a person-centred program of care.

Acknowledgement This chapter has been adapted from the following chapter.

Deb S. (2016) Psychopharmacology. In: N. N. Singh (Ed.), 'Handbook of Evidence-Based Practices in Intellectual and Developmental Disabilities, Evidence-Based Practices in Behavioral Health.' Springer International Publishing, Switzerland, Cham. pp. 347–381.

Key Points

- Off-licence psychotropic medications are used commonly to manage problem behaviour in people with intellectual disabilities.
- Evidence to support pharmacological intervention for problem behaviour is equivocal.
- Non-pharmacological interventions should always be considered first for the management of problem behaviour in people with intellectual disabilities.
- The person with intellectual disabilities and their family carers where available should be involved from the outside in the decision of using pharmacological and other interventions along with the multi-disciplinary team.

Learning Objectives

The reader of this chapter will learn which interventions are available for addressing mental health and/or challenging behavior in individuals with intellectual disabilities. S/he will also learn what the evidence-base is of these interventions. Important is that interventions are directed not only toward the client but also toward caregivers. The reader will learn ways of how to adapt interventions to the learning style and characteristics of these individuals.

12.1 Introduction

A range of nonpharmacological interventions have shown promising results in the treatment of behavioral and/or mental health problems in individuals with intellectual disability (ID). This chapter presents a selective overview of interventions that are often applied in clinical practice and that have been documented in the scientific literature. Two main categories of interventions are distinguished: client-oriented and contextual approaches. In client-oriented approaches, the focus of the intervention is the client who is the main recipient of the intervention. We will describe the assumptions, common components, and evidence-base of behavioral interventions, cognitive behavior therapy, and interventions such as mindfulness and relaxation. In contextual approaches, the intervention is primarily directed at persons in the environment of the client such as parents, staff members, and others. The assumption is that a client's well-being will improve and behavioral/mental health problems will be reduced through a change in behavior and attitude of carers and other in the client's environment. Case examples will illustrate the interventions.

12.2 Client-Oriented Approaches

12.2.1 Behavioral Interventions

Behavioral interventions – now referred to as the first wave of behavioral therapies – have been widely used in the treatment of individuals with developmental disabilities. For this population, behavioral interventions have been successfully used to treat a variety of commonly reported excesses and deficits, including (a) aggression, (b) disruption, (c) elopement, (d) feeding disorders, (e) inappropriate sexual behavior, (f) pica, (g) property destruction, (h) rumination and operant vomiting, (i) self-injury, (j) sleeping disorders, (k) stereotyped mannerisms, (l) tantrums, (m) academic failure, and (n) adaptive skill deficits [1–4].

Behavioral intervention has also been successfully used to treat anxiety and mood disorders [2, 4]. Overall, behavioral intervention has a long and continuing history of success in the education, rehabilitation, and treatment of individuals with developmental disabilities. For this purpose, the behavioral approach can be considered a well-established, evidence-based therapeutic model [2, 4].

Behavioral interventions are derived from basic principles of operant conditioning [5]. A considerable amount of research has accumulated since the 1960s showing effective application of behavioral/operant principles for the treatment of individuals with developmental disabilities [2–4].

Key operant principles are listed, defined, and illustrated with examples in Table 12.1.

An important assumption associated with the behavioral treatment model is that human behavior is largely learned and sensitive to environmental contingencies [5]. Another underlying assumption is that the consequences of behavior can have powerful and predictable effects on the topography, frequency, intensity, and patterns of responding [6]. The topography, frequency, intensity, and/or patterns of responding are also assumed to be highly modifiable, provided that the environment, especially the consequences of behavior, can be modified.

In line with these assumptions, contemporary behavioral interventions include an initial assessment phase to identify the operant function(s) of the presenting problem behavior; a procedure that is called functional analysis. This assessment information is then used to design an appropriate course of treatment [7]. Identifying the operant function

Table 12.1 Key operant conditioning principles underlying behavioral interventions

Basic principle	Definition	Example
Positive reinforcement	This term refers to a relation between a response and a consequence in which the future probability of the response increases when it produces or is followed by a specific type of consequence. When a response is followed by a specific consequence and thus becomes more likely to occur in similar conditions, then that consequence can be defined as a positive reinforcer.	Bouts of self-injury by an adult with severe intellectual disability are frequently followed by a caregiver coming over and attending to the person. This attention serves as positive reinforcement and therefore the self-injury is maintained.
Negative reinforcement	This term refers to a relation between a response and a consequence in which the future probability of the response increases when it results in the removal or termination of a specific type of stimulus. When a response results in the removal or termination of a specific stimulus and this becomes more likely to occur in the future, the presence of that stimulus, then the removal or termination of that stimulus can be defined as a negative reinforcer. The stimulus can also be defined as aversive.	An adolescent with autism tantrums and hides under his desk when the teacher tries to engage him in an instructional activity. As a result of this tantrum, the teacher concludes that the student 'needs some alone time.' The teacher therefore removes the task demands and leaves the student alone. The removal of the task demands serves as negative reinforcement for the tantrum behavior.
Punishment	This term refers to a relation between a response and a consequence in which the future probability of the response decreases when it produces or is followed by a specific type of consequence. When a response is followed by a specific consequence and thus becomes less likely to occur in similar conditions, then that consequence can be defined as a punisher.	A child's frequent swearing in the classroom is reinforced by peers laughing and so the teacher decides to punish each instance of swearing by using a 2-min time-out contingent upon each instance of swearing. With this time-out procedure, the frequency of swearing decreases, indicating that the time-out period served as a punishing consequence for swearing.
Extinction	The gradual decrease in the frequency of a response when that response no longer results in reinforcement.	Tantrums that occur at bedtime might be extinguished by making sure that the child is not allowed to stay up later by having a tantrum.
Antecedent control	A stimulus that when present in the environment will either increase (discriminative stimulus) or decrease (inhibiting stimulus) the probability of responding.	A child tantrums when presented with foods that are mixed together on the plate, but does not tantrum when these same foods are arranged in separate piles.
Shaping	The gradual development of new forms of behavior by reinforcing closer and closer approximations of the final desired form.	A child might be taught to request a preferred object, rather than having a tantrum to gain that object by first making any speech-like vocalization (e.g., *ahh*). Over time, the child would be required to produce closer and closer approximations of the correct object label (e.g., *ba*, *ball*).
Chaining	The processes of developing complex skills by linking separate individual responses into an integrated sequence.	A child might be taught to speak in more complete sentences by first teaching and reinforcing single word utterances (e.g., *Ball*), then teaching 2-word utterances (*Want ball.*), and then 3–4 word utterances (*I want the ball.*).

(continued)

Table 12.1 (continued)

Basic principle	Definition	Example
Prompting	Providing an additional cue (e.g., a verbal instruction, gesture, or physical assistance) to increase the probability that a response will occur in the presence of the discriminative stimulus and thus can be reinforced.	During a receptive vocabulary task, if the child does not select the correct picture when instructed (e.g., *Point to the picture of the truck*.), then the teacher could prompt the correct response by pointing to the correct picture or by physically moving the child's finger to the correct picture.
Modeling	A special type of prompt in which the required responses are demonstrated or modeled by another person.	A job coach shows the individual how to operate the photocopier and then gives the person the opportunity to imitate.
Fading	The process of gradually removing prompts so as to promote independent responding.	If a child correctly names pictures only when given a model (*This is a cat, Say cat*), the prompt is faded by giving less and less of the model over successive opportunities (i.e., *Say caa*; *Say ca*; *Say …*).

Table 12.2 Examples of three-term contingencies and operant functions

Antecedent	Response	Maintaining consequence	Operant function or purpose
When an adult is present, but not attending to the child	The child begins to cry and quickly escalates to a full-blown tantrum.	The adult attends to the child in an attempt to calm the child and stop the tantrum.	Social positive reinforcement: Recruit attention
When asked to make his bed	An adult with autism hits the staff person and spits on the bedsheets.	The staff person removes the adult from the room and makes the bed.	Social negative reinforcement: Escape task demands
When greeted by a peer …	The student responds by attempting to bite the peer.	The peer moves away and is less likely to greet the student in the future.	Social negative reinforcement: Avoid social interaction
During playtime …	A child throws objects (e.g., sand, rocks) at peers who play with the child's preferred toys.	Peers are required to give the toy to the child.	Social positive reinforcement: Access preferred objects or activities
On the playground at school …	A child with autism pulls out some weeds and waves these back and forth.	The movement provides visual and vestibular stimulation.	Automatic reinforcement: Gain reinforcing sensory stimulation.

of problem behavior involves an analysis of the environment to isolate the variables that evoke and maintain that behavior. Behavior can be analyzed in terms of the three-term contingency [5, 8]; that is, in terms of the: (a) antecedents that set the occasion for or evoke the behavior, (b) the problematic response forms, and (c) the nature and scheduling of the consequence(s) that are reinforcing problem behavior. Examples of scenarios related to various contingencies are presented in Table 12.2.

The behavioral principles outlined in Tables 12.1 and 12.2 have been applied in numerous flexible ways to the treatment of problem behavior in individuals with developmental disabilities. Three case studies are provided here to illustrate a range of behavioral interventions. These are real cases from our own research or clinical experiences, but some details have been changed to protect confidentiality.

Case Study 1: Treatment of Aggression in an Adult Man with Severe Intellectual Disability by Pairing Staff Presence with Reinforcement and Using a Shaping Procedure

Dean was a 26-year-old man with severe ID living in a community-based group home. He attended a sheltered workshop during the day. When he returned home from the sheltered workshop each weekday, he would typically sit in his favorite chair and attempt to kick or aggressively grab anyone who came near him. Observations over three afternoons suggested that Dean was highly likely to aggress whenever staff approached him, which they often did to request that he engage in some activity, such as asking him to help set the table, come to dinner, or wash his hands. Based on these observations, it was hypothesized that Dean had learned to engage in aggression to escape from these types of staff requests. It was further hypothesized that the approach of a staff person had become a conditioned aversive stimulus that now reliably evoked aggression. To turn this around, the first step was to attempt to establish the approach of staff persons as a signal or cue for positive reinforcement. This was attempted by having staff slowly approach Dean while offering him a preferred snack or beverage. Approximately 10 times each afternoon, while Dean was seated in his favorite chair, a staff person would slowly approach him while holding out a drink or snack that Dean was known to prefer. Staff did not make any demands of Dean at these times. He only had to take the object from the staff person's outstretched hand. With this procedure in place, Dean began to tolerate staff approaching him without attempting to kick or grab them. The next step was to shape up increasingly levels of tolerance by having staff approach more closely to Dean, then approach and actually touch him briefly on the arm or shoulder. Once he was tolerating this, staff then began to approach him and make a simple request (e.g., "Hey Dean, give me a high-five"). When he was tolerating this, staff increased the complexity of the demands, such as by requiring Dean to help set the table. Within a month, aggression had decreased and compliance to staff requests had increased. To maintain these gains, it was agreed that Dean would be allowed to "cool down" for 30 min when he first returned home from the workshop. After this, staff would implement at least three conditioning trials in which they would approach with a preferred snack or beverage and deliver this freely. After this, the general plan was to then approach and present reasonable demands as necessary, which Dean was now highly likely to comply with.

Case Study 2: Treatment of Self-Injury in a Child with Severe Intellectual and Physical Disability by Teaching a Replacement Behavior [9]

Joe was an 11-year-old boy with severe intellectual and physical disability. He could not walk and had no speech and language. He was referred by his classroom teacher for the treatment of self-injury, which had begun when he was about 6 months old. His self-injury consisted of forcibly banging his forehead on the laptray of this wheelchair, hitting his nose with the base of his hand, and – when seated on the floor – banding his head against his knee. His self-injury was frequent and severe. Head banging, for example, was observed to occur at rates

that often exceeded once per second with hundreds of such responses occurring each day. His self-injury had left a permanent welt on his forehead and caused frequent nose bleeds. The first step of this treatment process involved assessing his rate of self-injury under different classroom conditions (e.g., play activity, learning tasks, snack times, independent/alone times). After 90 min of observations conducted over 3 days, a clear pattern had emerged. Joe engaged in almost constant self-injury anytime he was left alone and almost no self-injury when he was engaged in task or interacting with the teacher. Based on this, we hypothesized that Joe has learned to use self-injury as a way of recruiting attention and getting the teacher to engage with him. His intervention program thus focused on teaching him to request attention using a speech-generating device, rather than engaging in self-injury, an intervention approach known as functional communication training [10]. The intervention involved providing Joe with a communication device that required him to press a switch. When he pressed the switch it activated the prerecorded message, "Come here please." Upon production of the message, Joe would receive attention/social interaction. He was taught to press the switch using a discrete-trial training procedure [11]. Specifically, an adult would tell Joe that he had to leave and if Joe wanted to interact he should press the switch. At this point, the adult would walk away and another adult, standing behind Joe, would immediately prompt Joe to press the switch, thus preempting self-injury. Prompting consisted of guiding Joe's hand to press the switch. Over successive trials, the delivery of the prompting was delayed by 3, at which point Joe began to independently press the switch without having to be prompted. As Joe learned to use the switch, he was less likely to show self-injury. In essence, the intervention appears to have replaced self-injury by teaching Joe to engage in a requesting response that seemingly served as same purpose or operant function as his self-injury.

12

Case Study 3. Treatment of Depression Disorder and Challenging Behaviors in an Adult with Severe ID

Diana is a 55-year-old nonverbal woman living in an institutional setting since she was 10, with a diagnosis of severe ID and schizophrenia. She was evaluated for treatment because of various challenging behaviors: aggressive (physical and verbal) and destructive behaviors (throwing and destroying objects), refusing to eat, and a range of other dysfunctional behaviors (taking off clothes and wandering around naked, lying on the floor, etc.). The staff members conducted an analog functional analysis, adapting the original conditions introduced by Iwata, Carr, and Durand [12]. They also conducted a preference assessment on single stimuli. Besides, staff members were interviewed on environmental stressors, functional communication skills, support needs, quality of life aspects, and natural/family supports, medical conditions and needs. A psychiatric examination revealed a depressive disorder.

The treatment was aimed at reducing her psychosocial vulnerability and at implementing immediate support by staff on the antecedents of her challenging behaviors (i.e., irritability, low mood, isolation). Once the function (including: avoidance/escape, attention seeking, access to material, and stimulation) of each challenging behavior was assessed, the staff developed a treatment package including the following strategies:

- Modification of antecedents: daily agenda using picture communication, noncontingent reinforcement for not displaying challenging behaviors [13].
- Environmental modifications and protection from threat and physical aggression displayed by others
- Differential reinforcement
- Extinction

More specifically, the treatment was aimed at: increasing her control on environmental variables, behavioral activation (BA), increase of choice-making and self-determination opportunities, demand training (teaching Diana to make more and/or better requests), exposure to success (in order to fade the learned hopelessness), increasing motivational operations, and increasing contact with her family and friends. Diana learned to make more often and more appropriate requests, she accepted to be involved in multiple settings, she showed increased access to available reinforcers and extended her range of preferences, and she agreed to stay with all staff members including male staff members (previously she avoided men). She also began to eat regularly and sleep at night (previously she only slept 2 h per night, spending the rest of the time screaming). A substantial increase in the occurrence of indices of "happiness" was observed, and all the signs of depression decreased in frequency as well as in intensity. Concomitantly, the frequency of her challenging decreased.

12.2.2 Cognitive Behavior Therapy

Cognitive behavior therapy (CBT) – now referred to as the second wave of behavioral therapies – has received increased attention from clinicians and researchers during the past decades (see e.g., Vereenooghe and Langdon [14]). It combines principles from behavioral and cognitive psychology and is referred to as the second wave of behavioral therapies. The assumptions underlying CBT are that behavior, thoughts, and emotions are interconnected, and that cognitive distortions and maladaptive coping strategies increase the risk for psychological and behavioral problems. These problems can be reduced by improving information processing (e.g., through cognitive restructuring – see ► Box 12.1) and the learning of adaptive coping skills.

Contemporary (cognitive) behavioral and other types of interventions should be based on a comprehensive and functional assessment.

Therapists use functional analyses and case formulations to understand the nature and cause of the problems and as a guide to developing treatments (see e.g., Didden [15]). CBT is a composite therapy in which a range of components are used: some of the most common of which are listed in ► Box 12.2.

Box 12.1: Cognitive Restructuring: An Example

- Event: a client who is living in the same community home collides with A.
- Thoughts: He did this on purpose. He does not like me.
- Emotions: Angry, afraid, distressed.
- Alternative thoughts: He did not do this on purpose. He just bumped into me.
- He did not see me. He often comes into my room and starts a friendly chat.
- Outcome: Feels calm, confident.

Box 12.2: Common Components of CBT

- Cognitive restructuring: identifying and challenging negative (automatic) thoughts, also called cognitive distortions. Irrational and/or negative thoughts are replaced by rational and positive thoughts.
- Exposure and response prevention: confront the situation that induces fear or anxiety and decrease avoidance of that situation until anxiety reduces. Response prevention is often used in case of obsessive-compulsive behavior where the client is taught to not carry out his or her impulses to reduce his or her distress.

- Relaxation: any activity or method that leads to a state of calmness if a person feels distressed or tense. Often progressive muscle relaxation techniques are used, as well as breathing exercises and mindfulness.
- Problem-solving and adaptive skill building; the development of conceptual, social, and practical skills that individuals use in daily life. Adaptive skills with which a problem may be solved.
- Functional analysis: assessing the operant function of problem behavior by identifying its antecedents and reinforcers.
- Case formulation: hypothesis or model about the nature and cause of the presenting problems. It provides a framework for treatment.

12.2.2.1 Manualized CBT

CBT is a treatment package containing a large range of techniques that address thoughts, emotions, and behaviors of clients. CBT is a manualized approach in which therapeutic protocols are outlined. At present, there are many protocols available for the treatment of behavioral problems and/or mental health problems in individuals with intellectual or developmental disabilities (IDD). For example, Hassiotis and her colleagues [16] have published a therapist manual for the treatment of anxiety and depression containing case vignettes and examples, exercises, information sheets, resources, and worksheets adapted for use with clients with mild ID. The manual illustrates the process of CBT, from the introduction of CBT and initial assessments to case formulation, treatment planning, intervention, and termination.

Lindsay and his colleagues [17] used a manualized CBT approach for emotional problems (excluding anger). The treatment consists of five modules:

- Module 1: assessment of problems.
- Module 2: preparation phase promoting engagement with CBT. Introducing the concept of CBT, establishing a list with the client's key difficulties that will be addressed, and identifying a family member or carer who will support the client.
- Module 3: recognizing and differentiating between emotions through role-play and scenarios, exploring links between emotions and events that trigger them.
- Module 4: development of a formulation with predisposing factors for the emotional problems, exploring feedback loop from client's behavior to event.
- Module 5: relapse prevention which takes the form of a sort of passport that the client could continue to use following treatment. Key elements of a passport are a simple formulation, adaptive strategies, information about early warning signs, and risk factors. At this stage, the family member or carer was introduced.

12.2.2.2 Adapting CBT to Individuals with ID

Until recently, cognitive and adaptive skill deficits were seen as precluding the use of CBT in individuals with ID. Potential obstacles are limited verbal communication skills, recognizing emotions, executive functioning deficits, and limited working memory, among others. In clinical practice, CBT is often used with individuals with mild ID and CBT is adapted to their skill deficits and needs. Hronis, Roberts, and Kneebone [18] provided suggestions for adapting CBT to children with ID who present with a range of cognitive skill deficits. Below are some examples:

- Attention: use shorter, more frequent sessions, reduce task length (smaller units), and prevent distractions
- Working memory: use memory aids (e.g., visual prompts), present one task at a time, and use short, simple, subject-verb-object sentences

- Executive functions: use structured sessions (e.g., visual schedule), minimize switching between tasks, and redirect uninhibited responses

Cooney, Tunney, and O'Reilly [19] conducted a systematic review of cognitive therapy skills assisting adults with ID to participate in CBT programs. The following skills and prompts were identified that may help adults with ID to benefit from CBT:

- Recognize emotions by using photographs of people's faces.
- Discriminate between thoughts, emotions, and behavior by using personally relevant scenarios and pictorial stimuli.
- Make a connection between events and emotions, and recognize the mediating role of thoughts in the relationship between thoughts, emotions, and behavior by using examples of situations, emotions, and behaviors that are congruent and by using pictorial stimuli.

Willner and his colleagues [20] have adapted the CBT approach to the needs and skill deficits shown by individuals with ID by training their care staff to deliver the CBT. In this multicenter study, a manualized anger management group intervention was compared to a waiting-list control condition. Staff or home carers participated as lay therapists and were trained by a clinical psychologist explaining the principles of anger management and the use of the CBT manual. The outcomes showed that anger management resulted in an improved anger control by participants with ID and an overall reduction in challenging behaviors. Analyses also showed that staff members delivered the CBT intervention with reasonable fidelity.

Dagnan, Jahoda, and Kilbane [21] point to the fact that establishing a therapeutic relationship between client and therapist during CBT is of particular importance, as this has been viewed by the client as one of the most positive aspects of therapy. A positive relationship improves client's motivation to attend the sessions and his or her confidence in learning skills.

Hassiotis and her colleagues [16] have given many suggestions on how to adapt CBT interventions for clients with mild ID.

12.2.2.3 Evidence-Base of CBT

CBT has most often been applied to the treatment of anger and/or aggressive behavior in individuals with ID (see e.g., Willner et al. [20]). Nicoll, Beail, and Saxon [22] have conducted a systematic review of 12 studies assessing the effectiveness of CBT for the treatment of anger problems in adults with ID. Overall, high effect sizes were found for CBT.

However, the authors note that some studies had large confidence intervals, for example, as a result of small sample sizes. CBT has also been applied in individuals with ID who present with mood problems and anxiety. Unwin, Tsimopoulou, Stenfert Kroeze, and Azmi [23] have reviewed 11 studies and concluded that CBT is feasible and may be effective in reducing symptoms of depression in these individuals including negative automatic thoughts. No controlled studies were found for anxiety. Clients and carers perceived CBT in a positive way.

The authors found that most studies had methodological shortcomings such as small sample size and lack of procedural integrity assessments and that data were collected during short-term follow-ups only.

12.2.2.4 CBT Expanding to Other Domains

The range of behaviors or disorders in ID that are being targeted by CBT is extending: substance misuse [24], obsessive-compulsive disorders [25], sexual offending [26], and hoarding. Kellett, Mattuozzo, and Kotecha [27] have assessed the effectiveness of CBT in 14 adults with mild ID who showed hoarding behaviors. They showed excessive acquisition of objects, had a substantially cluttered home environment, and had difficulties with discarding possessions. CBT consisted of 12 individual 2-h sessions via weekly visits to the participant's home. Elements of CBT were goal setting, enhancing motivation, exposure methods, problem-solving, cognitive strategies, and relapse prevention. Carers were used as co-therapists where possible and homework

assignments were given. CBT elements were adapted by reducing the amount and complexity of homework, extending time length of sessions, and simplifying psychoeducation[1] and hoarding formulations. All 14 participants completed the CBT program. Data showed that hoarding was reduced following treatment, a finding that was maintained at follow-up.

12.2.3 Trauma-Focused CBT and Eye Movement Desensitization and Reprocessing

Individuals with ID are at increased risk of experiencing traumatic events, such as sexual and physical abuse, separation, and life-threatening illness, compared to their peers without ID. Processing potentially traumatic events is particularly difficult for individuals with ID. Also, the range of events may be greater for individuals with ID. It is assumed that events, such as early institutionalization and out-of-home placement, few positive experiences in managing negative life events, and limited availability of social support, make individuals with ID vulnerable for developing posttraumatic stress disorder (PTSD) (see Mevissen et al. [29]). Moreover, understanding oneself as having ID may be traumatic in itself. Given the disruptive effects of trauma, PTSD assessment and treatment of PTSD in individuals with ID have gained attention in the literature in recent years. Mevissen et al. [29] have reviewed the literature on two interventions for PTSD in individuals with ID: trauma-focused CBT and eye movement desensitization reprocessing (EMDR), which are evidence-based first-line treatments recommended by the World Health Organization.

Trauma-focused CBT consists of a combination of behavioral and cognitive techniques and focuses on the relationship between events and behavior, cognitions (thoughts, attitudes), and emotions (also see above). Until present, only case studies have been published on the feasibility and outcomes of CBT for the treatment of PTSD symptoms in individuals with ID. A paper by Carrigan and Allez [30] describes the case of Damon who was a 26-year-old who had been diagnosed with mild ID and comorbid autism spectrum disorder (ASD). He lived at home and had no employment. He showed anger outbursts and complained of sleep problems at the time of referral to a community learning disability team. He disclosed that he had been the victim of a sexual assault some years before. He had regularly reexperiences of the event and had nightmares about what happened. He had difficulty concentrating; he had flashbacks and did not want to leave the home because he was afraid he would meet his attackers. In the paper, a case formulation is presented on how his behaviors, cognitions, and emotions are related to Damon's trauma and other symptoms. For example, negative appraisal of the trauma produced a sense of current threat and Damon believed that people wanted to get him and that they are not to be trusted. He blamed himself for what happened. Also, he watched television programs that triggered his memory of the event. His strategies to manage his sense of threat were to avoid people and places where the event had happened and to respond aggressively. He tried to avoid thinking about what happened.

The CBT intervention took 12 one-hour sessions at a hospital. Part of the intervention was anger management for his aggressive outbursts, which was focused on cognitive restructuring of beliefs about the intentions of other people. The intervention had three goals, of

1 Psychoeducation is an intervention for clients, their family members, and/or carers in which information is provided on the symptoms and possible cause of a mental health or behavior problem. Its goal is to understand the problem and provide support, which may help in recovery and well-being. There are very few psychoeducation programs available for individuals with intellectual disabilities and/or autism spectrum disorders. A recently published study by DaWalt, Greenberg, and Mailick [12] showed that an 8-week family group psychoeducation program, called Transitioning Together, resulted in significant improvements in parental depressive symptoms and problem-solving. Social interactions improved for their children.

which the first was to modify negative appraisals of the trauma and its consequences.

Psychoeducation was used to achieve this goal. The second goal was to reduce reexperiencing the event by elaboration of the traumatic memories and discrimination of triggers. For this purpose, imaginal reliving the event was used, whereby Damon was instructed to describe the event in as many details as possible. Thirdly, Damon was helped to drop dysfunctional behaviors and cognitive strategies and to avoid not thinking about the traumatic event. The outcomes showed that trauma-focused CBT – if adapted – is a feasible treatment option for individuals with ID and that the intervention resulted in a reduction of PTSD symptoms.

Eye movement desensitization and reprocessing (EMDR) therapy is an intervention aimed at reducing symptoms that result from traumatic experiences. The theory underlying EMDR is the adaptive information processing theory. Eye movements during the recall of aversive memories reduce their vividness and emotionality. Recalling a traumatic memory is assumed to tax working memory capacity, which is limited. If a second task – for example, eye movements – is executed during recall, less capacity will be available for recalling the distressing event. This makes that the memory is experienced as less vivid and emotional.

Mevissen and her colleagues [29] distinguish eight phases in the planning and execution of EMDR:

- Phase 1: history taking and case formulation, resulting in a treatment plan.
- Phase 2: the client is prepared for the trauma work. Skill building and resource development are typically necessary.
- Phases 3–7: reprocessing of the traumatic memory. The client is asked to bring up the traumatic memory and concentrate on the most distressing image and dysfunctional negative cognition of oneself in relation to that image, as well as the accompanying emotions that go along with it. A core feature of EMDR is the performance of eye movements (typically, the therapist moving his fingers back and forth in front of the client, asking him or her to track the movements while keeping his or her head still), while concentrating on the trauma memory.

  Following the image and negative cognition, access to the emotional and somatic aspects of the memory takes place. Repeatedly, the client is asked to report emotional, cognitive, somatic, and/or imagistic experiences, until intern disturbances reach a SUD (subjective unit of disturbances scale) of zero and adaptive and positive beliefs are rated as strong on a VoC (validity of cognition) scale.
- Phase 8: reevaluation and integration.

Instructions as to how to activate the trauma memory and how to support the client during the desensitization and reprocessing phase are age related and are adjusted to the person's developmental age, taking into account any comorbid disorders such as autism. Task variations might be necessary, for instance, the therapist putting stickers on his fingers to facilitate tracking, using buzzers to vibrate alternately between the person's right and left hand, administering alternating tones via a headphone or audio speakers placed on either side of the person, or tapping on the person's hands or knees.

The evidence-base for EMDR in individuals with ID is still small. In the literature, mostly case descriptions have been published (see Mevissen et al. [29]). Mevissen, Didden, Korzilius, and De Jongh [31] assessed the effectiveness of EMDR in two individuals with mild ID who met the diagnostic criteria of PTSD. Data were collected in a multiple baseline design and EMDR comprised of four 60-min sessions. The results show that for both participants, the number of PTSD symptoms, as measured by the ADIS-C PTSD section (see Mevissen et al. [32]), decreased in response to the treatment and both no longer met the PTSD criteria following treatment.

12.2.4 Relaxation

Relaxation is often a component in a treatment package. There are few studies evaluating relaxation as a stand-alone approach in individuals with ID and/or ASD. Bouvet

and Coulet [33] assessed the effectiveness of relaxation on anxiety, self-esteem, and emotion regulation in 30 adults with mild-to-moderate ID who worked in a French center of supported employment. In 1-h groupwise sessions, clients practiced with relaxation techniques during 10 weeks. They found that, contrary to a waiting-list control condition, relaxation significantly reduced state anxiety and improved the clients' self-esteem and cognitive reappraisal. A recent systematic review by Bellemans and her colleagues [34] showed that relaxation – particularly through progressive muscle relaxation – on average was effective in reducing aggressive behavior in individuals with ID. It should be noted however that the results were somehow mixed. There are relatively many techniques of relaxation. Harris and Robbins [35] used three basic relaxation techniques in the treatment of three clients who suffered from anxiety. For example, relaxation was applied to a female with moderate ID who showed symptoms of anxiety related to the behavior of other clients in her house. The intervention started with controlled breathing (she was able to follow basic instructions regarding her breathing exercises). Unfortunately, because of her communication difficulties the second technique – guided imagery – turned out to be problematic. During guided imagery, the client is guided toward a relaxed and focused state with the help of verbal instructions from a therapist or script. A state of relaxation is reached, if the client succeeds in imaging the details of an event or a safe place, which eventually results in a decrease of tension or anxiety. In her case, the technique was applied in an adapted way, in that a script was developed in which a trip to the zoo was detailed with vivid descriptions of each animal enclosure. This imagery was chosen because she loved animals. It appeared that she responded well to imagery plus controlled breathing. In the third technique – progressive muscle relaxation – she was prompted to use stress balls in each hand to grip and promote tension of the arms. This technique was also adapted in that she was prompted to "squeezing the juice from fruit." The combination of techniques helped her to get some degree of control over her anxiety, particularly regarding her fear of other clients in her house and some of her outreach activities. The case descriptions by Hart and Robbins show that relaxation techniques can be applied to individuals with ID, provided they are adapted to the individual.

12.2.5 Psychodynamic Psychotherapy

Psychodynamic psychotherapy is based on psychoanalysis. At the center of this therapy lies the concept of defense mechanisms which may be defined as the mental operations that remove thoughts and feelings from conscious awareness. Individuals keep something out of thoughts or alter the perception of events as a strategy to manage emotional conflicts or internal and external stressors. The therapy may support individuals to identify what they are doing and to help them to come to terms with why they are doing it. In this way, individuals move beyond the level of "problem statement" (e.g., aggressive behavior). During psychodynamic therapy, a strong focus is placed on the relationship, interpersonal relations, expression of emotions, and exploration of fantasy life (see Beail and Jackson [36]). McInnis [37] reviewed the evidence-base for psychodynamic therapy in adults with ID. On the basis of 14 papers, she concluded that this type of therapy may be of benefit to these individuals. However, the review revealed a range of limitations such as the small number of studies published and the reliance on case studies.

12.2.6 Mindfulness and ACT as Examples of Third Wave of Behavioral Therapies

Behavioral treatments have developed significantly in the last two decades. After the first-generation behavioral therapies – that is, behavior modification – and the spreading of cognitive behavioral approaches (see previous section), recently a "third wave" of behavioral models have been developed. They are mainly focused on the *function* of problematic

cognitions rather than their *content* [38], and put a strong focus on private events without trying to change the form or frequency of these private events (thoughts and emotions). The third wave of behavioral psychotherapies is an important arena of modern psychotherapy development, which has added extensively to the empirically supported treatments for mental suffering [39]. These approaches include a diversity of new techniques and open up possibilities for the treatment of mental disorders. The third wave usually consists of acceptance and mindfulness procedures in combination with behavior modification principles. It is acknowledged that people with ID are more susceptible than others to challenging behavior and mental health problems, but in order to apply a psychological treatment effectively with a person with ID, a conscious effort is needed to adapt the content and the style of presentation to take account of the client's limitations. Table 12.3 [39, 40] summarizes the deficits and potential solutions in four domains of cognition: intellect, emotional literacy, memory, and executive functioning. These issues must be considered during the assessment phase to drive the adaptation of the treatment process.

The main categories of the third wave of behavioral therapies are summarized in Table 12.4.

There is a specific interest in the outcomes of mindfulness-based and ACT interventions for individuals with ID who present with challenging behaviors (mainly aggressive, self-injurious, and stereotypic behavior) and mental health problems because of the negative consequences associated with such problems including the increased risk of exposure to stressful or even dangerous events for staff [39, 49]. ACT can help people with mild-to-severe ID [50], enabling the client to participate in the therapeutic process more readily than in a more traditional CBT approach. In individuals with high-functioning ASD, for example ACT may result in reduced levels of stress, hyperactivity, and emotional distress, and in improved prosocial behavior [51]. The option of treatment using ACT for individuals with ID and/or ASD appears stimulating and convincing, for which a wide range of potential applications are available [52, 53].

Table 12.3 Cognitive deficits and their implications for therapy

Cognitive domains	Specific processes	Implications for therapy
Intellect	Verbal understanding and reasoning	Simple words and short sentences
	Nonverbal understanding and reasoning	Use of nonverbal techniques and materials
Emotional literacy	Emotional vocabulary	Psychoeducation
	CBT skills	Psychoeducation and provision of ideas
Memory	Assimilation	Frequent repetition and more sessions
	Recall of experiences	Involvement of carers
	Prospective memory	Use of reminders and involvement of carers
Executive functioning	Working memory	Chunking of information
	Behavioral inhibition	Greater use of behavioral self-control techniques
	Initiative	Provision of ideas

Research on mindfulness-based interventions and ACT for carers reports positive findings for both staff and the individuals with ID they support (see e.g., Harper, Webb, and Rayner [54], McConachie et al. [55], Noone and Hastings [56], Leoni et al. [49], Ó Donnchadha [57]). Mindfulness-based interventions can also facilitate staff to integrate behavioral and psychopharmacological treatment with more positive outcomes [58], reduce the use of physical restraints [59], and increase indices of happiness in individuals with profound ID [60].

Table 12.4 Categories of third wave of behavioral therapies

Behavioral activation (BA)	BA emerged from studies analyzing the necessary components of classical cognitive therapy [41], and has evolved from a long behavioral tradition seeking to increase positive reinforcement by scheduling appropriate patient behaviors and thus achieving antidepressant action [42].
Dialectical behavioral therapy (DBT)	DBT conceptualizes that skill deficits in the area of emotion regulation are at the center of these disorders [43]. DBT includes the practicing of different skills in the areas of mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness [[44], 45].
Metacognitive therapy (MCT)	Metacognitive therapy (MCT; [46]) postulates that at the core of depressive and anxiety disorders there is the 'cognitive attentional syndrome' (e.g., worrying, rumination, dysfunctional threat monitoring, and dysfunctional cognitive and behavioral copying). MCT uses attention training techniques to develop skills in cognitive flexibility, teaches detached mindfulness, and guides cognitive and behavioral experiments to change metacognition.
Schema therapy (ST)	ST uses emotion activation techniques originating in Gestalt and Psychodrama; but it is strictly behavioral in the models communicated to the patient [43]. A basic ability reinforced in ST is to recognize the present dysfunctional modes of functioning, such as the detached protector mode, and to have behavior guided by the healthy mode [47].
Mindfulness-based cognitive therapy (MBCT)	The focus of MBCT is to learn to experience dysfunctional thoughts as internal events separated from the self [48]. Like cognitive-behavioral therapy itself, mindfulness-based approaches encompass a wide range of techniques that are customized to the needs of the individual. MBCT uses psychoeducation and encourages patients to practice mindfulness meditation. A core goal is to develop metacognitive awareness, which is the ability to experience cognitions and emotions as mental events that pass through the mind and may or may not be related to external reality [40].
Acceptance and commitment treatment (ACT)	ACT is a behavioral therapy system that is based on functional contextualism and the relational frame theory (RFT). It postulates the following psychopathological processes as central to human suffering and mental disorders: (1) cognitive fusion; (2) experiential avoidance; (3) attachment to a verbally conceptualized self and a verbally conceptualized past; (4) lack of values or confusion of goals with values; and (5) absence of committed behavior that moves in the direction of chosen values. The treatment contains experiential modeling, psychoeducation about key mechanisms, exercises in mindfulness, and cognitive defusion. The value orientation of the patient is elicited and shared, and the patients are reinforced in value-driven behavior in contrast to behavior driven by emotional or experiential avoidance. There are an impressive number of randomized controlled trials (RCTs) testing the efficacy of ACT in heterogeneous clinical conditions. (For a more detailed description of ACT process in individuals with ID, see Leoni et al. [49].)

Case Study 4: Acceptance and Commitment Treatment (ACT) for an Adult with Mild ID

Pietro is a 45-year-old man with mild ID living in a residential setting. Prior to his admission to the residential setting, he lived in the community in a private house, with daily supports. He spent most of his time wandering in the streets, trying to talk with people or to collect money. He was constantly worried about being mislabeled and teased, to the point that he displayed severe challenging behaviors. He was charged for aggressive behavior multiple times and often refused his prescribed psychotropic medications. The community services

decided to refer him to a residential facility, with a diagnosis of psychosis and moderate ID. At admission, he showed severe limitations in communication, inclusive activity, daily routine (self-care, home care), and job activities. He displayed a high frequency of dysfunctional behavior antecedent to problem behavior: he engaged staff members in continuous talk, thereby repeating topics, questions, and phrases, and he was constantly worried about the behaviors displayed by other persons; he felt threatened and was intimidating toward others. Staff initially used a range of behavioral interventions: antecedent modifications (environment management, supports to communication, and structuring of daily activities), and contingency management (token economy), without satisfying results. At some point, the staff introduced a treatment based on acceptance and commitment treatment (ACT), using the Matrix, a tool in which the Hexagon Model used in ACT is simplified; [49, 61] (see Fig. 12.1). Individual sessions of 45 min were held twice a week in order to work with Pietro on the main levels of the Matrix.

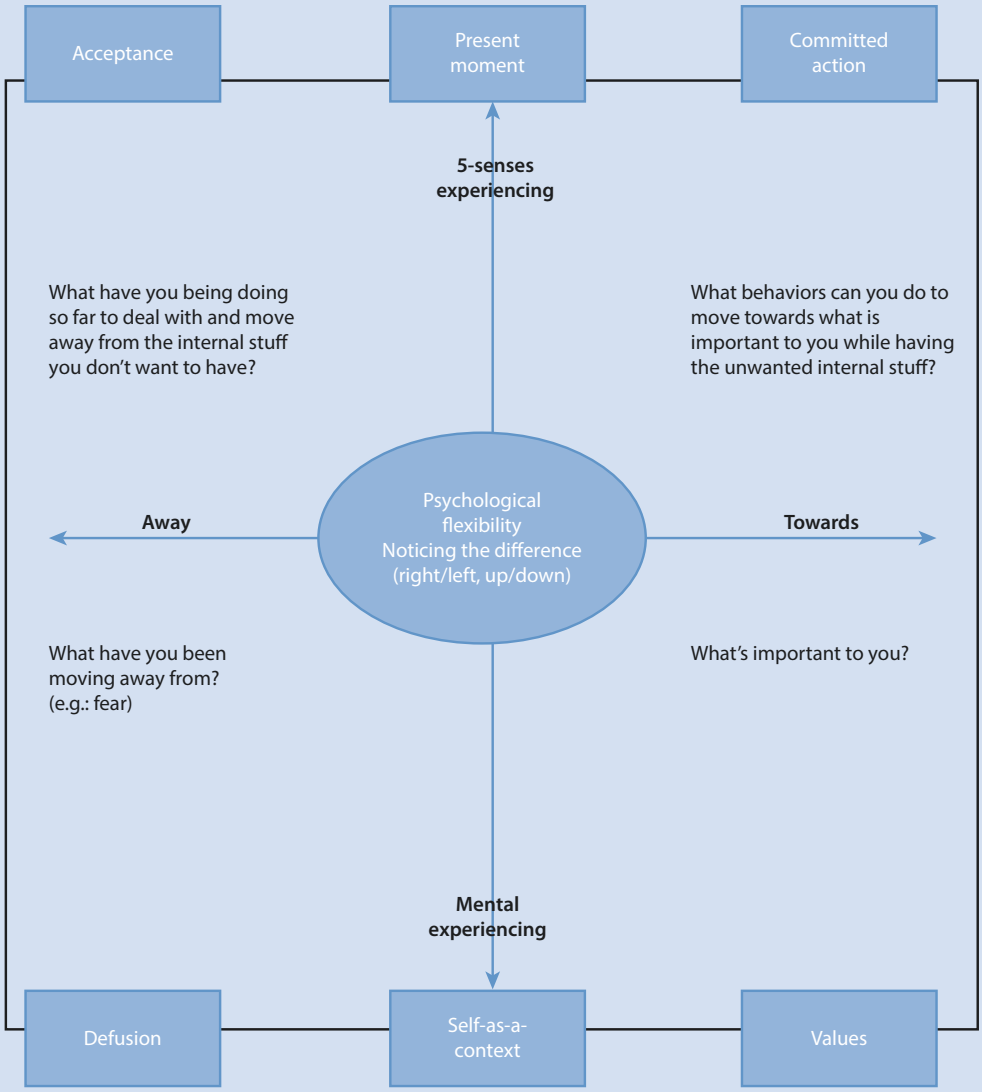

Fig. 12.1 ACT "Hexaflex" model simplified through the Matrix [49]. (Source: Polk and Schoendorff [61])

Firstly, the therapist increased Pietro's awareness of his body sensations and thoughts using instructions and physical exercises. The goal was to identify avoidance patterns in Pietro's behavior. Next to this, a preference assessment was done as well as a life-values analysis (i.e., important directions in life, to be pursued through goals and actions), and connections between values and daily choices were made. Additionally, observation and self-monitoring sheets that Pietro could use were introduced, and behaviors displayed in the previous days were evaluated using the Matrix (see Fig. 12.1), addressing the "away moves" (i.e., avoidance, usual habits, and dysfunctional problem-solving; left part of the Matrix) and the "moving forward" acts (i.e., behaviors aligned with preferences and values; right part of the Matrix). Pietro complied with the treatment (although many adaptations were required, due to his cognitive limitations), and after 4 weeks of treatment, he showed first signs of improvement.

Treatment lasted (with progressive fading of supports) for 24 months, and the staff observed a clear increase in adaptive choices, in reported and observed awareness, in the quality and quantity of the request for supports, and in the frequency and quality of activities. He was able to deal with the grief after his mother passed away, and to move in another group home and negotiate new objectives in the support plan. Challenging behaviors were significantly reduced in terms of frequency, duration, and intensity.

12.3 Contextual Approaches

Contextual approaches are very common in the treatment of mental health problems or challenging behaviors in individuals with intellectual or developmental disabilities (IDD). By contextual, we refer here to approaches that target changes in the *environment* of individuals with IDD. The environment consists of the structural environment (e.g., residential setting and its operational model) and, crucially, the social environment, that is, the people who live and interact with the individual with IDD (paid carers and family carers). The rationale underlying contextual interventions is that challenging behaviors or mental health symptoms of individuals with IDD will improve, if the people who live with them change some aspect of their own behavior (overt or covert behavior) that relates directly or indirectly to challenging behaviors or mental health problems experienced by people with IDD.

Contextual approaches *directly* targeting reductions in challenging behaviors focus on altering overt behavior of carers (i.e., parent training, staff training) so as to alter the contingencies that maintain challenging behavior. This may be combined with changes in the broader system aiming to improve quality of life or activity participation (whole environment interventions such as Active Support or Positive Behavior Support). Contextual approaches that target *indirectly* mental health problems or challenging behavior aim to alter the covert behavior or, else, emotional well-being of carers (family or paid carers). The latter approaches consist of psychological therapy for carers or psychological therapy combined with behavioral skills training.

Figure 12.2 maps some of the contextual factors related to the mental health or challenging behaviors of individuals with IDD using Bronfenbrenner's ecological systems framework. The intervention approaches described below focus on the micro- and mesosystems, though the latter ones actually span across both micro- and mesosystems.

> Challenging behaviors or mental health symptoms will improve, if the people who live with them change some aspect of their own behavior.

12.3.1 Parent Training

As a contextual intervention, parent training is a behaviorally based approach that

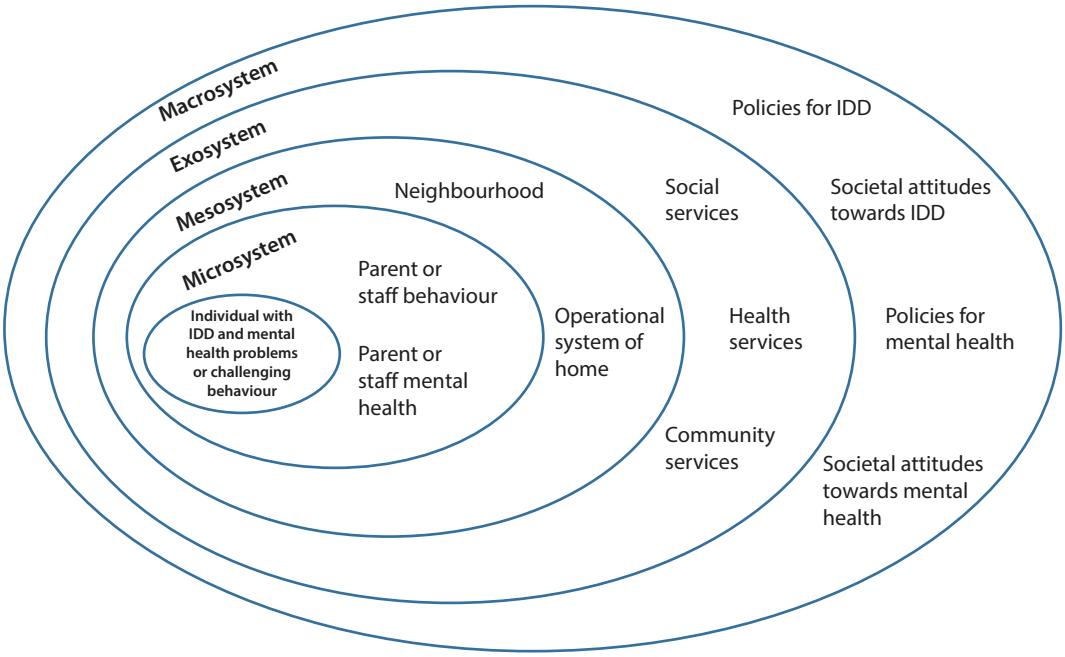

Fig. 12.2 A schematic representation of contextual influences on individuals with IDD and mental health problems or challenging behaviors

targets changes in the parenting behavior of parents of children with IDD, typically in response to emerging or established behavior problems. Most parent training models incorporate approaches from social learning theory and applied behavior analysis to reduce child behavior problems by increasing the use of positive parenting practices (e.g., praise for appropriate child behavior, use of positive behavior management approaches such as differential reinforcement; also see Table 12.1). There are several packaged models, and some may also include other theoretical principles, but social learning and behavioral principles underlie most approaches. Several randomized controlled trials (RCTs) and, subsequently, meta-analyses of RCTs indicated that parent training is effective in reducing child behavior problems (and in particular, conduct problems), increasing positive parenting (e.g., praise), decreasing negative parenting (e.g., ineffective discipline) while also improving maternal mental health, and making parent training an evidence-based (and cost-effective) approach for reducing behavior problems in childhood [62, 63]. There are various parent training models, but there is no evidence of differential effectiveness for different evidence-based models [64]. Notably, some programs, such as Triple P [65] and Incredible Years Parent Training (IYPT; [66]), have a very large evidence-base across several countries.

These parent training models address the general population. They have not been developed for families of children with IDD. However, parent training is gaining momentum as a contextual approach to reducing behavior problems in children with IDD. For parents whose children have IDD, parent training might involve one of the three options: (a) attending a parenting program that has been developed for the general population, for example Triple P or Incredible Years, (b) attending a parenting program that has been *adapted* for use with families with a child with IDD (e.g., Stepping Stones Triple P, [67]; Incredible Years Parent Training for Developmental Disabilities; IYPT-DD, [68]), or (c) a parenting program that has been developed specifically for these families (e.g., Signposts, [69]; Confident Parenting, [70]).

Table 12.5 Some key features of parent training targeting children's challenging behaviors

Content[a]	Format	Additional IDD focus
Positive parenting: when/how to use positive reinforcement; engaging in positive interactions and activities with child Child behaviors to attend to and child behaviors to ignore Behavior management: when/how to use extinction, how to use punishment (time out) Responding to the child in a consistent manner	Small group with/out 1–1 sessions Weekly meetings Facilitator led with/out parent co-facilitator Parents expected to practice new skills with own child and then report back to the group	Behavioral phenotypes of various syndromes Understanding the function of (challenging) behavior; focus on working out functions of own child's challenging behaviors and plan for change Communicative dimension of challenging behavior; adapting communication Changes in the environment to prevent challenging behaviors Supporting alternative behaviors (e.g., teaching a child to communicate a need as replacement for challenging behavior)

[a]See also Kaminski et al. [72] for a component analysis of effective parent training

At the moment, we have no evidence of the relative effectiveness of these different options, as approaches have not been directly compared.

Most parent training models involve parent training in small groups (8–12 parents), attending weekly groups ranging from 4 to 20+ weeks. Therapists are trained and/or accredited in the model delivered, and in some programs they are accompanied by parent expert trainers who have undergone similar training. The latter approach is considered to have high levels of acceptability from parents. Groups typically involve direct teaching, group discussion, modeling, experiential learning, homework, and reflection. Parent training in this population is typically available as a targeted or specialist intervention (i.e., after challenging behavior develops or worsens), whereas preventative approaches are not typically available, despite the fact that challenging behaviors are present from a very young age in children with IDD [71]. Table 12.5 summarizes some of the key features of parent training approaches.

Attending a parent training group that is not adapted or developed specifically for parents of children with IDD might not always be the preferred option for parents of children with IDD but in some areas it might be the only program to offer within a reasonable distance. A degree of inference is applied there, as we assume that families of children with IDD will benefit from programs that do not take into account the child's disability [73]. A recent evaluation with mixed disabilities (families of children with special educational needs) indicated that these families benefit from parent training similarly to families with children without special educational needs [74]. Parents in this evaluation received several programs, with about 80% attending Triple P groups. Clinicians need to be aware that where parents receive generic parent training as part of regular service provision (where services lead on all aspects of delivery including outcome evaluation), longer-term gains (at 12 months past training) are likely not maintained well, and these parents will benefit from top-up or repeat parent training.

Some parenting programs developed for the general population are adapted for families whose child has an IDD. Two such programs are worth noting: Stepping Stones Triple P (SSTP; [67]) and IYPT-DD [68]. Adaptations typically include additional content to provide IDD-specific information (for example on the nature and causes of IDD, behavioral phenotypes in various IDD), a focus on parental

adjustment (what does it mean to have a child with IDD), as well as a focus on the function of behavior problems. Stepping Stones Triple P has been based on Triple P, while IYPT-DD is an adaptation of Webster-Stratton's parent training variant of Incredible Years.

In their adapted versions, both these programs are available in a tiered format moving from less intensive to more intensive (e.g., weekly small parent groups with additional 1–1 meetings) as child need increases. At the moment, most of the evidence available to support the effectiveness of adapted parent training programs refers to small group format that meets on a weekly basis: level 4 for SSTP includes 6 group meetings and 3 1–1 consultations spanning 9 weeks in total, and 12 weekly meetings for IYPT-DD [68, 75]. In the case of IYPT-DD, a small-scale RCT with parents of young children (2- to 5-year-olds) with developmental delays suggested significant gains for observed and parent-rated behavior problems [76]. Incredible Years has also been adapted for families of children with autism and is currently being evaluated in a pilot RCT [77]. The autism adaptation places emphasis on parents helping their children with their communication needs as a functional approach to reducing behavior problems. The evidence-base for SSTP is much larger: a recent meta-analysis of 12 RCTs concluded that reductions in behavior problems of children with IDD are significant and approximately medium-sized, that is, an effect size of about half a standard deviation [75]. Of note, most of the evidence came from level 4 SSTP evaluations (i.e., small group format with 1–1 support meeting on a weekly basis for 9 weeks), whereas gains from level 2 SSTP (one or two large group seminars) were not present for child behavior problems or any other outcomes. Overall, IDD-adapted parent training is the parent training option with the largest evidence supporting its effectiveness in reducing behavior problems, though clinicians should be mindful that reductions in children's behavior problems are evident following more intense input; there might be little value in less-intense approaches.

Last, attending parent training, specifically developed for parents of children with IDD, is a very appealing option for parents who feel that being surrounded by people who experience the same challenges as them is a very important feature of parenting groups [78]. Parents value opportunities to share while not feeling judged or criticized by the other parents, and they also feel that they learn more by other parents in their group. Examples of such programs are Signposts in Australia [69], Confident Parenting in the UK [70], and (a soon to be evaluated by an RCT) Early Positive Approaches to Support in the UK (E-PAtS; Coulman et al. [79]). Some programs specifically target child challenging behavior (Signposts, Confident Parenting), but mostly take a broader view of family needs, by also addressing parental psychological well-being and other child needs, such as sleep or adaptive skills (Confident Parenting, E-PAtS). To date, we have no rigorous evidence that IDD-specific parent training improves challenging behavior or child mental health problems.

Therefore, while the option of attending an IDD-specific parent training group might be valued by parents for the social support networks, it is uncertain whether benefits in challenging behaviors or child adaptive skills will follow.

12.3.2 Parent Therapy

Parents of individuals with IDD experience significantly worse mental health than other parents, and this increases the risk for behavior and mental health problems in their offspring with IDD [80, 81]. Therapy to improve mental health in parents has focused on decreasing negative affect (e.g., CBT) or increasing mental well-being (e.g., mindfulness, positive psychology approaches). Overall, parent therapy is effective in reducing psychological distress in parents, especially mothers, of children with IDD, and the most effective approaches are the ones that combine behavioral parent training with therapy [82].

However, there is little direct evidence that parent therapy is associated with improvements in offspring mental health, as parents

tend to receive therapy because they experience poor mental health themselves (therefore, services or researchers tend not to measure offspring mental health). A contextual approach with some evidence of reduction of child aggressive behavior is mindfulness. Parents who receive mindfulness therapy tend to report lower aggression, more compliant/easier behavior for their children with IDD [83, 84], despite the fact that mindfulness therapy does not directly target parenting skills or child behavior at all. It is thought that the practice of mindfulness increases acceptance of the child with IDD and its behavior, and therefore increases positive interactions between the parent and the child. It is likely that parents who practice mindfulness become more aware of the ways they respond to their child's aggression and, as such, better able to interrupt unhelpful responses. It should be noted that other mindfulness evaluations have replicated the gains in parental mental health but did not find gains in child challenging behaviors [52].

12.3.3 Staff Behavioral Training

As with parents, staff behavioral training aims to improve staff skills in managing challenging behaviors using a variety of principles derived from applied behavior analysis. Staff behavioral training is an evidence-based approach for reducing challenging behavior in adults and children with IDD [4, 85]. See ▶ Sect. 12.3 outlining how behavioral training can support reductions in aggression and self-injury as well as anxiety. Overall, systematic evidence on the effectiveness of stand-alone carer behavioral training on the mental health of people with IDD is scarce (compared to effects on challenging behavior), and clinicians tend to implement direct interventions for mental health problems in this population (see ▶ Sect. 12.2). In the case of severe IDD, there is no evidence on how staff stand-alone behavioral training might impact on mental health problems with the exception of single case evaluations of enriched environment for low mood, and relaxation with interruption for treatment of tics [86]. More evidence is available for sleep problems. A recent meta-analysis demonstrated that carer behavioral training is a promising evidence-based approach for sleep problems, which can be symptoms of broader mental health difficulties [87]. Training caregivers on extinction, and positive reinforcement of appropriate behavior (e.g., going to bed), while also implementing environmental modifications that promote sleep (e.g., no naps during the day, exercise, no television in bedroom) were associated with very large increases in both sleep initiation and sleep maintenance behaviors [87].

12.3.4 Staff Psychological Therapy

Staff psychological therapy is a contextual approach that primarily aims to improve staff mental health. Staff who support adults with IDD and challenging behaviors, and in particular aggression, experience higher levels of burnout and emotional exhaustion [88]. Job-related stress is one of the main reasons staff in IDD services leave their jobs [89]. At the same time, it is considered that burnout and stress lead to a worsening of staff attitudes regarding challenging behaviors, which in turn has been associated with more restrictive staff practices [90]. Two staff therapy approaches that have attracted attention in the past few years are acceptance and commitment therapy (ACT) and mindfulness-based approaches. At the core of these approaches is that the increase in psychological acceptance that comes through ACT or the practice of mindfulness will lead to more positive and less avoidant interactions with adults with IDD and challenging behaviors [91]. Most of the (still very limited) evidence to date suggests that ACT and mindfulness-based approaches reduce psychological distress in staff working in IDD services [55, 56, 92]. However, despite the hypothesized relationship with challenging behaviors, there is very little evidence that staff ACT or mindfulness-based therapy impacts on challenging behaviors of adults with IDD, mostly because studies have not collected such data. There is some evidence that mindfulness-based therapy for staff leads

to a reduction in the use of restraint or similar restrictive practices from staff, especially when combined with systemic approaches (see below).

12.3.5 Systemic Approaches

Systemic approaches target at once several aspects of the environment of the person with IDD. Systemic approaches are warranted when there are concerns about the overall quality of life of people with IDD, not just their levels of challenging behavior or mental health problems.

Active Support aims to improve the quality of life of adults with IDD by increasing participation in meaningful daily life activities, with appropriate support from staff [93, 94]. Active Support was developed to provide an operational model for community homes for adults with IDD. As a philosophy of care, it promotes active participation, choice, and independence. As a systemic intervention, it focuses on each resident at a time, while changing the way the whole home operates. Active Support draws on behavior analytic principles and techniques, teaching staff behavioral skills to support resident engagement in activities, and also using behavioral technologies for organizing life in the home in such a way that opportunities for activity participation are always available along with staff support, that resident experience is monitored through ongoing data collection, and that increased independence is achieved by practicing and learning new skills [95, 96]. In community settings, Active Support significantly increases the amount of time residents spend engaged in daily life activities, and the amount of time staff support them to do so [97].

Active Support does not directly target challenging behaviors, instead it promotes engagement in activities *despite* challenging behaviors, that is, challenging behaviors should not be put forward as a reason not to support a person to participate in daily life activities, such as shopping, cooking, and looking after their own home. Active Support is considered to impact indirectly on challenging behaviors by changing the establishing or abolishing operations that facilitate them (i.e., by changing the motivation to engage in challenging behaviors): Active Support creates a "helpful environment," one where staff attention is available and contingent on appropriate resident behavior, where access to activities and food/drink is always available, where residents know their schedule, and where staff support matches resident skill, so that the "need" to escape difficult instructions or activities is minimized [94]. In other words, Active Support is expected to impact on challenging behaviors by indirectly impacting on their function(s). Active Support does not target mental health problems directly. However, increasing levels of activity should reduce depressive symptoms in adults with IDD [98].

A recent meta-analysis indicated that there was actually very little change in resident challenging behaviors following Active Support implementation, and unclear change in depressive symptomatology [97]. Overall, however, the quality of included studies was moderate to low, and until better quality studies are available it will be difficult to determine whether the hypothesized effects on challenging behavior and depression can be brought about by a systemic intervention that only indirectly targets these outcomes. Clinical case work has shown that when Active Support is combined with Positive Behavior Support (PBS), significant reductions can be achieved [99].

This raises the possibility that systemic approaches work best to improve mental health and challenging behaviors when combined with direct interventions for reducing challenging behavior. Positive Behavior Support (PBS) is a multicomponent intervention that targets change in the environment, in which challenging behavior is displayed as well as change in the individual who presents with these behaviors. Contextual approaches within PBS can take many forms (from behavioral staff training to ensuring that daycare placements are available), and this depends on (a) preferences of the person with IDD and (b) the results of a systematic, in-depth analysis of the function of challenging behaviors (i.e., functional analysis; [100]). As a systemic intervention in community settings

for adults with IDD who already present challenging behavior, PBS can reduce challenging behaviors and lower the probability of mental health disorders (namely affective, psychotic, and organic disorders; [101]). Contextual interventions within PBS are variable, and not clearly documented, whereas PBS approaches directly targeting challenging behavior reductions are more standardized, that is, functional analysis and function-based interventions. In the absence of a component analysis, it is unclear which PBS components (the contextual approaches vs the direct ones) are associated with improvements. Systemic approaches also work well when coupled with other contextual interventions, such as staff therapy. Offering staff mindfulness training (with a focus on personal meditation) alongside training in PBS seems to produce higher reductions in aggression (and staff use of restrictive practices) than just training staff in PBS [102]. It is not clear why this happens, but if PBS focuses on the reduction of challenging behavior through the implementation of positive interventions, it may improve staff skill in managing resident behavior, but does not necessarily improve staff skill in managing their own behavior consistently; the addition of mindfulness strengthens staff awareness of own thoughts and emotions leading to increased psychological flexibility, which in turn may enable a more adaptive behavioral response to resident aggression [103].

Overall, systemic approaches are not the first port of call for reducing mental health problems or challenging behaviors that are already present. Systemic approaches aim primarily to improve quality of life, but where challenging behaviors are present, a whole environment approach that combines direct work to reduce challenging behavior, environmental modifications to improve quality of life and reduce opportunities or motivation for challenging behavior, as well as support for the mental well-being of the social environment appear to be particularly beneficial for challenging behaviors and mental health problems of people with IDD.

12.4 Conclusion

In this chapter, we have summarized nonpharmacological treatments for behavioral and/or mental health problems in individuals with IDD. We provide a selective review of strategies that are often used in clinical practice and for which there is some evidence on their effectiveness for such problems. This chapter provides practical guidelines for adapting interventions to these individuals.

Adapting interventions to individuals with ID remains challenging for clinicians and established first-line interventions such as CBT may not always be accessible for these individuals, given their communication difficulties and cognitive and adaptive impairments. Clinicians and researchers continue searching for interventions that are focused on behavior change rather than cognitions. Behavioral activation may be an interesting development, in that this strategy is relatively easy to implement and it is less cognitively demanding. Recently, Jahoda and his colleagues [98] used an intervention called BeatIt in adults with moderate-to-mild ID for the treatment of depressive symptoms. The focus of BeatIt was on increasing activity, scheduling activity, and addressing barriers to activity. The results showed that behavioral activation was effective in reducing depressive symptoms, although the treatment was not more effective than a comparison condition of guided self-help intervention. A strong feature was that the intervention was delivered on an outreach basis by nurses and health professionals supporting the clients.

On the basis of this selective review and other reviews, we may conclude that a range of behavioral, cognitive, and other types of interventions are promising in the treatment of challenging behaviors and/or mental health problems in individuals with ID and comorbid conditions. The evidence-base has grown during the past two decades but is still relatively small when compared to individuals without IDD. Most studies have addressed challenging behaviors in individuals with

ID. Particularly, interventions for mental health problems in individuals with severe ID are lacking (see Vereenooghe et al. [86]). This chapter also shows that many studies reflect methodological shortcomings and that there remains a lot of work to be done by practitioners and researchers. We would like to paraphrase Vereenooghe and colleagues who state that bidirectional knowledge transfer is particularly important: research into ID making its way into the training of practitioners, as well as practitioners highlighting difficulties in assessment and treatment that need addressing (p. 18).

Tip

Adapt the intervention to the characteristics and learning style of individuals with intellectual disabilities.

Key Points

There are a range of interventions that may be effective in reducing challenging behaviors and/or mental health problems in individuals with intellectual disabilities.

Contextual interventions are just as important – and sometimes even more important – as client-directed interventions.

In both cases, interventions should be adapted to the characteristics and learning style of the client or his or her caregivers.

Learning Objectives

- To achieve a holistic consideration of physical, behavioural and mental health issues related to persons with intellectual and developmental disabilities, involving in their care a range of disciplines and health professionals.
- Integration across care may have many real and potential advantages, including identification of mental health issues, increased accessibility to mental health services, reduced costs and better outcomes.
- Integration requires the adoption of a person-focused approach which in turn is defined by a bio-psycho-social model.
- Given the high prevalence of physical and mental disorders in persons with intellectual and developmental disabilities and the high rates of physical–mental comorbidity, integrated care and approaches based on inter-disciplinarily input are urgently needed.

13.1 Introduction

Guaranteeing effective and appropriate integrated assistance for people with complex social and health needs represents one of the major challenges of healthcare systems. In Western countries, we are witnessing an increasing ageing of the population and a growing increase in the costs of services. The interest of researchers, service providers and policy makers in integration is not only limited to the elderly, but also to those who simultaneously use services deriving from multiple assistance systems, such as individuals with physical and intellectual disabilities or mental illnesses.

People with intellectual and developmental disabilities (IDD) are more vulnerable to physical and mental health problems than the general population. Besides this higher predisposition, they are often confronted with fragmented healthcare systems in which primary and specialty care is unable to meet their needs. Traditionally, healthcare for these persons has been parsed out to multiple providers and/or agencies and their physical and mental health are managed by different entities.

This lack of integration is made worse by a range of complicating factors, including barriers to the access and healthcare professionals who have received limited trainings about the peculiarities of these disabilities. Furthermore, several disparities emerge between the health sector and the social and education sectors which have significant implications for service planning and delivery. Changes need to be made in order to improve accessibility and integration of services necessary to meet the complex health needs of this population.

The development of integrated care pathways involving different professionals, family and life environments will help ensure that the needs of people with IDD are met. The necessity to address individual needs considering them in their entirety requires a planning of interventions which must take in account the principles of coordination, integration and cooperation between the various institutional levels that participate in the implementation of healthcare and social services. Integration allows the connection between healthcare (including acute care, primary and specialist care) and other assistance systems, improving outcomes both in terms of clinical results and quality of life. Identifying the links between different systems requires the adoption of a holistic approach which considers all major aspects of a person's life interrelated.

To date, the promotion of integrated and person-centred care represents an obligatory step for the improvement of public health policies outcomes. In order to achieve this goal, general understandings about integrated care should be converted into practical terms, in order to make available more effective health services able to improve quality of care and quality of life for the individuals. In this chapter, we discuss the notion of 'integrated care' and its features, exploring the many advantages deriving from its adoption in the field of IDD.

13.2 Integrated Care and Person-Centred Approach in Intellectual and Developmental Disabilities

Integrated care has more than one meaning and it is often used by different people to mean different things. The word 'integration' comes directly to us from the Latin verb 'integer', which means 'to complete'. Consequently, the definition of the adjective 'integrated' is 'combining or coordinating separate elements so as to provide a harmonious, interrelated whole'. It is mostly used to express the bringing together or merging of elements that were formerly separated [1].

The notion of integration in the fields of physical and mental health was first introduced more than a century ago by psychologist Alfred Adler (1870–1937) who codified concepts at the basis of individual psychology. According to this theoretical framework, the relationship between physical health and mental health is inextricable. The adoption of this concept in healthcare allows professionals to examine health status as a whole.

In its joint position statement on health, mental health, vision and dental care (as adopted in February 2013), the American Association on Intellectual and Developmental Disabilities has declared that 'all people, including people with IDD, should have timely access to high quality, comprehensive, accessible, affordable, appropriate healthcare that meets their individual needs, maximizes health, well-being and function, and increases independence and community participation'. Healthcare and social services face patients who have composite problems and this holds particularly true for people with IDD who are far more likely to have multiple comorbidities. People with IDD represent a vulnerable group of patients requiring well-timed, adequate and sensitive care interventions but actually, in several European countries, healthcare does not succeed in providing adequate services for them. Major difficulties refer to access to primary care, medical prescriptions, return of information, treatments for serious mental illnesses, communication between health and social services, lack of clear lines of responsibility and accountability for implementing care, and shortage of financial supports and resources [2, 3].

In the last two decades, the average life expectancy for persons with IDD living in high-income countries has increased, due to the improvement of life conditions and healthcare practices, although it remains lower than in the general population [4–6]. According to some studies, average age of death for persons with IDD is now 63.3 years for males and 69.9 years for females [7, 8]. Simultaneously, a rise of ageing-related diseases has been recorded [9]. These demographic trends suggest that the need for healthcare delivery systems and approaches should be able to coordinate primary, mental and behavioural care in order to address a variety of complex healthcare needs [10]. Nevertheless, people with IDD are still frequently confronted with fragmented healthcare in which primary and specialty care are unable to meet their peculiar needs [11, 12]. In fact, there are very few systems in which different components are integrated and this lack of integration is made worse by a number of complicating factors, such as the limited training received by healthcare providers about issues related to IDD [10, 13]. As a result, unmet physical and mental health needs are common across the lifespan of persons with IDD, and the challenges arise accordingly with increased severity levels of the impairments [14].

To date, the scientific evidence suggests that integration across care may have many real and potential advantages [15, 16]. Integrating primary healthcare with mental and behavioural healthcare entails a number of benefits which includes identification of mental health issues, increased accessibility to mental health services, reduced costs and better outcomes [17–20]. Integrated care was described by

Leutz as a broad inter-sectorial system approach that aims to connect the healthcare system with other human service systems in order to improve outcomes (clinical, satisfaction and efficiency) [21]. Over the last few years, the concept seems to have received attention in the field of IDD and now it is widely supported for improving accessibility and quality of healthcare. Nevertheless, a comprehensive shared knowledge about issues related to integrated care is still lacking. According to Dowling and collaborators, the barriers perceived to prevent its successful implementation could be due to philosophy or culture of care, power and funding structures, high levels of staff turnover and lack of training, lack of experience among service management, inadequate staff supervision and ambiguity among some stakeholders [22].

From a clinical point of view, integration requires the adoption of a person-focused approach rather than a disease-focused one. The main characteristic of person-focused care is defined by a bio-psycho-social approach applied to health which is aimed at comprehending the personal meaning of a disease attempting to comply with individual needs and preferences. From this point of view, diseases are simultaneously a medical, psychological and social problem [23]. Focusing on the disease reveals a clinical perspective that links the specific needs of an individual to separated biological entities [24, 25]. Commonly, health systems in Western countries adopt this perspective which often disregards the implicit reasons of illness. Nevertheless, a disease-focused approach seems to be inappropriate for patients with chronic and overlapping diseases [26]; in these cases, adopting a person-focused approach is more functional as it allows a holistic vision where most health and social issues are interrelated and the identification of the links. Integration is also required to supply an ongoing and comprehensive provision of services matched to the needs of the users. The major challenge is to convert general understanding about integrated care into practical terms to make available more effective health services able to improve quality of care and quality of life for the individuals [27].

An important contribution has been made by the International College of Person-centred Medicine (ICPCM) and the Person-centred Integrative Diagnosis (PID) multi-dimensional matrix [28]. The PID focuses the attention to the importance of involvement and partnership in the clinical care process and supports the patients' autonomy, responsibility and dignity while advancing the recovery and promotion of well-being. The construction of this theoretical model has been carried out by the World Psychiatric Association (WPA) through an Institutional Program on Psychiatry for the Person (IPPP) [29, 30]. Emerging features of the PID model include them being a diagnosis of health (of both illness and positive aspects of health), involving collaborative and empowering engagement of patients and serving as informational basis for prevention, treatment, rehabilitation and health promotion [31]. PID uses descriptive categories, dimensions and narratives, to manage patient-family-clinician partnerships for achieving shared diagnostic understanding and shared commitment to care. The application of this model to the assessment of personal well-being, experiences, satisfaction and aspirations of persons with IDD faces significant challenges as the self-reported assessment of these complex concepts is limited due to the cognitive and communication impairments which frequently occur in persons with IDD [32].

IDD may be a good example of how the holistic and comprehensive approach is useful for comprehending these complex constructs in healthcare. Integrated care and person-centred approach lay on the same conceptual frame of practice-based research. What is effective in evidence-based studies, including first-level studies, does not always have the same efficacy in the real world of everyday practice [33, 34]. The same applies to the relationship between costs and benefits of interventions: the dynamic interaction of the many factors conditioning the psychic state of persons with IDD and those who implement professional interventions can substantially change what is indicated by evidence-based studies. Moreover, some researchers have identified that even in organic medicine – in which the variables involved in the genesis and in the

resolution of the disorders are lower than those of the psychological and psychiatric clinic – the portion of patients to whom evidence-based guidelines are applicable without major adaptations often remains below 50% [35, 36].

An attempt to overcome these limitations is represented by research based on practice (practice-based research (PBR)), or by a collection and analysis of data derived from daily clinical practice and aimed directly at improving it. PBR is applied to professional studies, in outpatient clinics, in schools, in rehabilitation centres and in all other contexts in which people with IDD actually receive the interventions they need, becoming themselves an active part of the research process [37, 38]. The application of PBR can identify and solve the problems of applicability of the evidence from the scientific literature to the practices in various care settings [39, 40].

Integrated care promotes a holistic vision in which health and social problems are interconnected, allowing the identification of links between the different systems. Multiple perspectives may lead to the development of new intervention models based on person-oriented approaches to address individual characteristics and needs.

Tip

- Integrated care may be defined as a coherent set of methods and models regarding the provision of administrative-organizational and clinical services designed to create connectivity and collaboration within the healthcare contexts.
- From a clinical point of view, integrated care models require the adoption of a person-focused approach, in order to improve the patient's general well-being and take into account his/her needs.
- The integration of different health disciplines in the treatment of persons with IDD is increasingly indicated as a useful method, which may result in improved accessibility, appropriate use of healthcare services and higher quality of healthcare.

13.3 Integrated Care and Physical Ill-Health

It is widely proven that persons with IDD present a higher vulnerability to mental and physical health problems [41] (see ▶ Chap. 3) and face a much greater burden and earlier onset of physical ill-health than the general adult population [42, 43]. Given the high prevalence of physical and mental disorders in persons with IDD, they often tend to coexist. According to the findings of the Adult Psychiatric Morbidity Survey 2014 [44], chronic physical conditions such as asthma, cardiovascular disease, epilepsy and diabetes seem to be associated with common mental disorders (e.g. anxiety and depression) and poorer mental well-being in the general adult population. Barnett and colleagues [45] found the prevalence of physical–mental comorbidity to be 8.3% in the general population, and the likelihood of presenting mental disorders seemed to go up as the number of physical illnesses increased. It is widely known that physical–mental comorbidity is associated with poorer outcomes compared with the presence of either physical or psychiatric conditions alone [46, 47]. These high rates of comorbidity have some serious consequences, such as higher mortality [48], increased risk of suicide [47], functional impairments [49], poorer quality of life [50] and higher medical care costs [48].

To date, only few researches have examined the relationship between physical and mental ill-health in adults with IDD and those which have been identified have some limitations. Three studies have examined this relation focusing on older adults with IDD [51–53]. Cooper [52] observed a positive association between physical ill-health and dementia in a sample of 134 of older adults (aged 65 or over) but her study did not show further connections with other mental disorders. A complex relationship between the presence of epilepsy and mental health among adults with intellectual disabilities has been described [54], while McCarron and collaborators [53] have identified a significant

association between gastrointestinal disease – but no other physical conditions – and mental ill-health in a sample of 753 adults with IDD over the age of 40. More recently, Dunham and colleagues have found no significant correlations between physical multimorbidity and mental ill-health in adults with intellectual disability [55]. Nevertheless, this result could be due to the width of physical multi-morbidity (99.2% of the sample had physical conditions), which was so high to compromise the chance to identify associations.

Findings of some recent studies have shown that obesity is associated with mental ill-health and aggression [56–58]. Endocrine disorders were found to increase the risk of having problem behaviours by 22.4%; in particular, hyperthyroidism has been shown to be associated with psychosis, irritability/behaviour changes, restlessness and hyperkinesis [59]. Respiratory disorders have been identified as protective factors against problem behaviours and every type of mental disorders; this finding could be attributed to the ease of detection of symptoms (e.g. cough, breathlessness and wheeze), resulting in more attention by family members and/or carers which in turn produces a positive psychosocial effect [55].

Another significant association was found with reference to musculoskeletal problems. Actually, their presence seems to reduce the risk of mental disorders of any kind by 15.8%; this may be due to the anti-inflammatory effect of the drugs prescribed to treat these conditions. Some researchers have suggested that inflammation can induce depression. Makhija and Karunakaran have demonstrated that increased inflammatory cytokines are mechanistically linked to a number of interacting neural pathways that may contribute to the onset of depressive symptoms [60]. Other important findings concern ischaemic heart disease that has been found to increase the risk for the onset of problem behaviours by three-fold. Thombs and colleagues have shown that depression is around three times more common in patients after an acute myocardial infarction than in the general population [61]. The authors have also suggested that the mechanisms behind these associations in adults with IDD may be similar to those seen in adults who do not have IDD.

Given the high prevalence of physical and mental disorders in persons with IDD and the high rates of physical–mental comorbidity, integrated care and approaches based on interdisciplinarily input are urgently needed. The collaboration between psychiatrists and other professionals such as general practitioners, family doctors, neurologists, dental practitioners or orthopaedic surgeons [62–64] is, therefore, recommended. Good interdisciplinary communication seems to be associated with improvements in personal outcomes and in diagnostic and prognostic abilities of health professionals [65]. Providing specific trainings in the field of IDD for all health professionals seems to be fundamental in order to achieve a better knowledge of issues related to the identification and treatment for chronic health conditions which affect people with these conditions. Moreover, greater efforts should be made in order to improve the understanding of how to monitor mental and physical health among ageing IDD population.

13.4 Integrated Care and Mental Ill-Health

Diagnosing psychiatric symptoms in persons with IDD faces several difficulties, particularly in evaluating the impact of the specific symptoms on daily functioning. Assessment, diagnosis and treatment of mental problems in this group of patients demand specific adjustments due to the cognitive impairment, limited communication, sensory impairments, skill deficits, difficulties in adaptation and other disabilities [66]. Despite their complex and specific general health and mental health needs, people with IDD continue to experience disparities in healthcare provision. Unmet mental health needs are common across the lifespan of IDD, and the challenges increase accordingly with increased severity levels of the condition [14]. Particularly, the most urgent intervention required is the reduction of health

disparities, addressing to those issues which represent barriers to their access to services and appropriate treatments. Adopting adequate strategies is necessary to include people with IDD in health prevention programs, through an early identification of such problems, and to develop structured assessment tools coupled with tailored interventions [27].

As mentioned above, IDD presents several positive implications for psychiatry, such as providing assessment models, support system and diagnostic frameworks in severe mental and cognitive disorders. As suggested by Bertelli and colleagues, models of care – such as residential care, respite care and multi-disciplinary approach to care – as well as social issues of health – such as stigma and labelling and self-advocacy – were developed first in the IDD field, and now they are widely used in general psychiatry [27]. The usefulness of an integrated psychiatric assessment results from the consideration of several factors. Taking into account the high vulnerability of persons with IDD and the significant prevalence of mental health problems in this population, the adoption of a holistic approach that comprehends as many points of views as possible seems to be the most appropriate in their assessment.

Problem behaviours may be a significant example of the usefulness of an integrated assessment. In persons with IDD, the first choice treatment for problem behaviours is often pharmacotherapy and the search for a non-pharmacological therapy which considers the individual-specific conditions and individual quality of life as an outcome is often ignored. Actually, clinical practice suggests that an effective intervention of problem behaviours should be characterized by a simultaneous consideration of organic, psychiatric and socio-functional aspects and their pathogenetic contribution, on the basis of a multimodal analytical approach [27]. According to NICE guidelines [67], assessment on problem behaviours should be integrated into a comprehensive assessment for adults with autism. When assessing problem behaviours, practitioners should undertake a functional analysis in order to identify and evaluate any factors that may trigger or maintain the behaviour, including any physical health problems, the social environment (including relationships with friends, families and carers), the physical environment, coexisting mental health disorders, communication problems, changes to routine or personal circumstances.

The involvement of various disciplines in an integrated assessment might be useful in the identification of problems in the classification systems, strictly connected to clinical practices, and in identifying more and more sensitive diagnostic tools, instead of starting from very generic symptoms in assessing skills and performances [27]. Persons with IDD are uniquely positioned to benefit from the coordination of care that originates from integrated medical and mental and behavioural healthcare [10]. In fact, more than any other mental health condition, IDD provides opportunities to explore the clinical expression of the body-mind link. In order to have a clear understanding of it, all parameters of a quality mental healthcare such as holistic consideration of individual and sensitive diagnostic methods are highly relevant [32]. Multiple perspectives may lead to the development of new intervention models based on person-oriented approaches to address individual characteristics and needs.

The adoption of Patient-Reported Outcomes (PROs) is widely encouraged in assessing patients' performances and evaluating the efficacy of the treatments. These measures include the model of Quality of Life, widely applied in the field of IDD. In the field of IDD, since it is difficult to think about rehabilitative, educational and medical objectives that restore functional capabilities similar to those of most people, Quality of Life becomes a fundamental reference. It allows the assessment of the distance between individual expectations in the different areas of life and the results that are actually achievable; it helps to identify the most important and satisfying areas among the various interests and capabilities of individuals. Thus, a contextualized multi-modal assessment and a multi-disciplinary integrated intervention, involving different professionals, family and life environments, have several positive implications in achieving a comprehensive consideration of physical, behavioural and mental health issues related to persons with IDD, involving in their care a range of disciplines and

health professionals [27]. ► Box 13.1 summarizes the main factors supporting the relevance of an integrated care in psychiatry for IDD.

Tip

- Compared to the general population, persons with intellectual and developmental disabilities show a higher prevalence rate of both mental disorders and physical disorders.
- Due to their clinical peculiarities, persons with intellectual and developmental disabilities could particularly benefit from the coordination of multiple interventions deriving from the involvement of several specialists in the medical, mental and behavioural fields, as well as from different disciplines, services and supports for health promotion.

People with intellectual and developmental disabilities have complicated and ongoing needs and require a mix of services delivered by multiple providers. Integrated care improves mental and physical health treatments for people with intellectual and developmental disabilities establishing a comprehensive approach to patient, which enhances both quality of healthcare and quality of life.

Box 13.1: Reasons for Integrated Psychiatric Care in Persons with IDD Experiencing Mental Disorders

- Higher prevalence of psychiatric disorders than in the general population
- Identification of problems in the classification systems (i.e. ICD)
- New understanding for intelligence
- Models for the assessment of problem behaviours in severe mental disorders and cognitive deficit
- Genetic models for psychiatric disorders
- Direct clinical expression of the body-mind link
- Changes and adaptation of diagnostic criteria and diagnostic process for psychiatric disorders
- Sensitive diagnostic skills and tools (one often has to start from very generic symptoms, like behavioural changes or problems)
- Models for the assessment of adaptive skills as well as supports
- Life-span approach
- Holistic consideration of the person which requires multi-disciplinary intervention
- Model for high vulnerability to distress
- Person-related outcome measures, like generic quality of life

Bertelli et al. [27]

13.5 Conclusion

IDD represents an interesting area for the exploration and the understanding of the implementation of person-centred integrated care in classification, assessment, interventions, care delivery and policy planning [27]. In recent years, interest in healthcare integration has grown, with increasing evidence of its role in achieving better outcomes for mental health services' users. Nevertheless, reliable models and guidelines for daily practice still seem unclear, although persons with IDD, their families and an increasing number of healthcare providers are demanding them. To this purpose, health, social and educational professionals should collaborate to produce or enhance inter-disciplinary model of intervention and support, as well as to prove them through research trials and include them in the training curricula. This should be addressed also to primary care [10]. The necessity to encompass the existing models developed for the general population with the specific characteristics of IDD needs immediate attention [68].

Key Points

- Integrating primary healthcare with mental and behavioural healthcare entails a number of benefits.

- The early development of strategies of both person-centred care and integrated care in the field of intellectual disability and autism spectrum disorder may contribute to a better knowledge of the challenges of developing integrated care both in the interaction between primary care and secondary care and in the integration of health and social care.

Learning Objectives

- Understand the difference between various outcome measures, especially between traditional medical outcome measures and person-centered outcome measures
- Understand the difficulties in assessing the psychometric properties and validity of outcome measures
- Understand the meaning and evolution of functioning, empowerment, subjective well-being, and quality of life as outcome measures in the field of ID and/or ASD
- Comprehend the articulation of inclusion outcomes and the issues associated with their measurement

14.1 Introduction

Since the end of the last century, outcome frameworks for mental health services, social care, and education have considerably changed and the last decade's policy of the World Psychiatric Association, "No Health Without Mental Health" [1], identified new high-level outcomes related to the aims of greater prevention, recovery, quality of life, and social inclusion. This shift in focus started earlier in the field of neurodevelopmental disabilities than in other areas of mental health as a key strategy to promote quality of patient's life and equity of healthcare.

The criteria to identify the most suitable interventions and to evaluate their effectiveness are extremely variable among different studies, or even in a single study, and differ depending on the purpose and the specific contexts, the level of assistance to be assessed, clinical characteristics of participants, and the sources of the available data. Many outcome measures were developed for use in population surveys or clinical trials and not for monitoring individual patients in daily practice, other measures were thought of as performance or cost indicators in mental health services (payment-by-results model) [2, 3]. Therefore, outcome measures and related tools are extremely heterogeneous, including assessment of symptom reduction, adaptive skills, functioning, specific abilities, intensity and pervasiveness of problem behaviors, level of use of services, and quality of service provision.

Measuring outcomes in persons with intellectual disability (ID) and autism spectrum disorder (ASD) poses even greater problems than in the general population because of the differences in sources of information and raters, the availability of specifically adapted tools, influence of cultural aspects, such as the conceptualization of developmental disabilities and their possibilities of improvement across the life span.

Research and clinical practice in this area have been scarcely developed and tended to generate outcome measures on their own rather than contributing to create and improve standard ones, although an excess of standardization could limit the applicability to such a wide range of individual variability as in ID and ASD.

Outcome measures are related to the very meaning of social health and educational practice and their optimization should represent a research priority in the field of mental health of neurodevelopmental disorders.

14.2 Outcome Measures

14.2.1 Heterogeneity of Outcome Measures

The evaluation of outcomes of therapeutic, rehabilitative, and educational interventions is becoming a key requirement for reliable and effective clinical practice and social-health services. However, the parameters that should be considered to evaluate the final result of an intervention are still widely discussed by the clinical and scientific community, and a consensus definition of the adequacy of the outcome measures and efficacy criteria has not yet been reached.

According to historical definitions, such as the one proposed by Donabedian [4, 5], outcome measures represent a part of a quality assessment system which also includes struc-

ture and process indicators, considering them a fundamental aspect of the assessment of the quality of interventions.

Outcome measures have been grouped by Epstein and Sherwood [6] into clinical, economic, and humanistic, with the clinical ones being the most frequently used in practice and research. Authors of the present chapters (in particular Bertelli and Bianco) propose a classification in four groups, clinical, economic, social, and person-centered, as in Table 14.1, although they believe that some measures straddle two groups, such as functioning with respect to the clinical and social groups or empowerment with respect to social and person-centered groups.

In addition to type, outcome measures can be framed on the basis of the source of information, mostly as clinician-rated outcome measures (CROM) and patient-reported outcome measures (PROM). Process measures, such as patient-reported experience measures (PREM), represent another important resource in the evaluation of healthcare quality, but they cannot be considered as a subtype of outcome measures and must be distinguished from them. PROMs allow evaluations of patients' perceptions of the efficacy of a clinical intervention, general health condition, or health condition related to a specific disease, while PREMs gather information on patients' views of their experience while receiving care (e.g., communication and timeliness of assistance).

In the field of ID and ASD, the term "outcome" refers in most cases to the final result of a process simplistically aimed to the reduction of the symptoms and dysfunctions related to the developmental disorder, mostly in terms of quantitative deviation from a standard (general population mean). However, there is considerable variability of outcomes definition and measurement, also according to numerous factors, such as the type and goal of the intervention they refer to, the clinical condition they address, and the context in which they are set. The age of the person to whom an intervention is directed is

Table 14.1 Main outcome measures by type

Clinical	Economic	Social	Person-centered
Intensity and pervasiveness of symptoms (by both patient and clinician reports)	Direct and indirect medical cost	Inclusion	Individual perception of symptoms impact on life quality
Functioning (by both patient and clinician reports)	Reduction of the need for admission to hospital	Occupation	Subjective well-being
Mortality	Utility (preference-weighted scales used in economic evaluation)	Caregiver burden	Quality of life
Life expectancy	Cost–benefit ratio	Education level	Patient satisfaction
Laboratory and instrumental examinations	Quality-adjusted life-years	Empowerment	
Intensity, frequency, and duration of problem behaviors			
Transition outcomes: engagement, adaptation, and continued growth and development			
Staying on treatment			
Safety and tolerability			

also important for the choice of the outcome measure, especially during the developmental age, in which the acquisition of nonspecific basic skills is relevant for all individuals.

This heterogeneity can also be found in scientific research, even in relation to the same intervention [7, 8]. Provenzani and collaborators have recently observed that 69% of the outcome measures found in the literature for ASD had been used only once and that only seven assessments had been included in over 5% of the studies. They also outlined that many of the assessments were not developed as outcome measures nor as specific for ASD [9].

As an example, the efficacy of psychopharmacological treatments for ASD has been alternatively evaluated in different studies in terms of overall clinical improvement, reduction of severity of core symptoms (i.e., social withdrawal or stereotypies), reduction of "non-core" (also called "associated") symptoms (i.e., aggressiveness, irritability, or hyperactivity), functioning, adaptive skills, and quality of life, to the point that precluded the possibility for providing precise conclusions in meta-analytic reviews [10–12].

Therefore, it is very complex to define whether an intervention is reasonable, useful, successful, and of good quality, especially when referring to persons with ID/ASD and co-occurrence of psychiatric disorders.

14.2.2 Validity and Reliability

Most current outcome measures were developed primarily for research purposes and with a consequent preoccupation with reliability and validity. Reliability is best interpreted as the repeatability of an assessment both over time and by different raters. If the same measure is used more than once on the same patient or the same group of patients within an appropriate time period, then the agreement between the two measures is an estimate of the stability over time, also called test–retest reliability. Similarly, the agreement between different raters assessing the same patient or group of patients is defined as interrater reliability. The more reliable the measure, the more stable and consistent should the various assessments result be.

A measure can be extremely reliable but have no validity whatsoever. Validity is the extent to which the scores from a measure represent the outcome they are intended to measure and is commonly judged through three main aspects: face, content, and criterion. Face validity is the extent to which a measure appears "on its face" to assess the outcome of interest and represents a very weak kind of evidence that a measure is measuring what it is supposed to. Construct validity is the extent to which a measure "covers" the outcome of interest and is assessed by carefully checking the measurement method against the conceptual definition of the construct. Criterion validity is the extent to which scores on a measure are correlated with variables that one would expect them to be correlated within reasons of their interconnection with the outcome of interest. When the criterion is measured at the same time as the construct, criterion validity is referred to as concurrent validity, while when the criterion is measured to predict a future outcome, it is referred to as predictive validity. Criteria can also refer to other measures of the same outcome, which is known as convergent validity.

Although in the last two decades, new outcome measures have been developed with increasing reliability and validity, practices for persons with ID/ASD have continued to rely on traditional ones concerning objective and standardized aspects of health, such as symptoms intensity and pervasiveness, biomarkers (blood tests or radiographic images), behavior, functioning, mortality, hospital, and services utilization, or other aspects related to morphological and functional integrity [13, 14]. The theoretical model of these traditional measures was developed for the general population and foresees that therapeutic, rehabilitative, and educational interventions tend toward normalization, that is to make a person as close as possible to the structure and functioning of most people. These measures have the advantage of being easy to measure, highly reliable, and suitable to a system for costing mental health services that links quality and outcome to funding, but they lack

appropriateness, responsiveness, precision, acceptability, and feasibility for ID and ASD population, in particular, they do not include actual possible goals of many conditions of disability and fail to capture the patient's experience [2, 7].

Traditional outcome measures concerning objective and standardized aspects of health have the advantage of being easy to measure, highly reliable, and suitable to link healthcare quality and outcome to funding, but they do not include actual possible goals of many conditions of disability and fail to capture the patient's experience.

14.2.3 Functioning

Individual "functioning" is an umbrella term which has been used across time with very different meanings and in reference to very different characteristics of human beings and their environment as well as life activities. The focus of functioning as one of the last 25 years' most important outcome measures of interventions for persons with ID and/or ASD [15] reflects the 1980s' and 1990's movement away from a primary emphasis on diagnosis and classification to a prevalent consideration of planning and provision of individualized supports [16]. In fact, research findings of the last few decades showed that medical diagnosis alone does not predict service needs, level of care, work potential, the likelihood of social integration or functional outcomes, and that the incidence and severity of disability in a population can be reduced by modifying those features of the social and physical environment that can enhance the functional capacity of persons and improve their performance [17]. This increasing consideration in healthcare of people with ID/ASD and other lifelong disabilities of aspects other than those defined by the impairment has implied the medical and the social models to interact with each other and try to come to a common ground.

The medical model deals with disabled bodies and minds for their part that is considered to be pathological or defective, while the social model approaches disability for what results from attitudes and other features of the social environment.

A relevant attempt to measure the impact of illness and its consequences on individual functioning was realized in 1980 by the World Health Organization (WHO) through the International Classification of Impairments, Disabilities and Handicaps (ICIDH) [18]. The ICIDH is based on a tripartite distinction between impairment, disability, and handicap, where impairment refers to a loss of structure, or abnormality of function at the organ level, disability to a restriction of actions at the person level, and handicap as a set of disadvantages within the individual's social context [19]. Comparison of impairment and disability profiles highlights the role of functional limitation in mediating between disease (medical model) and disability (social model).

Another interesting perspective toward understanding the implication of human functioning in the definition of disability, specifically ID, was proposed by the American Association on Mental Retardation (currently American Association on Intellectual and Developmental Disabilities; AAIDD) in its 1992 manual [20] and further refined in 2002 [21]. In this view, substantial limitations of functioning and associated dimensions, determined by the dynamic interaction between health condition and environmental factors, represent the main diagnostic criterion for ID and the main outcomes to be pursued through an adequate system of interventions and supports. This enhancement of human functioning has to address all its dimensions, which are identified in intellectual abilities, adaptive behavior, health, participation, and context [22]. Intellectual abilities include reasoning, planning, problem-solving, thinking abstractly, comprehending complex ideas, learning quickly, and learning from experience; adaptive behavior, on the other hand, refers to the collection of conceptual, social, and practical skills that have been learned and are performed by persons in their everyday lives. However, health describes a state of complete physical, mental, and social well-being; participation

addresses the performance in actual activities of social life domains; context refers to all the interrelated conditions within which persons with ID live their everyday lives; and context represents an ecological perspective that involves the micro (family and immediate social setting), meso (neighborhood, community, and support services), and macrosystems (overarching patterns of culture and socio-political influences) around the person. Furthermore, as mainly defined by the level of individual functioning, ID is no longer seen as necessarily a lifelong condition, but its existence or degree is dependent on the provision of appropriate supports [21].

A similar framework was proposed around the same time by the WHO in the International Classification of Functioning, Disability, and Health (ICF) [17], which represents the evolution of the ICIDH and the main reference system to date for the definition of functioning as a descriptor of health and health-related states. In ICF, human functioning is articulated in the three levels of body or body part, the whole person, and the whole person in a social context, while disability refers to impairments, activity limitations, and participation restrictions (see Table 14.2).

The ICF "mainstreams" the conditions of ill-health and disability and redefines them as universal human experiences by acknowledging that every human being, not only a minority of the population, can experience a decrement in health and thereby some disability. By shifting the focus from causes to impact, it also places all health conditions on an equal footing allowing them to be compared using a common metric.

The ICF is based on the biopsychosocial model [23] and provides a coherent view of the biological, individual, and social perspectives of health. As such, it complements the International Classification of Diseases [24] to create a broader and more meaningful picture of the experience of the health of individuals and populations.

At the beginning of the last decade, the AAIDD produced an upgrade of its systems approach to human functioning, whose input and impact (output) could be evaluated based on three human functioning outcomes: social-economic status, health status, and subjective well-being [25, 26]. This model reflects the twenty-first-century style of systems thinking, synthesis, and alignment, which focuses on the factors that affect human functioning, integrates information from multiple sources, and places critical organization and system functions into a logical sequence. These out-

Table 14.2 Levels of human functioning classified by the ICF

Level	ICF component	Definition
Body or body part	Body structures	Anatomical parts of the body such as organs, limbs and their components
	Body functions	Physiological functions of body systems (including neuropsychological and psychological functions)
	Impairments	Problems in body function or structure such as a significant deviation or loss
Whole person	Personal factors	Particular background of an individual's life and living, such as gender, age, coping styles, social background, education, profession, past and current experience, overall behavior pattern, character
	Activity	Execution of a task or action by an individual
Whole person in a social context	Environmental factors	Physical, social, and attitudinal environment in which people live and conduct their lives
	Participation	Involvement in a life situation

come measures were proposed in responsive to the move toward evidence-based practice, quality management of health and social services, and the need for indicators associated with subjective well-being and human rights [25, 27]. A further extension of this concept has been developed recently, to address the current scientific and cultural shift from a person-environment paradigm to a multidimensional contextual paradigm. According to this update, context is defined as "a concept that integrates the totality of circumstances that comprise the milieu of human functioning" and is conceptualized as being multilevel, multifactorial, and interactive. The multilevel component describes the ecological systems within which people live, are educated, work, and recreate. The multifactorial component refers to the potentially influential factors within the ecological systems, and the interactive component identifies the variety of ways in which levels and factors interact to influence personal outcomes [28].

In the ICF, functioning is conceptualized as the result of a dynamic interaction between individual health conditions, environmental factors, and personal factors. This conceptualization is aligned with a biopsychosocial model of disability, based on an integration of the social and medical models of disability.

14.2.4 Empowerment

Since the 1980s, empowerment has been recognized by the WHO and other health agencies around the world as a core concept in health promotion [29] and has been used widely in the disability field to describe both a desirable process and a desirable outcome for health and social policies and services. It reflected a parallel development of the areas of advocacy, consumer rights, and professional practice and integrates the achievement of social equity.

One major contributor to the development of the concept of empowerment was the social scientist Julian Rappaport, who defined empowerment as a "concept that suggests both individual determination over one's life and democratic participation in the life of one's community … both a psychological sense of personal control or influence and a concern with actual social influence, political power, and legal rights" [30]. Furthermore, he indicated that "empowerment is a process by which people, organizations, and communities gain mastery over their affairs. Consequently, empowerment will look different in its manifest content for different people, organizations, and settings" [30].

Empowerment appears in the literature of several disciplines such as psychology [30–33], social welfare [34–40], education [41–43], and medicine [44, 45], especially psychiatry [46–48].

Despite its widespread use across decades, a systematic definition of the concept is still lacking. It has much intuitive appeal and arouses images of growth, fulfillment, triumph, righteousness, and achievement of justice despite circumstances that may hinder such an outcome. Empowerment is more often defined according to some of its anticipated outcomes rather than its very nature [49]. In the field of mental health, empowerment refers to the level of choice, influence, and control that users of mental health services can exercise over events in their lives. The keys to empowerment are the removal of barriers between individuals, communities, services, and governments, the attention to self-help and self-reliance of service users, and the recognition that services may be delivered in ways that promote, rather than inhibit, personal growth and focus on individual strengths instead of deficiencies [37, 50, 51]. Rappaport argued that empowerment may be easier to define by its absence (e.g., alienation and powerlessness) than by its presence [52].

Dunst and collaborators asserted that the term empowerment has been used in six interrelated ways, such as philosophy, paradigm, process, partnership, performance, and perceptions, which can be further grouped into the three key elements of ideology (comprising philosophy and paradigm), participatory activities (including process and partnership), and outcome indicators (comprising performance and perceptions) [53].

Table 14.3 Key components of empowerment

Component	Description
Self-efficacy	Belief in the ability to produce intended results; self-perception of being capable of exercising some control over the quality of life
Participation and collaboration	A collaborative relationship between help-seeker and help-giver in which the former is encouraged to assume as much responsibility as possible in decision-making
Sense of control	The attribution of attitude or behavior change to one's own actions; it is rather near to the concept of *locus of control* (see ► Chap. 10), which represents an allied construct of empowerment
Meeting personal needs	Empowering interventions must address the needs and aspirations of individuals in ways that may make the individual more capable and competent
Understanding the environment	Aspects of the environment that an individual may utilize to meet his/her own needs
Personal action	Taking personal actions to address a need. Several authors pointed out that it may not be an essential component of empowerment, since empowerment may also be expressed in ways other than personal action such as an improvement in attitude about dealing with a problem or an increased awareness of the options that may be pursued to meet a personal need
Access to resources	Personal influence on the possession of relevant resources, information, and skills. Resources include sources of support such as friends and relatives, community groups and organizations, government assistance, and self-help groups

At the end of the last century, a literature review by Dempsey and Foreman [54] found some explicit and implicit similarities between various definitions of empowerment as an outcome of disability service provision and some general consensus on its components. They also identified key components of these definitions of empowerment through a process of content analysis, which are summarized in Table 14.3.

Several attempts have been made to integrate the components of empowerment into a consolidated model, with three component models being the most common which includes personal, interpersonal, and community (or political, or social, or behavioral) level engagement [55–57]. Koren and colleagues proposed to add a second dimension of classification referred to as individual expressions of empowerment comprising three components, attitudes, knowledge, and behavior [58]. A very comprehensive model has been developed by Dunst and colleagues, which includes three dimensions (levels, form, and context) articulated in a 96-cell matrix. It provides a precise framework of the concept of empowerment and offers a schema to conduct research that may systematically refine theoretical assumptions [53].

A wide range of scales have been developed for the measurement of empowerment, but the qualities of these have not been rigorously assessed. A systematic evaluation was carried out by Cyril and colleagues using the following six criteria: use of an a priori explicit theoretical framework, content validity, internal reliability, structural validity, confirmatory factor analyses to determine internal construct validity, and external construct validity. Only 9 (45%) studies on as many tools were rated as high quality (15% of studies scored 6 and 30% scored 5), 10 (50%) studies were rated as medium quality (30% scored 4 and 20% scored 3), and 1 study was rated as poor

quality. The vast majority of studies measured individual empowerment, only 15% measured community (10%) and organizational (5%) empowerment [59].

In the field of ID and ASD, empowerment has received a lot of attention in research and social-health policy papers over the last decades and it has been reported as the main outcome of self-advocacy [60]. Some studies found support and assistance to families, programs of rehabilitation from education services and non-governmental organizations to be key aspects in the development of social empowerment of persons with ID/ASD [61–69]. Other studies indicated a significant contribution of social empowerment on life quality, social well-being, and social welfare, while communicative empowerment has been shown to improve personal communication skills [61, 69–74]. Some authors have also suggested standards and indicators to facilitate the social empowerment of individuals with ID related to social justice, healthcare, social rehabilitation, and job opportunities [61].

Many important aspects have yet to be explored or addressed, some of which have great implications for applying empowerment to daily practices such as the extent to which empowerment is influenced by the severity of cognitive and other individual characteristics, stability of empowerment over time, the importance of behavioral versus attitudinal components of empowerment, the nature of the relationship between empowerment and community intervention, the overlap and the differences between empowerment and whole-person quality of life (see ▶ Chap. 15), and the extent to which persons with more severe ID may become empowered.

Despite its widespread use, a systematic definition of empowerment is still lacking. In the field of mental health, it refers to the level of choice, influence, and control that users of services can exercise over events in their lives. Fundamental aspects are represented by the promotion rather than inhibition of personal growth and the focus on individual strengths instead of deficiencies. Research on ID and ASD found improvement of communication skills, support and assistance to families, programs of rehabilitation from education services and non-governmental organizations to have a major positive impact on personal empowerment.

14.2.5 Person-Centered Outcome

During the last four decades, there has been a profound transformation of practices and interventions addressed to persons with ID and ASD. The typical models of treatment and rehabilitation, mainly aimed at restoring structures and functions that have been affected by the developmental disorders and any co-occurrent morbid conditions, have progressively been shown as inadequate to these persons and gave way to new multidimensional and person-oriented approaches, which pointed at promoting satisfaction with life regardless of the severity of disability and co-occurrent physical and mental health issues. In fact, setting the goal of therapeutic interventions for people with ID/ASD on the achievement of a personal functioning that is as similar as possible to that of people with typical development is not just unreasonable but may favor the development of prejudices of irrecoverability and health disparities [75].

This progressive, sometimes nonlinear, change of models also involved the definitions of ID and ASD, leading to the adaptation of the main nosographic systems [76, 77], the legislative framework, the services organization, the planning of therapeutic-rehabilitative interventions, and the consideration of the person with ID and/or ASD as part of society.

The adoption of a "person-centered" perspective, based on holistic, multidimensional, and bio-psychosocial definitions, is fundamental in the evaluation of the outcomes of the interventions and the state of health of persons with ID and/or ASD. In fact, the physical and mental health needs of this population address an area of care that straddles health and social services, general and specialized medicine, services for the developmental age, adulthood, and aging.

This broadening of focus in the measurement of health, beyond traditional health

indicators started in the second half of the last century, when the increasingly mechanistic model of medicine, concerned only with the eradication of disease and symptoms, raised the need for the introduction of a humanistic element into healthcare (revalued in its component of humanistic transaction) and the consideration of the patient's well-being as a primary aim. In that time, the WHO expanded the definition of health to "a state of physical, mental and social well-being, not merely the absence of disease and infirmity" [78, 79] and suggested to policy makers to increasingly include measures of the impact of disease and impairment on daily activities and behavior, perceived health measures, and measures of functional status. Nevertheless, while beginning to provide a more articulated perspective of the impact of diseases and their treatment on patients' life, these measures did not include patients' desires, values, family situations, social circumstances, and lifestyles [80].

The increasing emphasis of the last two decades upon person-centered outcomes in healthcare, and related disability and rehabilitation literature, seems to have represented an attempt to contrast the persistence of the tendency to focus outcome measures of interventions on illness and disability, rather than health and ability. That is, health continues to be seen primarily as the absence of illness or disability rather than a resource for daily living [81]. On the contrary, person-centered care, especially mental healthcare, see patients as individuals to work with rather than passive recipients of aid and tries to help them to feel satisfied with their own lives in ways that are customary to them and valued by them [14]. These and other main principles underlying person-centered care that have been found by research to be most important for affecting outcomes are summarized below:

- Approaching the patient as a person
- Identifying patient's values, interests, preferences, and goals
- Seeing the patient as an expert about their own health and care
- Providing good communication, information, education, and emotional support
- Involving family and friends
- Sharing power and responsibility
- Taking a multidimensional approach to assessing people's needs and providing care (continuity between and within services).

In this sense, person-centered outcome measures do not coincide with subjective outcome measures but represent only a part of them. In fact, as mentioned earlier in the text, many subjective outcome measures refer to the patients' perception of their own clinical condition or functioning compared to that expected by the norm. On the other hand, person-centered outcomes include some objective measures, whose relationship with subjective ones has yet to be clarified as well as the impact of personal characteristics (i.e., cognitive profile, adaptive skills, and problem behaviors) and environmental variables (i.e., living arrangement, family, professional caregivers, services) on the variation of either objective or subjective outcomes.

Perry and collaborators found person-centered outcome measures, such as satisfaction, to correlate little with objective indicators and to be not predicted by personal and environmental characteristics. In contrast, objective measures of other subjective outcomes, such as choice, involvement in activities, and social and community affiliation were significantly dependent on personal and environmental characteristics [82].

The literature is consistent in pointing out that person-centered outcome measures can promote the development of a more accessible, efficient, and cost-effective service network to provide effective and satisfying assistance.

In the United States, Australia, and European countries, where the implementation of healthcare models based on this type of approach is prevalent for a long time, the most important obstacles have been the resistance to change in the philosophy and culture of care, problems related to financing, the high turnover of staff, and the lack of experience of professionals involved in management and organization [83–85]. A very interesting contribution was provided by the International Network of Person-Centered

Medicine (INPCM), which proposed the use of evaluation and intervention procedures based on the collaboration between clinicians, patients, and family members, in perspective which is complementary to the traditional nosological one [86].

Contrary to what is commonly believed, person-centered outcome measures can favor the development of a more accessible, efficient, and economical services network.

Person-centered outcomes focus on holistic and multidimensional aspects of health than symptoms intensity or pervasiveness of a disease or a disorder. Thus, person-centered outcome measures do not coincide with subjective outcome measures, which instead may refer to traditional clinical indicators.

14.2.6 Subjective Well-Being

The term subjective well-being (SWB) refers to a general area of scientific interest rather than a single specific construct as it is commonly used to describe a broad category of psychological phenomena that include individual emotional responses, feeling, and mood (e.g., contentment, happiness, absence of depression, or anxiety), satisfaction with different aspects and situations of life, fulfillment and positive functioning, and global judgments of life satisfaction [88–90]. Thus, SWB is often subdivided into different constructs, which correlate substantially with each other and need to be specified in their own [90]. In some contexts, SWB is used in a restrictive way with a specific reference to good living conditions (e.g., housing, employment). Tracking these conditions is important for public policy. However, many indicators that measure living conditions fail to measure what people think and feel about their lives. According to Knight and McNaught, SWB has to be understood as dynamically constructed interconnections among people's circumstances, locality, activities, and psychological resources, including family and wider interpersonal relations [91].

In simple terms, well-being can be described as judging different aspects of life positively and feeling good. In the field of mental healthcare, emotional well-being and psychological well-being (e.g., feeling very happy and full of energy) are viewed as critical to overall well-being. The different aspects of well-being that have identified and examined by researchers from different disciplines [87, 89, 92–96] are summarized here down:

- Physical well-being
- Economic well-being
- Social well-being
- Development and activity
- Emotional well-being
- Psychological well-being
- Life satisfaction
- Happiness
- Domain-specific satisfaction
- Engaging in activities and work

Emotional well-being, happiness, and satisfaction are closely related. Cummins asserted that "some combination of happiness, or positive affect, and life satisfaction" are frequently involved in the definition of SWB, "but while such a view has intuitive appeal and face validity, closer inspection reveals very different ideas on the nature of the component parts and almost no information on how the components combine. Some authors simply declare happiness and life satisfaction to be synonymous, but this view is not supported by a considerable body of literature. Measures of happiness and satisfaction share a maximum of 50–60 common variance. These data confirm the view expressed by others that while happiness and satisfaction may indeed form part of the SWB construct, it is heuristically useful to measure and analyze them separately" [97]. According to Helm, happiness represents one component of satisfaction and is more transitory than the latter, as it reflects the positive and negative affects of positive or negative emotions and moods [98]. Satisfaction has been appointed by Diener, Cummins, and other authors to express global judgments about one's life overall or specific life domains, to show trait-like stability over time, and to be not predicted by environmental situations or personal characteristics such as skills or challenging behaviors [87, 99–101].

Considerable research involving the predictors of SWB in the general population has been done by Myers and collaborators, and Cummins, who have found that people are happier with overall life than one might expect (average of 6.5 on a scale from 0 to 10) and that happiness seems to be associated more with a combination of personal characteristics and sociocultural factors, such as extroversion, meeting intellectual challenges, social belonging, social support, health, religiosity, personal freedom, and income, than with external circumstances and individual backgrounds such as age, economic class, race, and education level [97, 102, 103].

One aspect of high importance is the individual capacity to change the way of thinking about one's own life. Brickman and Campbell argue that an individual can learn how to be more optimistic by changing how they think about themselves [104].

The development of the concept and application of SWB started in the process of implementing research on the quality of life (QoL) with consequent confusion between the two concepts, which is still frequently found. SWB is often regarded as a subjective or psychological aspect of QoL [105]. Actually, the two concepts, although presenting some overlap and interconnection, have been progressively distinguished. QoL represents a complex evaluation of the quality level reached by an individual in those aspects of life that can apply to anybody's life, whereas SWB refers to an affective state toward any aspect of life. Cummins [106] claims that the QoL variables that are closest to SWB are the least sensitive, while Diener and Suh [107] think that measures of SWB, economic indices, and social indicators can complement each other in assessing QoL.

Despite a voluminous literature on the general population, there are only a handful of studies on SWB on individuals with disabilities. Results from available studies show that the persons with disability have a significantly lower SWB than persons without disability and among the former, the lowest level of SWB is reported by individuals between the age of 45 and 54 and by those with physical health impairments as compared with those with mental disabilities and sensory impairment [108]. In the field of ID, research appears to have been limited by measuring issues such as the construction and administration of scales, and validity or reliability of self-reports. Proxy reporting, which involves the provision of responses by another person (e.g., a relative, friend, healthcare professional) on behalf of the person with ID, has also raised serious concerns about its reliability and validity and whether it accurately reflects the perceptions of the individual concerned [109, 110].

An interesting line of research was conducted by Cummins and colleagues, who also adapted for mild and moderate ID a tool widely used in the general population, the Personal Wellbeing Index [111]. This scale includes eight life domains (standard of living, personal health, achievement in life, personal relationships, personal safety, community connectedness, future security, and religion/spirituality), which represent the first-level deconstruction of "life as a whole" and provide insights into the various aspects that shape SWB [99, 112, 113]. The authors of these studies also formulated a theory to explain a possible cause of the repeated finding of similar levels of SWB in individuals with and without ID [113–115]. This theory, named "theory of SWB homeostasis," posits that all humans, independently form their cognitive characteristics, have the psychological ability to homeostatically maintain levels of SWB within a relatively narrow range even in the presence of persistent adverse factors [116–118]. A similar theory was developed by Brickman and Campbell with the name of "hedonic treadmill," which is focused on the idea that individuals tend to fast adapt to changes in life and return to the baseline level of happiness [104].

In persons with ASD, IQ and happiness emerged as highly interconnected central factors that can funnel and influence the network of factors more than others [119, 120]. Self-reported IQ appears to be connected to SWB indirectly, as a resource that allows the individual to engage in social relations and adaptive functioning and increase in turn self-esteem, self-confidence, and self-efficacy [120, 121].

Also, social satisfaction emerges as highly important for SWB in persons with ASD. Nevertheless, the number of social contacts from different contexts (such as family, work, leisure activities) does not seem to influence SWB directly, but merely through one's satisfaction with these contacts [120, 122]. Moderate use of Facebook has resulted to enhance SWB and has a protective action against co-occurrence of anxiety and other mental health issues [123].

One of the strongest risk factors for low SWB in ASD has been reported to be the number of physical problems [120]. Pain and physical stress also act as causes or triggers for problem behaviors that, in turn, seem to influence an individual's level of well-being [124]. Another factor with a considerable negative impact on SWB is the co-occurrence of other neurodevelopmental disorders or other psychiatric disorders [121].

- SWB is commonly used to describe a broad category of psychological phenomena that includes emotional responses, feeling, and mood, satisfaction with different aspects and situations of life, fulfillment and positive functioning, and global judgments of life satisfaction.

- Despite a voluminous literature on the general population, there are only a handful of studies on SWB on individuals with disabilities. In the field of ID, research has been limited by measuring issues such as the construction and administration of scales, and validity or reliability of self and proxy reports.

- In persons with ASD, IQ, social relations, adaptive functioning, and physical problems have been reported among the factors with the highest impact on SWB.

14.2.7 Quality of Life

Among person-centered approaches, Quality of Life (QoL) has raised particular interest in the scientific community in the last three decades with a large number of publications of research and conceptual articles as well as textbooks. At present, QoL is an important and commonly held goal in services and supports for people with ID and ASD and takes place across all interventions such as social care, education, and medicine, especially in psychiatry.

Despite its long history in the literature and the last decade's shift of scientific interest from theoretical issues and implications to ways of measurement, there is still disagreement as to how QoL should be defined and measured.

The quality of existence has been an important human concern since antiquity and can be placed at the origin of ethics and philosophy. The duty to care for the quality of living of those who have a disability represents the principles of charity and brotherhood which were already shared in early Christian societies and which were included in philosophic models of the state since the renaissance [125, 126]. Nevertheless, scientific research into the concept of QoL gained prominence only following Thorndike's [127] work on life in cities and environmentally based social indicators. In the 1960s, large cross-cultural studies were carried out, which aimed at investigating QoL in different countries, with a prevalent reference to socio-economic indicators, infant mortality, opportunities for access to study, work, and healthcare. A more individual-focused approach was developed in the 1980s, especially in the United States, although the first research aimed at systematically exploring the subjective perception of psychiatric patients about their living conditions was carried out already in 1969 by Fairweather and collaborators within a wider evaluation of the outcomes of a program of community intervention [128]. During this period, various models and definitions of personal QoL were produced, among which the three that have most influenced the evolution of the concept up to now: the satisfaction model, the importance-satisfaction model, and the role functionality model.

The first two models basically refer to a subjective perspective, which favors the subjective experience of persons with disabilities and/or mental health problems, the third

instead refers to an objective perspective, which favors objective indicators of QoL, such as social, environmental, and occupational conditions.

According to the satisfaction model, initially proposed by Lehman and collaborators [129], and Baker and Intagliata [130], QoL consists of the subjective perception of satisfaction with life, determined by the relationship (or gap) between current living conditions of a person and those conditions desired by the same individual. This gap has been called the Colman's gap, from the name of the scholar who elaborated it [131]. The satisfaction model includes three components: personal characteristics, objective living conditions in various areas of life, and personal satisfaction with the same areas [132]. McDowell and Newell [133] suggested that QoL "relates both to the adequacy of material circumstances and to people's feelings about these circumstances" (p. 205), while Coulter [134] defines QoL as "a sense of personal satisfaction with life that is more than just pleasure or happiness and yet something less than meaning or fulfilment" (p. 61).

The combined importance-satisfaction model incorporates both the subjective satisfaction with the various areas of life and the importance that each of these areas has for the person. Importance, which is aligned with preferences, desires, expectations, and values, significantly influences the subjective perception of QoL and allows to explain why persons living in totally different conditions can express similar levels of satisfaction or, on the other hand, why persons living in very similar contexts perceive very different levels of satisfaction [135].

The combined importance-satisfaction model is the model on which two of the main QoL evaluation tools for persons with ID and/or ASD are based, which are the one of the WHO [136, 137] and that of the Toronto University [138, 139]. The WHO defines QoL as the "individuals' perception of their position in life in the context of the culture and value systems in which they live, and in relation to their goals, expectations, standards and concerns" [140], while the researchers of the Toronto University refer to "the degree to which a person enjoys the important possibilities of his or her life" in the three categories of "being," "belonging," and "becoming," which respectively describes who one is, how one is not connected to one's environment, and whether one achieves one's personal goals, hopes, and aspirations [141]. This model of the Toronto University is linked in a straightforward way with the Hans Reinders' QoL concept and the well-known capability theory proposed by Amartya Sen [141]. According to Reinders [142], a dynamic approach to QoL "is oriented toward the goal of human flourishing. Human beings flourish to the extent that they are enabled to develop their own capabilities … when they receive sufficient opportunities to develop their own gifts and talents". In Sen's perspective, agency goals are those objectives that people set themselves, even if they do not benefit directly from them, or indeed even if they undermine other capabilities [141].

The role functionality model is based on the assumption that the social environment demands a variety of role performances from the individual. For example, in the friend role, one is expected to support, give advice, be loyal, and protect. In the work role, one must concentrate, get along with colleagues without excessive conflict, be punctual, and be productive. The individual meets society's demands through his cognitive, affective, behavioral, and perceptual abilities, and he/she receives in return opportunities to have his or her needs satisfied. As far as adequate satisfaction and performance are achieved, the individual is adjusted to his or her social context and has a high QoL [143].

In other words, in this theoretical framework, QoL consists of a state of satisfaction for the individual related to the extent to which he/she meets the performance requirements of his or her environment. At the level of the social and healthcare system for mental health, the negotiation between client's and service's outcomes is expressed in this QoL model under the heading of satisfaction and performance (functioning), which together constitute adjustment.

An alternative classification of QoL models has been proposed by Borthwick-Duffy,

based on the following four main groups: life conditions, satisfaction with these conditions, a combination of life conditions and satisfaction, and a combination of life conditions and satisfaction modulated by personal values, aspirations, and expectations [144].

Michalos carried out a thoughtful analysis of the various uses of the term "quality" in QoL, finding that at a minimum it can describe the characteristics of a population, such as gender, income, age, etc., while in a second sense, it can depict the value or worth of something. Michalos termed the former as the descriptive use and the latter as the evaluative use of quality in QoL [145].

Cummins argued that one of the characteristics of a good QoL model and measure is that it should refer to characteristics of individual life that are shared with other people (shared QoL) and enable comparison between groups of people regardless of their characteristics, including cognitive and relational difficulties [146, 147]. Other main characteristics of a good QoL model are the consideration of the person as a whole (whole-person QoL) and the exclusion of standardized goals. The QoL approach has to be interpreted in qualitative rather than quantitative terms, as it does not coincide with the achievement of a high quality of living but with an exploration of the rich intricacies of the personal perception of quality toward life and the provision of a way for healthcare professionals to view the patient-person and his/her relationship with the system of care. QoL assessment should not represent a classification of individuals, services, or systems, but it should help provide, within service systems and organizations, a value system that is consistent with those values held by people with ID/ASD [14].

In contrast to this view of whole-person QoL, a completely different interpretation has been publicized widely over the past two decades with the main focus on those domains of life that are considered to be affected by a particular illness. This branch of QoL practice and research, which is called health-related QoL (HR-QoL), typically tries to measure both the degree to which symptoms of a specific disease are present and their effects on daily functioning. Thus, although it focuses on the individual in a way that is of some benefit, they still support a theoretical perspective of QoL that has not significantly departed from the traditional medical approach [14].

In the field of ID/ASD, QoL models and measures are further distinguished on the basis of the consideration of personal QoL and family QoL. The first aspect proceeds from the fact that each individual has a changing set of personal attributes that determine the subjective experience of life, while in the second aspect, shared and personal QoL are applied to the family that includes a person with ID/ASD. Disability impacts the whole family and the determination of appropriate conceptualization of family outcomes requires an understanding of the impact of members with a disability on family QoL [148, 149].

At the current state of knowledge, it seems that the best way to carry out a QoL assessment is to follow a comprehensive approach, which integrates subjective and objective aspects, self-reports and multiple evaluations [150]. Such assessment may be used effectively with all people with NDD, independently from the severity of their functioning impairment. Individuals with higher communication and cognitive limits may express their inner states through consistent behavioral repertoires, which can be discerned by people closest to them and validated by more independent others. A good example of how this can be implemented is the Lyons' Life Satisfaction Matrix [151].

The field of QoL has developed rapidly, and QoL measures have been improved to a degree that they have several solid uses. Still, there is much to do, as currently available tools, although they have some common conceptual and evaluation characteristics, still show considerable differences in the areas to be included in "shared QoL," the dimensions used to evaluate "Individual QoL," and the role attributed to indicators of QoL.

A more detailed discussion of all the aspects of QoL mentioned in this paragraph and other aspects has been provided in the specific chapter included in this textbook (► Chap. 15).

Despite its widespread implementation, QoL measurement is still associated with numerous problems, related to the definition of the QoL concept, the way it can be effectively measured, for whom, by whom, and to what purpose. QoL measures can be grouped as referring to three main aspects: shared QoL, personal QoL, and family QoL. An optimal measure should be as much comprehensive as possible in terms of areas of shared QoL and dimensions of individual QoL. QoL assessment should not aim at classifying individuals, services or systems, but at providing, within social and health services, a value system that is consistent with those values held by persons with ID/ASD.

14.3 Inclusion

Social inclusion is increasingly recognized as a key outcome for evaluating global mental health programs and interventions [152], particularly for persons with ID [153], who in many parts of the world are still excluded from participating in social environments, have limited opportunities to develop meaningful interpersonal relationships, experience stigma, discrimination, and lack of access to basic services [154, 155].

In the 1950s, families of children with disabilities who did not want to institutionalize their children began to advocate for schooling, day programs, and community homes for their children. Up until about the 1970s or so, children with disabilities could be excluded from school programs and there were few alternatives for adults. Once programs began to start, however, many were segregated ones—for example, special schools, special classrooms just for students with disabilities, and special day programs.

As all students with disabilities started to attend school, and as more and more people with ID started to attend special day programs and live in community homes, advocacy increased for inclusive programs. Schools began to "mainstream" students. Homes started to be in regular neighborhoods, and people with ID began to work in community jobs. These shifts came about due to philosophical changes, advocacy, lawsuits, and legislation, for the right of individuals to live as normal a life as possible and to be as integrated as possible with the larger community.

The outcomes and benefits of such inclusion have been researched over the years, in several different ways. In school programs, the academic and social benefits for students with disabilities have been documented, as well as the benefits for students without disabilities. For adults, the benefits and outcomes of inclusion have been documented in residential, employment, and other community programs. There has also been some research about the benefits to other community members, with a call for additional research in this arena.

14.3.1 Overall Benefits and Current Outcomes

It is important to note that "inclusion" means not just physical presence in community settings, but also includes social inclusion, including interactions and relationships with other community members, and a sense of community membership and belonging. While many people with ID participate in community activities such as shopping and going to restaurants or movies, there is a great need to also increase their inclusive relationships. Physical inclusion has not necessarily translated to improved social inclusion for people with ID. As argued by Cummins and Lau [156], social exposure, as fostered through typical community living or employment settings, is not a suitable proxy for social inclusion in which a person with ID has rich social relationships and is also an active participant in his or her community.

Social inclusion of young adults with ID seems to be strengthened when social interactions are supported and streamlined through structured and guided social activities, which also increase the chances to foster new and stronger social bonds [157].

Relationships affect physical, mental, and emotional health. Extensive studies at the University of Chicago have found that

some health benefits of friendship include less depression, increased resiliency, and increased capacity to recover from adversity and strength to deal with stress [62, 158]. An example of effects on physical health includes a study of US nurses that found that nurses with no close friends were four times as likely to die from cancer as those with many friends [159]. Social relationships also play a vital role as a contributing factor to happiness in the general population [160, 161] and the role of social relationships in happiness has also been established among people with ID [162].

Despite the importance of relationships, many people with ID experience significant challenges in maintaining meaningful friendships and developing close relationships. Solish et al. [163] found that children with an ID participate in significantly fewer social activities with friends and have fewer reciprocal friendships than reported by fellow students who do not have disabilities. Buttimer and Tierney [164] reported that adolescents with ID spend more time without the company of close friends and more time alone than their age peers. Tint and collaborators [165] found that parents of adolescents and young adults with co-occurrence of ID and ASD identified social demands and peer relationships to represent barriers to community participation. Adults with ID consistently identify fewer friendships than those without disabilities. Also, the relationships they have are most often with other people with ID [166–168]. Bigby and Knox [169] surveyed older adults and senior citizens with ID and they reported that their closest relationships are primarily with other individuals with ID, paid support staff, or family members.

> It is important to note that inclusion means not just physical presence in community settings but also acceptance by other community members, interactions and relationships with them, and a sense of community membership and belonging.

14.3.2 Outcomes of Inclusion in School Programs

Benefits of inclusion for students with disabilities have been documented in several areas, including academic achievement, social capacities, and improved behavior [170, 171]. Students with disabilities who are supported in general education classes have been able to achieve grade-level academic standards [172]. Causton-Theoharis et al. [173] demonstrated that instruction in inclusive settings was more effective than self-contained classrooms in the acquisition, maintenance, and generalization of skills for students with disabilities. Instructional practices that are paired with tiered support improve learning for all students, those with and without disabilities [174]. Inclusive education has also been demonstrated to predict post-school success such as employment, postsecondary education, and independent living [175].

Inclusive school programs also benefit all students in the classroom, including those without disabilities. The use of differentiated instruction, which is tailored to fit individual needs, leads to increased student engagement and every student accessing the full curriculum. School inclusion creates a welcoming environment and a positive learning environment for all students [176].

14.3.3 Inclusion for Adults

Several studies have found that individuals with ID in the services system have a paucity of a variety of relationships in their social networks. For example, Verdonschot and his colleagues [177] found that there was an average of 3.1 people in the social network of individuals with ID, and that of those relationships, one of the 3.1 was a staff member. They contrasted the small size of these social networks of people with ID with studies of the general population, which have found an average of up to 125 people

in the social networks of those without disabilities [178]. Emerson and McVilly [166] found that people with ID reported that they typically had only two instances of engaging with a friend in a 4-week period, and none of those were typically with an individual without ID.

The experience of loneliness and feelings of isolation are a common experience for adults with ID. Studies in the United States and Australia have found that up to half of persons with ID experience frequent feelings of loneliness [179, 180], as opposed to reports in the general population of 15–30% experiencing loneliness [167]. Thus, although many individuals with ID are physically integrated into their community and frequently participate in community social activities, they still report few close friends and a lack of meaningful social connections in the community [181].

Many research and demonstration projects have shown that there are simple, pragmatic ways that can be used to increase relationships and a strong sense of belonging and community membership. A summary of many of these programs can be found in Amado, Stancliffe et al. [182] and include interventions in faith communities [183], local neighborhoods [184], recreational programs [185], and retirement networks [186]. Volunteering, for example, is one useful avenue in supporting adults with ID to establish meaningful, socially valued roles in their communities, particularly in the absence of paid employment [187]. Furthermore, participation in spontaneous and voluntary engagements has been reported to foster more valued accounts of social interaction and a better quality of social roles with people without disabilities, compared with the more organized social activities [157].

While interventions such as these have been demonstrated to be successful in increasing social inclusion, they are yet to be brought to a larger, community-wide, or system-wide scale.

14.3.4 Outcomes for Community Members

Mahar et al. [188] among others have noted the power of inclusion to truly impact the lives of people both with and without disabilities. There have been a few studies that have documented the benefits and outcomes of inclusion for those without disabilities. Chadsey and Beyer [162] and Irvine and Lupart [189], among others, have documented the beneficial outcomes to employers and co-workers of having employees with disabilities.

Amado and her colleagues [183, 190] studied two national programs in faith communities that were aimed at increasing the inclusion of people with disabilities. Congregation members reported increased outcomes of acceptance, knowledge, and relationship/emotional ties. Of congregations surveyed that had participated in the Accessible Congregations Campaign, some congregation members in 76% of the congregations achieved enduring relationships with their fellow congregants who had ID [191]. Respondents to surveys about the BeFrienders social ministry program reported that when the BeFrienders ministers became connected to individuals with ID, there were outcomes such as increased awareness of disability-related issues, recognizing gifts in all people, and closer relationships. In a study of membership of people with ID in community groups and associations in four US states [191], community members reported outcomes of increased tolerance/acceptance, learning experiences, recognition of talents and abilities, and friendship.

For older adults with ID, studies in Australia have demonstrated that social inclusion can be increased through recreation and volunteering as people with ID move into retirement. The transition-to-retirement program outlined by Bigby and colleagues [186] combined a gradual transition to retirement with opportunities for inclusion in community groups with other older adults without ID. Establishing mentors in these groups,

in which an older adult without ID assisted an older adult with ID become a part of the group, had positive results, both for the mentors and the mentees with ID [192].

14.3.5 The Measurement of Inclusion Outcomes

The challenge of measuring the outcomes of inclusion efforts is tied to the difficulty in measuring inclusion itself. Both physical and social inclusion have been conceptualized in a number of different ways and have faced the use of varying terminologies, including community "inclusion," "integration," "participation," and "belonging" [183]. The difference between these terms is not always clear, and the definition of each has varied.

Different authors have conceptualized the factors which compose inclusion in multiple ways, all of which would lead to differentiated approaches to measure and determine outcomes. Martin and Cobigo [193] proposed that social inclusion encompasses relationships, leisure, productive activities, accommodation, and informal supports. Hall [194], in her qualitative meta-analysis of the literature on social inclusion, concluded that six core themes defined social inclusion: (a) being accepted as an individual, (b) relationships, (c) involvement in activities, (d) appropriate living accommodations, (e) employment, and (f) supports. Simplican and colleagues [195] developed an ecological model of social inclusion and proposed that it consists of two domains: interpersonal relationships and community participation. They also posited that inclusion can be addressed at the individual, interpersonal, organizational, community, and socio-political levels.

In the absence of a unified definition of inclusion, examination of its outcomes becomes challenging. Most conceptualizations of social inclusion have included both dimensions of Simplican's [195] model: relationships (e.g., [193, 198]) and community participation (e.g., [177, 194, 196]). Community participation has been frequently studied in at least three different community environments: in neighborhoods, in recreational activities, and within faith congregations.

Different studies have utilized different measurement approaches. For example, McConkey [197] studied the degree of social inclusion for individuals with ID living in different settings in Ireland. Using the definition of social inclusion as the combination of the number of social contacts and uses of community resources, his measurements of these two factors found higher levels of social inclusion among adults who lived in semi-independent supported living arrangements, compared with those who lived on larger residential campuses. These results were also found in a similar British study [198].

Besides "inclusion," relationships and friendships are also defined in many different ways. Matheson et al. [199], for example, asked teens with developmental disabilities to identify the elements of friendship, and the teens in their study identified themes of doing activities together, companionship, sharing interests, and proximity. These are all factors that could be measured, and different outcomes evaluated.

Current measurement approaches of different elements of inclusion have varied, with some effort to determine both the quantity and the quality of inclusion. Many researchers have used the frequency of social activities to measure social inclusion, and some measurement instruments, such as the National Core Indicators [200], include questions about who else participated in the activity (e.g., staff, family, housemates, friends, etc.). Other common domains are connectedness and citizenship, with citizenship being the least covered. No single instrument measures all aspects within these most common domains [201].

While such measurements provide a solid foundation reflecting the degree of community participation, they do not effectively measure the degree of inclusion, personal satisfaction

with the social interaction, or other indicators that would indicate the level of the quality of the interaction. Qualitative studies have effectively examined some elements of the different degrees of quality in social inclusion efforts [194], but the quality has been difficult to measure precisely in quantitative studies.

Absent from many attempts to measure inclusion and its outcomes is individual preference and interpretation of one's own social involvement and interactions with others [165]. For example, it is often assumed that a wider social network including both more people and/or more community members without disabilities is preferable than only interactions with other people with ID. However, for a number of reasons, this may not be preferable to all people with ID. It is also often assumed that more social activities result in more satisfaction, but some individuals with ID may prefer a less active social life.

Ideally, the measurement of inclusion and its outcomes would account for individual preferences and self-determination. Measurement could then also gauge the extent to which an individual's vision of inclusion for themselves is fulfilled or not, as the contexts of personal experiences can either facilitate or hinder community involvement [202]. Since one size does not fit all, approaches to measurement and outcomes should include such individualization.

In this debate about how to define and measure the construct of inclusion, there is consensus that it goes beyond simple community presence or participation in activities, and that real inclusion embodies a true presence and relationships in the broader community. However, without a more unified theoretical understanding of the various elements of what entails inclusion, the measurement of the construct and its outcomes remains difficult, perhaps more than almost any other areas of supports and quality of life.

Inclusion has been conceptualized in a number of different ways and using different terminologies, such as community "inclusion," "integration," "participation," and "belonging." Core aspects of inclusion are being accepted as an individual, relationships, involvement in activities, appropriate living accommodations, employment, and support. No single instrument measures all aspects within these most common domains. Absent from many attempts to measure inclusion and its outcomes is individual preference and interpretation of one's own social involvement and interactions with others.

Tip

Future research and practice should address the actual possibilities of choice that are left to persons with ID by the members of their family, professional assistants, and the organization of services. Furthermore, there is a shortage of studies on community members' awareness of, acceptance, and respect for persons with ID.

Key Points

- There is considerable variability of outcomes definition and measurement, also according to numerous factors, such as specific intervention, clinical features, the person's own factors, and context of use;
- Outcome measures can be classified into four groups, clinical, economic, social, and person-centered;
- Outcome measures concerning objective and standardized aspects of health have the advantage of being easy to measure and highly reliable, but fail to capture the person's experience;
- Functioning is intended as the result of a dynamic interaction between individual health conditions, environmental factors, and personal factors. This conceptualization is aligned with an integration of the social and medical models of disability;
- Empowerment refers to the level of choice, influence and control that users of services can exercise over events in their lives;

- Person-centered outcomes focus on holistic and multidimensional aspects of health other than symptoms intensity or pervasiveness of a disease or a disorder;
- Subjective well-being is commonly used to describe a broad category of psychological phenomena that include emotional responses, feeling, and mood, satisfaction with different aspects and situations of life, fulfillment and positive functioning, and global judgments of life satisfaction;
- In persons with ASD, IQ, social relations, adaptive functioning, and physical problems have been reported among the factors with the highest impact on subjective well-being;
- Quality of life measures can be grouped in three main aspects: shared QoL, personal QoL, and family QoL. An optimal measure should be as much comprehensive as possible in terms of areas of shared QoL and dimensions of individual QoL;
- Inclusion means not just physical presence in community settings, but also acceptance by other community members, interactions and relationships with them, and a sense of community membership and belonging;
- Core aspects of inclusion are represented by being accepted as an individual, relationships, involvement in activities, appropriate living accommodations, employment, and supports.

Learning Objectives

This chapter explains what is meant by quality of life, and it explores how quality of life can be used as an outcome measure. Readers will learn that quality of life is a social construct, subject to changing meanings over time and place, and thus, its corresponding measurement is subject to change. They will come to understand that there is no absolute method to measure quality of life and that different approaches to measuring quality of life as an outcome may be taken according to the purpose of applying the measure. Whatever method is used, it is best interpreted the results through the lens of the lived experience of individuals and families.

15.1 Introduction

It has sometimes been said that the ultimate outcome of everything we do in human services, including the overlapping fields of mental health and neurodevelopmental conditions, is to enhance a person's quality of life (QoL). In the broad context of human services, we have set for ourselves quality-related goals and ideals that set the direction for us to follow in providing support, and our fields are developing more and more strategies that help us move in that direction. Ideals such as human equality, full and meaningful participation, respectful inclusion, and full access to opportunities for all dominate the thinking of those of us providing supports and services today because we have increasing evidence that moving toward such goals will result in a greater degree of quality in our lives.

Intellectual disability (ID) and other neurological disability alone can make this challenging, and it is even more challenging when such disability co-occurs with mental health and behavioral problems. For individuals and families who experience such challenges, it is particularly important for services and supports to focus on QoL. They need skills, strategies, and supports as tools to help them along the path toward quality living, and it is for this reason that innumerable ways have been developed, and are continuing to be developed, to help individuals take their steps forward.

An important aspect of stepping forward toward quality living is assessing the impact of our supports and interventions by taking outcome measures. The concept *quality of life* has increasingly gained a central and essential place in person-centered outcome measurement of supports and interventions for people with neurodevelopmental disabilities. QoL has been especially applied to individualized planning, assessing the impact of interventions, and evaluating the effectiveness of services and policies offered by professionals and professional organizations. As QoL is a developing approach to individual and family life, further development is occurring and more will occur in the future. In this chapter, we attempt to provide an overview of what has been developed and usefully employed to date, and to identify areas where further refinements, including in outcome measurement, are needed.

15.2 Understanding Outcomes and Quality of Life as Outcome Measures

Outcomes are the longer-lasting results of what we accomplish in human services. QoL measures of individuals or groups of people with neurodevelopmental disability, when taken and compared at points over time, can record longer-lasting changes in people's lives or aspects of people's lives. As such, they can be used as valid indicators of the effectiveness of the practices, structures, and environments we have in place, and of the actions we have taken – or not taken – to support them.

Outcomes are ongoing and lasting changes that occur as a result of something. In human services, we strive to bring about ongoing and lasting *positive* changes in people's lives. We then assume that such changes improve their quality of life.

15.3 The Importance of Quality of Life as an Outcome Measure

People with neurodevelopmental disabilities are among those for whom assessment of life quality is of particular concern. Compared to those without disability, or with other types of disability, people with neurodevelopmental disabilities have lower rates of employment, tend to be socially isolated, and are generally afforded fewer opportunities for meaningful community participation. To deal with the many challenges of their varied conditions and the barriers to inclusion that exist in our society, they often need specific, and sometimes unique, skills, strategies, and supports to use as tools in moving forward. In the past, we have not always recognized the need for all people with neurodevelopmental disabilities to experience quality in their lives, and thus the goal of achieving QoL is a relatively new one and an especially important one.

Services and supports for people with neurodevelopmental disability have fostered numerous types of helpful policies and organizational structures (the physical buildings, the many types of professional supports, skill development through training and education, etc.). They have, at the same time, recognized that such people, as well as their families and supporters, sometimes have personal needs and characteristics that need to be taken into account and addressed when providing support. The uniqueness of individuals is also an important guide for us in developing QoL strategies, because a great deal of what adds quality to any one person's life involves aspects that are of particular value and importance to each individual. Thus, enhancing quality of life for people with neurodevelopmental disabilities can and should be addressed at the policy, organizational, and personal levels, and quality of life outcomes are probably much better if all three levels are aligned in intent as well as in practice [1–3]. The position taken in this chapter is that professional duty to enhance QoL outcomes for people with neurodevelopmental disability is best achieved when a comprehensive approach – involving an amalgam of practices at the policy, organizational, and individual and family levels – is taken, and when all work together toward the same purpose.

> People with neurodevelopmental disabilities are an important focus for quality of life, because our services and supports to date have not always resulted in them experiencing the "goodness" of life. Quality of life outcome measures can help us identify strategies to help remedy this.

15.4 Two Approaches to Quality of Life Measurement in Health

The concept QoL is, by necessity, a general construct that is widely understood to describe the "goodness" of life. When applied to individuals, the concept describes a balance of the degree of "goodness" in the various aspects of a person's life and in its various circumstances. Several definitions and descriptions of QoL are available that try to capture this balance. One well-known such definition is provided by the World Health Organization (WHO) [4]: "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns" (p. 3).

The concept QoL overlaps somewhat with closely related concepts. *Standard of living* is sometimes used as a substitute for QoL, although high or low standard of living does not necessarily mean good or poor QoL, especially for individuals. *Happiness* is another term that is sometimes assumed to be synonymous with QoL, though, again, the two concepts differ because human beings characteristically create quality that relates to their own abilities, interests, and circumstances, and they often create happiness in circumstances that by other standards would not seem to be of high quality. Similarly, *life satisfaction* is not necessarily QoL, as humans often become satisfied in situations of low quality, especially when other needs are being met or when alternatives are not available.

When understanding QoL as a measure, then it is important to base measurement on the "goodness" of life as inherent to the concept, rather than on related concepts that may not fully capture quality.

Within the broad health field, two distinct ways of thinking about measurement using the QoL concept have emerged: generic or "whole-person" QoL and health-related QoL (HR-QoL). Generic QoL evaluates the perceptions of quality by people with respect to the full range of areas that have shown a qualitative value in human life – areas of life and values that are common to the human condition. The focus here is on the quality of a person's whole life as a social human being, regardless of the presence of particular pathologies, disabilities, or existential conditions. To date, the whole life of individuals has been measured by identifying life domains that are important across the human spectrum (e.g., positive social interaction), by identifying the most important indicators of those domains (e.g., friendships are an important indicator of social interaction), and determining specific ways to measure those indicators (e.g., number of close friends, time spent with friends, and ratings of satisfaction with friends might all measure friendships). Although this method of measuring QoL captures a great deal of the quality of most people's lives, it is not a full assessment. For example, time spent with friends may not be "quality" time or even highly enjoyable, and time spent on other activities that are not captured by the indicators of the domains may be much more important to the individual. Similarly, a person may be satisfied with her friends, but times spent with those friends may not be among the most enjoyable aspects of the person's life. On the whole, though, the generic measures that have been developed correlate highly with people's overall assessment of the quality of their lives [5].

HR-QoL is a more specific focus on QoL, relating to patients' or others' perceptions of their health status, and, more specifically, on physical and mental aspects of well-being and functioning (see the Quality of Life Instrument Database of the Mapi Research Trust for a list of available instruments; [6]). HR-QoL measures focus on either overall health and functioning or health and functioning as it relates to a specific disease or condition (e.g., cancer, arthritis, schizophrenia, depression, and many others). HR-QoL instruments typically try to measure both the degree to which symptoms are present and their effects on daily functioning. Thus, although these measures may not capture the broader range of life that generic QoL measures try to capture, they do expand upon the traditional medical approach (treating an identified problem) by considering the effects of identified diseases or conditions and treating them with various interventions [7]. As the use of HR-QoL measures is only a few decades old and is still developing, there is an international agreement that some caution should be exercised in interpreting their scores [8].

One aspect of both these approaches to QoL measurement that merits special attention is that the perception of individuals about their own lives may differ – sometimes quite considerably – from the perception of others [9]. The reason for this is that people with disabilities, like all humans, appear to have personal criteria for understanding the quality in their lives, as well as a tendency to cope with their particular life circumstances and find their "own" degree of life quality.

Over the past 30 years, these two approaches to QoL measurement have led to the development and application of numerous valid tools to measure the QoL of many groups of people, and there are ample QoL outcome measures available within the field of intellectual disabilities [10]. These have developed rapidly over the past few decades, and their use has resulted in a widely held view within the field of neurodevelopmental disabilities that QoL is a key outcome measure for the effectiveness of interventions and services.

Because individuals with disabilities include a wide range of persons, the nature of self-assessment or perception often requires diverse means of assessment. For example, if an individual is severely or profoundly disabled cognitively, or has major deficits in specific areas such as vision or hearing, specific and innovative assessment may be required.

For example, it may be beneficial to assess the individual in their most familiar environment, acclimatizing an individual to a new environment, or developing specific assessment tools to circumvent the disability such as painting and drawing as an interplay between the person with disability and the professional involved in assessment [11].

Tip

If we are most interested in the effects of a specific disability condition or a specific disease, we may choose to use one or more health-related quality of life tools to assess quality of life. However, if we are most interested in understanding people function in general, or in relation to their families or communities, we may choose to use a whole-person approach to assessing quality of life.

15.5 When to Use Shared and Unique Aspects of Human Life as Outcome Measures

Available QoL outcome measurement instruments for groups of people make use of measures that are assumed to be shared by all people and thus to indicate the QoL of all people. If the purpose of QoL outcome measurement is general in nature, such as evaluating the effectiveness of a larger service or policy or providing a "snapshot" of the QoL of a larger group of people, the shared aspects of life may provide sufficient valid information. Typically, these use perceptual measurement methods that combine subjective and objective approaches [12].However, if the purpose of QoL measurement is to provide a basis for individual planning or for evaluating individual interventions, a full assessment should include both shared and unique aspects of the individual's life. This section describes what unique and shared aspects of human life are, and it addresses their utility as outcome measures. The section that follows stresses the importance of relating both types of outcome measures to the lived experience of individuals and families.

15.5.1 Measuring Uniqueness that Enhances Quality of Life

Although all individuals share characteristics that are central to the human condition, they also have varied characteristics and interests that are very meaningful in their own lives, and thus add to their life quality but may mean little or nothing to other people. Personal uniqueness emerges from such factors as genetic makeup, personality, abilities, life experiences, culture, environmental conditions, and even chance (some of life's "quality" moments arise spontaneously and unexpectedly). These factors determine not only how a person's life is experienced, but also how it is interpreted across time and different conditions. Moreover, personal uniqueness is dynamic, changing over time with changing interests, age, and life conditions. Reinders explained that "...the concept of QoL is necessarily open- ended. There is on any account of the matter a dimension of incompleteness in assessments of QoL in the sense that we may discover things about ourselves that in due time will change our judgments. Precisely as a comprehensive concept, QoL must entail an element of the unknown future of our existence" ([13], p. 210). Thus, all of us, as human beings, develop and use over our lifetimes sets of unique interests, values, and capabilities that add to and intersect with those we share with others.

Sometimes, personal uniqueness takes on particularly strong positive meaning in our lives such that they become what Brown, Raphael, and Renwick [5] referred to as dominant and driving forces. When this is the case, they can add tremendously to an individual's QoL. There are innumerable examples, but some commonly recognized ones are enjoying a particular sport, developing a particular talent such as drawing, or spending time with a favored pet. For a very few people, such things can even take up a very large part of

their lives and, if experienced in a highly positive way, form a very large part of the quality within their lives. Some examples include the musician who spends hours every day playing her instrument, an athlete who single-mindedly hones his physical skills, the spiritual follower whose life activities are strongly directed by a set of beliefs and values, a parent who is highly dedicated to the welfare of her children, the family that closely follows the customs of its cultural heritage, or the social activist who strives untiringly for social justice. Whatever their form, dominant and driving forces can add enormously to an individual's QoL in ways that are different from most other people.

Some aspects of QoL can also be negative for individuals. Such things as abuse, poverty, neglect, unsafe conditions, lack of access to food and water, war, and many others can become dominant and driving forces in an individual's life. When this occurs, either temporarily or in an ongoing way, the individual's QoL can be compromised, sometimes severely so.

The methods developed to date in QoL measurement enable us to capture personal uniqueness to some degree, but not fully. For example, an indicator of productivity may be variously interpreted by respondents as work in a paid job, a volunteer position, child-minding, or helping family with chores. What they do not do, except to the extent that there is an opportunity to provide comments or to identify additional factors that add to QoL, is ask specifically about unique personal interests and activities that provide (or detract from) QoL, especially if these are thought of as dominant and driving forces in the person's life. For this reason, when QoL as an outcome is applied to individuals, it is important to gather individually based information about unique interests, values, capabilities, and satisfaction with different areas of life and to assess their importance and value to each person's QoL. As no specific method has been set out in the QoL literature for doing this to date, standard professional assessment and counseling methods should be useful for this purpose.

> Individuals differ widely in the degree to which specific things affect their quality of life. But whether or not these factors are dominant or minor influences in their lives, they need to be taken into account. We do not have standardized methods for accomplishing this, so we have to rely on qualitative assessment methods to estimate outcomes.

15.5.2 Measuring the Quality of Shared Life Domains

Shared QoL refers to characteristics of individual life that are common to, or shared with, other people, such as sociability, productivity, or spirituality. In the field of neurodevelopmental disabilities, the measurement tools that have been validated are all based on these shared characteristics of human life. That is, they identify areas of life (referred to as domains) that groups of people identify as being important to the human condition and to almost every person. Although the various available measurement tools do not all feature the same life domains (see Table 15.1 for a comparison of four tools), there is considerable overlap among them (see [18] for a comprehensive list of available tools) and overall scores correlate quite highly (e.g., [19]). For individuals, well-researched and validated domains include physical, psychological, and spiritual well-being, personal development, social and community inclusion, and opportunities to achieve and be productive (e.g., [20]). Civic involvement and rights are also sometimes part of a measurement system for individuals and families, although it might be argued that these are determinants, rather than outcomes, of QoL. For families, well-researched QOL domains are family interaction, parenting, emotional well-being, personal development, physical well-being, financial well-being, community involvement, and disability-related supports [21, 22].

Shared QoL is relatively easy to assess, even in persons with severe cognitive impairment. The domains are most often not measured directly, but rather indirectly through

Table 15.1 Comparison of domains in four QoL tools

	WHOQOL-BREF and disabilities module [14]	Personal well-being Index – intellectual disabilities [15, 16])	Quality of life questionnaire [17]	Quality of life instrument package [5]
Number of QoL areas/ domains	4 + disability module	7	8	9
Total number of items	39	8	40	54
List of QoL areas/domains	Physical Psychological Social relationships Personal environment + Disability	Standard of living Health Life achievement Personal relationships Personal safety Community-connectedness Future security Spirituality-religion (optional)	Physical Well-being Emotional Well-being Interpersonal relationships Material Well-being Personal development Self-determination Social inclusion Rights	Physical being Psychological being Spiritual being Physical belonging Social belonging Community belonging Practical becoming Leisure becoming Growth becoming

specially developed and validated indicators. These are typically measured on a 3–6 point Likert-type scale [23] for each of the tool's measurement indicators, sometimes for more than one measurement concept such as importance, satisfaction, opportunities, choice, attainment, initiative, and stability [24].

In scoring these dimensions, self-report by people with disabilities should be central, and any means should be mobilized to enable such people to express their own views. In all cases, information on the background of the person, descriptions of the person's current context and living/working environments, and the perceptions of close caregivers constitute additional sources of information that are potentially valuable to add to self-perceptions. Such assessment may even be used effectively with people with severe cognitive disabilities, as they express their inner states through consistent behavioral repertoires [25].

QoL scores are derived from measuring the indicators of life domains specified in the QoL tool. The resultant raw scores can be transformed into standard scores, then analyzed and reported as QOL area/domain scores, or aggregated into a total QOL Score [26]. Since these domains have been validated as aspects of human life that are important to all people with some leeway for cultural influence [27], scores from these tools are considered to be credible measures of shared QoL values.

Several tools that feature shared domains have been developed to assess individual QoL in persons with ID and low functioning-autism spectrum disorder (LF-ASD). Four well-known scales are described briefly below, and their main features are compared in Table 15.1.

A commonly used QoL measure for people with disabilities is the *WHOQOL-DIS*, developed by the World Health Organisation (WHO). The *WHOQOL-100* is a QoL measure of 100 items for the general population, and it has a brief form of 26 items (*WHOQOL-BREF*). The *WHOQOL-DIS* is the brief form with an additional 13-item section specifically addressing disability. The *WHOQOL-100* was designed with a hierarchical structure that includes overall QoL, six life domains, and then 24 facets within the domains with four specific items to measure

each facet. The *WHOQOL-BREF* has a similar hierarchical organization, except that each facet is represented by a single item. The widespread international use of the *WHOQOL* provides for cross-cultural validity for QoL assessment across the adult lifespan and a range of physical, mental, and neurodevelopmental disabilities [28].

The *Personal Wellbeing Index* (*PWI*), developed by Robert Cummins and emerging from his previous *Comprehensive Quality of Life Scale* [16, 29] at Deakin University in Australia, has a useful ID version (*PWI-ID*). The seven domains and one optional domain, each represented by the same single item on the *PWI* (adult version) and the *PWI-ID,* are shown in ◘ Table 15.1. This scale was carefully constructed by a large cohort of international researchers, and takes a short amount of time to administer. Special features of the *PWI-ID* include a detailed set of pre-tests to help ensure the validity of responses, simplified wording of the *PWI* items, and, to promote comprehension, the possibility to use 2-, 3-, or 5-point rating scales in place of the 0–10 scale used in the *PWI* or to use a set of happy and sad faces [9]. The limited number of items on the *PWI-ID* suggests that its principal utility might be as a survey and program evaluation tool rather than a tool for individual assessment and support planning, but its robust psychometric properties ensure its overall credibility. Another consideration in using the *PWI-ID* is that it measures subjective wellbeing, a person's own perceptions of his or her life. The other tools in ◘ Table 15.1, as well as Deiner's well-regarded *Satisfaction with Life Scale* [30] and Heal's *Life Satisfaction Scale* [31] also use self-perception as an information source for measurement, although perhaps not quite as explicitly. But it might be kept in mind that these tools do not use objective observation of others as primary information sources for measurement.

One of the most internationally used QoL tools for ID populations evolved from the Schalock and Keith [32] *Quality of Life Questionnaire* (now known as *QOL-Q*), developed in the United States. The *QOL-Q*'s eight domains, as listed in ◘ Table 15.1, were expanded from the original four domains (satisfaction, competence/productivity, empowerment/independence, and social belonging) but, like the original, contain 40 items. The eight domains, listed in parentheses here, group within three main factors: (1) Independence (personal development and self-determination), (2) social participation (interpersonal relationships, social inclusion, and rights), and (3) well-being (emotional well-being, physical well-being, and material well-being). Like the original questionnaire, the *QOL-Q* has been extensively tested in a series of population and cross-cultural studies. Core indicators operationally define each QoL domain, and indicator items represent specific items that are used to measure the person's perception ("self-report") or an objective perspective based on the person's life experiences and circumstances ("direct observation"). The *QOL-Q* has been widely applied for a variety of purposes, especially in Schalock's far-reaching work in policy and organizational evaluation, and as such it is useful as a focus point for comparisons of QoL of populations across time and place.

A fourth QoL assessment tool is the *Quality of Life Instrument Package* (QoL-IP; I. [5]), developed in Canada. The QoL-IP features nine domains, organized into three macro-areas: being, belonging, and becoming (as listed in ◘ Table 15.1), each of which features three domains. QOL domain indicators are rated from three perspectives: the person being assessed, others who know that person well, and a trained assessor. Each indicator is assessed in four dimensions: (1) importance, (2) satisfaction, (3) opportunities that the person had/has to develop importance and to perceive satisfaction; and (4) choices that the person could/can make in the same areas. Importance and satisfaction interweave by mathematical formula to produce a basic QoL score, with satisfaction being weighted by importance. This idea had been put forward by a number of scholars in the 1990s, including Becker et al. [33], but was described by Bertelli et al. [34] this way: a thing that is highly important and gives high satisfaction has a considerable positive impact on a person's QoL, while a thing that does not interest a person or is not valued will never add

satisfaction or quality to the person's life. Decision-making from choice and the availability of opportunities from which decisions can be made act as moderators to basic QoL scores.

Uses of QoL Scores Based on Shared Life Domains QoL scores based on shared life domains can be appropriately applied to evaluation for groups of people, for services, and for supports and policies that address the needs of large numbers of individuals. They can be used to keep track of progress made by policies and programs over time, where QoL is considered an excellent indicator of progress. In this way, they can be used to evaluate the effectiveness of an organization or system's services and supports over time [35, 36], and thus to assess organizational or system quality improvement [37, 38]. Table 15.2 provides an integrated approach to quality improvement based on the work of Baker et al. [39], Gomez et al. [40], Lee [41], Reinders and Schalock [42], Schalock and Verdugo [35], Schippers et al. [3], and van Loon et al. [43].

For individuals and families, QOL outcome measures of shared life domains can and should be used as one good source of data for individual and family assessment and developing person-centered and family-centered plans. An area of life that adds quality is one in which a domain is valued in the person's life, and the domain QOL score is high. These areas should be actively maintained, as they contribute quality to the person's life. An area of life that detracts from quality is one in which something is valued in the person's life, but it is scored low on achieving it or satisfaction with it. These areas require attention to eliminate the causes of the problems or to develop strategies to improve them. Individual indicators, too, can be used in a similar way.

Table 15.2 Quality improvement strategies

Focus	Examples
Individual	Determine QOL-related personal goals Assess individual support needs across QOL domains Use an outcomes focused planning format that aligns personal goals, support needs, and QOL outcome categories Use an ISP format that is user friendly and one developed and implemented by a support team composed of the service recipient, a family member or advocate, direct support staff, relevant professionals, and a supports coordinator Assess QOL domain indicators
Organization	Provide improved access to technology that allows for real time planning/reporting Provide training programs focusing on QOL and its multidimensionality Adjust job descriptions and hiring practices to reflect the QOL framework Evaluate staff as to whether necessary support is given (rather than activities were completed) Change to person-centered planning process Develop policies that promote the use of natural /community supports Base strategic planning efforts on QOL as the aligning construct
System	Develop and launch a web portal for service providers to share ideas that promote QOL for individuals served Train systems-level staff on the importance of QOL and its difference from goal attainment paradigms Provide workshops and conferences that promote a deeper understanding of the QOL concept and its application Conduct strategic planning with QOL as the aligning construct and the strategic driver for organization and system transformation Move toward using QOL outcomes as key performance indicators Fund pilot projects that focus on the key role of the QOL concept in agency change Modify contractual arrangements to reflect QOL assessment and continuous quality improvement

For example, if spending time with friends is a specific indicator of social well-being and this is important to the person, a low QOL rating for this indicator can strongly suggest action should be taken to improve the quantity and quality of time spent with friends.

QoL scores for individuals or families do need to be used judiciously. Often, other factors need to be considered alongside such scores for their use to be effective. For example, at the systems level, a relatively high score on QoL indicators may suggest that policy changes such as increases to income assistance and sustainable funding for communities are unnecessary when in fact such changes might significantly improve the "goodness" of the lives of individuals. At the personal level, a low outcome score might suggest a needed intervention, but that intervention may not be desired by the individual or helpful if it is implemented.

Continuing Work Needed in QoL Measurement Based on Shared Aspects of Life There is still work to be done in QoL measurement, and some examples are provided here:

- Most instruments set out QoL indicators under a number of logical domains, but it is not clear whether the domains identified to date accurately capture QoL as a whole, and the extent to which these domains make unique contributions to overall QoL. For example, the factor scores on importance did not fit clearly into the core domains proposed by current available tools to describe the set of cross-cultural factors that can impact personal well-being [34].
- We are not certain that QoL tools actually measure the whole concept, or whether they simply measure their domains [13].
- Our current tools do not show exactly how people experience QoL. We might assume, however, that people do not typically experience their QoL as divided among separate domains, but rather evaluate how their experiences within these various domains interact with one another and to their whole lives.
- The relationship between QoL measures and those of other closely related concepts, such as self-determination, personal development, and the possibility of choice, needs further exploration [44].
- The distinction between indicators of QoL and factors that cause QoL is not clear in the available literature [2].
- Work might be carried out to organize QoL indicator variables for life as a whole in a hierarchical way, a process that would help us to better define a minimum set of domains with equal variance [2].
- Work needs to be done around including people with disability more meaningfully in designing projects related to QoL measurement and application.
- In numerous countries of the world, there is a superficial understanding of the nature and causes of neurodevelopmental disabilities, autism spectrum disorder, and other disability conditions. Such limited understanding may influence the treatment of people with disabilities and, in turn, influence perceptions of individual and family QoL [45, 46].

Tip

Quality of life measures based on shared aspects of life may be more reliably assessed when more than one measurement tool is used.

Tip

Scores from quality of life indicators that are based on shared aspects of life provide a solid information base for assessing outcomes – the ongoing and lasting effects of a program or an intervention. This should be amended by considering unique aspects of life and the lived experience of individuals and families.

15.6 Relating QOL Measurement to the Lived Experience of Individuals and Families

The *lived experience* of individuals and families is a term used for the reality of people's lives, and understanding lived experience is considered to provide the most important understanding of people with neurodevelopmental disabilities and family life that includes disability [47]. It follows that, for individuals or families with disability, QOL outcome measures based on both unique and shared aspects of life need to be applied within the context of their lived experience.

Lived experience sometimes modifies, or even reverses, the strength of specific QoL outcome measures. For example, some aspects of life may score low on quality, but the person is not unhappy about that or does not necessarily want change. They may also be addressing some positive function that is "working" in the larger context of the person's lived experience. Conversely, some aspects of life may score high on quality, but they are not of particular interest or value to the person, change may be desired for other reasons, or they may contribute little to positive functions. Such considerations stress the importance of the lived experience context, and they suggest that it may not be fruitful to spend time and resources on some QoL improvement interventions suggested by the QoL scores alone.

But real life experience complicates the interpretation of QoL scores even more than this. Individuals and families have a variety of coping strategies that they may or may not use, to tolerate life adversities. Some stressful aspects of life may be tolerated even without such strategies when they are balanced by others that are enjoyable. Some unpleasant aspects of life are temporary and will go away on their own, so it is often a matter of coping temporarily then waiting them out. Some people enjoy a little challenge or chaos in their lives and others do not. There are many other factors relating to lived experience that may affect how QoL outcome measures can be applied effectively. The "art" of helping a person or a family enhance the quality of life involves exploring the various factors that need to be addressed within the context of their lived experience and to determine the most effective ways to address them.

> Since quality of life is experienced by people in the context of their lived experience, quality of life outcome measures need to be interpreted through this lens.

15.6.1 Individual Lived Experience

The unique and shared QoL measures that we might assume affect an individual's QoL are not always reflected in how an individual perceives his or her own life or lived experience. The early research on individual QoL, reported in the 1990s, strongly hinted that this might be the case – QoL scores from individuals with ID and those from trained assessors, support workers, and family members did not correlate well, suggesting a difference in perspective related to differences in lived experience (see [5], for example). The questions that emerged were: how do people with ID perceive their own lives and why do they perceive their lives in those ways?

The work of Cummins and colleagues in Australia provides an intriguing hypothesis. Based on extensive research and analysis, Cummins noted that almost all adults, including those with ID, no matter what their life circumstances may be, rate their own lives as positive but not perfect, typically between 70 and 80 on a scale of 0–100. From this base, Cummins developed his *theory of subjective well-being homeostasis*, meaning that human beings have a genetically generated tendency to look for happiness, satisfaction, and meaning in their lives despite the circumstances, and that their levels of happiness are quite stable across time and across geographic areas [48, 49]. Life satisfaction can go down in difficult times or it can go up in good times – and it fluctuates with temporary emotional highs and lows – but the tendency is to move back toward a stable point. A few years later, Cummins coined the term *set-point of happiness,* which is the point on the scale that

ratings of life satisfaction tend to fluctuate around and to which mood returns under normal circumstances [50, 51]. What this suggests for QoL outcome measures is that people with neurodevelopmental disabilities, like all people, are highly likely to be subject to the homeostatic effect and rate their own lives around their set-points of happiness as their life circumstances change. Through extensive research from his *Australian Unity Wellbeing Index,* Cummins and colleagues also reported that three factors particularly influenced people's sense of well-being, which he called the "golden triangle of happiness": satisfaction with income, relationships, and life purpose [52]. These three factors, Cummins maintained, are especially strong in protecting us from ongoing negative mood and moving us homeostatically back to our set-points of happiness.

This hypothesis suggests an amendment to people perceiving their own lives within the context of their own lived experience. It suggests that people both with and without neurodevelopmental disabilities may have a genetically based tendency to return from both high and low emotional levels to their set-points of happiness, using both inherent and learned strategies, and, moreover, that this is a preferred process for humans. What this might mean for QoL is that a measure of quality or the "goodness" of life might best be described as the person's lived experience that has some enjoyable high emotional states, a few low emotional states, and very effective sets of skills both to recognize the effects of fluctuating emotional experiences and to return to the person's set-point in a timely way [53]. Those whose lives cannot be described this way might be thought to reflect lower QoL, especially where there is incapacity to return easily from negative experience to the set-point or incapacity to return at all and thus be mired in negative emotions and experiences.

Another interesting way to look at individual lived experience and QoL is by examining the "disability paradox" coined by Albrecht and Devlieger [54]. This refers to the fact that, when recording subjective well-being, it is often noted that QoL scores of people with intellectual or other disabilities do not differ significantly from those of the general population. This so-called paradox has been explained variously as a psychological mechanism of adaptation, coping, resilience, research methodological bias, or even poor conceptualization of persons with ID. But another explanation is that people with ID perceive their own lives through the lens of their own lived experience since this is the only lens they have, and their perception of their lives is of a higher quality than the perception of others. Simply put, life is experienced by all individuals through their unique sets of perceptions, and because of this subjective well-being may be an essential pathway to understanding "true" personal QoL.

An additional view of lived experience for people with ID is that personal perceptions may differ from other people's perceptions because those with neurodevelopmental disabilities view situations differently. As mentioned briefly in ▶ Sect. 15.3 above, this often results in non-significant correlations between ratings by people with ID and by proxies. For example, people with ID generally have clear views on what their choices are and what they want to do, while parents appear to respond to the barriers that they believe will inhibit the individual from attaining their wishes. It is therefore important to be aware of the different perspectives [55]. It is appropriate at this point to recognize that what are often referred to as subjective responses are in fact objective in the sense that they are heard and recorded. It is a fact that the statements were made by the two parties. The subjective component is the interpretations that are made of such data [1].

These perspectives on lived experience and QoL shed new light on scores derived from QoL tools. High or low scores (overall scores, domain scores, or indicator scores) may indicate seemingly clear courses of action that may sometimes need to be amended or abandoned when considered in the context of live experience. A challenge for disability professionals is that people with intellectual and other disabilities may not see themselves as needing support as much as others do, and they may not want

the types of "improvements" that others assume will benefit them as a result of such support. Another issue that emerged from this is that QoL scores for individuals and families with disability would not be expected to be atypically low, and when they are, as Cummins [48] has pointed out, there is real reason for concern and assistance might well be needed.

> Individuals with disabilities very often rate the quality of their own lives differently than others rate their lives. They are probably looking at their own lives through the lens of their abilities and their own lived experience. Moreover, people with disabilities, like all people, may have a natural tendency to "make good" of their particular life situations.

15.6.2 Family Lived Experience

The overriding issue in considering the lived experience of families is that, when parents and siblings find it difficult to deal with the challenges they face, it is not only the child with a disability who is further restricted, but also every member of the family. Families differ, sometimes quite markedly, in their willingness and ability to deal with disability, seek and implement solutions, work with those who can give support, manage their families, and cope with the ever-changing nature of family life. Thus, there is no "typical" or "normal" lived experience for families that have a member with a disability. Yet, like individuals, they have things in common, including set-points of happiness to which they have a tendency to return. Still, it is clear that certain disabilities and mental health problems, especially when difficult behavior is involved, have noticeable impact on the QoL of families (e.g., [56]).

Since the year 2000, family quality of life (FQOL) has been assessed in many countries of the world and in many languages using two main FQOL instruments: the *Family Quality of Life Survey, 2006* [57], and the *Beach Center Family Quality of Life Scale* [58]. These instruments produce FQOL outcome measures similar to those produced from individual QoL measurement. FQOL outcome measures are derived from indicators in identified family life domains such as parenting, family relationships, finances, support from services, support from others, leisure time, and others [7, 28].

Although the more complex family lived experience needs to be understood and taken into account when supporting families, the results from the many studies in FQOL around the world provide a basis for understanding where to begin. In a comparative analysis of 8 and 19 research studies, respectively, I. Brown [59, 60] noted that study respondents in every country rated satisfaction with supports and services as quite low, and as not nearly as important to their QoL as family relationships and values. Other analyses have reported that FQOL scores are lower when family members with ID have behavior disturbances [44], that health and financial challenges compromise QoL for many families, and that support from friends, relatives, and neighbors is low in every country studied [60]. Lack of respite means that many families are unable to take vacations or parents are unable to spend time together. A parent – usually the mother – frequently has to interrupt or stop a career to provide care for a child with a disability. Such results and the substantial general literature about families suggest that families face some major challenges, and that many of these challenges appear to cause exclusion for family members.

In many ways, this is sobering information for professionals supporting families that include a son or daughter with a neurodevelopmental disability. It tells us that much of the real quality in families' lived experience may be derived from things other than the things that those of us in the service industry are addressing. This poses a serious challenge to our services, because a great many families who have children with disabilities do need support, solving practical family and social issues as well as finding adequate intervention for mental health challenges. When additional challenges arise in the broader society (such as the COVID-19 pandemic that began in

2020), there is a considerable increase in family stresses that often result in mental health challenges. At times, FQOL measures may capture this, such as lower ratings of financial, social, or community involvement indicators, but their impact may not be fully reflected by outcome measures alone.

What steps, then, can we take to understand better families' actual lived experience, and to support the aspects of that experience that add to their measured QoL outcomes? Four key steps in this journey are briefly described below.

- *Base our efforts on practical principles embedded in the FQOL approach*. These principles have been described in detail by several authors and are expanded in R. Brown et al. [61]. General principles include, among others: dignity of disability, ethically based policy and practice, personal and professional values, duty of care, risk and safety, normalization, and exclusion/inclusion. Individual and group principles include: resilience, perception, self-image, empowerment, personal control, and intra- and inter-personal variability. Other principles are: holism, lifespan issues, opportunities and choices, and imaging the future [62]. Critical to all these principles is the perception of the individuals involved.
- *Focus on family functioning.* Family QoL research clearly shows that family relationships are very important to families in all countries yet, at times, having a member with an ID is associated with challenges in family functioning. Suggestions for professional services include developing education and support for families around effective parenting styles and family unity strategies. This education and support seems to be particularly effective when families are given opportunities to share information and expertise with each other in an organized peer support model [44]. The need to have opportunities to simply talk about issues that bother a person appears in the qualitative data from virtually all FQOL studies.

Understanding and supporting the role of siblings in a family that includes a child with a disability may also be important in supporting the on-going QoL of the entire family [63]. These supports might include sibling support groups, and the meaningful inclusion of siblings in decision making and planning. Beyond siblings, it is important to understand the function of all family members, no matter how minor that might be.

- *Design family-centered supports.* As mentioned, a lack of satisfaction with service support appears as a challenge in all countries where FQOL research has been carried out [44]. Moreover, families have indicated high levels of stress related to interactions with formal disability-related staff and professionals [64]. Some common concerns that have been voiced are a lack of information about available services, difficulties in trust and communication with support providers, and a shortage of provider focus on family functioning and family relationships. An important practical suggestion for disability support workers is to develop supports based on family-centered approaches with the family controlling and contributing to their own support, rather than having plans and programs generated by providers. This approach emphasizes the rights and capabilities of families to direct and participate in their own social welfare experience and may result in more positive FQOL outcomes [65]. In addition, professionals who support families may see benefit from working in partnership with families on an equal basis [66]. Suggestions for providers wishing to build trustworthy, responsive family services include [67]:
  1. Focusing upon improved communication with families, such as sharing information and listening to feedback from families. To have available personnel to undertake such activity in the early stages of increased stress may have important implications for reducing complete breakdown later in the family's life.

2. Providing high levels of professional competence and ensuring disability professionals who are in contact with families are well-trained experts with relevant knowledge and experience. Professionals working with families should be trained in FQOL principles, be able to provide information about disability service and funding options, and be able to assist families in navigating the service landscape.
3. Providing an environment of respect, commitment, equality, and trust. Disability professionals may find a focus on building strong relationships with families beneficial for all involved.

- *Pursue inclusion of families in physical and social communities.* It has been noted that there is often a lack of support from informal sources such as friends, extended family, and neighbors [68, 69]. One way that providers might assist families in making and maintaining social connections and building social support is through family support groups. R. Brown et al. [70] recognized the need for such groups but noted that they need to include trustworthy, safe support for the child with disability and siblings so that family members can relax and have sufficient time to network with other family members. Faragher et al. [71] suggested that formal services may assist families in family support groups by suggesting ways to access the supports they need. For their parts, family members indicated that sharing meetings with others is highly supportive across the lifespan. The initial meetings need to be led by a skilled mediator, though family members will often run later meetings themselves.

Research has also suggested that service providers might become community connectors rather than simply caregivers, empowering families to make the social connections needed to find formal and informal supports [72]. These connections in the community might assist families in finding pathways to information and collective action for service and policy improvement. The enhancement of social connections can also enable the growth of relationships leading to the emotional and practical support that are so important for ensuring the health of the family ([69]; see [73] for further practical approaches).

Tip

Families that include a member with disability often have difficult lived experience. Quality of life outcome measures, especially for people with disabilities living with their families, need to include family quality of life outcome assessment – which needs to be interpreted through the families' lived experience.

15.7 Putting It All Together

Valid QoL outcome measures have been developed and reported for both individual and family QoL. These measures provide evaluation and assessment data for helping individuals and families move toward enhanced QoL, for improving the quality of disability-related services, and for policy and practice accountability. They also provide a strong basis upon which new or amended policy and practice models can be developed. A robust body of research on the QoL of individuals and of families is currently available in the published literature, a body of work that has established the utility of applying QOL outcome measures that are common to individuals and families. The work of Schalock and his numerous colleagues have steadily moved the application of QOL outcome measures to policy and practice forward over the past several years, and this is proving to be very helpful in shaping policies and services that focus on quality outputs and outcomes.

Although future work will offer advances, the considerable knowledge that has been generated to date on QoL as an outcome measure allows us to understand that there are various options for use with people who have neurodevelopmental disabilities or autism spectrum

Table 15.3 Options in using QoL as an outcome measure for people with ID or ASD

Issue	Options
Purpose of using QoL outcome measure	Individual planning Evaluating individual interventions Program planning Program evaluation Policy evaluation
Focus of QoL measurement	Shared QoL Personal QoL Family QoL
Content of QoL measurement tools	Domains/areas (objective assessment) Dimensions (personal appraisal) Indicators (individual objective assessment)
Person whose QoL is being measured	Person with ID (mild to profound) Person with ASD (any degree of support need)
Information source	Individual with ID/ASD Proxies (persons who know the individual well) External assessors
Understanding QoL data and scores	Overall, domain, and indicator scores Subjective and objective data Amendments based on lived experience of individuals and families

Expanded from Bertelli et al. [34]

disorder. Table 15.3 lists the options that have been described in this chapter as they pertain to: the purpose of using QoL as an outcome measure, the focus of the QoL measurement, the content of the measurement tools, the person whose QoL is being measured, the information source, and understanding the QoL data and scores. Together, these options illustrate that a variety of QoL outcome measures may be used in a variety of ways for a variety of purposes.

15.8 Moving Ahead

The development of QoL, both from a conceptual and from a measurement point of view, is not complete. The term *quality of life* itself is a social construct and, as such, its meaning changes over time. QoL conceptualization and outcome measurement will both have to adapt to such changes in meaning. Moreover, we cannot assume that we fully understand the complexity of QoL at the present time, despite its simple surface meaning illustrated by the question, "How good is your life for you?" [5]. But the various combinations of factors that combine to make up a "good" life or a "quality" life at any one time, for any one person or family, is a complexity that we have perhaps only begun to describe. Finally, the task of enhancing QoL for individuals and families by drawing together the outcomes of policy, practice, and people's lived experience – so that they work together toward a common goal – is one that is somewhat daunting but nevertheless an exciting challenge ahead.

We have come a long way since QoL first became a widely recognized concept in the late 1980s. It is now understood to be the overall goal of almost everything we do in the field of neurodevelopmental disability, and it is a commonly stated policy and practice goal in almost every country of the world. As the concept of QoL continues to evolve in the future, its outcome measures will also evolve and, as they do, they show real promise of being useful tools for moving toward our goals.

Key Points

- Quality of life is a social construct that is used to encompass the general notion of the "goodness" of life.
- Outcome measures are measures of ongoing and lasting changes. Quality of life as outcome measures use the scores derived from quality of life indicators

to assess ongoing and lasting changes to the "goodness" of people's lives.

- Two general approaches to attaining scores from quality of life indicators in the human services are: (1) a focus on specific conditions or diseases (health-related quality of life) and (2) a focus on the person's whole life in relation to the environment (whole-person quality of life).
- Numerous tools are available to measure health-related quality of life, and several valid tools have been developed to measure whole-person quality of life for people with intellectual and other neurodevelopmental disabilities.
- The available whole-person tools provide quality of life scores for domains of life that are deemed to be common to, and important to, almost all humans. These quality of life scores can be used as the primary assessment information in determining outcomes (ongoing and lasting changes).
- To make a final determination of outcomes, the primary assessment information obtained from the scores of quality of life tools needs to be amended by: (1) considering life factors that are unique and important to the individual and (2) interpreting the information through the lens of the lived experience of individuals with disabilities and families that have a member with disability.

Learning Objectives

The primary objective of this chapter is to provide a broad overview of ASD in terms of its worldwide prevalence and etiopathogenesis including genetic, epigenetic, and environmental influences. The chapter also provides a review of the definition leading to the current conceptualization of ASD, including the evolving changes in diagnostic criteria, its clinical features, and diagnostic assessment measures. The question of comorbidity and treatment considerations, including both pharmaceutical and nonpharmaceutical approaches, is also discussed. The emphasis on person-centered, evidence-based, multidisciplinary, and collaborative inclusionary framework on ASD across health, education, and social sectors is underscored.

16.1 Introduction

Autism spectrum disorder (ASD) represents a group of lifelong neurodevelopmental disorders emerging during early childhood and interfering with a person's ability to socially relate to and interact with others. Over the past 30 years, there has been an unprecedented increase in the prevalence of ASD worldwide with impressive strides made in increasing awareness of the condition and developing innovative ways to improve the lives of children, young people and adults with ASD. In particular, since 2007, with the passage of the United Nations General Assembly resolution [1] creating the World Awareness Day, April 2 every year is now recognized by member states to not only raise responsiveness but also report on tangible outcomes of interventions as part of the implementation of the UN Sustainable Development Goals (SDGs) [2].

There are still large gaps in the dissemination of the evidence base on ASD, and in particular, in terms of implementation of effective treatment across the lifespan. There is a need to provide persons with ASD and their families with adequate supports, and especially to ensure that children and adolescents with ASD have access to public education and services. There is also a need to recognize persons with ASD as participants in the social fabric of countries worldwide. Although this chapter emphasizes the cutting-edge science in terms of etiopathogenesis, psychiatric comorbidity, assessments, and treatment, it is important to acknowledge at the outset that ASD cannot be effectively addressed by the health sector alone and national policies require collaboration across health, education, and social sectors [3]. To accomplish the multidisciplinary goals, policymakers worldwide must:

- Encourage early detection and diagnosis of ASD, allowing children, adolescents, as well as adults to access services needed as early as possible
- Ensure that children, adolescents, as well as adults with ASD have access to evidence-based therapies by providing additional training to parents, teachers, and clinicians around the most effective interventions
- Provide those with ASD and related neurodevelopmental conditions access to public education, vocational training, and assisted employment with the goal of inclusion
- Encourage participation in high-quality surveillance and research

16.2 Prevalence

The prevalence of autism doubled from around 0.5/1000 during 1960–1970s to 1/1000 by 1980s when DSM-III definition was introduced, doubling again to 2/1000 by early twenty-first century [4]. The current prevalence of ASD is accepted to be 1% worldwide [5–7]. The prevalence has been noted to be as high as 1/38 among South Korean children in a population-based study [8], a figure that may be an overestimate [9]. The Center for Disease Control and Prevention (CDC) Autism and Developmental Disabilities Monitoring (ADDM) Network in the United States has estimated ASD in 8-year-old children to be 1/54 in 2020's analysis [10] and 1/44 in 2021's analysis [11]. This surveillance figure is an average with variation by race/ethnicity as well as state of residence of the children with notable disparities in the prevalence

depending on ascertainment from health and educational sources [12].

ASD is now universally regarded as present in all geographical regions of the world, among people of all ethnic backgrounds in both low- and middle-income country settings. A Swedish population-based study has shown that risk of offspring with autism is consistent across all parental socioeconomic strata [13]. ASD is reported to be 4 times more common in males than in females [14, 15]. Although the terms high-functioning autism (HFA) and Asperger disorder are not formally used, the M:F ratio among children and adolescents without intellectual disabilities (intellectual developmental disorders) ranges from 6:1 [16] to 10:1 [17]. Some studies have emphasized that lower representation of prevalence among females may reflect lower probability of the condition being identified in females altogether [18], or misclassified as having affective, anxiety, personality, or eating disorders [19]. A recent systematic review approached this issue by analyzing 54 studies including 13,784,284 participants, with findings pointing to a M: F ratio closer to 3: 1 [20]. It has also been noted that a "female protective effect", that is, females requiring greater familial loading to manifest the ASD phenotype in multiplex families, cannot explain the sex imbalance in ASD prevalence and there is no supportive evidence that a single common locus on chromosome X might mediate such a female protective effect [21]. Women are also reported to have much higher efficacy in compensation mechanisms of social difficulties than men, aptly called "camouflaging" [22]. This higher discrepancy between externally observable behavior and inner experience of socialisation has been found to be independent from the intellectual quotient [23], implying that it may exist even in persons with borderline intellectual functioning and mild intellectual disability.

ASD is now universally regarded as present in all geographical regions of the world, among people of all ethnic and racial backgrounds living in both low- and middle-income country settings.

16.3 Etiopathogenesis

16.3.1 Genetics

Genetics provides major findings underlying ASD as well as endorsing great interindividual variability [24, 25]. The opportunities offered by new technologies, including chromosomal microarray (CGH) to Next Generation Sequencing (NGS), have overcome the limitations of linkage and candidate gene association studies, expanding our knowledge of its genetics. ASD is now viewed as the leading neurodevelopmental disorder with the highest genetic loading, initially based on the results of twin studies in the UK and Scandinavian countries that provided heritability estimates greater than 0.90, with significant differences in concordance rates between monozygotic and dizygotic twins (73–95% vs 0–10%, respectively). In addition, the mean prevalence of ASD in the general population of 0.01 is significantly lower than the recurrence risk recorded in families with an ASD sibling with the prevalence of second ASD sibling ranging from 0.15 to 0.25 in males and 0.05 to 0.15 in females [26]. In addition, the presence of "autism spectrum" traits among first-degree relatives of individuals with ASD underscores important genetic contributions and points toward its complex nonlinearity in most cases [27]. Recent twin studies have provided lower heritability estimates, ranging from 0.37 to 0.60 [28, 29], reflecting differences in methodological issues [30], differences depending on the presence of de novo mutations and copy-number variants (CNVs), with estimates occurring in 15–25% of ASD [31]. There are putative epigenetic influences triggered by environmental factors on the fetus and/or on parental gametes (see Par. 16.3.2). Nonetheless, genetic contributions remain substantial [30] that represent a valuable path to reconstruct the pathophysiology of ASD. Based on the underlying genetics, therefore, ASD can be broadly distinguished in a variety of forms, namely syndromic vs idiopathic, de novo vs inherited, monogenic vs oligogenic vs polygenic [32].

1. *Syndromic Autisms* – Genetic syndromes significantly associated with ASD are listed in ◘ Table 16.1 [24, 34]. Syndromic patients typically display facial and physical dysmorphisms, malformations, intellectual disability of variable degree, and epilepsy of varying severity. Neurological signs and symptoms are more frequent than in idiopathic forms. The M: F ratio is collectively close to 1. Anomalies of body and cranial growth yield microsomy/microcephaly, and less frequently, macrosomy/macrocephaly. Altogether, syndromic forms explain approximately 10% of ASD and can be diagnosed through clinical genetic testing, either targeted (e.g., fragile-X screening, Sanger sequencing of single genes, FISH) or unbiased (e.g., karyotype, array-CGH, NGS for gene panel or exome) sequencing. The medical management of these patients often requires surveillance over multiple organs beyond the Central Nervous System (CNS), given their multisystemic nature [34].
2. "*Mitochondrial" Autisms* – This term here designates all forms of ASD due to deficits in oxidative phosphorylation (OXPHOS) and mitochondrial malfunctioning [24]. OXPHOS requires over 80 proteins, the vast majority encoded by genomic DNA (gDNA) while only 13 are encoded by mitochondrial DNA (mtDNA). Therefore, these forms can stem from mutations or rearrangements affecting the mtDNA, or more often, the gDNA [35, 36]. It is important that the reader bears in mind that the terminology "mitochondrial autisms" has been used by some authors to designate rare forms of ASD carrying specifically mtDNA mutations or rearrangements. These patients will vary in severity and clinical presentation, based on the degree of heteroplasmy present in different tissues and especially in the CNS (i.e., the percentage of mitochondria carrying the mutation). However, these are indeed rare conditions, whereas OXPHOS parameters are often abnormal in ASD probably due to excess of oxidative stress [35, 37]. Examples of more common gDNA rearrangements yielding ASD with these characteristics include the following:
   (a) ch. 15q11–q13 deletions involving the COX5A gene, encoding the 5A subunit of cytochrome C oxidase.
   (b) cr. 13q13–q14.1 deletions involving MRPS31, which encodes the mitochondrial ribosomal protein 31.
   (c) cr. 4q32–q34.68 deletions affecting ETFDH, encoding the flavoprotein dehydrogenase which transfers electrons.
   (d) cr. 2q37.3 deletions involving the NDUFA10 gene, which encodes for the NADH dehydrogenase (ubiquinone) 1 alfa subcomplex subunit 10 [36].

Clinically, mitochondrial forms are associated with rather unusual neurological signs and symptoms, including ptosis, oculomotor anomalies, dysarthria, sensorineural hearing loss or deafness, prominent muscle hypotonia, or at times, hypertonia and movement disorders [32, 35]. Such children with ASD may regress with fever, whereas many idiopathic children with ASD improve in social cognition due to the transient abatement of hyperactivity. Except in the presence of mitochondrial depletion, family history is often positive on the maternal side, as the fetus receives mitochondria essentially from the oocyte. Microcephaly and microsomy are present in approximately 20% of cases, whereas it is macrocephaly and macrosomy that are prevalent in idiopathic forms of ASD [38, 39]. Several biochemical parameters associated with abnormal OXPHOS may be positive; muscle biopsy is usually negative in such children, whereas ragged red fibers are often seen in adults with "mitochondrial" autism, with brain MRI showing a variety of neuroanatomical abnormalities more often in these children than in those with idiopathic forms of ASD [32, 35].

Table 16.1 Main genetic syndromes associated with autism

	Gene/ch. region	Prevalence	Incidence of the syndrome in ASD	Incidence of ASD in the syndrome	Main signs and symptoms
Fragile X syndrome	FMR1	1/3500–1/9000	2.1%	25–33%	Facial dysmorphisms, macroorchidism; poor eye contact, social anxiety, language disorders, stereotyped/repetitive behaviors, hyperactivity, sensory hypersensitivity
Tuberous sclerosis	TSC1, TSC2	1–1.7/10,000	1–4% (8–14% if seizures present)	16–65%	Hamartomas of the skin, brain, kidneys, heart, lungs, retina, intellectual disability, learning disability, seizures
Neurofibromatosis type 1	NF1	1/3000–1/4000	<1.4%	4%	Cafe-au-lait spots, neurofibromas, axillary or inguinal freckling, optic glioma, bone dysplasias
Untreated phenylketonuria	PAH	1/10,000–1/15,000	–	5.7%	Microcephaly, muscle hypertonia, intellectual disability, language impairment, aggressiveness, psychomotor agitation, seizures
Adenylosuccinate lyase deficiency	ADSL	Not known	<1%	80–100%	Intellectual disability, severe autism, seizures, psychomotor regression
Smith–Lemli–Opitz syndrome	DHCR7	1/10,000–1/60,000	<1%	46–53%	Microcephaly, facial dysmorphisms, malformations (sometimes lethal, mostly cardiac, cleft palate, hypospadia), short stature, intellectual disability, sensory hypersensitivity, language impairment, self-injurious behavior, sleep disorders, opistokinesis, and other stereotyped behaviors
Cohen syndrome	COH-1, unknown	1/105,000	<1%	48%	Microcephaly, facial dysmorphisms, truncal obesity developing in mid childhood, hematologic and ophthalmic abnormalities, intellectual disability, motor clumsiness, language disorders
Cornelia de Lange syndrome	NIPBL SMC1A SMC3 unknown	1/10,000	<1%	35–50%	Facial dysmorphisms, short stature, malformations (cardiovascular, gastrointestinal, and musculoskeletal), developmental delay, intellectual disability, difficulty with swallowing, other- and self-directed aggressiveness, ADHD, obsessive-compulsive disorders (OCD), depression
Sotos syndrome	NSD1	1/10,000 – 1/50,000	<1%	Not known	Macrocephaly, excessive pre- and postnatal body growth, facial dysmorphisms, development delay

Cole–Hughes macrocephaly	Not known	Not known	<1%	Not known	Macrocephaly, intellectual disability, ADHD, developmental delay and bone maturation, language disorders, obesity, facial dysmorphism
Lujan–Fryns syndrome	UPF3B MED12	Not known	<1%	80%	Mild to moderate intellectual disability linked to the X chr. with marfanoid habitus, muscle hypotonia, ascending aortic aneurysm, aggressiveness, hyperactivity, emotional liability
San Filippo syndromes:		0.3–1.6/100,000	<1%	Not known	Behavioral regression or developmental delay, motor and verbal stereotypes, hyperactivity, aggressive behavior, sleep disorders, inappropriate affect, malformations (visceromegaly, facial, skeletal, etc.). Age at onset generally (but not always) after 3 years
A	SGSH				
B	NAGLU				
C	HGSNAT				
D	GNS				
ARX syndrome	ARX	Not known	<1%	Not known	Intellectual disability linked to the X chr. with or without autism; X-linked infantile spasms due to mutations or insertions; X-linked lissencephaly with agenesis of the corpus callosum and ambiguous genitalia in the presence of stop mutations, which lead to death due to developmental delay and drug-resistant epilepsy
Ch 2q37 deletion syndrome	2q37.3	Not known	<1%	Not known	Brachymesophalangy, intellectual disability
Williams–Beuren syndrome	7q11.23 del	1/7500–1/25,000	<1%	7%	Elfin facies, supravalvular aortic stenosis and in other large arteries, short stature, hypodontia, microdontia, hypercalcemia, friendly and gregarious personality or more rarely autism, ADHD, anxiety, visuocognitive dysfunction
Williams–Beuren region duplication syndrome	7q11.23 dup	1/12,500–1/20,000	<1%	35.7%	Growth retardation, facial and dental dysmorphisms, intellectual disability, developmental delay, expressive language disorder, seizures
Ch 13 deletion syndrome	13q	?	≤1%	?	Intellectual disability, language disorder, retinoblastoma, growth retardation, malformations (cardiovascular, craniofacial, gastrointestinal, renal, skeletal limbs, and fingers)
Ch 15q syndromes: Angelman syndrome	Del/mutation in maternal UBE3A	1/10,000–1/12,000	≤1%	42%	"Happy puppet" syndrome, facial dysmorphisms, developmental delay, language disorder, stereotyped behaviors, intellectual disability, ataxia, ADHD, psychomotor agitation, microcephaly, and seizures

(continued)

Table 16.1 (continued)

	Gene/ch. region	Prevalence	Incidence of the syndrome in ASD	Incidence of ASD in the syndrome	Main signs and symptoms
Prader–Willi syndrome	Del in paternal 15q11–q13	1/10,000–1/15,000	?	25.3%	Developmental delay, short stature, intellectual disability, hyperphagia, obesity, hypotonia, hypogonadism, OCD
Isodicentric cr. 15q	Dup 15q11–q13, GABRB3	1/30,000 (?)	≤1%	70%	Short stature, diabetes, anal and jejunal atresia, acanthosis nigricans, severe autism, developmental delay, intellectual disability, hypotonia, seizures
Hypomelanosis of Ito	Mosaic dup/del 15q11–q13	1/10,000	≤1%	10%	Macular hypopigmented whorls, streaks, and patches, neurological deficits, intellectual disability, seizures, multiple malformations (cerebral, ocular, and musculoskeletal)
Smith–Magenis syndrome	Del 17p11.2	1/25,000	≤1%	93%	Intellectual disability, developmental delay, self-injurious behavior, facial dysmorphisms, hearing loss; skeletal, renal, cardiac, and ocular abnormalities
Potocki–Lupsky syndrome	Dup 17p11.2	?	≤1%	?	ADHD, intellectual disability, developmental delay, short stature, hypotonia, facial dysmorphisms, cardiac and dental abnormalities
Down syndrome	Trisomy cr. 21	1/1000	≤2.5%	1–42%	Facial dysmorphisms, cardiac and intestinal malformations, intellectual disability of variable degree
Velocardiofacial/ Di George syndrome	Del 22q11.2	1/4000	≤1%	20–31%	Facial dysmorphisms, cleft palate, cardiac malformations, hypoplasia or aplasia of the thymus gland, hypoparathyroidism, autism, intellectual disability, developmental delay, ADHD, psychosis, seizures
Ch 22q11 duplication syndrome	22q11.2 dup	Not known	<1%	Not known	Facial dysmorphisms, velopharyngeal insufficiency, intellectual disability, developmental delay
Phelan–McDermid syndrome	22q13.3 del	Not known	<1%	50–70%	Minor dysmorphisms, severe muscle hypotonia, intellectual disability, developmental delay, language impairment

Del deletion; *Dup* duplication; *Ch* chromosome. Modified from Persico and Napolioni [24] and Persico [33]

3. *Autisms due to* de novo *or inherited rare genetic variants* – Genetic variants are defined "rare" when their minimum allele frequency (MAF) is <1%, as applied to the term "mutation," whereas they are defined "polymorphisms" when their MAF is ≥1%. In this class of autisms, a *single genetic variant* is entirely responsible for the onset of ASD [24, 25]. Rare pathogenic variants can be distinguished as follows: (a) large chromosomal aberrations, detectable by classical G-banding karyotype (many yield syndromic forms, as listed in ◘ Table 16.1); (b) CNVs, microdeletions, or microduplications ranging from 1Kb to several Mb in size and detectable only by array-CGH; (c) small insertions/deletions (indels), up to 1Kb in size, including frameshift mutations due to codon insertions resulting in additional amino acids being inserted into proteins; or (d) mutations, that is, single-nucleotide variants (SNVs) typically generating stop codons, yielding functionally inactive truncated proteins, or missense mutations causing amino acid changes resulting in "loss of function" or "gain of function." Both indels and mutations require Sanger sequencing or NGS for detection. Additional pathogenic mechanisms can include triplet repeat expansions, uniparental isodisomy, or CNVs which impact promoters, long noncoding RNAs, miRNAs or imprinting centers, affecting gene expression through epigenetic dysregulation. In reference to their *allele frequency*, pathogenic variants are often "very rare" or even "private" (i.e., found in a single patient or in very few patients worldwide, as can be seen on the Decipher database [40]). There are, however, some recurrent forms, due to pathogenic CNVs of identical or similar size which, albeit rare, are found in several patients (e.g., dup/dels in ch 1q21, 15q13, and 16p11.2). In terms of *inheritance pattern,* pathogenic gene variants can be dominant, recessive, X-linked or de novo. Clearly, pathogenic variants inherited from a parent either completely healthy or displaying only minimal ASD traits with variable penetrance require additional genetic variants or epigenetic contributions to express full pathogenicity. De novo mutations are estimated to occur in 15–25% of cases [31].

To date, there are well over 200 genes that if mutated, deleted, or duplicated, yield ASD [41]. Updated lists of these genes can be found in several databases like that of the Simons Foundation [42] and the "autismKB" database of the University of Beijing [43]. In general, ASD due to rare genetic variants is not clinically identifiable in any specific way, as carriers often do not display dysmorphisms or systemic signs/symptoms, especially when CNVs affect only genes expressed in the CNS. Nonetheless, mutation or indels in specific autism-associated genes can produce peculiar systemic signs, such as macrocephaly or oculomotor deficits for PTEN and HOXA1, respectively [44, 45], albeit with sizable interindividual phenotypic variation. Finally, it is important to consider that CNVs and SNVs are typically nonspecific in their neurodevelopmental outcome, due to the pleiotropy of many genes in psychiatric disorders [46]. It is thus not unusual that mutations affecting the same gene or at times even the same mutation may yield clinically different neurodevelopmental disorders, ranging from ASD, intellectual disability, global developmental delay, language development disorder, learning disability, as well as schizophrenia spectrum (see also Chap. 10).

4. *Autisms due to common genetic variants and gene–environment interactions* – Collectively, 10% of individuals with ASD are syndromic, another 8–10% carry one pathogenic CNV detectable by array-CGH [47], and the yield of exome sequencing for indels and mutations located in the coding sequence reaches 8–16% [47] with even higher positive rates reported for developmental delay [48]. Another 10–20% of ASD patients carry likely pathogenic CNVs or functionally relevant CNVs able to contribute, in conjunction with other genetic variants, to the disorder. At this time, it is not yet clear how much whole

genome sequencing (WGS) shall add in providing additional variants that may be responsible for ASD [49]. Therefore, at this time, at least half, and possibly the majority of genetic risk for ASD, appears to be carried by common variants able to negatively affect neurodevelopment by influencing gene expression or protein function [50, 51]. Single-nucleotide polymorphisms (SNPs) are SNVs with MAF >5% in the general population. Each single common variant obviously cannot be pathogenic (otherwise, it would not be "common" in the general population), and explains on average <1% of phenotypic variance, in some instances reaching 1–5% [52]. However, an unfavorable combination of common variants can additively increase vulnerability, enhancing the penetrance of rare variants and/or decreasing the sensitivity threshold for environmental factors able to disrupt neurodevelopment [51, 53]. Several genes encompass common variants with replicated and well-established functional relevance in ASD, including genes encoding the GABA-A beta3 receptor (GABRB3), the oxytocin receptor (OXTR), reelin (RELN), the serotonin transporter (SLC6A4), subunit 2B of the glutamate NMDA receptor (GRIN2B), arginin-vasopressin receptor 1A (AVPR1A), engrailed2 (EN2), integrin beta3 (ITGB3), the proto-oncogene MET, and contactin-associated protein-like 2 (CNTNAP2) [24, 25]. Many other genes are listed in the databases and gene lists mentioned above.

Over the years, the genetics of ASD has moved away from single gene analysis and has been focusing more on "gene networks," the genetic substrate of "molecular pathways" whose dysfunction would explain ASD in each individual [54, 55]. The concept of "gene network" refers to the functional role of the protein encoded by each gene, and collects into a single network all those gene-encoding proteins which interact in a single molecular pathway (examples of gene pathways can be found in the "Gene Ontology Resource" [56]). Genes located at the intersection between different pathways can be identified as "hub genes," whose dysfunction can negatively affect multiple functional pathways. These hub genes often correspond to genes which, if mutated, deleted, or duplicated, yield ASD due to rare single variants.

Gene networks more frequently involved in ASD, as identified through array-CGH, NGS, and/or RNAseq for genome-wide transcriptomics, are involved in synaptogenesis and synaptic management, neurite outgrowth, chromatin remodeling, cytoskeleton and synaptic scaffolding, cell proliferation, transcriptional regulation, and activity-dependent translation [54, 55]. Molecular pathways include Wnt (Wingless and Int-1) signaling, PI3K/mTOR, and Ca^{2+}/calmodulin [57].

16.3.2 Epigenetics

The study of rare and common genetic variants has provided converging evidence for transcriptional dysregulation as one of the pathways most able to lead to ASD. Epigenetics refers to variation in gene expression as a cause for (a) interindividual phenotypic variability, when genetic factors are held constant (e.g., phenotypic differences between monozygotic twins) and (b) nongenetic transmission of traits from one generation to the next [58, 59]. Governing the interaction between genomic DNA, histones and the transcriptional machinery, epigenetic mechanisms, primarily involving DNA methylation/demethylation with the formation of 5-methylcytosines in CpG (C-phosphate-G sequence of DNA nucleotides) islands and histone deacetylation/acetylation, respectively, control chromatin structure [58, 59]. This, in turn, determines the accessibility of coding genes to the transcriptional machinery, as well as the production rates of regulatory miRNAs and long noncoding RNAs. Epigenetics is highly organ- and tissue-specific, even brain region-specific, if we refer to the CNS. This regional specificity in epigenetic markings (i.e., cytosine methylation and histone acetylation patterns) is paralleled by regional differences in gene expression, as evidenced by genome-wide transcriptomics

[60, 61]. While functionally ideal to provide maximum adaptation to different tissues, organs and systems [58], this aspect poses a relevant experimental limitation, preventing from extending conclusions beyond the cell type, organ, or brain region directly assessed in each specific study.

At least three aspects of epigenetic contributions to ASD deserve attention:

(a) Prenatal and early postnatal exposure to environmental factors during critical periods in neurodevelopment, produce permanent changes in DNA methylation patterns able to influence gene expression throughout the lifetime of the individual. This mechanism is a primary contributor to the teratological consequences of prenatal exposure to pharmacological and illegal drugs [62], as well as to malnutrition and gestational complications, during pregnancy [63, 64].

(b) Abnormal methylation patterns have been recorded in individuals with ASD applying various technologies to different tissues and brain regions. These differences impact several genes relevant to neurodevelopment, such as OXTR, RELN, EN2, MECP2, and GAD1 [65]. Interestingly, several of these genes also contain common genetic variants contributing to ASD risk, as discussed above. Epigenome-wide changes are usually complementary to differences reported in genome-wide transcriptomic studies [65], highlighting enhanced expression of immune genes likely due to neurinflammation and microglial activation in ASD brains, as opposed to hampered expression of neural activity genes [60, 61]. Interestingly, also epigenetic mechanisms are under the influence of common genetic variants particularly enriched in the proximity of immune genes [66].

(c) DNA methylation is removed from gDNA following fertilization during preimplantation development through the process of "DNA methylation reprogramming," only to be reestablished subsequently in the blastocyst [67]. However, in real life, the process of demethylation can be hampered, as it occurs in cloned embryos which display reduced demethylation and precocious de novo methylation already at the 4- and 8-cell stages [69]. Even in normal embryos, DNA reprogramming is far from complete: some DNA methylation marks present in parental gametes do remain and foster the multigenerational transmission of phenotypic traits in the absence of direct contributions by the DNA sequence [69]. Classical studies following up the offspring of mothers pregnant during the Dutch famine of 1944 have recorded an epigenetically driven increase in incidence of obesity and metabolic disorders in the second-generation offspring of fathers exposed to the famine in utero [70]. Interestingly, hypo- or hypermethylation has been uncovered in the gDNA extracted from sperm cells of fathers of autistic children, especially in the vicinity of loci relevant to neurodevelopment, including several SNORD genes [71]. Initial evidence of possible correlations between the degree of abnormal methylation at some of these loci and clinical scores at the Autism Observation Scale for Infants (AOSI) [71] is indeed exciting but requires caution until replicated.

In conclusion, epigenetic mechanisms represent the bridge between genetic predisposition, environmental influences, and dysimmunity/neuroinflammation, the three components currently viewed as most relevant to the etiopathogenesis of multifactorial forms of ASD. Possible contributions by epigenetic abnormalities present in parental gametes significantly broaden the time window of environmental influences potentially able to confer autism risk.

16.3.3 Environmental Factors

The role of environmental factors in the etiology of ASD has been the object of intensive research, especially spurred by the dramatic increase in ASD incidence recorded during the past 20 years [53, 72]. In interpreting the results, it is critical to keep in mind that a temporal correlation between an environmental

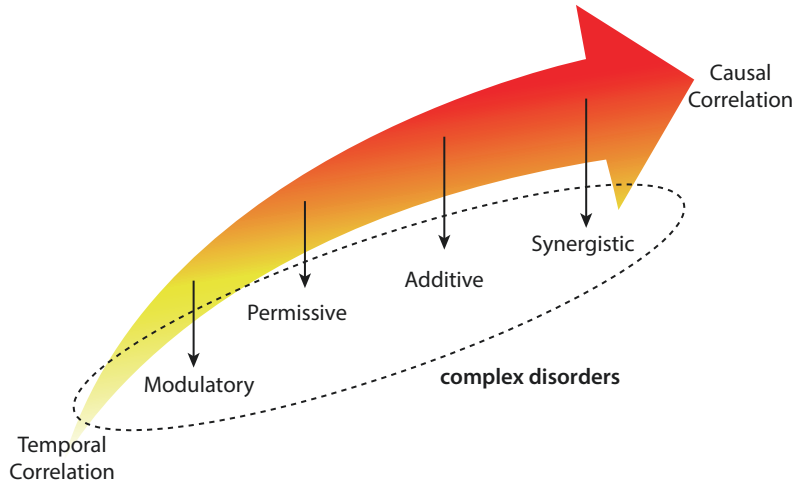

Fig. 16.1 Environmental factors in human disorders. (From Ref. [72], with permission)
A "none-to-all" upward scaling model, spanning from temporal coincidence without any pathogenic role to full causality. Environmental Factors (EF), in interaction among themselves and with Genetic Factors (GF), can exert: (a) modulatory effects: EF influence the phenotypic expression of GF only qualitatively; (b) permissive effects: one EF is necessary for another EF to exert damage, or for a GF to become penetrant and to achieve phenotypic expression; (c) additive effects: EF and GF act independently and their combined effect equals the sum of each contributing factor; (d) synergistic effects: EF and GF potentiate each other, so that the combined effect is greater than the predicted sum of each contributing factor

exposure and ASD phenotype will need to be further substantiated by means of cellular and animal models and understood at the molecular level with support through human epidemiological, neuropathological, and clinical studies. Furthermore, causal links can assume various forms (Fig. 16.1 from [72]). An environmental factor can play a variety of roles:

- *Causal* – the environmental factor alone is sufficient to cause the disorder.
- *Synergistic* – the environmental factor boosts the penetrance of a genetic predisposing factor or the damaging effects of another environmental factor, so that [1 + 1] > 2.
- *Additive* – environmental effects add up linearly with other environmental and genetic effects, so that [1 + 1] = 2.
- *Permissive* – the environmental factor does not exert direct damage on neurodevelopment, but sensitizes the CNS or produces the priming needed to allow the damaging effects of another factor (environmental or genetic), so that [0 + 1] > 1.
- *Modulatory* – the environmental factor cannot cause the disorder, which is caused by other genetic and environmental factors; however, once these are present and active, the environmental factor influences the timing of onset and the severity of the clinical phenotype.

Although not considered as sole cause of ASD, early environmental factors may play an important role (Table 16.2A) [53, 72] envisioned under prenatal, perinatal, and postanatal factors.

Prenatal Factors

The prenatal environmental factors include infections, mainly caused by neurotropic viruses, allergic or autoimmune problems, endocrinological problems, exposure to drugs or toxic substances, gestational hypertension, gestational diabetes, excess of testosterone in the amniotic fluid, threat of abortion and predelivery hemorrhage [73–78].

Fetal anticonvulsant syndrome – caused by prenatal exposure to valproic acid or, less frequently, to carbamazepine [79]. Clinically it is characterized by expressive language delay, global psychomotor delay, relatively preserved cognition. Facial dysmorphisms are typically

Table 16.2 Environmental factors able to (A) cause autistic disorder or (B) exert synergistic or additive effects (from Ref. [72], modified)

A	Critical period	Mechanism
Valproic acid	E18–E30	Altered gene expression due to histone hyperacetylation, inhibition of neural progenitor proliferation vie Ras-ERK, oxidative stress, folic acid antimetabolism
Thalidomide	E20–E30	Altered gene expression, ROS-mediated DNA damage, angiogenesis inhibition
Misoprostol	E18–E42	Altered gene expression, angiogenesis inhibition
Rubella	Up to E56	Direct viral damage, maternal and fetal immune response
Cytomegalovirus	Throughout pregnancy	Direct viral damage, maternal and fetal immune response
B		
Air pollution *Smoking during pregnancy*	Throughout pregnancy & early postnatal life	Oxidative stress, CNS and systemic immune activation, cerebral vascular damage, neuronal cell death, altered gene expression through dysregulated DNA methylation
Pesticides: *Organophosphates* *Pyrethroids* *PhtalatesPhthalates*	Throughout pregnancy	CNS and systemic inflammation, oxon disruption of neuroglial proliferation & differentiation, decreased Reelin expression and enzymatic activity, decreased BDNF expression, interference with intracellular Ca^{2+} signaling, disruption of GABAergic neurotransmission, disruption of androgen activity
Polychlorinated biphenyls (PCB) *Polybrominated diphenyl ethers (PBDE)*	Throughout pregnancy	Endocrine disruption of thyroid hormone homeostasis, oxidative stress, interference with intracellular Ca^{2+} signaling, altered gene transcription through decreased DNA methylation, immune system activation
Heavy metals	Throughout pregnancy	Neurotoxicity, immune system activation/autoimmunity, altered gene transcription
Antidepressants (prolonged and high-dose)	Throughout pregnancy	Extracellular serotonin excess

Legend: *E* embryonic day postfertilization [24].

present (see hypertelorism and frontal bossing in Figs. 1 and 2 of Moore and colleagues [80]). It is primarily caused by histone deacetilase inhibition, interfering with epigenetic control of chromatin structure [72].

Exposure to other theratogenic drugs – thalidomide and misoprostol exposures can also cause autism. Thalidomide was prescribed during pregnancy as a sedative-anxiolytic instead of barbiturates, but was withdrawn from public use in 1961 due to severe teratogenicity. Misoprostol is used to produce abortion in South America. Exposure to these two drugs, in addition to producing major systemic consequences, yields ASD when exposure occurs in a very early time window in pregnancy corresponding to the closure of the neural tube, that is, embryonic day 18–30 post fertilization (Table 16.2) [81].

Congenital viral infections (rubella, cytomegalovirus) – Prenatal infection with rubella virus and cytomegalovirus have been

the most linked to ASD, typically associated with severe intellectual disability, deafness, and malformations, often affecting the eye and heart. Epilepsy and cerebral palsy are also frequent among outcomes. Brain MRI typically shows a heterogeneous variety of abnormalities, ranging from cortical malformations (polymicrogyria, pachygyria, heterotopias) to periventricular leukomalacia, due to defects in neuronal migration and myelination, respectively [82, 83]. This damage is due both to direct viral damage and indirect disruption produced by the maternal immune reaction and local neuroinflammation.

These agents have been conclusively demonstrated to cause ASD, although their effects depend on the timing of exposure during pregnancy and on the genetic and immune predisposition of the maternal-fetal pair.

Converging evidence is also supporting additive or synergistic effects for other environmental factors, with conflicting results due to confounding (Table 16.2B) [53, 72]. The association between air pollution and ASD, for example, is primarily supported by studies performed in the United States, with results influenced by confounding factors such as socioeconomic status and living close to sources of traffic and/or industrial air pollution. European studies do not support such an association with air pollution and prenatal exposure to cigarette smoking has also yielded inconclusive results [53]. Pesticides and insecticides, especially the organophosphate clorpyrifos, used in households by exterminators until a few years ago, were noted as potential candidates due to genetic predisposition in common variants of the PON1 gene being associated with ASD in North American, but not in Italian families [84]. This initial genetic evidence was subsequently followed by studies demonstrating an association between prenatal exposure to organophosphates and various neurodevelopmental outcomes, including ASD or autistic traits, ADHD, mild intellectual disability or borderline cognitive level, language development disorder, and learning disability [85–91], with some studies yielding no association [92]. Studies regarding phthalates and pyrethroids have also been suggestive, but with less consistent findings compared to studies involving organophosphates. Similarly suggestive, yet still inconclusive, has been evidence of contributions by heavy metals and persistent pollutants like polychlorinated biphenyls (PCBs) used in electric equipment [53]. Prenatal exposure to selective serotonin reuptake inhibitors (SSRIs) was initially proposed as a potential disruptor of neurodevelopment, based on minor barrel cortex anomalies observed in serotonin transporter Hz knockout mice [93]. This proposal was later confirmed by seven studies collectively demonstrating a 1.8-fold increase in ASD risk for children prenatally exposed to SSRIs [94].

Other prenatal factors, ranging from gestational complications (diabetes, preeclampsia, and prenatal birth) involving maternal folic acid, vitamins, iron, and fatty acids, have also been recently discussed [53]. For these latter set of factors, effect sizes appear inconsistent; the association with gestational complications may likely stem from shared genetic underpinnings and the demonstration of putative add-on environmental effects on ASD risk is complex.

Perinatal Factors

Perinatal factors are mainly represented by obstetric problems, such as the abnormal duration of gestation, the pharmacological induction of childbirth, low birth weight, and perinatal asphyxia. Children born at 28-week gestation have a high risk of neuropsychic problems that remains high up to the 33-week gestation particularly for ASD. The specific determinants of these risk factors have not yet been precisely identified. Research is investigating the role of alterations in the intestinal microbiome, the use of synthetic oxytocin to induce or stimulate delivery, excessive production of stress hormones, in particular CRH (corticotropin-releasing hormone), and derivatives of oxygen reduction (ROS - Reactive Oxygen Species) [95–99].

Postnatal Factors

The postnatal factors that have been evaluated are numerous and heterogeneous, includ-

ing the breakdown of the equilibrium between the production and the elimination of oxidizing substances (harmful to nerve cells), anomalies of development of the amygdala, vitamin D deficiency, heavy metals, increase of intestinal permeability by food toxicity (especially gluten and casein), and vaccines. For all these factors, there is no convincing evidence of causal value.

The recommendations of the National Institute for Health and Care Excellence (NICE) state not to consider special diets in the management of ASD symptoms. Analyses of numerous case–control and cohort studies have shown no association of vaccines with ASD risk over the last two decades [100]. The hypothesis that measles-mumps-rubella (MMR) vaccine causes ASD by damaging the intestinal lining [101] has been refuted with retraction of the Lancet paper in 2010. Further, neither the changes in vaccination policies nor the elimination of the mercury containing preservative thimerosal from vaccines has been followed by changes in ASD incidence trends in countries where these changes have been applied [100]. Thimerosal is ethylmercury, whose toxicological target organ in case of intoxication is the kidney because it crosses the blood–brain barrier only to a very limited extent; instead, it is methylmercury that readily crosses the blood–brain barrier targeting the brain and that has been responsible for the tragic incident of Minimata Bay in Japan [102]. The World Health Organization has also endorsed safety of vaccines: "The overall evidence clearly indicates no association of MMR vaccine with either inflammatory bowel disease or with developmental disorders, including autism" [103] and "There is no evidence of a link between measles-mumps-rubella (MMR) vaccine (or any other vaccine) and autism or autistic disorders" [104].

A possible increase in ASD prevalence risk is linked to some autoimmune diseases and viral infections with temporal correlation reported by some parents in the setting of developmental and behavioral regression, with potential for enhanced oxidative stress that accompanies immune reactions, but the same phenomenon can be observed in children with syndromic ASD, as well as those with idiopathic form who have regressed following immune activation due to recurrent infections, such as otitis media, or different forms of allergies, both significantly more frequent among in children with ASD compared to typically developing children [105, 106]. This phenomenon may characterize a cluster of what has been termed as "dysimmune" children with ASD with relatively specific clinical features and family history [38, 107, 108].

Anatomopathological Correlates

The application of recent neuroimaging techniques has made it possible to study the anatomical development of the brain and neural connectivity, providing in vivo information on the structure of the brain in people with autism. Structural magnetic resonance studies have shown an early and accelerated development of the brain, both of the gray and the white matter, and of the cranial circumference in about 20% of children with ASD [109], detectable in the early childhood and estimated at 5–10% of total brain volume [110]. This acceleration seems to occur starting from the first year of life (9–12 months) [111] and peaks around 2–4 years of age, and is followed by a gradual reduction, until recovery of normal dimensions at the end of adolescence [112, 113].

Abnormalities of the cortex at the dorsal-lateral, superior parietal, intraparietal sulcus, anterior cingulate, as well as insula, amygdala, and the caudate nucleus were found [114]. Further studies with magnetic resonance imaging and other imaging techniques of CNS functioning have explored the abnormalities of activity in various brain areas in relation to the neuropsychological skills frequently compromised in ASD. Alterations of the corpus callosum, cingulate gyrus, superior longitudinal fasciculus, temporoparietal junction, orbital-frontal cortex, and cerebellum have been reported. These brain areas have been repeatedly associated with complex cog-

nitive and motor functions, such as attention, working memory, muscle coordination, or inhibition [115].

- **Electrocortical Correlates**

Research on this topic has mainly used electroencephalography and magnetoencephalography. The most frequently detected alterations are a reduction in long-range connectivity in low-frequency waves [116–119] and an increase in connectivity to short range for high-frequency waves [120]. In general, alterations in wave frequencies have been reported, interpreted as correlates both of excess and defect of connections between neural areas [120, 121].

Multiple types of genetic factors influence the continuum of behavioral and developmental characteristic, with the extreme end of the continuum resulting in ASD. Insights into genomic variability and biology of ASD are increasingly being uncovered with rapid progress in establishing a correspondence between behaviorally defined clinical symptoms of ASD and genetic causation. However, finding the genetic variations and understanding their meaning are equally important, including identification of protein networks affected by many different gene mutations that lead to similar brain dysfunction. The study of rare and common genetic variants has provided converging evidence for epigenetic factors and transcriptional dysregulation as one of the pathways also able to lead to ASD. The role of environmental factors in the etiology of ASD has also been the object of intensive research. In interpreting the results, it is critical to keep in mind that a temporal correlation between an environmental exposure and ASD phenotype will need to be further substantiated by means of cellular and animal models and understood at the molecular level with support through human epidemiological, neuropathological, and clinical studies.

16.4 Diagnostic Criteria and Clinical Features

16.4.1 Definition and Diagnostic Criteria

ASD represents a group of heterogeneous conditions sharing two key features: (a) impairment of socialization and qualitative deficits of communication, for example, reluctance to make eye-contact, lack of appropriate peer relationships, lack of emotional reciprocity, delay in verbal responses, poor conversation skills, lack of pretend play; and (b) restricted and/or repetitive behaviors or interests, for example, repetitive motor movements, preoccupation with parts of objects, hyperfocused interests, and hyper- or hyporeactivity to sensory input [122–130].

The term "autism" was coined by Eugen Bleuler in 1911, to describe one of the four fundamental aspects of schizophrenia, reflecting the affected individual's 'inward turning' into his/her own world and thereby losing contact with the outer world. Bleuler's overall conceptualization of schizophrenia is focused on the loss of interpretative and relational skills, as summarized in the 4A theory: inappropriate or flattened *Affect*, cognitive, affective, and volitional *Ambivalence*, loosening of thought *Associations*, and *Autism*, which was defined as "preference for living in a fantasy world," a gap between the patient's inner fantasy world, inaccessible to reality, and the unloving environment [131, 132]. European phenomenological psychiatry in the field of schizophrenia offered other views to grasping the nature of autism: Eugene Minkowski considered it as "a loss of vital contact with reality" [133, 134], Ludwig Binswanger identified its main characteristic in the "inconsistency of natural experience" [135], and Wolfgang Blankenburg defined it as "the global crisis of common sense" [136].

The discovery of autism owes its origins to the separate works of Leo Kanner and Hans Asperger, who in 1943 [137] and 1944 [138], described a series of children with clinical

picture consistent with current descriptions. The "Autistischen Psychopathen" patients described by Asperger were different from those of Kanner in three aspects: (1) more fluent speech; (2) difficulty in carrying out gross motor movements but not fine movements; (3) different level of learning ability. Asperger called such patients "abstract thinkers" or "little professors," which, according to Kanner, have great problems with mechanical learning. Even with important common traits, two different clinical forms were determined: Kanner's Autism and Asperger's syndrome. During the period 1994–2013, Asperger's syndrome became the term applied to the individuals with ASD without deficits in intellectual functioning and significant language delay.

The term autism had been used in pediatric circles in Europe as early as 1920s to describe the social withdrawal experienced by young children [139]. In this perspective, the transition from the Bleulerian autism to current use has its roots in a literature of clinical descriptions produced between the end of the nineteenth century and the beginning of the twentieth century. Children with a marked tendency to self-isolation and poor affective contact were characterized under the rubric "hereditary insanity" or hereditary psychosis, many of whom with remarkable intelligence, as described in his textbook by Heinrich Schüle, a German physician [140]. By the 1880s, similar features associated with catatonia were noted in children with developmental delay. In 1887, the English pediatrician Langdon Down associated autistic behavior with catatonia in "developmental idiocy," although he used neither the term autism nor catatonia. In his descriptions of the children with poor social reciprocity he noted, "returns your kiss by a bite," inflexibly mute, withdrawn, and scarcely reactive, regardless of the circumstances around them, and sometimes fascinated by peculiar sensory stimulations, for example, the rhythm of music. Langdon Down also described automatic movements of the fingers and rhythmical movements of the body, now termed as stereotypies [141]. In 1913, Kraepelin described a form of childhood-onset dementia praecox, akin to the current picture of autism. He referred to these individuals by embracing the Bleulerian autism [142]. In the ensuing years, the term autism got widespread use across Europe. In 1924, Moritz Tramer described gifted children with developmental delay, idiosyncratic language, and excellent memories and drawing skills. In Russia, the pediatric neurologist Grunya Sukhareva was the first to describe infantile autism but entitled her paper published in 1926 as "schizoid psychopathy"; she applied Kretschmer's idea about autism and underlined the association with catatonia among these children [143]. The work of Sukherava was expanded in Moskow by Ewa Grebelskaja-Albatz, who in 1934 published a case series on 22 children with autism, psychosis, and/or catatonia, focusing on patients with lower functioning [144]. Due to the language, these remarkable works were not widely publicized, until the 1981, as was the case with the translation of Asperger's paper by Lorna Wing. Even in the United States, some authors had descriptions of young individuals with schizophrenia who can now be considered as having an ASD, as with description by Howard Potter, Lauretta Bender, and Juliette Louise Despert in the context of childhood schizophrenia [145] consistent with the notion of a neurodevelopmental continuum of social deficits that may be shared by these conditions [146–148].

Advances in the clinical conceptualization of ASD as a spectrum are attributed to Lorna Wing who was a mother of a son with autism and founder of the National Autistic Society in the UK. Wing distinguished three types of social interaction:

- ALOOF: individuals indifferent to other people, detached, characterized by the presence of motor stereotypes, good mechanical skills and visual-spatial abilities, and medium-severe cognitive impairments ("classic" autistic disorder)
- PASSIVE: individuals who tend to allow others to interact with them but drift back soon to isolation if left to their own routines or devices; in comparison to the aloof type, this type may be detected later in life

- ACTIVE/ODD: individuals who make spontaneous approaches to others but in a peculiar, naive, and/or nonreciprocal way; they present good cognitive abilities (high-functioning autism) [149]

During the 1950s and 1960s, autism was still considered an early manifestation of schizophrenia, which was thought of as an emotional disorder caused by pathological parent–child interaction. Even the subsequent editions of Kanner's textbook on Child Psychiatry during this period grouped autism under childhood schizophrenia. Bruno Bettelheim, an Austrian-born psychologist, used the term "refrigerator mothers" to characterize a cold and unemotional mother theory [150]. Melanie Klein published a paper on child personification in which she argued that if a child's instinctual wish fulfillment took precedence over their recognition of reality, the child was suffering from a form of 'psychosis' [151], a term Freud coined in 1894 to describe 'hallucinatory confusion' [152]. In the first two editions of the DSM, autism was classified under the terms "schizophrenic reaction, childhood type" [153] and "childhood schizophrenia" [154], respectively. During the 1970s, the psychogenic paradigm was abandoned, and the scientific community began to consider biological roots of autism, especially with the publication of Bernard Rimland's book on infantile autism in 1964, written after his son was diagnosed with the disorder, on "its implications for a neural theory of behavior" [155].

The International Classification of Diseases – Ninth Revision, ICD-9 [156] considered autism as a diagnostic subcategory of the childhood schizophrenia. The publication of DSM-III [157] was an important threshold and represented a cleavage between the international classification systems. The DSM-III [157] introduced six inclusion criteria for infantile autism, with symptoms onset early by 30 months of age, communication and language impairments, narrow interests, and fear of change. For the first time, the distinction between childhood schizophrenia and autism was emphasized with the introduction of overarching metacategory of pervasive developmental disorder (PDD) with five subcategories: infantile autism, residual infantile autism, childhood-onset pervasive developmental disorder, residual childhood-onset pervasive developmental disorder, and atypical autism. The concept of autism as a "syndrome" was also mentioned.

The DSM-III-R [158] provided a more complex definition requiring at least 8 of 16 criteria to be met in three domains of social interaction, communication/imagination, and interest/activity. The age of onset was moved to first 36 months of life. A new subcategory under the umbrella PDD term, pervasive developmental disorders-not otherwise specified (PDD-NOS) was also introduced. The PDD-NOS was defined by subthreshold symptoms, with no specification of requisite symptoms and often too mild to allow a diagnosis of true autism that could be considered if a child does not meet the diagnostic criteria for PDD-NOS. Revisions made in the DSM-III-R included changing infantile autism to autistic disorder, while childhood onset pervasive developmental disorder and residual infantile autism were dropped.

The DSM-IV [159] further refined the diagnostic criteria and increased the number of conditions included under PDD to five subtypes: autistic disorder, Asperger's disorder (introduced for the first time), Rett's disorder, childhood disintegrative disorder, and PDD-NOS. The DSM-IV also added autism to the general chapter "global alterations of psychological development" and particularly to "generalized developmental disorders."

In the DSM-IV text revision (DSM-IV-TR) [160], the diagnostic categories and criteria remained consistent with the earlier edition, with the diagnosis of autism requiring the following criteria:

A. A total of six (or more) items from (1), (2), and (3), with at least two from (1), and one each from (2) and (3):

1. Qualitative impairment in social interaction, as manifested by at least two of the following:
   (a) Marked impairments in the use of multiple nonverbal communication
   (b) Failure to develop peer relationships
   (c) A lack of spontaneous seeking to share enjoyment, interests, or achievements with other people
   (d) Lack of social or emotional reciprocity
2. Qualitative impairments in communication as manifested by at least one of the following:
   (a) Delay in development of spoken language or absence of spoken language not accompanied by an attempt to compensate through alternative modes of communication
   (b) In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
   (c) Stereotyped and repetitive use of language or idiosyncratic language
   (d) Lack of varied, spontaneous make-believe play or social imitative play
3. Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least two of the following:
   (a) Stereotyped and restricted patterns of interest that are abnormal either in intensity or focus
   (b) Excessive adherence to specific, non-functional routines or rituals
   (c) Stereotyped and repetitive motor mannerisms
   (d) Persistent preoccupation with parts of objects

B. Delays or abnormal functioning in at least one of the following areas, with onset prior to age 3 years:
   1. Social interaction
   2. Language as used in social communication
   3. Symbolic or imaginative play

C. The disturbance is not better accounted for by Rett's Disorder or Childhood Disintegrative Disorder.[1]

Given the symptom variability and inconsistency across clinical and research settings in diagnoses, the DSM-5 [161] combined the four previous subtypes into ASD, as single condition with three severity levels. The DSM-5 also introduced a new symptom of hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment. The DSM-IV autistic disorder, Asperger's disorder, childhood disintegrative disorder, and PDD-NOS (atypical autism) were no longer included and Rett's disorder was now considered as an independent genetic disorder [162]. According to DSM-5, the diagnosis of ASD requires two core symptoms: (a) deficits in social communication and social interaction and (b) restricted repetitive behaviors, interests, and activities [163]. The age of onset is modified from 36 months to "early childhood," with the possibility of other ages of onset in which deficits may not become fully manifest until social communication demands exceed limited capacities. In DSM-5, concurrent diagnosis of ADHD with ASD is allowed.

According to DSM-5, the ASD diagnostic criteria include the following:

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history:
   1. Deficits in social-emotional reciprocity, ranging from abnormal social approach and conversation to reduced sharing of interests, emotions, or affect
   2. Deficits in nonverbal communicative behaviors used for social interaction, ranging from poorly integrated verbal and nonverbal communication to abnormalities or even absence of eye contact, facial expressions

1 The text of these diagnostic criteria is not the same as that of the DSM-IV-TR. For the exact wording of the criteria, please refer to the original manual.

3. Deficits in developing, maintaining, and understanding relationships, ranging from difficulties in adapting to various social contexts and making friends to absence of interest in peers

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history:
   1. Stereotyped or repetitive motor movements, use of objects, or speech
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior
   3. Highly restricted, fixated interests that are abnormal in intensity or focus
   4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities or may be masked by learned strategies in later life)[2]

The DSM-5 defines three levels of severity based on a person's limitations in adaptive functioning and management of daily life:

- Level 1: Requiring support
- Level 2: Requiring substantial support
- Level 3: Requiring very substantial support

Level 1 ASD is the mildest, or the most "high-functioning" form of autism. Persons diagnosed with this level are usually able to speak in full sentences and communicate but have problems with engaging in back-and-forth conversation with others, initiating interactions, and making friends as well as with flexibility, organization, planning, and switching between activities.

Persons with level 2 have more problems with verbal and nonverbal communication and social skills. Likewise, they find it harder to change activities or focus and present markedly restricted and repetitive behaviors.

Level 3 corresponds to the highest impairment of functioning. Persons in this level show severe impairment of verbal and nonverbal communication and social interaction. They also face extreme difficulty in changing their daily activities or routine and experience a high level of distress if a situation requires them to alter their focus or task.

In the ICD-11 [164], ASD is defined by a) persistent deficits in the ability to initiate and to sustain reciprocal social interaction and social communication, and by b) a range of restricted, repetitive, and inflexible patterns of behaviour, interests or activities that are clearly atypical or excessive for the individual's age and sociocultural context.

- Understanding of, interest in, or inappropriate responses to the verbal or non-verbal social communications of others.
- Integration of spoken language with typical complimentary non-verbal cues such as eye contact, gestures, facial expressions, and body language. These non-verbal behaviors may also be reduced in frequency or intensity.
- Understanding and use of language in social contexts and ability to initiate and sustain reciprocal social conversations.
- Social awareness, leading to behavior that is not appropriately modulated according to the social context.
- Ability to imagine and respond to the feelings, emotional states, and attitudes of others.
- Mutual sharing of interests.
- Ability to make and sustain typical peer relationships.

Manifestations of alterations of patterns of behavior, interests, or activities include the following:

- Lack of adaptability to new experiences and circumstances, with associated distress, that can be evoked by trivial changes to a familiar environment or in response to unanticipated events.
- Inflexible adherence to particular routines; for example, these may be geographic such as following familiar routes or may require precise timing such as mealtimes or transport.

2 The text of these diagnostic criteria is not the same as that of the DSM-5. For the exact wording of the criteria, please refer to the original manual.

- Excessive adherence to rules (e.g., when playing games).
- Excessive and persistent ritualized patterns of behavior (e.g., preoccupation with lining up or sorting objects in a particular way) that serve no apparent external purpose.
- Repetitive and stereotyped motor movements such as whole body movements (e.g., rocking), atypical gait (e.g., walking on tiptoes), unusual hand or finger movements, and posturing.
- Persistent preoccupation with one or more special interests, parts of objects, or specific types of stimuli (including media) or an unusually strong attachment to particular objects (excluding typical comforters).
- Lifelong excessive and persistent hypersensitivity or hyposensitivity to sensory stimuli or unusual interest in a sensory stimulus, which may include actual or anticipated sounds, light, textures (especially clothing and food), odors and tastes, heat, cold, or pain.

As for the DSM-5, the onset of the disorder is referred to the developmental period, typically to early childhood, although symptoms may not become fully manifest until later, when social demands exceed limited capacities. Deficits are requested to be sufficiently severe to cause impairment in personal, family, social, educational, occupational or other important areas of functioning and are usually a pervasive feature of the individual's functioning observable in all settings, although they may vary according to social, educational, or other context. Individuals along the spectrum exhibit a full range of intellectual functioning and language abilities. The ICD-11 [164] divides ASD into 5 subcategories based on whether or not a disturbance of intellectual development is present, as well as the degree of functional language impairment.

The core symptoms that characterize ASD include qualitative impairments in (i) communication and social interaction and (ii) restricted and repetitive patterns of behavior, activities, and interests, with an important feature now included in the latter criteria set in the DSM-5 and ICD-10 involving the alteration of sensory modulation.

16.4.2 Onset and Presentation

Complementary sources of information have contributed to the notion that early signs of ASD are detectable during the first year of life. The observations of Leo Kanner in 1943 [137] of infantile autism as an innate disorder of emotional contact are reminiscent of this view that include the following:

1. Studies noting parents' memories of the early characteristics of their child's development collected through parents' questionnaires or interviews
2. Retrospective analysis of family videos recorded by parents before diagnosis was made and through which it is possible to have a direct view of the child in the first 2 years of life
3. Population-based early screening and observational diagnostic tools
4. Prospective studies of early development of high-risk siblings of children with ASD.

Research on the early presentation of ASD historically coincides with the continuous growth of knowledge on the social development of the young child. The research emphasis on early detection of ASD has progressively shifted from identifying positive symptoms to defining difficulties in social behaviors. Nonetheless, even if the socio-communicative difficulties are the most important indices for early identification of ASD, data also indicate early presence of repetitive movements [165]. The onset of ASD symptomatology may range from emergence by age 12 months to more commonly between age 18 and 24 months. According to the epigenetic perspective, the growth of the social brain, typically immature at birth, depends on the environment. This perspective has increasingly led to emphasis on early intervention and efforts for alleviation of communicative and social impairments. Early screening and identification efforts and timely implementation of therapeutic interventions have therefore become one of the most priority research topics as they can significantly mitigate the developmental impact of the disorder. Research on the early signs of autism has shown that during the first 3 years of life,

the children with ASD show fluctuation in the organization of their intersubjectivity, particularly in terms of their facial, vocal, and gestural synchrony with reduced frequency, coordination, and dependence on external stimulation. In addition, they present with hyporeactivity, poor eye contact, communicative babbling, pointing, and gesturing [166].

Early identification of ASD and timely implementation of therapeutic interventions are the foremost priority as they can significantly mitigate the developmental impact of the disorder.

16.4.3 Communication and Social Interaction

The first set of core symptomatology that characterizes ASD is the qualitative impairment of communication and social interaction. The delay or plateau in the progression of the development of children's social communication skills, especially in the first and second years of life, remains as the first alarm signal perceived by parents that is also the foremost reason why they seek specialist attention. Communication difficulties are also enhanced by language developmental anomalies. The latter can manifest themselves in various ways along a continuum from total absence to the presence of a well-developed language, with vocabulary that often lacks contextual flexibility and reciprocity. These communication problems emerge both in relation to the comprehension and language production skills and are an obstacle in the overall development of social competence. Problems in understanding are often associated with the literal interpretation of language, in turn linked to the deficit in imaginative and/or abstraction skills and to scarce attention paid to communicative stimuli. The absence of verbal language characterizes about 20–50% of children with ASD, with children acquiring a certain number of words (five or more) between 12 and 18 months of age, with some children undergoing a regression with loss of language as well as other acquired developmental skills.

Parallel to the developmental anomalies of language, difficulties in nonverbal communication are also characteristic in ASD communication deficits. Whereas children with simple delays in development of language show sufficient compensatory communication at a non-verbal level, children with ASD often have reduced or atypical use of nonverbal and pragmatic communication. For this reason, it is fundamental to pay attention to the idiosyncratic ways that each child with ASD uses nonverbal communication. Echolalia, or literal repetition of a word or a group of words heard from an external source, may also affect about 25% of children with ASD. The echolalia can be immediate, if the repetition takes place immediately after listening, or delayed occurring some time from listening. The use of echolalia by the child can be understood in some children with ASD as an expression of a communicative intent, in others as a form of self-stimulation with a reassurance function. The proportion of children with ASD who are "minimally verbal" is estimated to range from 25% to 50% [167, 168]. However, there is no universal agreement on what constitutes minimally verbal communication (i.e. no words, few words, the extent to wich words are used for communication), and different definitions and assessment instruments result in different groupings of children and adults [167, 169].

Children typically learn within their everyday interactions; they understand that their actions can have an effect on others and they learn the meaning of words and function of objects. From the first moments of life, the experiences of the newborn are guided by the actions of adults. The presence of ASD prevents this natural learning process by reducing the child's sensitivity to the most salient social and affective stimuli, such as the baby talk, characterized by spikes and changes in intonation that their parents use when they turn to the newborn during the first months of life. It has been shown that among children with ASD, the ones who are more attune to baby talk develop better language skills than those who do not. A crucial skill in the acquisition of language is joint attention (JA), as characterized by their ability to direct attention toward a common focus, such as activities

looking at an object with carer. JA is acquired around 18 months and is a precursor of language and indication of intentional nonverbal form of communication. Frequently, children with ASD show difficulties in JA that are strictly correlated with a delay in the development of language and symbolic activities. At the base of the development of social competences, there is the ability, already present in the newborn, to preferentially orient itself toward social stimuli. Children with ASD, on the other hand, preferentially orient their attention toward the stimuli of physical–mechanical world characterized by perfect contingencies and an aversion toward unpredictable stimuli. Such unpredictability in paying attention to people, and in particular to faces, is not only the basis for learning and understanding the behavior of others, but is fundamental for the development of emotions, relationships, and attachments. Persons with ASD and/or other neurodevelopmental problems are more likely than the general population to have transgender identity, non-heterosexual sexual orientation, and other gender non-conformities. Clinicians and family members may mistake gender dysphoria for an autistic feature, an uncommon or too concentrated interest. In contrast, if teenage social issues are attributed to gender dysphoria, ASD may go unnoticed.

16.4.4 Interest and Behavior

A second set of core symptomatology that characterizes ASD is the presence of restricted and repetitive patterns of behavior, activities, and interests. Children with ASD appear to be attracted by the details of objects, a particular sound or specific body sensations. They often put into practice stereotyped behaviors, such as flapping their arms repeatedly, rocking their body, moving their fingers in front of their eyes, and walking on their toes. Their propensity to obsessively repeat the same routine of actions, such as putting objects in a row and stacking the cubes, is attributable to a deficit of imagination and abstraction, or to a particular propensity to focus on detail rather than on the globality of the stimulus. Moreover, these behaviors make the child resistant to changes in his environment.

16.4.5 The Anomalies of Reactivity to Stimuli

An important feature of ASD now included in the core symptoms of restricted and repetitive behaviors in DSM-5 is the alteration of sensory modulation. The sensory profile of children with ASD is different from that of children with neurotypical development. These sensory abnormalities are not due to deficits in the visual, auditory or sensory apparatus that are often normal in tests of visual or auditory acuity. Sensoperceptive anomalies represent a possible basis of the central characteristics of the disorder. The majority of children with ASD show significant impairment of the integration and subsequent organization of sensory information with which they come into contact.

The impossibility of developing a direct line with the outside world, and often also with the internal world, negatively affects their general functioning, altering their mode of response to stimuli. The anomalies of sensory responsiveness can be divided into two broad categories: hyper-responsiveness and hypo-responsiveness. The same child can be hypersensitive to certain stimuli and hyposensitive to others. It has in fact been established that these two patterns of sensory response coexist; despite this, hypo-responsiveness appears to be prevalent and specific to autism in early childhood.

The investigations on hypo-responsiveness to social and nonsocial stimuli have shown that the increase in mental age, even more than the chronological age, corresponds to an increase in responsiveness, both in the social and nonsocial context: this may be due to maturation of general processing mechanisms and attention skills, learning skills and/or development of compensatory strategies. The presence of sensory hyper-responsiveness has been associated with a greater likelihood of increasing stress in parents, restrictions in family life, as well as behavioral problems and anxiety in children. These findings underscore the need to assess the practical and psychological impact that sensory symptoms have on

children and their families, to develop even more effective intervention plans.

16.4.6 Mental Functioning

Over the years, various psychological theories have been developed in an attempt to better clarify the mechanisms of mental functioning of ASD. The main models are shown below.

■ Deficit of the Theory of Mind

Baron-Cohen, Leslie, and Frith [170] identified a deficit of the theory of mind (ToM) underlying the difficulty of people with ASD to interact with others and with the outside world, stemming from the inability to attribute mental states to other people. Having a theory of mind is interpreted as a prerequisite for understanding the full range of own and others' mental states (i.e., beliefs, desires, intentions, imagination, and emotions) that cause actions and behaviors based on the reading of these states. The concept of theory of mind is closely related to the more general concept of metacognition, in the sense that, it would be a specific aspect of larger metacognitive capacities acquired during the ontogenetic development.

■ Primary Deficit in Interpersonal Relationships

All children, from birth, are involved in mutual exchanges with others and emotional expressions of their carers form the basis for understanding the mental states of others and for using facial expressions. Hobson [171] has argued that children with ASD are not able to perceive the expressions of emotions of those who care for them. The author believes that these children fail in the competence acquired through the experience of relationships with others and therefore do not learn to recognize and express mental and emotional states by observing adults and sharing such mental states with them. Similarly, Trevarthen [172–174] has postulated that children with ASD display deficits in intersubjectivity during communicative acts. According to Trevarthen, this ability is innate and does not require abstract cognitive abilities nor does it depend on cultural learning. Intersubjectivity is therefore postulated to manifest itself as an immediate natural awareness of the presence of the other, made possible by the production and recognition of body movements, especially of the face, mouth, and hands, adapted to this communicative function in the course of evolution as social beings. The process of intersubjectivity cannot be completely articulated in children with ASD. The first phase of the process, called primary intersubjectivity, is generally experienced by all children with ASD. The phase of secondary intersubjectivity or collaboration, which requires shared attention, is the most compromised and altered. The hypothesis of the primary deficit in the interpersonal relationship has received renewed attention, supported both by the discovery of the neurophysiological systems of empathy and the mirror neuron system and by the observational studies on the primary relationships of children at high risk of developing ASD [175].

■ Deficit of Planning Executive Functions

The term executive functions (EF) refers to the neuropsychological activities that regulate the processes of planning, control, and coordination of cognitive and motor activities. Examples of the main EF are the organization of actions in hierarchical sequences of objectives, the focus of attention on the most useful information for the task to be performed or the inhibition of responses not adequate to external stimuli. The use of executive functions is indispensable in all types of problem solving, not only in the most complicated and abstract ones, such as the solution of mathematical problems, but also in the acquisition of social skills. Despite numerous studies conducted, the impairment of EF in ASD has not yet been clarified, with a persistent finding of high variability by clinical subgroups or even interindividual [176]. The most frequent anomalies concern inhibition, working memory, flexibility, attention, planning, behavioral monitoring with respect to its planning, preparatory processing, fluency (ease or difficulty in performing a task), and concept formation [176, 177]. Executive dysfunctions also seem to depend on gender: males appear to have less marked alterations in working memory, while females in flexibility [178].

Central Coherence Deficit

Persons with typical development show the ability to organize the various stimuli present in the various contexts in a coherent situation, giving meaning to the experience. The hypothesis of a deficit of central coherence, developed for the first time by Frith in 1989 [179] and subsequently taken up by Happé in 2001 [180], is based on the idea that in ASD there is difficulty in the operations of synthesis and integration of cognitive components and affective information. These difficulties would be associated with a marked propensity to focus on detail rather than on the global nature of the stimulus. This problem could explain the social anomalies found in people with ASD, which would be unable to integrate social skills and competences into everyday life. However, this mode of perceptive processing would make people with ASD more skilled in perceptual discrimination by favoring the development of islands of abilities and talents that sometimes characterize them.

Deficit of Mental Simulation and of the Functioning of Mirror Neurons

Difficulties of joint attention, for example, not alternating the orientation of the gaze from the object fixed by an adult to the adult himself, and simulation, for example, not anticipating or inducing the reactions of an adult, are frequently found in children with autism. These functions have been judged in close relationship with each other, with the activity of the so-called mirror-neurons [181], and with that of the other brain areas appointed to corporatized cognition (embodied cognition), or to the integration of higher cognitive functions with the sensorimotor system.

The first mirror neurons identified were those belonging to the motor system and took their name from the ability to activate not only when the individual to whom they belonged performed an action but also when he saw it performed by others. The results of recent research suggest that this function, technically called "mirror mechanism," is managed by complex networks of neurons rather than single cells and that it suffers from numerous contextual variables, such as the familiarity with the observed action, the position in which it is executed, the perspective from which it is observed or the value attributed to it [182–185]. In animals, mirror mechanisms have been identified in many different cortical areas and brain centers [186–188]. The repeated finding in people with ASD of alterations in the functioning of neural networks with mirror mechanisms [189–195] seems to support the hypothesis that the disorder is caused by a defect in the motor representation necessary to simulate the mental state of others.

Irrespective of many theories that have been postulated to clarify the mental functioning of children with ASD, the delay or plateau in the progression of the development of their social communication skills, especially in the first and second years of life, remains as the first alarm signal perceived by parents that is also the foremost reason why they seek specialist attention.

16.5 Psychiatric Comorbidity in ASD

The psychiatric comorbidity in children, adolescents, as well as adults with ASD, is a subject of critical scientific importance, affecting their quality of life, prognosis, and functional outcomes. The prevalence of psychiatric conditions in persons with ASD vary considerably according to factors such as setting, sample characteristics and diagnostic methods used. Many studies reference clinical or treatment samples, those in treatment in tertiary care or rehabilitation centers, as well as subjects enrolled in clinical trials and cross-sectional studies. Such samples carry a potential for overestimation of both the frequency and severity of psychiatric comorbidity. Nevertheless, a better understanding of the relation between diagnostic constructs, prognostic insight, and preventive as well as treatment approaches in ASD can be gained in the assessment of population-based psychiatric comorbidity. Furthermore, diagnosis of co-occurring psychiatric disorders is also challenging due to several difficulties including the impact of ASD symptoms and behaviors on the assessment procedures, communica-

tion deficits, atypical presentation of psychiatric symptoms, and scarcity of standardized diagnostic tools [196]. Moreover, the clinical manifestations of ASD often overlap with the symptoms of other disorders; thus, it can be difficult to distinguish between them [197–199]. The prevalence estimates of co-occurring psychiatric conditions therefore vary widely, and improved estimates and identification of moderators are needed to improve care [200].

16.5.1 Prevalence of Psychiatric Disorders

Co-occurring psychiatric conditions are more frequent in the ASD population compared to the general population. The prevalence reported in most studies varies from 70% to 72% [201–203] and about 40% of persons with ASD may have two or more comorbid psychiatric disorders [204]. Individuals with ASD are likely to experience a higher prevalence of common mental disorders compared to the general population [205]. A recent comprehensive systematic review and meta-analysis conducted by Lai et al. [200] identified eight co-occurring psychiatric diagnoses most reported in the literature among people with ASD, and indicated that the overall pooled point prevalence figures varied between 4% and 28% [200]. Anxiety and attention-deficit/hyperactivity disorder (ADHD) are the most prevalent psychiatric disorder in children as well as adults with ASD. Recent finding showed that older age was associated with lower prevalence of ADHD and higher prevalence of depressive, bipolar, and schizophrenia spectrum disorders than younger age [200]. Studies with a high proportion of female participants report higher prevalence of depressive disorders. Studies with a high proportion of people with intellectual disability report higher prevalence of schizophrenia spectrum disorders than those with a low proportion of people with intellectual disability did.

In contrast, report from the Simons Simplex Collection (SSC), a deeply phenotyped sample of more than 2800 individuals with ASD that includes only simplex cases, that is, lack of another affected family member closer than first cousins, have shown higher rate of family history of psychiatric disorders (including bipolar disorder and schizophrenia) among higher functioning cases of ASD with higher IQ scores [206].

▪ Anxiety Disorders

The most recent studies on adults with ASD estimate that rates of co-occurring anxiety range from 17% to 27% [200, 202, 207, 208]. In addition, the prevalence of anxiety disorder was highest among adults with autism who did not have a comorbid intellectual disability, although this figure may be skewed due to the inadequacy of the diagnostic criteria utilized [208]. Clinically significant anxiety is common in individuals with ASD and is related to increased psychosocial and familial impairment [209]. People with ASD and comorbid anxiety may show increased ritualistic behaviors and PBs [210]. However, anxiety disorders can be difficult to diagnose in this group, due to difficulties in expressing worry and fear. Study found that individuals with ASD, especially high functioning, are likely to suffer from social anxiety, which may contribute to the avoidance of social interaction typically seen in this population. An important difference between social anxiety disorder and ASD is the presence in this latter group of social awkwardness [211].

▪ Mood Disorders

Studies on prevalence of psychiatric disorders in adults with ASD have identified high rates of mood disorders [212–214]. A recent systematic review reported a pooled prevalence of mood disorders at about 19% [202].

Depression spectrum disorders were the most frequent mood disorders described throughout the studies when considering the specific categories, with prevalence ranging from 11% to 23% [200, 207, 212]. The difficulty in detecting depression in this population is due to problems in communicating and expressing feelings of sadness, hopelessness, low self-esteem, guilt, or suicidal ideation [215]. Furthermore, individuals with ASD often show flat or constricted affect, so that changes associated with the onset of depression may not be identified [196]. Depression in people with

ASD is characterized by a variety of symptoms, including decreased interest in favorite activities, worsening in self-care capabilities, and decline in personal hygiene [216, 217]. In other cases, stereotyped and repetitive behaviors may intensify [218], and there may be worsening of problem behaviors (PBs) such as agitation, aggression, or self-injury [217, 219]. Also, neurovegetative symptoms as changes in sleeping patterns, appetite, and weight are common, especially in those with lower verbal abilities [196].

Bipolar disorder presentation in ASD may give unique challenges depending on several factors, such as age, the subtype of bipolar disorder, the subtype of ASD, the presence of intellectual disability, and the presence of concurrent psychiatric and medical comorbidity. In persons with low-functioning ASD, aggressive behavior toward others, irritability, and hyperactivity may be more common during elevated to hypomanic mood phases, whereas loss of appetite, associated weight loss, sleep disturbance, and decreased communication may be more common during the depressed phase [220, 221]. In addition, during phases of elevated moods, pressured speech or phonations, laughter, and intrusiveness are notable including sexualized impulsive behaviors. Bipolar disorder has been more frequently reported among adults with ASD, although prevalence rates are not consistent across studies especially towards persons living in the community. Some clinic-based studies have suggested high rates of up to 21% [202, 222], with Lai and colleagues reporting a rate around 5% [200]. In prototypical bipolar disorder, the symptoms related to mood dysfunction are severe in its expressive range, with euphoria, irritability, and sadness. With disruptive mood dysregulation states, the reactivity to events and provocations vary, as well as levels of physical energy levels, sleep, and appetite disturbance.

■ Obsessive-Compulsive Disorder

The prevalence estimates for obsessive-compulsive disorders (OCD) co-occurring in ASD range from 9% to 22% [200, 207, 223]. Rigid thinking and stereotypical behaviors are commonly observed in ASD and overlap with OCD in the symptomatic profile [224]. So it can be difficult to distinguish symptoms that are related to a comorbid OCD, particularly in people with lower functioning levels. However, studies have indicated that rigid and repetitive thoughts and behaviors in ASD differ from those of the OCD [225, 226]. In OCD, typical obsessive themes include worries about germs, harm coming to self or others, distinguishing right from wrong, and guilt about morals, or religiosity. Therefore, typical compulsions include ritualized washing, checking, ordering, apologizing, or mental rituals such as counting or praying, whereas people with ASD show a pervasive need of sameness and perform repetitive or ritualistic behaviors such as arranging, counting, or touching/tapping [227]. However, people with ASD are not likely to think about their rituals and may present with limited insight into the reason behind their ritualized behaviors. People with ASD are also less likely to be using their ritualized behaviors to neutralize fear or anxiety as would be true for OCD. Rather, ritualized behaviors and repetitive thoughts may satisfy other needs, such as modifying sensory input, knowing what is going to happen next in their daily routine, controlling and gaining reinforcement from the environment, or preserving routine and identicalness in their daily lives.

■ Psychotic Disorders

Recent meta-analyses reported prevalence rates of psychotic disorders ranging from 4% to 12% among adults with ASD. When considering the specific categories, Schizophrenia was the most frequent reported throughout all the studies [200, 202]. Transition into adulthood and exposure to stressful events are related to the onset of brief psychotic episodes in adults with ASD. Furthermore, psychotic symptoms are often sign of an underlying mood disorder or a schizoaffective disorder [199].

■ Eating Disorders

Of the 5381 adolescents with autism traits in the Avon Longitudinal Study of Parents and Children (ALSPAC) answering reporting on their eating habits at age 14, nearly 8% had engaged in some form of disordered eating monthly, and almost 3% did so weekly, with female adolescents three times more likely to

report such behaviors as males. Furthermore, adolescents with disordered eating habits had more autism traits at ages 7, 11, and 14, and greater the loading of autism traits, the more frequent was the prevalence of eating disorders [228]. Furthermore, adolescents' eating disorders predict psychiatric high-risk behaviors in young adulthood [229].

The prevalence of eating disorders among adults with ASD ranged from 1.4% to 7.9% across recent reviews [202, 230]. The specific category more prevalent is anorexia nervosa [230]. Eating disorders are often reported among adults with ASD, particularly pica, food refusal, and food selection for color, type, or texture. Selective food refusal is also associated with food spitting, obsessions, and rituals in ASD [231, 232]. Persons with ASD and eating disorders, especially anorexia nervosa, have some common features concerning cognitive style and behaviors [233], such as the tendency to focus on details and the insistence on sameness [234].

■ Posttraumatic Stress Disorder

Reported prevalence estimates for posttraumatic stress disorder (PTSD) ranges from 3.6% to 40% [200, 235]. Although negative life events, physical and sexual abuse are quite common in people with ASD, studies are lacking. Furthermore, the range of life experiences that are perceived as traumatic appears to be significantly greater than in the general population [235, 236]. Traumatic events and clinical presentation of PTSD are difficult to detect in people with ASD, especially in view of difficulty in defining their inner psychic state [237]. Diagnosis of PTSD requires an accurate assessment to understand cognitive interpretation, PBs, emotional disorders, and recognize signs of increased physiological arousal and sensory processing of the traumatic events, which might otherwise be misdiagnosed as exacerbation of ASD symptoms.

■ Attention-Deficit Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) is the most frequent psychiatric diagnosis found in adults with ASD. The pooled prevalence derived from the most recent meta-analyses ranges from 25% to 28% [200, 202]. Although ASD and ADHD have distinct clinical symptoms, they show overlapping features. Inattentive, hyperactive, and impulsive symptoms are frequently reported in persons with ASD and on the other hand, impairments in social communication, as well as repetitive and stereotyped behavior, have been described in person with ADHD. In addition, there is behavioral, biological, and neuropsychological overlap between the two disorders. Below-threshold cross-disorder symptoms are also common, that is, having symptoms of the other disorder despite not having the diagnosis [238]. Missing a diagnosis of ADHD not only leads to inadequate care but can also result in inadequate treatment and poor outcomes [239]. While there is a very high rate of comorbidity of ASD and ADHD, caution is needed in prescribing stimulants to children with ASD that may lead to increase in irritability, and careful documentation of adverse effects is paramount.

> The prevalence estimates of co-occurring psychiatric conditions vary widely across studies and improved estimates and identification of moderators are needed. Anxiety and ADHD are the most prevalent psychiatric disorders in children as well as adults with ASD. Recent finding showed that older age was associated with lower prevalence of ADHD and higher prevalence of depressive, bipolar, and schizophrenia spectrum disorders than younger age subjects with ADHD.

16.6 Specific Assessment

ASD is highly stable over the lifetime and is often associated with a poor overall outcome and high mortality rates [240, 241]. Diagnostic clarification of ASD is crucial in order to align targeted treatment and support and to avoid overmedication due to diagnostic misclassification. In accordance with the United Nations Convention on the Rights of Persons with Disabilities and the Charter for Persons with Autism adopted by the European Parliament, a right to diagnostic clarification and treatment assistance applies across the entire autistic spectrum, that is, including people with additional intellectual disability. Due to the lack of

distinct biological markers, the diagnosis of ASD is based on the course of development and the individual's current symptomatology [242]. Diagnostic criteria are defined in the current diagnostic manuals of the American Psychiatric Association (DSM-5, [161]) and the World Health Organization (ICD-10, [243], from 2018 ICD-11 [164]). In the ICD-11, ASD (6A02) is incorporated in the chapter on neurodevelopment disorders [164].

The WHO has long advocated for complementing the clinical diagnosis (ICD) with a functioning profile as attainable through the WHO International Classification of Functioning Disorders (ICF, [244]). The ICF marks a paradigm shift in the way health and disease are understood and recorded. A comprehensive set of different aspects of functioning, including biological, psychological, social, and environmental aspects, offers the possibility to precisely describe the support needed for the various activities of daily living (see Chap. 1). Current ASD research aims to outline clusters of characteristics in "core sets" incorporating strengths and potentials [245]. This refines the level and type of support and might also impact future diagnostic assignments.

16.6.1 Diagnostic Challenges

Neither ASD nor intellectual disability is a discrete disorder, but rather presents as syndromes with a multitude of symptom compositions [246]. As a result, diagnosing ASD in adults with intellectual disability is challenging, and the availability of evidence-based standardized measures is limited. Several issues impede the assignment including tendency for diagnostic overshadowing, attribution of the symptoms to intellectual disability, or ASD rather than comorbidity, and in more recent years, diagnostic substitution of intellectual disability by ASD alone [247]. For many adults with limited contact with their relatives, obtaining a complete medical history is unlikely. Physical conditions, such as hearing or vision impairments, may further complicate the differential diagnoses [248]. According to the ICD-11, ASD may be diagnosed in individuals with intellectual disability "if deficits in initiating and sustaining social communication and reciprocal social interactions are greater than would be expected based on the individual's level of intellectual functioning and if the other diagnostic requirements for ASD are also met. In these circumstances, both ASD and the Disorder of Intellectual Development should be assigned and the 'with Disorder of Intellectual Development' qualifier should be applied with the ASD diagnosis. Because ASD inherently involves social deficits, assessment of adaptive behaviour as a part of the diagnosis of a co-occurring Disorder of Intellectual Development should place greater emphasis on intellectual functioning and the conceptual and practical domains of adaptive functioning rather than on social skills. The diagnosis of ASD in individuals with Severe and Profound Disorders of Intellectual Development is particularly difficult, and requires in-depth and longitudinal assessments. However, the diagnosis may be assigned if skills in social reciprocity and communication are significantly impaired relative to the individual's general level of intellectual ability" [2]. Further information on the differential or co-occurrent diagnosis of ASD in persons with intellectual disability are provided later on in the chapter.

Another relevant diagnostic challenge is related to cultural variation in norms of social communication, reciprocal social interactions, as well as interests and activities. The ICD-11 states that "signs of impairment in functioning may differ depending on cultural context. For example, in some societies it may be normative for children to avoid direct eye contact out of deference, which should not be misinterpreted as impairment in social interaction" [2].

16.6.2 Diagnostic Assessment

Early developmental history is crucial for correct diagnostic classification. In the first 6 months, developmental indicators include absence of social smile or joyful expressions directed to people, limited or no eye contact, and inappropriate eye gaze. Within 9 months, additional signs are absence of vocalizations or other nonverbal communication, while within

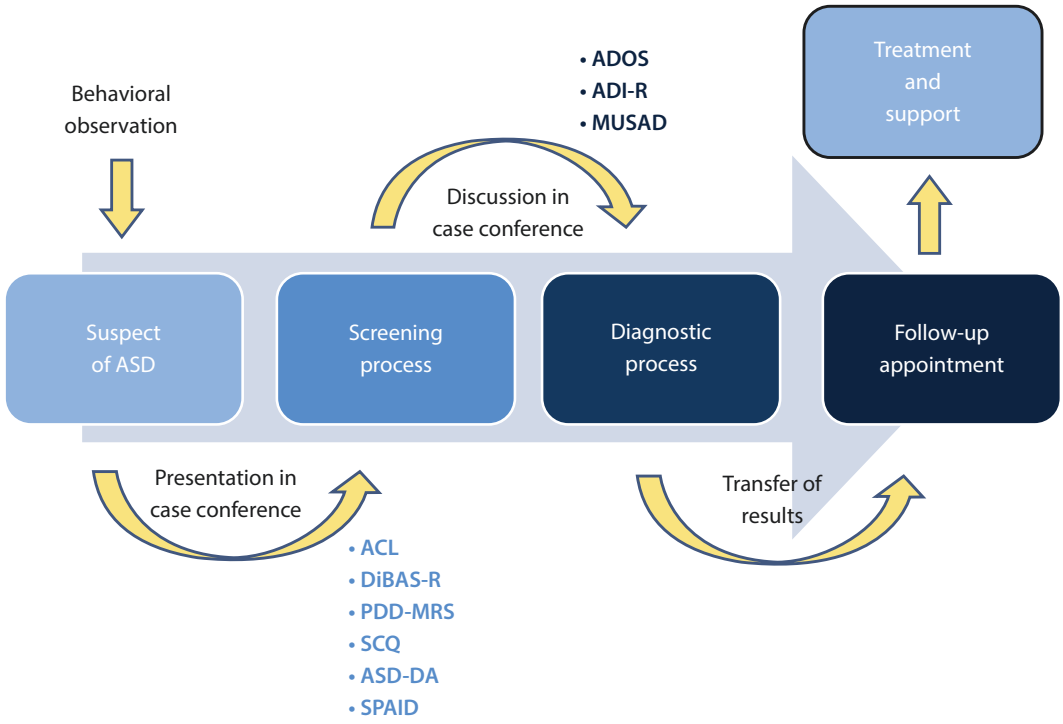

Fig. 16.2 Three-step diagnostic process for ASD

12 months, absence of babbling and communicative gestures. For example, reaching, pointing, and response to name are relevant. In the second year of life, main symptoms refer to lack of verbal communication, with absence of words within 16 months and no meaningful or two-word phrases within 24. Loss of any previously acquired speech, social skills, babbling, or deficit in social interactions at 2–3 years are clear indicators [249–251].

Also peculiarities in frequency and other structural parameters of the cry, as well as repetitive games, repetitive movement with objects, repetitive posturing of body, arms, hands, or fingers, repetitive language, selective feeding, lack of sharing interest or enjoyment, unusual prosody (little variation in pitch, odd intonation, irregular rhythm, or unusual voice quality) may indicate the presence of an ASD in early childhood [250, 252].

Beyond the information listed above, further aspects to investigate are the presence of neuropsychiatric disorders in parents or relatives, pregnancy course, birth, age of language development, age and way of walking, age of sphincter control, educational ability and need of educational support, sensory issues, self-harm, other medical and neurological disorders in childhood [253].

In adulthood, the NICE guidelines recommend a stepwise process for suspected ASD [254]. Initial assessment may be supported by the application of screening instruments such as the Autism-Spectrum Quotient (AQ) questionnaire [255], the Social Communication Questionnaire (SCQ) [256]or the Scale of Pervasive Developmental Disorder in Mentally Retarded Persons (PDD-MRS: [257]). If suspicion of ASD is affirmed, a more comprehensive assessment should be conducted by trained professionals. The assessment should examine the core symptoms of ASD, early developmental history, behavioral problems and adaptive functions, past and current physical and mental disorders, other neurodevelopmental conditions and sensory peculiarities. The results of the diagnostic process ought to be provided to the affected person, family members, and care team and support needs addressed. Figure 16.2 shows the three-step diagnostic process for ASD.

Tip

"Although diagnosis is an important aspect of most assessments, the focus of assessment should not only be on diagnosis but should also consider the person's physical, psychological and social functioning, and any risks that they might face. Crucial to the effective delivery of any assessment is the competence of the staff who is delivering it, including the ability to conduct an assessment, interpret the findings of the assessment and use these findings to support the development of appropriate care plans and, where necessary, risk management plans" ([258], p.118).

No single diagnostic procedure can solely define the diagnostic decision. The combination of all relevant present and past information provided by several team members and carers and the results of structured tools, interviews, and behavioral analyses by trained experts provide a basis for the diagnostic decision. Due to the complexity of the ASD, a range of professions and skills have to be part of the diagnostic process in order to use a wide range of resources to obtain diagnostically relevant information [258] supported by interdisciplinary conferencing and approaches to increase knowledge and capacity of the care team [259].

16.6.3 Diagnostic Instruments

The following screening scales have been validated for assessment of ASD in persons with intellectual disability:

- The *Autism Spectrum Disorder – Diagnosis Scale for Intellectually Disabled Adults* (ASD-DA: [260]) is a structured interview that is used to screen for ASD in adults with intellectual disability. It is administered to direct care staff who have known the person for at least 6 months. The staff member have to compare the person to similar persons living in the community.
- The *Social Communication Questionnaire* (SCQ) [256] – current or lifetime versions validated for adults with intellectual disability [261]. The *Social Communication Questionnaire for Adults with Intellectual Disability* (SCQ-AID) [262] is specifically tailored for adults with intellectual disability and consists of a core set of valid and adult-appropriate items.
- The *Autism Checklist* (ACL) [263] is a screening tool based on the ICD-10 research criteria. It facilitates a structured medical history and assessment in medical visits.
- The *Diagnostic Behavioral Assessment for ASD-Revised* (DiBAS-R) [264] is an ICD-10/DSM-5-based caregiver-report screening tool that consists of 19 Likert-scaled items validated in an independent sample [265].
- The Systematic Psychopathological Assessment for persons with Intellectual and Developmental Disabilities (SPAIDD) is an Italian tool package for diagnostic assessment in adults with intellectual disability. It consists of a general form and specific checklists for certain disorders, including ASD [266, 267].
- The *Scale of Pervasive Developmental Disorder in Mentally Retarded Persons* (PDD-MRS) [268] is a structured interview to be conducted by a qualified and experienced rater with a professional caregiver evaluating ASD-related problem behaviors in situations of daily life. It consists of 12 categorical items [257].

The following validated psychometric measures can be applied in the second step to diagnose persons with suspected ASD:

- The *Autism Diagnostic Interview - Revised* (ADI-R: [269]) is a semi-structured parent interview assessing social reciprocity, communication, and restrictive, repetitive behaviors between the ages of 4 and 5 years. It consists of 93 Likert-scaled items, and a selection of these is adopted by the final algorithm, resulting in a classification of 'autism' or 'no autism'. While showing good psychometric characteristics, the ADI-R is only applicable in about one-third of adults with intellectual disability [270].
- The *Autism Diagnostic Observation Schedule* (ADOS: [271]) is a semi-structured observation tool to assess social communication in persons suspected of having

ASD. Depending on their verbal abilities, one of four modules can be applied. It has been indicated to be applicable for some adults with intellectual disability, and for better discrimination, revised algorithms were proposed [270, 272]. In 2015, an update of the instrument has been produced, namely ADOS-2 [273].

- The *Music-based Scale for Autism Diagnostics* (MUSAD) [274, 275] was specifically developed for people with intellectual disability. In standardized musical settings, the quality and level of social interaction are prompted and assessed by the examiner. Due to its nonverbal interactive quality, it is particularly suitable for nonverbal individuals [276].
- The *Gilliam Autism Rating Scale* (GARS; [277]) is an interview used to assess ASD comorbidity with moderate–severe intellectual disability, when the cognitive impairment does not allow the patient to collaborate during the clinical evaluation. An updated GARS-3 has been published in 2013 [278].
- The *Social Responsiveness Scale - Second Edition* (SRS-2) [279] is a functional evaluation that can be used from childhood to adulthood. It identifies the presence and severity of social impairment and differentiates it from that occurring in other disorders.

In childhood, most common screening test are the following:

- The *Checklist for Autism in Toddlers* (CHAT) [280] assesses 18-month children and can be used also in the periodic health reports in pediatric settings. It includes 9 questions to parents and the direct observation of 5 target behaviors: eye contact, joint attention, play of fiction, and indication and ability to build a tower with cubes.
- The *Modified-Checklist for Autism in Toddlers* (M-CHAT) [281] can be used with children from 18 to 24 months, and it is comprised of 23 items. The 2009's version includes a revision with follow-up (M-CHAT-R/F) [282] which can be used between 16 and 30 months.
- The *Quantitative Checklist for Autism in Toddlers* (Q-CHAT) [283] consists of a 25-item questionnaire for parents, in which they are asked to quantify how many times their child has a particular behavior on a 5-point scale (0-4). CHAT, M-CHAT, and Q-CHAT are used to assess siblings of children with ASD or children born preterm [284].
- The *Childhood Autism Rating Scale* (CARS) [285, 286] is a 15-item measurement scale which evaluates, through direct observation and interview, social interactions, verbal communication, and behaviors starting from 24 months. The scores obtained also provide a severity level of the symptoms and allow an assessment of change over time. The standard version (CARS2-ST) is used for children up to 6 years or older with IQ scores 80 or below or children with established communication difficulties; the high-functioning version (CARS2-HF) is used for children 6 years or older with IQ scores above 80. The CARS 2 also contains recommendations on how to orientate treatment in each area.
- The *Checklist for Autism Spectrum Disorder* (CASD) [287] is composed of 30 items, based on the DSM-5 diagnostic criteria. It can be used in children and adolescents, regardless of the cognitive level and severity of symptoms.
- The *Gilliam Autism Rating Scale* (GARS) [277] is a checklist for parents, teachers and professionals based on DSM-IV diagnostic criteria. It allows both the identification and the estimate of the severity of the symptoms in subjects from 3 to 22 years. It is also useful to focus on the objectives of the enabling and educational interventions, as well as to document their efficacy. The third DSM-5 edition has also been updated [278].
- The *Gilliam Asperger's Disorder Scale* (GADS) [288] is specific for children with high-functioning ASD.
- The *Krug Asperger's Disorder Index* (KADI) [289] is a screening instrument for Asperger Syndrome, also useful for developing goals for intervention. There are two forms, covering 6–21 years.
- The *Childhood Asperger Syndrome Test* (CAST) [290] is a 37-item parent questionnaire designed to screen for high-functioning ASD that focuses on social behaviors and communication.

In addition to these tools, behavioral analysis of video recordings from everyday situations can provide insights into social interactions or stereotypical behaviors in a familiar environment with familiar persons.

The NICE guidelines do not consider specific instruments for routine use in the assessment of adults with intellectual disability and suspected ASD. However, the ADOS and the ADI-R may be of value in augmenting diagnostic assessment in some adults with intellectual disability, mostly those with milder cognitive impairment.

A useful complement to the diagnostic measures is the assessment of functioning and adaptive skills, which is commonly through the following tools:

- The Psychoeducational Profile- Third Edition (PEP-3) [291]
- The Psychoeducational Profile Revised (PEP-R) [292]
- The Vineland-II Adaptive Behavior Scales (VABS-II) [293]
- The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP) [294]
- The TEACCH Transition Assessment Profile (TTAP) [295]
- The Essential for Living scale [296].

16.6.4 Differential and Co-occurrent Diagnoses

The diagnostic process is further challenged by the fact that other neurodevelopmental disorders as well as physical and mental ill-health are frequent in persons with ASD. Although biological or genetic tests, as well as neuroimaging, should not be considered routine in the diagnosis of ASD [242, 297], they can be used to rule out other suspected conditions.

Intellectual Disability

Social communication deficits as well as stereotyped behaviors not caused by ASD are frequently observed in persons with intellectual disability. The deficit in social communication has to exceed the level of impairment which can be expected for a certain severity of intellectual disability to allow for additional diagnosis of ASD. According to Sappok, Matson and collaborators [270, 298], social reciprocity and non-verbal communication are especially valuable to distinguish between ASD and intellectual disability. Symptom presentations may change over the lifespan which can further increase the challenges of diagnosing ASD. Moreover, susceptibility to stress may lead to regressive behaviors further increasing the diagnostic difficulties. In those cases in which the differential diagnosis or the co-occurrence of intellectual disability and ASD has to be defined, a comprehensive cognitive assessment is indicated, using Wechsler Preschool and Primary Scale of Intelligence-III (WPPSI-III, [299]), Wechsler Intelligence Scale for Children-IV (WISC-IV, [300]), Wechsler Intelligence Scale–IV (WAIS-IV, [301]), Leiter International Performance Scale – Revised (Leiter-R, [302]), Raven Progressive Matrices (RPM, [303]), or Coloured Progressive Matrices (CPM, [304]), according to the different ages and individual characteristics.

Behavioral Phenotypes in Genetic Syndromes

Genetic syndromes may be associated with ASD. In tuberous sclerosis, especially type 2, interaction and communication as well as attention and impulse control are impaired, while ritualized and stereotypic behaviors can be observed less frequently. Fragile X syndrome is the most common monogenetic cause of intellectual disability. Many of its sufferers, who are predominantly male, show hyperactivity, deficits in attention and self-regulation and repetitive behaviors. Moreover, social anxiety and shyness in eye-contact may resemble ASD at first glance, while interest in social relations is unaffected.

Rett syndrome affects mainly girls. While development initially proceeds in a typical way, skills are progressively lost and head growth decelerates after the first year of life. Although presenting with pronounced stereotypical hand movements, loss of expressive language and rigid, poorly modulated eye contact, affected persons continue to show an interest in social interaction and seek attention. Therefore, knowledge about the underlying genetic syndrome and the associ-

ated behavioral phenotypes are supportive to prevent psychiatric misdiagnoses [305].

In Down syndrome, a higher rate of ASD is observed rather than in general population. In persons with this syndrome a complete neuropsychological assessment is recommended in adulthood to screen for dementia. Several genetic syndromes could lead to ASD and psychosis (as Del22q11 or Di George syndrome) or to different clinical phenotype in the same family (psychotic or ASD or personality disorder or mood disorders) [306, 307]. Further information on the characteristics of main genetic syndromes associated with ASD are provided in the paragraph 3.1.

Other Mental Disorders

ASD ought not to be misclassified with schizophrenia [308, 309]. Developmental history and careful appraisal of symptom phenomenology are necessary [310]. Abnormalities in attention, impulsivity, and physical hyperactivity that are frequently encountered in persons with ASD, especially in the most severe part of the spectrum, are shared with ADHD. However, as specified in the ICD-11, "individuals with ADHD do not exhibit the persistent deficits in initiating and sustaining social communication and reciprocal social interactions or the persistent restricted, repetitive, and inflexible patterns of behaviour, interests, or activities that are the defining features of ASD. However, ASD and ADHD can co-occur and both diagnoses may be assigned if diagnostic requirements are met for each" [2]. Disorders such as social phobia, depressive disorder, or avoidant personality disorder may show symptoms which may resemble ASD, as these disorders are often associated with social withdrawal, but a different age of symptom onset can be observed. Moreover, catatonia and tic disorders, which may be associated with psychomotor abnormalities may also need to be considered.

Sensory Impairments

Serious sensory impairments such as blindness or severe hearing impairment can also evoke autism-like symptoms. However, in these cases, social behavior is appropriate considering the existing sensory deficits.

Medical Assessment

Various physical and genetic disorders can co-occur in person with ASD with intellectual disability, especially endocrine, metabolic, and immunologic issues, which necessitate haematology tests including organic acid, plasma amino acids, ammonia, ferritin, copper, and porphyria. Moreover, epilepsy is a common comorbidity [311]. An immune dysregulation may be involved in tic symptoms in ASD, as in PANDAS syndrome [312, 313]. In persons treated with atypical neuroleptics, it is important to monitor blood glucose, cholesterol, triglycerides, lipase, liver function tests, thyroid function tests, and prolactin level. Among patients with limited nutritional intake, diet should be augmented with folate, B12, iron, ferritin, and D vitamin.

Deprivation and Hospitalism

ASD and intellectual disability have been associated with deprivation and hospitalism, especially in early childhood. Persons with ASD and intellectual disability are also exposed to emotional or sexual abuse and may have reactive attachment disorder (RAD) and PTSD that may further complicate social withdrawal, anxiety, stereotypies, as well as somatic preoccupations.

16.7 Treatment

16.7.1 Pharmacological

Although there is no evidence for the effectiveness of any particular drug on the core symptoms of ASD, pharmacotherapy is an important intervention within a person-centered treatment plan, to address associated problem behaviors as well as co-occurring psychiatric disorders [314]. It is reported that around 45% of people with ASD are on psychotropic medications [315, 316], the rate increasing with advancing age [317]. Polypharmacy is frequent [318] and often not prescribed appropriate to psychiatric diagnoses. Primary target behaviors include irritability, aggression, self-injury, temper tantrums, anxiety, and associated attention-deficit hyperactivity disorder (ADHD) symptoms.

Pharmacotherapy for people with ASD alone or with co-occurring intellectual disability should be part of an integrated person-centered multidisciplinary planning/intervention [258, 319–321]. It is also suggested that pharmacological treatments should be considered for severe challenging behavior after other nonpharmacological interventions have failed. Drugs should be used at the lowest possible dose and for the minimum duration, with nonmedication-based management strategies and the withdrawal of medication being considered at regular intervals [320]. Most commonly prescribed medications, in order of frequency, are antipsychotics, antidepressants, antiepileptics (AEs), and psychostimulants, many of them without definitive studies guiding their usage.

16.7.1.1 Antipsychotics

There is strong research evidence to suggest that some antipsychotics (APs) may be beneficial for the treatment of aggression, irritability, hyperactivity, self-injury, and repetitive behavior in people with ASD [322, 323]. The current role of first-generation antipsychotics (FGAs) is limited due to the high risk of severe side effects, which include cognitive deterioration, extrapyramidal symptoms, acute dystonia, withdrawal-emergent dyskinesia, and tardive dyskinesia. Because of this, second-generation antipsychotics (SGAs) are more commonly used now in people with ASD and/or other neurodevelopmental disorders. Risperidone and aripiprazole have undergone many studies, while there is little high-quality research available on most of the other SGAs.

In general, the use of APs needs some specific cautions in addition to the usual "go slow and stay low" rule valid for any psychotropic drug in people with ASD and/or intellectual disability. People with ASD, particularly with comorbid intellectual disability, are inclined to develop catatonic symptoms which can be precipitated by APs. Epilepsy can affect up to 22% of people with ASD. APs can lower the seizure threshold, alter EEG, induce, unmask, or aggravate seizures. Therefore, while prescribing APs for a person with a high risk of seizures, a concomitant use of AEs may need to be considered [324].

Some AEs (i.e., phenytoin, carbamazepine, and barbiturates) induce the metabolism of some APs such as quetiapine by the enzyme CYP 3A4, which reduces APs' blood levels. Valproic acid may be an inhibitor and/or inducer of clozapine and olanzapine, an inhibitor of paliperidone, and a weak inducer of aripiprazole. Also, for other AEs which do not seem to have a major impact on APs metabolism, individual differences of effect have to be carefully considered, especially for drugs which have a complex metabolism by multiple enzymes [325, 326]. APs do not seem to have major influence on AEs metabolism and do not seem to affect their blood levels [327].

APs and AEs may also reciprocally potentiate their side effects. Additive sedation with APs seems to be relevant for many AEs, while weight gain is particularly evident for olanzapine in combination with valproate, pregabalin, gabapentin, and carbamazepine. Carbamazepine increases the risk of agranulocytosis of clozapine and valproate can lead to leukopenia when taken with clozapine or olanzapine.

Many people with ASD may also be more vulnerable than the general population to brain volume changes induced by APs. In fact, ASD has been associated with complex alterations in lifetime trajectories of several brain regions and gray matter volumes which underpin social-cognitive and motor functions [328, 329]. Also, studies on the general population receiving long-term treatment with APs suggest that these drugs may determine regional brain volume changes over time, with FGAs in particular being related to neurotoxic effect and global gray matter volume reduction [330, 331]. In elderly adults of the general population and in patients with dementia, the use of APs, especially FGAs, has also been reported to increase the risk of cerebrovascular incidents [332]. These side effects deserve special consideration in persons with co-presence of intellectual disability or genetic syndromes including premature brain aging and early-onset dementia, such as Down syndrome. Unlike FGAs, SGAs have been reported to exert measurable neuroprotective effects, ranging from preventative to restorative, mediated via multiple molecular mechanisms, which are often dose-dependent [333].

Persons with ASD are also at a higher risk of weight gain and associated metabolic disturbances attributed to a number of factors, including selectivity for unhealthy high-calorie foods, excess food intake, sedentary habits, sleep problems, genetics, gut microbiome, endocrine issues, and developmental risk factors. This vulnerability has to be carefully considered when prescribing and using APs, especially SGAs, which are known to increase the risk of hyperglycemia, peripheral resistance to insulin, type II diabetes, dyslipidemia, and weight gain [334–336]. Further attention is needed in elderly people with intellectual disability, in whom the use of SGAs has been associated with an increased risk of cardiovascular morbidity and mortality [337, 338]. For all the above-mentioned safety issues, APs should only be used with specific indications, as part of a comprehensive treatment program, under specialist supervision, and where other measures prove insufficient.

First-Generation Antipsychotics (FGAs)

Among the FGAs, the most used are chlorpromazine and haloperidol. Although some efficacy has been demonstrated in the management of problem behavior (PB), especially aggression, FGAs should not be considered as the first-choice drugs due to tolerability limits [339, 340]. For the same reason, they should be used at low dosage and for the minimum possible time.

Chlorpromazine

Chlorpromazine is often chosen for its broad receptor binding profile, which includes 5-HT2A receptors, and for sedative properties, despite the lack of evidence of its efficacy [341]. Chlorpromazine and clozapine have a relatively high epileptogenic potential, higher than the other APs [342]. Thus, caution should be taken in individuals who have a history of epileptogenic conditions, such as epilepsy, brain alterations, or brain damage.

Haloperidol

Haloperidol is indicated as short-term adjunctive therapy for the management of psychomotor agitation, excitement, and impulsive and violent behavior [343] in people with intellectual disability. Few observations and small open-label studies have shown efficacy also on hyperactivity, aggression, stereotypies, emotional lability, and temper tantrums [344, 345], although a more recent study on adults with intellectual disability and aggressive behaviors showed no statistically significant difference among risperidone, haloperidol, and placebo [346]. In persons with ASD multiple studies have found haloperidol to be efficacious for improving a variety of behavioral symptoms [322]. Sedation is the most common side effect, followed by motor symptoms, which occur in up to one-third of treated patients and include acute dystonia, withdrawal dyskinesia, and tardive dyskinesia. Another serious side effect is neuroleptic malignant syndrome, which seems to have a higher prevalence in people with ASD and/or intellectual disability than in the general population [347–350].

Second-Generation Antipsychotics (SGAs)

The SGAs have a better tolerability profile and a greater number of randomized controlled trials (RCTs) to support their use [351]. They show a complex receptor binding profile, which seems to have a lower impact on the cognitive and neuromotor vulnerability of many persons with ASD and intellectual disability [352].

Risperidone

Risperidone is included in the largest number of studies in ASD and intellectual disability including RCTs, most of which are aimed at exploring its effectiveness on disruptive and aggressive behavior [353–360] (see review by [361, 362]). In people with ASD and intellectual disability, risperidone has been shown to reduce severe PB such as aggression, anger, and self-injurious behavior by around 50% in approximately half of cases [363].

Short-term RCTs showed a significant reduction in irritability compared with placebo, with positive effects on overall functioning. In persons with low-functioning ASD, effectiveness on PB and adaptive skills seems to be dose-related [364] and to increase while associated with educational-rehabilitation interventions [365]. Some data on drug discontinuation show a relative maintenance of the effect even in the long term, with an increase of time to relapse [357, 366].

Side effects are frequent and, if not managed, can be a reason for treatment discontinuation. The most common are sedation (37–72%), especially in the initial phase of treatment [358, 367, 368], weight gain (up to 10% body mass index increase after 6 months) [367], and hyperprolactinemia [369, 370], which can in turn lead to amenorrhea and hypogonadism [371]. Among SGAs, risperidone shows the greatest risk of induction of extrapyramidal symptoms, especially tardive dyskinesia and parkinsonism [346, 372, 373]. Other side effects are lowering of seizure threshold, asthenia, dizziness, sialorrhea, hyperglycemia, and hyperlipidemia [343].

Paliperidone

Paliperidone is the primary active metabolite of risperidone. It offers some advantages over risperidone, especially for orthostatic hypotension. Nevertheless, RCTs supporting their effectiveness are lacking. A few open-label studies provided promising results particularly on effectiveness on irritability [374–376].

Aripiprazole

Aripiprazole is reported to have efficacy on irritability, aggressiveness, and disruptive behavior similar to risperidone, although less consistent [377, 378]. In adults with intellectual disability, it is indicated for the treatment of bipolar disorder and schizophrenia spectrum disorders, either as monotherapy or as an add-on to mood stabilizers [343]. The support for the treatment of self-injurious behaviors is less evident, despite promising data from open-label studies [343]. The most frequent side effects are sedation, extrapyramidal symptoms, and weight gain, whose intensity is commonly low and rarely lead to drug discontinuation [379], at least in the short or medium term [380]. Hyperprolactinemia is quite infrequent, unlike most drugs of the same class. In the long term, besides weight gain, aggression and dyslipidemia are reported [381, 382]. Longitudinal data did not support the hypothesis that in persons with ASD, aripiprazole has a better metabolic tolerance profile than risperidone, unlike what has been observed in other clinical conditions [383, 384].

Olanzapine

There is only one RCT on olanzapine, which mainly refers to people with intellectual disability [385], and all other studies are retrospective or naturalistic [386–391]. The designs of these studies are very different from each other and, therefore, do not allow to draw firm conclusions. In general, olanzapine seems to be effective in reducing symptoms related to psychotic and affective disorders, both alone and as an add-on to FGAs, as well as in the management of aggression and destructive behavior, especially if not associated with stereotypies or self-injurious behavior. In adults with intellectual disability, it may be a therapeutic option also for acute mania as an add-on treatment to lithium and valproate, for major depressive episodes including psychotic symptoms, at low dosage and in association with antidepressants, and for the prophylaxis of bipolar disorder [343]. Olanzapine allows dosage reduction and treatment discontinuation over time, although considerable discontinuation effects have been reported, eminently connected to its dibenzodiazepine structure and anticholinergic effects [361, 392, 393]. Most relevant side effects are metabolic disturbances, including increased risk of hyperglycemia, peripheral resistance to insulin, type II diabetes, dyslipidemia, and weight gain, which have been reported to be higher compared with risperidone and aripiprazole. Particular attention to these side effects needs to be paid for adolescent and elderly patients [334–336].

Metabolic side effects have been explained through several hypotheses, referring to (i) blockage of histaminergic (e.g., H1) and serotonergic (e.g., 5-HT2C) receptors, which would manipulate the satiety regulator AMP-K and lead to increased appetite and caloric intake; (ii) complex metabolic hormone imbalance, which would result in an alteration of the levels and functioning of leptin, ghrelin, GLP-1, insulin, and glucose [394–396]; (iii) accelerated adipose tissue lipogenesis and elevated liver fat content in SGA-treated subjects [397]; and (iv) decreased energy expenditure due to the sedative effect of SGAs [398]. Recent evidence points to the modification of

gut microbiome towards an obesogenic shift of the bacterial profile [399]. A screen for more than 1000 marketed drugs against 40 representative gut bacterial strains reported that almost one-quarter of non-antibiotic drugs used in humans, predominantly SGAs, possess antimicrobial property with potential to imbalance the gut ecosystem [400]. Other studies have indicated an association between SGA-induced weight gain and alteration of the microbiome composition [401, 402] as well as a potential impact of some gut bacteria on the systemic bioavailability of orally administered olanzapine or other SGAs [403].

Further research is needed to inform the clinical management of weight gain associated with the use of these drugs in ASD. This might include identifying patients who are more susceptible to this side effect as well as determining the best approach to management (e.g., diet and/or exercise, switching drugs, or pharmacological treatments).

▪ Quetiapine

Although insufficiently studied (no RCT and only few open-label studies), quetiapine does not seem to be particularly effective for the treatment of irritability and PBs, while the response rates for self-injurious behavior vary between 22% and 60% [404–408]. It is frequently used at low doses also for sleep disorders, and for the reduction of anxiety, especially in people with intellectual disability [343, 406, 409]. Like other SGAs, quetiapine can be used in the maintenance therapy of bipolar disorder and in the treatment of bipolar depression, while it seems to be less effective for psychotic disorders. The dosage varies according to the target symptom, with the most common range between 25 mgs and 300 mgs per day. In people with intellectual disability, the daily dose should not exceed 800 mgs. Most relevant side effects are weight gain, increased risk of diabetes, and orthostatic hypotension. In comparison with other SGAs, the risk of hyperprolactinemia and extrapyramidal side effects is low [343, 410].

▪ Clozapine

There are no RCT on the use of clozapine in people with ASD, with or without intellectual disability, but only case-reports, case-series, and retrospective studies. As for the general population, clozapine has to be considered a second- or third-choice drug for the treatment of psychoses refractory to other antipsychotics and psychosis complicated by the onset of chronic extrapyramidal side effects related to the use of other antipsychotics [411]. In schizophrenic patients, clozapine has shown specific anti-suicidal properties [412–414], as well as anti-impulsive and anti-aggressive effects [415, 416]. In persons with ASD, it has been widely used to manage severe PBs refractory to other treatments, including aggression toward others, self-injurious behaviors, hyperactivity, motor restlessness, negativism, tantrums, with indirect positive effects on social interaction [417–422], also in the long-term [421]. Findings supporting efficacy are stronger and more replicated for physical aggression toward others and objects than for self-injurious behaviors.

Clozapine cannot be used as a first-choice treatment because of the relevant safety issues, some of which are considered medical emergencies and potentially life threatening. These include hematological (neutropenia and agranulocytosis), CNS (seizures), cardiovascular (tachycardia, postural hypotension, myocarditis, and cardiomyopathy), metabolic (diabetes, metabolic syndrome), gastrointestinal (constipation, ileus), and neuroautonomic (sialorrhea, fever, urinary incontinence, and sweating) [343, 423]. Metabolic risk is reported to be one of the highest among all antipsychotics, as for olanzapine [424, 425]. Furthermore, monitoring requirements, that is, frequent blood tests and frequent clinic visits, may be difficult to carry out in persons with low-functioning ASD. Nevertheless, a full awareness of these side effects and competence to prevent and manage them can maximize the clear clinical benefit of this drug and minimize the known risks.

▪ Asenapine

Asenapine is a new SGA, available as a sublingual tablet, approved in Europe for the treatment of moderate-to-severe manic episodes in adults, and in the US for manic or mixed episodes of bipolar I disorder in adults and

adolescents. Despite its potential pro-cognitive effect and good metabolic tolerability, asenapine has not yet been considered for any RCT in people with ASD. A case series relating to people with low-functioning ASD or intellectual disability with co-occurrent bipolar disorder or schizoaffective disorder reported a significant improvement between second week and fourth week of treatment, especially on PBs. The dosage varied between 5 mgs and 20 mgs/day and side effects were limited, mainly represented by sedation and emotional flattening [426].

In the general population, few studies highlighted efficacy in borderline personality disorder, where asenapine was shown to be superior to olanzapine in reducing affective instability [427]. Together with clozapine, asenapine is more effective on aggression, particularly physical aggression, than other antipsychotics, which has been associated with the high affinity for D4 receptor (D4/D2 > 1) [428, 429]. Asenapine showed significant and clinically meaningful improvement also in posttraumatic stress disorder patients who had not responded to selective serotonin reuptake inhibitors or mirtazapine [430].

Until recently, asenapine was formulated only as a sublingual tablet and was found to be difficult to administer by this route in some patients with ASD or intellectual disability. At present, transdermal patches are also available, to be applied once daily to the hip, abdomen, upper arm, or upper back area.

Long-term flexible dose administration of sublingual asenapine is generally well tolerated. Somnolence, sedation, and headache are the adverse effects most commonly reported. There is also a considerable reporting of transient oral hypoesthesia with dysgeusia, which result from the local anesthetic properties of the sublingual formulation. Other less common side effects are weight gain, extrapyramidal symptoms, and akathisia.

▪ Ziprasidone

Ziprasidone is indicated for the treatment of psychotic disorders and acute mania, also in people with intellectual disability. Since it was originally designed as a cholesterol-lowering drug, ziprasidone has a favorable metabolic effect, with a low impact on body weight and even some benefits on lipid profile. In a small open-label nonreplicated study on patients with intellectual disability and severe maladaptive behaviors, ziprasidone showed response rates comparable to those of other SGAs and reversed metabolic side effects caused by previous treatments [431]. Other promising results, even if still limited to small open-label studies and case reports, concern its use in the treatment of severe disruptive and other PBs in persons with ASD [432–437]. The response rates that emerged were moderate for irritability, hyperactivity, and self-harm, while it was ineffective on repetitive behaviors [361].

Ziprasidone should be titrated from an initial dosage of 20 mgs/day to a maximum dosage of 80–160 mgs/day, in two daily administrations preferably after a meal of at least 500 kcal. Dosage above 200 mgs/day is not recommended. Adverse effect like insomnia is common. Other commonly reported side effects are drowsiness, dizziness, headache, nausea, respiratory problems, extrapyramidal symptoms, and orthostatic hypotension.

▪ Lurasidone

Lurasidone is a benzothiazol derivative, whose chemical structure resembles ziprasidone and risperidone. Several trials reported positive outcomes in adults with schizophrenia [438–442] and depression in bipolar disorder [443, 444]. The use in people with ASD has been evaluated only in children with and without intellectual disability through one RCT and one case report, which showed higher effectiveness than placebo only for irritability [445, 446]. Another multicenter, open-label, single and multiple ascending-dose study, which evaluated the pharmacokinetic and tolerability profiles of lurasidone in children and adolescents with psychiatric disorders, included a child with ASD [447]. Lurasidone has low risk of inducing weight gain, metabolic, or cardiac abnormalities, but its risk of akathisia may exceed that of other SGAs. Other common side effects are nausea, insomnia, and sedation.

▪ Cariprazine

Cariprazine is a partial agonist with high binding affinity at central D2 and 5-HT1A receptors, and antagonist with high-to-

moderate affinity for 5-HT2A receptors [448, 449]. It is approved for the treatment of schizophrenia and acute manic or mixed episodes associated with bipolar-I disorder in adults. The literature search on its use in ASD identified only one case series, in which all patients received other atypical antipsychotics and/or other psychoactive compounds; 87.5% showed improvement in aggression, impulsivity, and/or self-injurious behavior. No patients reported serious adverse effects [450]. Cariprazine is generally well tolerated, with most common side effects being insomnia, extrapyramidal symptoms, sedation, akathisia, nausea, dizziness, vomiting, and constipation [451, 452]. Due to its long half-life, patients need to be monitored for clinical response and adverse events for several weeks after starting and after each dosage change.

Pharmacotherapy for people with ASD alone, or with co-occurring intellectual disability, ought to be part of an integrated person-centered multidisciplinary planning/intervention. Second-generation antipsychotics (SGAs), such as risperidone and aripiprazole, are currently the most commonly used agent targeting irritability, aggressiveness, and disruptive behavior. They should be used at the lowest possible dose and for the minimum duration, always in combination with non-medication-based management strategies, with withdrawal of medication being considered at regular intervals. Close monitoring of side effects including metabolic parameters is paramount.

16.7.1.2 Antidepressants

Tricyclic antidepressants (TCAs) had been widely used in people with ASD, particularly those with low-functioning ASD, both for the treatment of symptoms linked to the ASD itself and for the associated psychiatric and behavioral disorders. Clomipramine had been the most studied drug of this class and some evidence of efficacy in reducing inadequate eye contact, inappropriate language, and repetitive behaviors is reported, whether the latter are attributable to stereotypies or obsessive-compulsive symptoms [453]. It was reported to be more effective than haloperidol in reducing irritability, temper tantrum, aggression, and hyperactivity [454], but these findings have not been replicated in all studies [455]. In some cases, in fact, TCAs have been associated with onset or increase of aggression, irritability, and hyperactivity [456]. Other frequent side effects are sedation, QTc prolongation, tachycardia, constipation, dry mouth, fatigue, lethargy, and seizures [454, 456–458]. Nortriptyline has shown equal efficacy in reducing hyperactivity, aggressiveness, and ritualized behavior [459], while imipramine has been shown to be poorly tolerated in children with ASD [460].

Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, fluvoxamine, sertraline, citalopram, escitalopram, and paroxetine, are the most prescribed drugs due to their greater safety profile than the TCAs, although the results of studies on their efficacy are equivocal. The systematic review of the literature showed some effectiveness in adults, but not in children and adolescents, who reported many side effects [461]. Based on the current evidence, SSRIs cannot be recommended for treatment of children or adults with ASD. The decision on the use of SSRIs for preestablished clinical indications that may occur concurrently with ASD, such as obsessive-compulsive disorder and depression, should be taken on a case-by-case basis.

Fluvoxamine showed low effectiveness and poor tolerability in children and adolescents with ASD, but had positive effects on the management of repetitive behaviors as well as on aggression, social skills, and language use in adults with ASD [462].

Fluoxetine has not shown efficacy in treating repetitive behaviors in children. It is found to be more effective on obsessive-compulsive symptoms in adolescents and adults, although reliability of study findings is poor [463–465].

Sertraline was moderately effective and relatively well tolerated in the treatment of aggression and repetitive behaviors in adults. Some open-label studies suggest some efficacy even in children and adolescents, with reduction of anxiety symptoms at low dosage, but a higher dose may precipitate PBs [466–468].

Citalopram has been shown to have limited efficacy in the treatment of repetitive behaviors in children and adolescents and to be more associated with side effects, in particular, hyperactivity, stereotypy, diarrhea, insomnia, decreased concentration and impulsiveness [469–471]. Studies on adults are lacking.

Escitalopram has been shown to have some beneficial effects in children and adolescents, although its use is limited because of little evidence and some side effects [472]. Studies on adults are lacking as well.

Venlafaxine, a dual selective serotonin and norepinephrine reuptake inhibitor, has shown some beneficial effect in the treatment of hyperactivity, self-harm, and repetitive behavior in children, adolescents, and adults. Safety issues have also been reported. However, at present, studies are very limited [473–475].

A few studies on duloxetine, another dual serotonin and norepinephrine reuptake inhibitor with a higher norepinephrine selectivity than venlafaxine, have shown some efficacy on neurovegetative dystonias, irritability, and somatic anxiety [476].

Trazodone, a heterocyclic antidepressant, appears to be effective in reducing aggression and self-injurious behavior, although the quality of evidence is very poor and refers only to case reports [477].

Mirtazapine, a tetracyclic antidepressant, has been shown according to some reports to be effective in the management of PBs, in particular, inappropriate sexual behavior [478, 479].

Agomelatine, a melatonin receptor agonist (MT1 and MT2) and serotonin receptor antagonist (5-HT2C and 5-HT2B), has been rarely used and studied, with some indications of efficacy on repetitive behaviors, sleep alterations, neurovegetative dystonias, irritability, and somatic anxiety [476, 480].

Vortioxetine has a receptor-binding profile particularly interesting for persons with ASD and cognitive issues. A dysfunction of the glutamatergic system and 5-HT7 receptors has been supported by some studies addressing behavioral flexibility and repetitive behavior in animal model of ASD [481, 482]. Nevertheless, clinical data to date are lacking [483].

Overall, while SSRIs appear to be effective in improving some PBs in adults with ASD, findings on childhood ASD are controversial, with some studies indicating a risk of induction of irritability and agitation.

16.7.1.3 Anti-anxiety Medications

There is little evidence supporting the use of benzodiazepines (BDZ) in persons with ASD, although they are often prescribed to treat anxiety disorders, unspecified anxiety symptoms and PBs [484]. Effectiveness of BDZ in the management of PBs has been found to be limited, and sometimes associated with aggravations [485]. Their long-term use may increase the risk of tolerance and dependence (with withdrawal symptoms), as well as develop cognitive difficulties, the latter frequently documented in older adults [486]. An important area of use, even at high doses, is in catatonia, especially in the acute phase. In fact, catatonia is reported to occur more frequently in persons with ASD than in the general population and represents a potentially fatal psychiatric and medical emergency. In fact, the most authoritative epidemiological studies on the subject report catatonia rates to range between 6.5% and 17% in clinical populations of patients with ASD, especially in late adolescence [487, 488].

BDZ represent the first-line treatment of catatonia. The standard therapeutic algorithm includes a lorazepam challenge test, in which an intravenous bolus of 1 mg lorazepam is administered, and catatonic symptoms are evaluated after 2–5 minutes. In case of lack of response, the procedure is repeated. For patients showing a symptoms reduction of at least 50%, therapy with increasing doses of lorazepam can be set, up to 24 mgs per day. In the event of rapid resolution of catatonia, BDZ-based maintenance therapy is continued for the next 6 months and then tapered off [489].

Among the other compounds for the treatment of anxiety disorders, buspirone is one of most studied, particularly in reference to the efficacy on PBs associated with anxiety. Findings are controversial [490–493]. Beta blockers have also been evaluated for the same purpose, with more consistent indications of efficacy, especially with respect to aggression [494–496].

16.7.1.4 Mood Stabilizers

Despite the lack of good-quality evidence in people with ASD, AEs are widely used in clinical practice with dual indication, that is, epilepsy and mood disorders. In fact, some kind of epilepsy occurs in about 20% of people with ASD, and a higher percentage has a history of seizures and EEG alterations [497, 498]. Mood disorders are also quite frequent in people with ASD, with a prevalence rate of up to 70% [499].

Many AEs are currently used as mood stabilizers in the treatment of bipolar disorder for both acute phase and prophylaxis. In people with ASD, particularly those who are low functioning, AEs are also used for the management of PBs, even if these behaviors are not symptoms of a mood disorder. The relationship between epilepsy, behavioral disorders, and psychiatric comorbidity is complex and to date research findings on this issue are not conclusive [500, 501]. In some cases, a good pharmacological control of epilepsy is associated with an improvement of the individual's general functioning and with an attenuation of co-occurrent neuropsychiatric and behavioral alterations; in other cases, an effective therapy on seizures is followed by the onset or the exacerbation of PBs [501]. These differences seem to depend on a number of factors, including the mechanism of action of the drug and the appropriateness of the prescription [502].

The prescription of AEs as mood stabilizers and for the management of PBs should always be made with caution and after a thorough physical and mental state assessment of the person with ASD. Sodium valproate is indicated for the treatment of complex partial epilepsy, absence seizures, myoclonic, tonic, atonic, and tonic-clonic seizures. In addition to this, valproate is used for the treatment and prevention of manic and depressive episodes of bipolar disorders. It has shown good efficacy on irritability, hyperactivity, stereotypy, impulsivity, sleep disturbances, aggressiveness, self-injurious behavior, and cyclical behavioral alterations that can be interpreted as symptoms of bipolar spectrum disorders in people with low-functioning ASD and intellectual disability [503–505]. The dose requirement of valproate varies depending on the patient's level of metabolism. The most common side effects are weight gain, dizziness, drowsiness, and, in particularly predisposed individual, tremor, ataxia, and hypopiastrinopenia. In young and susceptible women, it may determine polycystic ovary syndrome. Valproate can also cause a transient increase in liver enzymes, while a frank hepatotoxicity is very rare. Pancreatitis and hyperammonemia are also to be considered, although rare and dependent on individual idiosyncrasy. Valproate is contraindicated in women of child bearing age.

Topiramate is indicated as a first-line AE in myoclonic epilepsy, and as an adjunctive therapy in partial seizures, absences and other forms of generalized epilepsy. Some studies have shown good efficacy of topiramate as an add-on therapy to other AEs for the treatment of resistant epilepsy in young people and adults with intellectual disability [506, 507]. However, the low tolerability makes topiramate a second-line treatment, especially in people with cognitive deficits and vulnerability to behavioral alterations. In fact, sedation, psychomotor retardation, ataxia, and exacerbation of speech disorders are common side effects. Topiramate can cause mild-to-moderate worsening of cognitive skills and overall functioning in a considerable proportion of children and adolescents with intellectual disability [508]. Research findings on the efficacy on PBs are controversial. In some cases, emotional lability, irritability, and psychotic symptoms have been reported as possible side effects [343], while other studies have shown improvement of aggressiveness, especially self-directed, and disruptive behavior [509]. In people with Prader-Willi syndrome, positive effects have been reported on food intake, mood stability, and impulse control, especially on skin scratching [510, 511]. Another area of potential utility of topiramate is alcohol abuse [243], which is reported to be an increasing issue in people with ASD [513, 514].

Levetiracetam is an AE indicated for the treatment of some forms of partial and myoclonic epilepsy. It is chemically unrelated to other AEs and has a pharmacokinetic profile

that makes it easy to start and to manage. The risk of interactions with other drugs is very low, since it is primarily excreted through kidney, with little hepatic metabolism and no interaction with the cytochrome P450 enzyme. Furthermore, it has a low plasma protein-binding property (less than 10%).

Levetiracetam appears to be effective for controlling subclinical epileptiform discharges in pediatric patients with ASD and was also associated with improved behavioral and cognitive functions [515]. Effects on mood are still to be clarified, with some studies reporting an increase in irritability, anger, agitation, nervousness, aggressive behavior, mania, and depression in the general population [314, 516–520], and others showing efficacy in reducing hyperactivity, impulsivity, mood instability, mania, and aggression in the general population and in children with ASD [521, 522]. The presence of intellectual disability, poor seizure control, and the presence of psycho-organic syndrome and impulsivity have been shown to be possible predictors of adverse behavioral effects [523].

In general, levetiracetam is well tolerated, with the most common adverse reactions being mild-to-moderate dizziness, flu-like symptoms, headache, rhinitis, somnolence or sedation, and asthenia.

Lamotrigine is considered a first-line treatment for partial and secondary generalized seizures, absences, and tonic-clonic seizures. Another area of use is the prophylaxis of depressive phases in bipolar disorder. However, studies on ASD with or without intellectual disability are missing. Case series and case reports on epileptic children indicate that lamotrigine could induce mania and, in the presence of intellectual disability, increase aggressive behavior [524, 525].

More generally, research did not produce unequivocal results that would support the use of lamotrigine in people with ASD. Most studies do not report any improvement on stereotypies, lethargy, irritability, hyperactivity, emotional reciprocity, sharing pleasures, language and communication, socialization, and daily living skills [526, 527], while others indicate some beneficial effects on aggression/agitation, anxiety, and irritability [314], especially in those with co-occurrent intellectual disability [528].

Lamotrigine is usually very well tolerated, with rare sedative effect and no impact on weight and metabolism. Common side effects include headache, vertigo, and diplopia. Skin rashes, which may evolve in generalized erythema and Stevens-Johnson syndrome, represent a rare but severe side effect. It requires drug withdrawal for extinction and drug titration (25 mg every 7–10 days) for prevention. Dosage should be halved, and the titration time doubled if valproate is used concomitantly, although the combined use with valproate should be avoided, since the high reciprocal interference of the two drugs and the consequent high risk of unpredictable negative effects.

Carbamazepine is widely used in people with ASD, especially in those with low-functioning ASD, for the treatment of epilepsy. In general, it is indicated as a first-choice drug for simple partial and generalized tonic-clonic seizures [258], although some genetic syndromes associated with epilepsy such as Dravet Syndrome are a contraindication [529]. Like valproate, carbamazepine is used as a mood stabilizer in the treatment and prophylaxis of bipolar disorder with a specific indication in case of rapid cycles and significant mood fluctuations [343, 530, 531]. Most benefited symptoms are reported to be irritability and anxiety [314]. Other uses with less evidence base are for the management of aggression and self-injurious behavior, especially in the case of co-occurrence with epilepsy or mood disorder [532, 533]. Carbamazepine is a potent inducer of hepatic cytochrome enzymes and reduces the levels of various drugs including oral contraceptives, valproic acid, etosuccimide, clonazepam, aripiprazole, haloperidol, chlorpromazine, olanzapine, risperidone, quetiapine, and paliperidone. This effect has to be considered also in case of polypharmacy with nonpsychotropic drugs. Furthermore, the association with clozapine is contraindicated due to the synergistic pharmacodynamic interaction, which determines increased risk of agranulocytosis and aplastic anemia, while the association with lithium, often clinically useful, must

include very slow titrations and careful monitoring for neurotoxic effect. Hyponatremia, edemas, and bone mineralization disorders are relevant side effects, particularly in persons with low-functioning ASD and with physical vulnerability. Other side effects such as ocular accommodation disorders, dizziness, and instability are less common and dose-dependent [343]. The treatment with carbamazepine should be started at 100–200 mg/day, and slowly increased to the minimum effective dose, taking into account that about 2–4 weeks from the start a dose increase might be needed to see its effect since carbamazepine self-induces its own metabolism.

Gabapentin is used as an AE only for adjunctive therapy of simple partial seizures. In case of small seizures and atonic, tonic, or myoclonic epilepsy, it may have even a worsening effect [534, 535]. In people with ASD, gabapentin has been shown to have some efficacy for the treatment of irritability, anxiety, and depressive symptoms of a bipolar disorder, especially in people with low-functioning ASD and in case of co-presence of intellectual disability [314, 536]. It has also demonstrated some efficacy in sleep disturbances associated with psychiatric comorbidities and in adults with restless legs syndrome [537, 538]. Other studies report a controversial effect on anxiety and depression [314].

Gabapentin can also be used for the treatment of neuropathic pain as monotherapy or with other AEs and even in patients with severe cognitive and/or motor disability [539].

Gabapentin shows good tolerability and safety. Drowsiness, fatigue, and vertigo are the most common side effects, which can be managed in most cases through simple dose reduction. Behavioral alterations, such as hyperactivity, irritability, anger, or temper tantrum are less common and often require drug withdrawal [343].

Pregabalin is an antiepileptic medication, mostly effective as adjunctive therapy for refractory partial-onset epilepsy. In patients with intellectual disability and resistant epilepsy, it showed a response rate of 25% [540]. It is also indicated for the treatment of neuropathic pain, especially painful diabetic polyneuropathy and postherpetic neuralgia, as well as for pain with fibromyalgia. Studies also suggest mood-modulating properties and beneficial effect on sleep, generalized anxiety disorders, and anxiety symptoms, also when expressed at behavioral level as PBs [541–543]. Some authors of the present chapters experienced some efficacy also on self-injury, anxiety, and depressive symptoms in persons whose psychiatric history contraindicated the use of antidepressants. Pregabalin presents a good pharmacokinetic profile, with rapid absorption, lack of protein binding, linear kinetics, absence of enzyme induction, and lack of interference with other drugs. Most common side effects are mild-to-moderate dizziness, ataxia, somnolence, and diplopia. Weight gain was not prominent in pivotal pregabalin trials, but was more problematic in long-term postmarketing analyses in epilepsy patients. Due to the very low impact on cognitive functioning [544], it can also be used in people with intellectual disability.

Lithium salts can be considered a first-choice drug for treatment and prophylaxis of bipolar disorders, also in people with major cognitive and communication difficulties, who express part of the symptoms in the form of PBs. Nevertheless, research evidence is limited, and most study findings refer to small samples, open-label designs, and case reports, with the main focus on people with low-functioning ASD and intellectual disability [545–548]. Lithium salts seem to be particularly effective in the management of aggression in persons showing other observable and behavioral affective symptoms, with response rates between 46% and 73% [549–551]. Efficacy on other PBs is less replicated with discordant results on self-injurious behaviors, irritability, hyperactivity, and temper tantrums. Fragile X syndrome and some genotypes of Phelan-Mc Dermid syndrome seem to represent a specific indication for the use of lithium [552, 553].

The use is limited because of the narrow therapeutic window and the need for continuous blood testing for the monitoring of serum lithium levels as well as renal and thyroid function. The therapeutically effective dose of lithium has to be assessed individually based on the clinical response and emergence of side effects, especially tremor, which can also occur

when lithium does not exceed the therapeutic range. Other common side effects are polyuria and gastrointestinal disorders. Furthermore, adaptation is necessary over time, depending on the patient's age, presence of comorbidities, and other concomitant therapies, such as thiazide diuretics. Usually, children and adolescents require a high dose to reach therapeutic plasma level, while in the elderly, the low body water volume requires a drastic reduction in the dose.

The use of antidepressants, AEs as mood stabilizers, and anti-anxiety medications in subjects with ASD ought to be with caution following a careful mental state assessment and with expertise in psychopharmacology for persons with ASD. The management of PBs in ASD also ought to be with caution. The SSRIs are the most prescribed drugs in ASD due to their good safety profile, but have been shown to have limited efficacy in the treatment of repetitive behaviors in children and adolescents and to be more associated with side effects, in particular, hyperactivity, stereotypy, decreased concentration, and impulsiveness.

16.7.1.5 Stimulants and Atomoxetine

Pervasive hyperactivity, impulsivity, and inattention, which represent the central features of attention-deficit hyperactivity disorder (ADHD), are frequently present in people with ASD and/or other neurodevelopmental disorders, with rates between 6% and 80% [554–557]. If not adequately treated, they can greatly hamper the effectiveness of habilitative and psychoeducational interventions.

Psychostimulants are the first-choice drugs in children with ADHD, with a response rate of 70–80% [558]. Among these, methylphenidate is the most studied and the most used, both in the immediate release formulation and in the extended-release formulation. Currently available data mainly concern studies on children and adolescents, highlighting a considerable superiority compared to placebo in reducing hyperactivity and impulsivity at dosages ranging from 0.15 to 0.50 mg/kg/day [559]. Research findings also suggest a response rate of 49% and an effect size of 0.54 among the ASD children, lower than what is normally achieved in ADHD children in the general population [558, 560]. The impact of stimulants on ADHD symptoms appears to be even less striking in people with co-occurrence of ASD and intellectual disability [410, 561].

Methylphenidate may represent a trigger for hypersensitivity to frustration and subsequently for a series of PBs such as aggression or temper tantrum [562–564]. Emotional dysregulation may be worsened by sedative drugs and antipsychotics [565, 566]. The efficacy of methylphenidate and other stimulants is verifiable within minutes, especially in children. Therefore, it is convenient to carry out a preliminary test of the efficacy in a protected environment before starting the treatment. Another advantage is the short half-life, so, negative effects rapidly disappearing after drug discontinuation.

Treatment should be started with minimal doses, such as 5–10 mg/day, and increased gradually. The treatment plan can be tailored to the individual needs, with the possibility of combining the immediate and extended-release formulations. In children and adolescents, attempts of temporary discontinuation of the treatment can be done, especially during the weekend or in the summer period, as well as attempts of dosage reduction over the years. In adults, continuation of treatment is recommended, especially when effective also for emotional dysregulation and PBs [343].

People with ASD seem to be more vulnerable to side effects of psychostimulants than the general population, which represents a reason for treatment discontinuation in about 20% of cases [559, 567]. Irritability is the most frequently reported side effect, while seizure threshold lowering is one of the most common concerns for prescribers, especially in patients with complex neurodevelopmental disorders. Research findings based on large samples indicate that stimulants do not increase the number of seizure-related hospitalization, even in persons with intellectual disability, cerebral palsy, or congenital abnormalities of the central nervous system [568]. Other less common side effects are tics, stereotypies, agitation, loss

of appetite, and insomnia. Insomnia may be due to a medication rebound effect and, therefore, minimized through the postponement of the day's last dose or through the introduction of a prolonged release formulation. A side effect that may be of greater importance in patients with ASD than in other patients is "hyperfocusing," which can lead to an aggravation of social withdrawal [569]. Despite this, stimulants remain a valid and safe option for persons with ASD, with therapeutic effects being reached at lower doses than in the general population [567].

Atomoxetine is a selective norepinephrine and dopamine reuptake inhibitor that is not classified as a stimulant. Although it is indicated for the treatment of ADHD in patients of any age (from 6 years on), it seems to be more effective in adults than in children, probably for the reason of the different balance between dopaminergic and noradrenergic pathways in the prefrontal cortex. The drug presents a kinetic of action completely different from that of stimulants and develops its therapeutic effect after a period of 1–2 months from the start. RCT and open-label studies conducted in children with ASD and ADHD have given controversial results in respect of efficacy on ADHD core symptoms, irritability, verbal and motor stereotypies, social withdrawal, and other PBs. More concordance has emerged on side effects, which were found to be few and almost limited to the first period of treatment. The most common side effects are gastrointestinal symptoms, fatigue, palpitations, hyporexia, irritability, and sleep disturbance [570–577].

In persons with low-functioning ASD, atomoxetine seems to be a little less effective and tends to present more side effects, especially in children [578–581]. A case report describes the induction of psychotic symptoms in a teenager with intellectual disability treated with 60 mg/day [582]. Atomoxetine should be started at the dose of 0.5 mg/kg/day, increased after 1 week to 1.2 mg/kg/day, up to a maximum daily dosage of 70–80 mg. Slower titration should be observed in patients with high sensitiveness to side effects.

In general, the quality of studies is modest for all people with ASD [580, 583].

Children, adolescents as well as adults with ASD are more vulnerable to side effects of psychostimulants than the general population, and therefore co-occurring symptoms of ADHD ought to be tailored selectively, with treatment started with minimal dose and increased gradually.

16.7.1.6 Other Medications

Clonidine, an alpha2-adrenergic receptor agonist, has been shown to be effective in reducing impulsivity, inattention, and hyperactivity. It seems to be effective in reducing sleep problems, to a lesser degree in improving ADHD symptoms, mood instability, and aggressiveness in children with ASD. Its use is based on the hypothesis that some symptoms of autism could be the result of a dysregulation of the adrenergic system that leads to a state of hyperarousal. Many side effects are reported, especially on the cardiovascular system, sometimes even serious (e.g., dysrhythmias, hypotension, and conduction abnormalities). The short half-life (a few hours, determining the need for six daily transdermal administrations) and the appearance of tolerance after a few months of therapy limit its clinical utility [584–587].

Guanfacine, an alpha-adrenergic agonist, has been shown to improve hyperactivity, distractibility, impulsiveness, insomnia, and tics in children and adolescents with ASD. It has fewer side effects than clonidine and it is certainly more manageable given the greater half-life [588–591].

Naltrexone is an opiate receptor antagonist commonly used for the pharmacological treatment of alcoholism and opioid addiction. Its use in ASD starts from the hypothesis that autism is linked to a hypersecretion of opioids in the brain as a consequence of a dysfunction of the adreno-hypothalamus-pituitary axis. In several studies, it has been shown to be moderately effective in reducing hyperactivity, restlessness, and self-injurious behavior. Improvements in social withdrawal, attention skills, and speech production were also observed [592–594]. As far as side effects are concerned, naltrexone does not appear to increase the risk of serious adverse events over placebo [595].

Secretin is a 27-amino acid peptide hormone that stimulates the secretion of bile in the liver and insulin in the pancreas. With regard to the use of secretin in subjects with ASD, it should be pointed out that its widespread use and publicity are due to the disclosure made by the mass media of "dramatic" effects arising after infusion of it as a stimulus test for diagnostic purposes in three children with ASD and gastrointestinal symptoms. Rapid improvement in language and social skills were reported. Secretin has then been studied extensively in multiple RCTs, and there is clear evidence that it lacks benefit. However, some RCTs showed a potential efficacy in a specific subgroup of autistic children with chronic diarrhea compared with autistic children without gastrointestinal symptoms [596–600].

16.7.1.7 New Therapeutic Strategies

Many compounds are currently under study as a possible treatment for ASD core symptoms and the focus of drug design is progressively addressing communication and social interaction. Research has informed our understanding of ASD as a genetically and biologically based neurodevelopmental disorder. However, there still is a great unmet need for interventions that reliably address such core symptoms of ASD. The research studies carried out so far show many difficulties encompassing the genetic and phenotypic heterogeneity of ASD, which hampers the identification of common neurobiological pathways underlying the disorder. However, many pathogenetic theories are proposed and seem to be confirmed in some specific subgroups of individuals with ASD.

Cholinergic Agents

Acetylcholinesterase inhibitors have been approved by the Food and Drug Administration (FDA) for the treatment of Alzheimer's disease. Postmortem data suggest that cholinergic abnormalities may be implicated in ASD, although the precise pathogenetic mechanism has not yet been elucidated [601]. Acetylcholine (Ach) modulates attention, novelty seeking, and memory. Recent animal studies have shown that the increase in Ach following the inhibition of acetylcholinesterase is able to reduce cognitive rigidity and improve social interaction in autistic phenotypes [602]. It is interesting to note that the increase in Ach positively modulates the selective attention and the emotional processing, which are compromised in individuals with ASD [603].

Tacrine, the first drug available in this class, has shown modest efficacy in the short-term treatment of irritability and hyperactivity and in improving eye contact and language [604]. The poor safety profile, especially regarding the possible hepatotoxicity, prevented further studies.

Rivastigmine produced satisfactory results in a 12-week open-label study enrolling 32 children with ASD. Statistically significant improvements in expressive language capacity have been noted [605].

Galantamine has been shown to improve expressive language in 3 adults with ASD [606]. In subsequent studies with larger samples and one placebo-controlled, it showed improvement in irritability, distractibility, social withdrawal, and eye contact [607–609].

Donepezil has been shown to have some effect on the treatment of irritability and hyperactivity. No definitive results have been achieved regarding its effectiveness in improving language and social interactions. It seems that it could also induce a REM sleep augmentation, increasing its duration and decreasing its latency, and this could have positive effects on learning and cognition. In a recent double-blind, placebo-controlled trial, it has been shown to improve receptive language skills [610–614].

A pilot study with mecamylamine, a non-competitive antagonist of nicotinic receptors, showed no effectiveness on autism's core symptoms [615].

Glutamatergic Agents

Glutamate, the main excitatory neurotransmitter, is highly concentrated throughout the brain. It seems to have a crucial role in neuronal plasticity and the maintenance of cognitive functions. Glutamate is transformed into gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, through a

specific enzyme (glutamic acid decarboxylase). Excess glutamate has been shown to be a powerful neurotoxin that leads to neuronal cell death (proapoptotic effect) and has been believed to play a role in the pathophysiology of some neuropsychiatric disorders, such as schizophrenia, obsessive-compulsive disorder, and Alzheimer's dementia. The hyperglutamatergic hypothesis was also proposed in the genesis of the ASD. There are many hypotheses that have been formulated to explain the increase in glutamate in these individuals and equally numerous are the medications studied to modulate the glutamatergic system in order to effect ASD core symptoms. In general, those molecules that are able to promote GABAergic or modulate glutamatergic receptors could have a potential role in treating autistic symptoms.

D-cycloserine (an antibiotic approved for the treatment of tuberculosis), a partial N-Methyl-D-Aspartate (NMDA) agonist, has been shown to be effective in the treatment of the negative symptoms of schizophrenia [616] and in improving lethargy and social withdrawal in children with ASD [590]. These positive results have been confirmed in subsequent studies conducted on young adults with ASD, showing an improvement in stereotypies and social skills [617, 618]. The findings of a recent study suggest that D-cycloserine may help youth with ASD to maintain skills gained during social skills training [619].

Amantadine, an NMDA antagonist, was only evaluated in one placebo-controlled study. The study involved 39 children and adolescents with ASD, but did not achieve statistically significant results [620]. A further study, a double-blind, placebo-controlled trial on children with ASD, that aimed to investigate the effect of adding amantadine to risperidone for the treatment of behavioral problems in such population, showed it to be effective in reducing hyperactivity and irritability [621].

Memantine, an NMDA antagonist, approved by the FDA for the treatment of Alzheimer's disease, has been evaluated in several retrospective and open-label studies. It has been shown to be effective in treating hyperactivity, irritability, lethargy, social withdrawal, and distractibility in people with ASD. Its combination with risperidone was found to be superior to monotherapy of memantine in treating irritability, hyperactivity, and stereotypies in people with ASD. Several studies report an improvement in communication and memory skills and in self-stimulating behaviors [603, 604, 622–627]. Three phase 2 trials have recently been conducted to assess the efficacy and long-term safety of extended release memantine treatment in children with ASD showing considerable improvements in social responsiveness and no evident safety concerns [628]. A randomized, placebo-controlled study did not demonstrate clinical efficacy of extended release memantine in ASD, although it reassured about its tolerability and safety [629].

Acamprosate, a GABAa agonist, approved by the FDA for maintaining alcohol withdrawal in adults, has shown efficacy in improving hyperactivity, social withdrawal, and social response in youth with ASD [630–632].

Arbaclofen, a GABAb agonist, seems to improve social functioning in individuals with Fragile X syndrome [633] even if two recent phase 3 placebo-controlled trials by the same authors did not meet the primary outcome of improving social avoidance [634]. An 8-week-long open-label study enrolling 32 children and adolescents with ASD showed Arbaclofen to be effective on irritability and social withdrawal [635].

Bumetanide, a diuretic agent that reduces intracellular chloride and increases GABAergic inhibition, seems to improve interaction, social communication, and restricted interest in children with ASD. Mild hypokalemia and polyuria are reported as side effects [636–639].

Melatonin

Melatonin (N-acetyl-5-methoxytryptamine), a hormone produced by the pineal gland (or epiphysis), acts on the hypothalamus and has the function of regulating the sleep–wake cycle. Melatonin and other melatonin-agonist substances have chronobiotic effects, that is, they can regulate the rhythms of functioning of the body with respect to the alternation of day and night (circadian system).

Abnormalities of the melatonin system, in particular reduced production of melatonin during the night, seem to be associated with pathological changes in the sleep–wake rhythm that are very frequently found in persons with ASD. Sleep delay, night awakenings, and early awakening are the most frequent disturbances in ASD, with frequencies ranging from 40% to 86% [640]. These pathological changes in sleep are persistent and difficult to manage and are often associated with a worsening of social functioning, irritability, PBs, and a deterioration in quality of life. The efficacy of melatonin in people with ASD has been demonstrated by several studies, recently revised and collected in a meta-analysis [640]. Exogenous melatonin (variable dosage 1–6 mg/day) was able to reduce sleep latency and the number of awakenings per night and increase the total duration of sleep [640–643]. On the other hand, the production of melatonin appears to be closely related to the availability of serotonin, which we know to be involved in the pathogenesis of ASD core symptoms [644]. Most of the studies available have grouped small samples of subjects with ASD, often associating them with individuals with other neurodevelopmental disorders, detecting generic outcomes mostly related to the quality of sleep. Only a few studies have attempted to more specifically investigate other symptoms typically present in people with ASD. However, the results obtained seem to suggest that the exogenous administration of melatonin may improve social communication (verbal and nonverbal communication, social interaction), social withdrawal, repetitive and stereotyped behaviors, limited interests, and finally, the ability to adapt to changes [645–648]. An RCT involving 125 individuals aged 2–17 years with ASD showed a significant improvement of sleep duration and onset but also of externalizing but not internalizing behavior and caregivers' quality of life [649]. There is need for more RCTs to confirm these results.

Neuropeptides

Oxytocin is a 9 amino acids peptide hormone produced by the hypothalamic nuclei and secreted by neurohypophysis. Its main action is to stimulate the contractions of the smooth muscles of the uterus, especially in the last period of pregnancy when it plays an important role in the beginning and maintenance of labor and delivery. It seems that the genetic structure and the phenotypic basic expression of this neuropeptide are stable and phylogenetically very ancient, while the genetic regulation of its receptors would present an extreme variability. Such heterogeneity seems to underlie the differences in social behavior both among different animal species and within the same species. Animal experiments have shown the importance of this hormone in mating and offspring behavior. Many human studies have begun to explore the role of this neuropeptide in cognitive skills with relational implications. The first results confirm that the variations of the genes that code for its receptors can modify brain function and contribute to the individual characterization of social behaviors. Particularly interesting result are found in the studies that outline the role of oxytocin on empathy, relationship with others, and self-esteem.

It has been hypothesized that abnormalities in the production of oxytocin and vasopressin may contribute to the development of repetitive behaviors and social deficits found in ASD [650]. In this regard, several studies have been carried out in people (children and adults) with ASD showing significant improvement in stereotyped behaviors and a marked decrease in obsessiveness after treatment with oxytocin via infusions [651–654]. More recently, studies with nasal application of oxytocin demonstrated its effectiveness in improving social interactions and communication [655–660]. Other studies do not suggest significant clinical efficacy on core symptoms [657, 661]. In none of these studies, oxytocin produced any significant side effects [662, 663]. Research in the coming years may better clarify the role of oxytocin in the treatment of ASD core symptoms [664–667].

Vasopressin is also a neuropeptide used by neurons in the brain to communicate with one another. High levels of vasopressin are associated with anxiety, aggression, and sensory processing. Animal studies have shown that experimental alterations of the proper func-

tioning of vasopressin determine a variety of social deficits, including impaired memory for peers and a reduced interest in social interaction. Conversely, the administration of vasopressin to mice with a genetically induced form of ASD improves their social functioning [668]. Vasopressin is already approved by the Food and Drug Administration for use in humans and has proved to be successful in treating some common pediatric conditions, including bedwetting. Similar to oxytocin, it has also been shown to improve social cognition and memory in people who do not have ASD [669–672]. Given the connection between vasopressin signaling and social behavior, vasopressin receptors have been considered a therapeutic target for the treatment of ASD, and the preliminary evidence is provided through both animal and human studies [673, 674]. New researches are ongoing in persons with ASD of any age.

Balovaptan is an orally administered selective V1a receptor (Vasopressin receptor 1a) competitive antagonist, for which phase 1 and phase 2 clinical trials did not identify any safety or tolerability concerns in healthy male volunteers and in men with ASD [675]. In persons with ASD, balovaptan showed dose-dependent clinically meaningful improvements on the Vineland-II Adaptive Behavior Scales composite score (VABS-II-ABC) compared with placebo [675], which supports further study as a potential treatment for the socialization and communication deficits.

Conclusions

The elucidation of efficacious treatments for ASD is plagued with limitations in study design, statistical power, and clinical heterogeneity of the disorder. Evidence on efficacy, dosage, and safety is limited [676] and derived mostly from naturalistic studies or case reports, with a main focus on identification of side effects and discontinuation rate. Placebo-controlled or active-controlled studies are limited, with small sample sizes. No psychoactive drug has shown efficacy on ASD core symptoms. Some efficacy is reported only for antidepressants and antipsychotics, especially SGAs, on repetitive behaviors, although discordant results indicate that further research is needed. Newer compounds, including cholinergic, glutamatergic agents, and neuropeptides, have been associated with future potential utility, while studies of fenfluramine, secretin, opiates, and mood stabilizers generally found no effect.

Psychotropic medication used for comorbid psychiatric disorders shows some evidence of efficacy, albeit of poor quality, especially for mood disorders and ADHD. For anxiety, SSRIs continue to be widely prescribed, despite the lack of positive clinical trial results and the high risk of behavioral disinhibition. SGAs have become the most commonly used drug class targeting irritability, aggression, and other PBs. They show significantly reduced rates of side effects, particularly extra pyramidal symptoms, compared to FGAs. Specifically, risperidone and aripiprazole are the two approved agents in youth with ASD for the treatment of irritability marked by aggression, self-injury, and severe tantrums. More limited data are available on drug refractory aggression and self-injury, including those for clozapine. Some of the very new-generation APs show a receptor-binding profile that matches the characteristics of many people with ASD, with low metabolic effects. Antiepileptics and mood stabilizers have also shown promising results, but indications seem to be even less precise than for the other classes.

Frequent off-label prescriptions combined with potential tolerability issues render this area of psychopharmacological practice challenging, and more work is needed from the field to identify potential predictors of treatment response toward specific target symptoms.

Basing on current knowledge, psychoactive drugs should only be prescribed for the treatment of co-occurring psychiatric disorders. For the management of aggressive behavior or other severe PBs, the decision to intervene with a psychoactive drug should be preceded by a careful evaluation of all the aspects related to epiphenomena brought to the observation of the clinician, conducted with appropriate procedures and tools. It must be ascertained that PBs do not depend on pain or physical illnesses, environmental factors, or life events. The drug should be used

only in the best interests of the person, after exclusion of any possibility of nonpharmacological treatment, in accordance with scientific evidence and available guidelines, and after a careful evaluation of the cost–benefit ratio (see also Problem Behaviour chapter). Particular attention must be paid to the search for factors for which the drug could be contraindicated, ineffective or harmful (make sure that the necessary instrumental examinations and investigations have been performed), or with which it could negatively interfere.

Before choosing a treatment, it is also advisable to collect a good pharmacological history, taking note of efficacy, tolerability, and side effects of every previous drug. An appropriate consideration of the availability of services and supports for the regular intake of therapy and for the management of any unwanted effects or iatrogenic complication may be also useful in the identification of the best drug to prescribe.

Once the treatment has been started, it is very important to monitor its efficacy and safety at regular intervals, also through the appropriate laboratory and instrumental tests. When the drug has been introduced with the main purpose of managing a PB, it is indispensable to frequently reevaluate the dosage, and to use the lowest possible dose for the shortest possible time (see also the Psychopharmacology chapter).

Psychopharmacological therapies should also be shared with the multidisciplinary team, especially with respect to the rationale and objectives. All professionals involved in the care of the person with ASD should be informed at regular intervals. If no significant beneficial effects are noted after a three-month period, treatment should be discontinued.

In persons with ASD and/or other neurodevelopmental conditions, the usefulness of psychoactive treatments should be judged in terms of effectiveness rather than efficacy (on target symptoms) and safety, with the former including the capability to keep the patient on treatment for the right time and the impact on quality of life. Psychopharmacological therapies must be considered an integral part of a person-centered program of interventions and, therefore, take into account the impact on individual interest and satisfaction toward various areas of life.

Great attention must also be paid to the ethical implications of the treatment. The professional figures involved are required to document the assessment of the patient's ability to sign his/her informed consent to the proposed therapy. When this ability is lacking, consent must be reached with the involvement of the legal representative and the family.

The intervention plan must be clearly communicated to the person with ASD, even in case of co-occurrence of severe intellectual disability, resorting if necessary, to specific or innovative systems, such as use of pictures and accessible information (see ► www.ld-medication.bham.ac.uk) [677]. This must also include the explanation of a possible use of the drug outside its official indications (off label). In this case, information must be provided on the type and quality of the available evidence on effectiveness [320].

Frequent off-label prescriptions combined with potential tolerability issues render the psychopharmacological practice challenging. More research is needed to identify potential predictors of treatment response toward specific target symptoms and the impact of treatment on quality-of-life measures.

16.7.2 Nonpharmacological

The nonpharmacological interventions with scientific evidence based on developmental ages of persons with ASD include the following:

(a) Early intensive programs oriented to improve the trajectory of the children's developmental and adaptive functioning and (b) focused applied behavior analysis (ABA) that targets specific behavior that may interfere with the well-being regardless of the person's level of functioning and age.

Nonpharmacological treatments for people diagnosed with ASD are under constant development and, since their application in the 1980s, they have been proved to be effective in reducing the impact of the core symptoms

by improving communication and autonomy skills and reducing problem behavior in children and adults with ASD. Throughout the whole life span, effective treatments are derived from different applications of ABA and of contextual behavioral sciences. However, they greatly differ both for intensity and for treatment objectives from childhood to adulthood.

Besides treatments, assistive technology (AT) may be used to help persons with ASD to increase, maintain, or improve functional capabilities. It may aid in a variety of areas, including basic communication, reading, writing, and math, telling time and managing schedules, learning and applying social skills, managing sensory issues, remaining safe, and daily activities. Low-tech, mid-tech, and high-tech AT are the most common categories. Anything that does not require electricity, such as weighted vests, sensory balls, or graphic boards, is considered low-tech AT. Mid-tech AT is straightforward enough to be both affordable and simple to use. Battery-operated sensory devices, visual timers, and social skills movies are all examples. High-tech AT refers to the most complicated devices or equipment with digital or electronic components that can be computerized. It includes robots that are designed to aid in the development of social skills. One of the most significant applications of assistive technology is Augmentative and Alternative Communication (AAC), which can help persons with ASD of all ages to gain independence, communicate more effectively, and interact more socially. There are a variety of AAC devices and therapy tools available, with many new ones emerging in recent years, such as speech-generating devices [678, 679] and less high-tech methods of communicating using pictures [680].

The evidence-based non-pharmacological treatment, also referred to as psychosocial treatment or behavioral intervention, has extensively been considered in international guidelines (e.g., [254, 681, 682]). Currently, there are many intervention models based on ABA, which integrate the more structured approaches, such as the discrete trial training (DTT) used by Lovaas [683], with more naturalistic intervention models based on development stages such as ABA-Verbal Behavior (ABA-VB), Early Start Denver Model, TEACCH, and social skills training. From the mid-1990s, the research and dissemination of interventions for ASD mainly concerned a second generation of behavioral interventions. In addition, some interventions based on cognitive-behavioral therapy (CBT) have been adapted to deal with certain related psychological problems, such as anxiety and stress perceived in people with ASD [684]. A behavioral pattern of contextualistic matrix, the dialectical behavior therapy (DBT), has been shown to be effective in adults with ADHD, even though it has never been tested on people with ASD [685]. The literature on treatments based on the analysis of applied behavior (ABA) on high-functioning ASD is still limited compared to the extensive evidence demonstrated in the treatment of low-functioning disorders and early interventions. At the moment, treatment protocols that can promote health, facilitate self-management, and reduce stress in ASD are of great interest and importance to scientific research and for the improvement of the quality of life. Among modern cognitive behavioral therapies, acceptance and commitment therapy (ACT) has been used with high-functioning ASD people and has shown a reduction in stress levels, hyperactivity, and emotional distress, and an increase in prosocial behavior [686].

Despite being applied in many forms, with different durations, intensity and focus, and being declined very differently in protocols, all ABA-based interventions for ASD have the following core characteristics [687]:

1. An objective assessment and analysis of the person's condition by observing how the environment affects the person's behavior as evidenced through appropriate data collection
2. Importance given to understanding the context of the behavior and the behavior's value to the individual, the family, and the community
3. Utilization of the principles and procedures of behavior analysis in order to improve the person's health, independence, and quality of life

4. Consistent, ongoing, and objective assessment and data analysis to inform clinical decision-making

Behavioral and other psychological interventions for people with ASD may be divided into two main groups:

(a) Intensive behavioral and developmental programs aimed at improving overall functioning and altering outcome (also known as Comprehensive ABA Treatment or EIBI, Early Intensive Behavioral Intervention)
(b) Interventions which aim to address specific behavioral difficulties associated with ASD, such as sleep disturbance, decrease problem behavior or increase positive behaviors, such as initiating social contact with peers, or developing communication skills (also referred to as Focused ABA Treatment)

16.7.2.1 Intensive Behavioral and Developmental Programs

Comprehensive ABA or EIBI refers to the treatment of multiple developmental domains, such as communicative, social, cognitive, emotional, and adaptive functioning. Typically, maladaptive behaviors, such as noncompliance, tantrums, and stereotypy, are also included in the focus of treatment. Although there are different types of comprehensive treatment, in EIBI, the overarching goal is often that of closing the gap between the person's functioning level and that of typically developing peers. According to the Scottish Intercollegiate Guidelines Network (SIGN) [682], modern EIBI programs are best described as behavioral and developmental programs. These usually start when the child with ASD is 36–48 months, with some reviewed studies starting at 18 months. These intensive programs amount to around 30 hours of treatment per week (plus direct and indirect supervision and caregiver training), but more recent reviews include evidence from programs ranging from 13 to 28 hours per week [687]. Not all children diagnosed with ASD participate in intensive programs; however, a number of more specific focused ABA-based interventions are also available (e.g., PECS that focus on the communicative skills) and they do not require the same level of intensity. The program is highly individualized, taking into account the idiosyncratic and individual motivations and specific cognitive, metacognitive, and learning needs of each child. Initially, this treatment model typically involves 1:1 staffing and gradually includes small-group formats as it sees appropriate. Comprehensive treatment may also be appropriate for older individuals diagnosed with ASD, particularly if they engage in severe or dangerous behaviors across environments.

EIBI programs are manualized, intensive, and target a comprehensive range of skills for training, practice, and generalization; they also aim to engage the child with ASD in structured learning [688]. Although the programs vary broadly in the emphasis given to different skills (verbal behaviors, pivotal responses, play, joint attention, etc.), they all tend to start with very basic skills (simple communication skills, sitting, looking, listening) and over time, they work toward more complex, verbal and metacognitive skills, such as self-monitoring and perspective-taking. Initially, treatment is typically provided in structured therapy sessions, which are integrated with more naturalistic methods, as it seems more appropriate. As the children progress and meet the established criteria for participation in larger or different settings, treatment in those settings and in the larger community should be provided. Treatment components are generally drawn from areas that will influence the quality of life of the person. EIBI programs have different levels of parental involvement and international guidelines recommend that parent-mediated intervention programs should be considered for children and young people of all ages who are affected by ASD, as they may help families interact with their child, promote development and increase parental satisfaction, empowerment, and mental health [688]. NICE guidelines 170 [689] recommend including play-based strategies with parents, carers, and teachers to increase joint attention, engagement and reciprocal communication in the child or young person. Strategies should:

- Be adjusted to the child or young person's developmental level
- Aim to increase the parents', carers', teachers', or peers' understanding of, and sensitivity and responsiveness to the child or young person's patterns of communication and interaction
- Include techniques of therapist modeling and video-interaction feedback
- Include techniques to expand the child or young person's communication, interactive play, and social routines

The intervention should be delivered by a trained professional and supervised regularly. Generalization from prompted to spontaneous use of trained skills is a key element in caregiver training. NICE guidelines 170 [689] also suggest involving and training of different people based on the age and context of the person with ASD, with parent, carer, or teacher mediation for pre-school children, and peer mediation for school-aged children.

Training family members and other caregivers to manage problem behavior and to interact with the individual with ASD in a therapeutic manner is a critical component of effective treatment models. Acceptance and commitment training (ACT) processes and procedures have recently been integrated with traditional cognitive-behavioral procedures for parent training to enhance the parent-caregiver acceptance of difficult personal experiences related to the complexity of the educational and emotional interactions with their child, and the ability to act in synergy and full awareness for the management of problem behaviors, in a context of value and full acceptance of the other as a whole person [690, 691].

EIBI thus describes comprehensive teaching programs, rather than interventions aimed at reducing symptoms. A Cochrane review [692] concluded that while EIBI cannot be recommended universally, it should still be considered on a case-by-case basis. In this review, there were no clear predictors identifying which children will respond to it or not, and while intensity or total hours were moderately correlated with some outcomes, such correlations were not always significant. EIBI may not be cost effective when considered individually on the level of early-years service, but the cost effectiveness of it may change when considered on a societal level. Although interventions can be very intensive, no difference was found between EIBI and controls on measures of parental stress, parental anxiety, parental depression, or parental positive perception; however, no adverse sequel arising from EIBI has been reported.

16.7.2.2 Focused ABA Treatment

Focused ABA refers to treatment provided directly to the person for a limited number of behavioral targets. It is not restricted by age, cognitive level, or co-occurring conditions. Focused ABA treatment may involve increasing socially appropriate behavior (e.g., requests) or reducing challenging behavior (e.g., aggression) as the primary aim. It is crucial to target increases in appropriate alternative behavior even when reduction of challenging behavior is the primary goal. This is because the absence of appropriate behavior is often the precursor of serious behavior disorders. Therefore, individuals who need to acquire certain skills (e.g., communication, learning how to tolerate change in environments and activities, self-help, and social skills) are also suitable candidates for focused ABA.

Focused ABA plans are appropriate for individuals who: (i) need treatment only for a limited number of key functional skills (examples of key functional skills include, but are not limited to, establishing instruction-following, social communication skills, compliance with medical and dental procedures, sleep hygiene, self-care skills, safety skills, and independent leisure skills) or (ii) have such acute problem behavior that its treatment should be the priority. Examples of severe challenging behaviors requiring focused intervention include, but are not limited to, self-injury, aggression, threats, pica, elopement, feeding disorders, stereotypic motor or vocal behavior, property destruction, noncompliance and disruptive behavior, or dysfunctional social behavior.

Treating behavioral disorders and challenging behavior in people diagnosed with ASD pragmatically means following these five steps:

1. Operationally define the challenging behavior

To define operationally the challenging behavior, professionals and caregivers need to describe the behavior as it is manifested, reporting it in an operative and objective way. For a definition to be operational, it is necessary that this definition is understood and interpreted, unambiguously, in the same way by all the people involved (e.g., "she is aggressive" is not an operational definition, "hits the head of other people with left hand" is an example of operational definition). Elaborating an operational definition of challenging behavior is a fundamental action for several reasons: a) it allows to clearly and unambiguously identify the behavioral parameters to be observed and it is useful for both the collection of baseline data prior to treatment and data during treatment; b) it helps the clinician to keep the phase of data collection separate from the phase of interpretation of challenging behavior (definition of the hypothesis of the functional value of the behavior in the context); c) it facilitates the comparison between the care team and the caregivers in the selection of challenging behaviors of greater severity for the person with ASD and their contexts (priority decision for the intervention on the challenging behavior).

2. Measurement of challenging behavior

Data collection of the frequency, intensity, duration, and latency of the challenging behavior helps us to define the baseline as a necessary reference parameter to understand the effectiveness of ongoing treatments. The baseline and the systematic collection of data during the treatment phase will make it possible to identify ineffective procedures and, in addition, to verify the greater effectiveness of the chosen treatments. A record of daily progress can also function as a powerful reinforcement for the treatment provider, as well as for the family member or the person receiving the treatment.

Collecting the quantitative parameters on the challenging behavior means using the different observation systems which are available in a wide variety of scientific supported methods. An exhaustive analysis goes beyond the scope of this text, but it is important to remember that the purpose of this multiplicity of methods is to allow us to find a method that fits the behavior that is going to be observed and not vice versa.

To sum up, a distinction can be made between continuous and sample recording: continuous recording is the recording during the entire period of observation. Once the observation time has been chosen (which depends on the behavior), all the events of the operationally defined challenging behavior must be observed and measured for the entire duration of that period. The main alternatives to continuous recording are sampling techniques, which divide the observation period into time intervals. In sampling techniques, the observation period is divided into intervals and the observers record whether the behavior is occurring during each interval, thus leading to an estimation of the behavior. The most commonly used sampling techniques are: (a) whole interval, (b) partial interval, and (c) momentary time sampling.

3. Functional assessment

The collection of the frequency, duration, intensity, or latency of a behavior informs us about the characteristics of that behavior and is a useful parameter to evaluate the effectiveness of treatment. However, the sole "quantitative" measure of behavior does not provide accurate information about its meaning in the context. Functional analysis is useful in this very respect: it can help us understand why that specific behavioral repertoire, in a person's learning history, remains alive and active. Therefore, effective and deontologically based intervention on problematic behavior must necessarily make functional analysis and identification of the hypothesis of the functional value of behavior the center of one's line of thought and work. For this reason, there are various functional assessment methodologies aimed at providing data to answer fundamental questions,

such as: why does this specific behavior exist? What is the objective of that behavior? What is the need or desire that this behavior nurtures? What is the need or desire this behavior responds to? How can we support the same need or desire in a functional way for the person and adapt it with regard to their environment? What is the relationship between the challenging behavior and the context in which it occurs?

Understanding or identifying the hypothesis of the functional value of behavior will thus allow us to select psychoeducational procedures and, in some cases, effective pharmacological interventions, to reduce challenging behavior. However, it will, above all, show us which new behaviors should be taught and which should be promoted, or which new opportunities should be granted to the person.

This is the purpose of the functional assessment which, due to the complexity of behaviors and the life contexts in which they are potentially operated, may use different analysis tools that can be classified into two main categories: direct and indirect.

With indirect measures, information on the functional value of behavior is gathered through questionnaires, checklists, or interviews with parents, caregivers, and people who know the person with ASD well. Some of the tools used are as follows:

- The Motivation Assessment Scale (MAS, [693])
- The Functional Analysis Screening Tool [694]
- The Setting Events Checklist [695]

Direct measures, in which the behavior is directly observed by the professional or the parent, are carried out with the aim of verifying the presence of a behavior at the moment of its occurrence, that is, in real time, in a specific context.

ABC, which stands for antecedents-behavior-consequences, is the best-known form of functional behavior assessment. In order to understand ABC, it is necessary to start by focusing on B: the observable behavior. Then, A denotes the antecedent, which is an event or events that occur before the behavior begins, and C identifies the consequence that follows the behavior. As part of direct functional analysis, functional analysis for experimental or analogous conditions is particularly effective. This system of analysis is particularly useful in the analysis of hetero-aggressive and destructive behaviors. The experimental functional analysis implies the manipulation of the antecedents and/or consequences of the behavior in order to identify a functional relationship by testing the hypothesis of functional value between these contextual variables and the behavior itself.

4. The hypothesis of functional value and integrated intervention

This phase of the intervention, aside from being the most important, is also the most complex because it requires the professional to analyze the collected data and to construct hypotheses on the adaptive value of the problem behavior using their own analytical skills as regards that specific case.

Although not infinite, the functional values of a specific challenging behavior are often multiple and sometimes they can also be changing in time. These behaviors, like any other, may be related to the consequences of behavior observed in the external world, rather than having consequences on the internal world, that is, emotions, one's belief systems, values, and symbolic systems. The reason why the challenging behavior remains active can also be attributed to elements linked not only to the learning history, but also to physiological variables, for example, the pain or the variable of a reduced or qualitatively poor sleep. For this reason, in this phase of analysis of the hypothesis of the functional value of the behavior, it is important to share with the whole team, including with those figures that have specific professional skills (e.g., the medical doctor and the nurse). The joint work of the team will define more completely and correctly the different hypotheses that underpin the problem behavior and also share and participate in pharmacological and psychoeducational treatment procedures, as well as discuss jointly and constantly the data collected during the interventions.

5. Nonpharmacological intervention implementation

The consequent step after identifying the functional value of the challenging behavior is the choice of nonpharmacological interventions and the continuation of data collection to verify the effectiveness of treatments. There are many nonpharmacological interventions that can be used for the development of new behaviors and the reduction of maladaptive behaviors; in Cooper, Heron, and Heward [696], several hundred interventions are mentioned, and the selection of the most appropriate one must be carried out by paying attention to the consistency between the chosen procedure and the adaptive/disadaptive value of behaviors that are to be increased and/or decreased. In the choice of interventions, which are often multicomponent, it is equally important to remember to maintain a proportion between proactive procedures (80%) and reactive procedures (maximum 20%). Indeed, even if the opposite is often the case in clinical practice, an effective intervention program that respects the quality of life of the person and their context should favor more proactive interventions and limit the detriment of reactive ones.

In general, any nonpharmacological intervention should be chosen and implemented in accordance to tailored, dynamic, and developmentally phased life-span approaches that recognize and focus on periods of increased or decreased specific needs, as well as change monitoring over time in the individual or their family. The need of designing efficient delivery systems for complicated therapies has recently emerged as a prominent aspect of intervention research [697].

Although adults make up the majority of autistic people, because adulthood is a much longer stage of life, services and support for adults with autism are significantly fewer than for children and adolescents, and very few programs have been extensively assessed [698]. Addressing the needs of autistic people currently necessitates collaboration among local communities and stakeholders, as well as researchers and clinicians involved in the creation of relevant programs and systemic change. Adults have proved to benefit from treatments comparable to those used with adolescents, such as cognitive behavior therapy and social skills groups [699, 700]. Supported employment and job coaching programs are available in several parts of the world, and proof of their usefulness is expanding [701, 702]. Adult adaptive skill development programs and systems exist, although they are seldom recorded in research [703]. For many years, behavioural programs for adults with ASD have been documented, although few are evidence-based, and many involve people with co-occurrence of severe intellectual disability. Furthermore, some neurodiversity advocates disagree with the use of many behavioral techniques [704]. Services for adults with significant support needs appear to be the most crucial area in several high-income countries, and they require major improvement. In low- and middle-income countries requirements are even broader and encompass to the entire life span.

Nonpharmacological treatments cannot rely only on the expertise of autism specialists. In fact, non-specialized professionals are currently providing the majority of treatment for persons with ASD of all ages, even in high-income countries; most care is done in school and community settings, with or without professional input or assistance [705]. As a result, non-expert training and assistance must be included in research and system planning. Understanding what works for whom and when, as well as some of the expected requirements and differences that must be recognized while supporting persons with ASD, are critical elements [697].

16.7.2.3 Successes and New Challenges in Nonpharmacological Treatment

Treatments based on contextual sciences and applied behavioral analysis have changed the way we act toward ASD, moving from symptom containment to building abilities to improving adaptive skills and interaction. For example, many people with ASD can now develop a communication system (verbal, by images, or gestures) that allows them to improve their interaction with the social environment. The new challenges concern the diffusion of these interventions that require

years of training and high specialization of the professionals and their application not only in the early interventions: the acquisition of skills opens new scenarios, the possibility of supporting the person with ASD in the transition through adult age for an independent life and an inclusive job. In addition, interventions and professionals will be needed to allow a response to adult behavior and psychopathologies in people with ASD.

Because the bulk of behavioral treatments include numerous components, they can be complicated and articulated. As a result, it is advised that measurements be developed that enable for rigorous analyses and uniform change and progress tracking across time. Innovative methodological approaches, such as the Multiphase Optimization Strategy and Sequential Multiple Assessment Trial, have emerged to assess treatment effectiveness, define delivery strategies within complex interventions, and investigate the effects of each treatment on persons with ASD.

The Multiphase Optimization Strategy is a methodological approach for systematically and efficiently optimizing behavioral interventions by determining which components of a targeted intervention are active and potentially contributing to positive outcomes, and which dosage of each component produces the best results for a specific individual.

Sequential Multiple Assessment Trial is a randomized experimental design for time-varying adaptive interventions planning. This method may be used to determine the best intervention component sequencing and how frequently active components within the intervention should be reviewed. The treatment sequence for each individual is designed based on observed outcomes and is continually examined and recalibrated over time depending on the individual's reaction to therapy. Individual characteristics such as intensity of symptoms, preferences, and peculiarities are utilized to tailor the intervention to a particular person, and then individual outcomes (e.g., response to treatment, adherence) are used to dynamically adjust the intervention to maximize its efficacy. Furthermore, if the individual is not responding to a focused treatment, it is vital to gradually increase the intensity and kind of intervention in order to make progress or decrease new difficulties.

Lord and colleagues [697] proposed an innovative, adapted, health-integrated stepped care model for ASD intervention, with the goal of providing effective clinical practice approaches and rigorous clinically oriented research strategies that can have a positive short- and long-term impact on autistic people and their families while avoiding under- or over-treatment. The stepped care and personalized health model emphasizes autism's heterogeneity by recognizing that each autistic individual's and family's specific and unique profile of strengths, needs, and interests should guide intervention and support priorities, but that these can change over time as development and interventions produce effects. Furthermore, because ASD is so mutable, what works now for one person may not work later, and vice versa. By optimizing resource allocation, this phased and customized treatment model can be gradually calibrated as demands and needs emerge, change, and evolve over time, progressing from broader interventions to more specific and increasingly intense treatments tailored to specific personal needs and goals.

Multidisciplinary treatment needs to coordinate, share, and participate in both the nonpharmacological and pharmacological treatment approaches, as well as discuss jointly and constantly the data collected during these interventions.

Tip

Despite advances in increased awareness and research progress in early identification and diagnosis of ASD, harmonizing early interventions and services across the lifespan has remained a paramount challenge in the light of clinical heterogeneity of ASD and its variable treatment response, beyond the important global public health questions of within- and between- country disparities in terms of proximity to services.

Key Points

- ASD represents a highly heterogeneous group of lifelong neurodevelopmental disorders.
- There have been staggering strides made in increasing awareness of ASD worldwide.
- Understanding of factors associated with individual differences in response to early intervention is an important priority.
- Large gaps and disparities also remain in the dissemination of the evidence base on ASD, and in particular, in terms of implementation of effective treatment across the lifespan both within and across countries.
- The high rate of associated medical and psychiatric conditions represents a major burden on affected individuals and their families.
- Both pharmacological and nonpharmacological treatments can help reduce the impact of associated comorbidities.
- Person-centered, and multidisciplinary care services, as well as promotion of inclusionary social environment, need to be a universal standard worldwide.
- However, ASD cannot be effectively addressed by the health sector alone and national policies require collaboration across health, education, and social sectors.
- Access to public education, vocational training, and assisted employment with the goal of social inclusion is of paramount importance.

Learning Objectives

- To learn about the prevalence of ADHD in people with ID and ASD.
- To understand difficulties diagnosing ADHD in people with ID and low-functioning ASD, including distinguishing comorbidity from the differential diagnosis.
- To learn about specific presentation of ADHD in people with ID, including those with more severe cognitive and communication impairments.
- To understand the complex aetiology of ADHD in people with ID, including multiple genes, non-inherited factors, and their interplay.
- To learn about the current status of research and its impact on the advancement of treatment in this patient group.
- To be knowledgeable about available pharmacological and non-pharmacological treatment of ADHD in people with ID.

17.1 Introduction

There is a common misconception that attention deficit hyperactivity disorder (ADHD) is a relatively new diagnosis in modern society. However, there are well-documented cases of ADHD over 200 years. There are records describing abnormalities in attention as early as in the eighteenth century [1, 2]. Dr. George Still [3] was one of the first physicians to describe an 'ADHD-like' syndrome. He described a 'defect of moral control' in a series of lectures to the Royal College of Physicians in 1902. In 1937, Benzedrine, an amphetamine compound, was found to be effective in children with behavioural disorders. This is one of the earliest recorded medical treatments for the behaviour associated with ADHD [4]. In 1972, a case report was published of a 22-year-old man who was diagnosed with the hyperkinetic syndrome [5]. He was reported to have responded to an amphetamine which was described by the authors as a 'pathognomonic paradoxical calming of the hyperkinetic by amphetamine'. Over the next few decades, there have been significant advances in both the diagnosis and treatment of ADHD [6, 7].

Before its current diagnostic nomenclature, ADHD attracted several names including 'minimal brain damage' and hyperkinetic disorder (ICD-10) [8]. The current term used by both the Diagnostic and Statistical Manual of Mental Disorders-fifth Edition (DSM-5) [9] and the International Classification of Diseases-11th version (ICD-11) [10] is 'attention deficit hyperactivity disorder' (ADHD). It is categorised as a 'neurodevelopmental disorder (NDD)', relating to the onset of symptom manifestation occurring during the developmental period. According to the DSM-5 [9] criterion, the onset has to be before age 12 years. However, in the previous version of the DSM [11], the stipulated age of onset used to be before age 7 years. Other NDDs include intellectual disability (ID), autism spectrum disorder (ASD), dyslexia, dyspraxia, and Tics/Tourette's syndrome. NDDs frequently co-occur, hence the importance of recognising ADHD in people with ID as well as ASD [12]. In the previous version of DSM [11], there was no provision for making a diagnosis of ADHD in the presence of ASD. However, in the DSM-5 [9], this criterion has changed, and a diagnosis of ADHD can now be made in the presence of ASD.

ADHD is a phenomenological diagnosis defined by *impaired attention, hyperactivity, and impulsivity*. For a diagnosis of ADHD, symptoms must interfere with the day-to-day functioning of the individual. Symptoms of inattention, hyperactivity, and impulsivity must be experienced to a degree that is more than what is expected for the individuals' developmental age or intelligence. This can make it difficult to establish ADHD in people with ID as low intellect is associated with some of the symptoms of ADHD including inattention. As a result, ADHD can often be missed in people with ID as symptoms can be attributed to the person's low developmental age rather than considering the possibility of ADHD. The challenge for clinicians is to make a considered judgement about whether an individual's ADHD symptoms are greater

than what is expected for the person's level of ID. Despite all these challenges, ADHD is a diagnosis that needs to be part of the differential diagnosis given the evidence base for effective therapeutic strategies [13, 14] and avoidance of other inappropriate treatment [15–17]. Timely diagnosis and treatment can limit or prevent many of the risks associated with ADHD such as significant functional impairment, increased comorbidity with mental illnesses, substance misuse, accidental injury, unemployment, and premature death [18, 19].

Timely diagnosis and treatment can limit or prevent many of the risks associated with ADHD such as significant functional impairment, increased comorbidity with mental illnesses, substance misuse, accidental injury, unemployment, and premature death. The identification of ADHD can also prevent inappropriate treatment with antipsychotics, which is rather common in people with ID/ASD and problem behaviours.

17.2 Trajectory of ADHD

ADHD was initially thought to be a childhood disorder. In recent times, there has been a significant increase in the literature showing that ADHD symptoms can persist into adulthood and can cause functional impairment [20]. Sibley and colleagues [21] showed that 60% of the studied ADHD children continued to experience ADHD symptoms into adulthood and 41% continued to meet both symptom and impairment criteria. Lower IQ was found to be one of the predictors of persistence of childhood ADHD symptoms into adulthood [22]. Therefore, it is important that ADHD should be considered in adults with ID due to the high rate of persistence and the possibility of missed diagnosis in childhood.

However, to make a diagnosis of ADHD in adulthood for the first time, evidence of the onset of symptoms in childhood before age 12 is required. This may be difficult to establish as the memory of childhood events and behaviours is not always accurate. Whereas ADHD symptoms tend to improve in adulthood in many non-ID children, in a much higher proportion of children with ID the ADHD symptoms tend to persist into their adulthood [23]. One study reported a prevalence of ADHD among 2.9–16.4% of non-ID adults [24] which compares with 23% of 78 community-based young ID adults reported in another study [25]. Whereas in non-ID adults, it is the inattention symptoms that tend to persist into adulthood, in the case of children with ID and ADHD, it is the hyperactivity and impulsive symptoms that tend to persist more into adulthood. However, it is important to distinguish these symptoms from problem behaviour which is prevalent among adults with ID [26] (see ► Chap. 7).

17.3 Prevalence

There have been studies across the world, looking into the prevalence rates of ADHD. Polanczyk and colleagues [28] completed a meta-analysis of available literature on the topic, finding an estimated worldwide prevalence of ADHD in children and adolescents to be 5.29%. Differences in diagnostic criteria between DSM-IV [29] and ICD- 10 [8], as well as changes to diagnostic criteria over the last few decades, have made it difficult to compare studies on prevalence rates. Also included studies used different methodologies and variable sources of information to make the diagnosis. How the level of functional impairment was defined by different researchers also made an impact on the recorded prevalence rates [28]. Recent changes to the ADHD diagnostic criteria in the DSM-5 [9], particularly the reduction in the number of core symptoms required for diagnosis in adults, will likely lead to an increased prevalence rate of ADHD.

According to some studies, ADHD is found to be three to four times more prevalent in ID than in non-ID children and adolescents, the rate of which seems to increase with the increasing level of severity of ID [30–32]. However, it is worth pointing out that ADHD

symptoms are more common than an ADHD diagnosis in the ID population [33]. A large Swedish cohort study found that individuals with an ID were at an increased risk of ADHD compared with those without an ID with an odds ratio of 10.26 [34]. Studies on prevalence rates of ADHD in ID have reported a range of 6.8–28% compared with a prevalence rate of 3–5% for the non-ID general population [35]. Faraone and colleagues [34] found that the high prevalence rates of ADHD in the ID population are associated with genetic factors. Studies have also shown that people with ASD are at a higher risk of having ADHD compared with individuals who do not have ASD with an odds ratio of 22.33 [36]. In a recent systematic review and meta-analysis Lai and colleagues found the overall pooled prevalence estimates of ADHD to be around four times higher in people with ASD than in the general population [(28% (95% CI 25–32) vs 7.2% (95% CI 6.7–7.8), respectively] [37]. It can be hypothesised that the high prevalence rate of ADHD in people with ASD may also be a contributory factor for the increased prevalence of ADHD in ID, given the significantly high prevalence rate of ASD in ID [38].

Studies looking at prevalence rates of ADHD in the non-ID population have shown an increased prevalence in men compared to women. Nøvik and colleagues [39] found the ratio for the male to female varied from 3:1 to 16:1 depending on the country in Europe. A higher male to female ratio of 6:1 was found in adults with ID and ADHD in clinical samples [15]. However, in non-clinical samples the gender difference in the prevalence of ADHD among the ID population is not that prominent apart from the exception when there is a comorbid ASD when the male to female ratio increases to 2–3:1 [23]. Larger studies are needed to further establish the difference in prevalence rate between men and women in the ID population and explore the possible reasons.

Epilepsy is common among people with ID, [40] and it has been shown that comorbid epilepsy increases the ADHD symptoms among people with ID [41]. Antiepileptic drugs such as phenobarbitone and primidone which is metabolised into phenobarbitone also tend to precipitate ADHD symptoms in people with ID [42]. Other antiepileptic drugs such as lamotrigine, levetiracetam, topiramate may also lead to ADHD symptoms in the ID population. However, sometimes the same antiepileptic drugs are used to control problem behaviour and affect dysregulation symptoms that are often coexistent with ADHD in people with ID [43].

17.4 Lack of Evidence

There is only low-quality evidence available for the diagnosis or treatment of mental illness in people with ID [26, 27]. Although ADHD in the non-ID population is a widely researched area, the lack of high-quality research in ADHD in ID has been a barrier to the advancement of treatment in this patient group. Most studies name ID as an exclusion criterion. This has potentially led to a lack of emphasis on ADHD in people with ID even when the clinical presentation is suggestive of possible ADHD.

17.5 Diagnostic Classification

The DSM-5 [9] diagnostic criteria for ADHD include symptoms of inattention, hyperactivity, and impulsivity. Hyperactivity and impulsivity are categorised together, and symptoms of inattention are kept within a separate domain. There are nine symptoms in both the hyperactivity/impulsivity domain and the inattention domain. Six or more symptoms of inattention and/or hyperactivity and impulsivity are required for the diagnosis of ADHD in childhood. However, the number of symptoms required to make a diagnosis in an adult over the age of 17 is five from one or both domains. Symptoms need to be developmentally inappropriate which is an important consideration with regard to an individual with lower intellectual functioning. When diagnosing ADHD in an adult, there should be evidence that at least three of the symptoms were present before the age of 12. Symptoms of inattention and/or hyperactivity

and impulsivity need to be present in two or more settings.

For a diagnosis of ADHD to be made, symptoms should cause functional impairment. Defining the functional impairment poses challenges due to subjectivity. Difficulties in education, employment, relationships, and day-to-day activities are considered as some of the areas for assessment of functional impairment. ADHD symptoms can also cause functional impairment in an individual's mental health by causing emotional distress, poor self-esteem, and mental illness such as mood or anxiety disorders. Functional impairment in people with ID and ADHD needs to be assessed in the context of the level of functioning expected for the person's level of ID. People with ID may not have the same level of responsibility and roles in the community as people without an ID. It has been proposed that functional impairment can manifest as challenging behaviour in people with ID [16, 44]. However, one drawback of applying the DSM-5 [9] criteria to people with ID is that, as these symptoms are highly correlated, some may have a total score of 6–10 according to the DSM-5 [9] criteria yet scored less than 6 in each section of inattention and hyperactivity/impulsivity. These people may be more impaired with a higher rate of psychopathology than those who may have a score of more than 6 in any one of the subsections only [23].

Diagnostic assessment includes a detailed neurodevelopmental and psychiatric history followed by specific questions on ADHD symptoms to assess whether a person meets the criteria for ADHD. Perera and colleagues [45] in their study showed that strict application of DSM-5 [9] criteria can lead to low sensitivity (missing the diagnosis of ADHD in people with ID) compared with clinician's overall opinion which had high sensitivity and specificity. Reasons, why the strict application of DSM-5 criteria can lead to underdiagnosis, are examined below.

A comprehensive report aimed at guiding clinicians working with adults with ID to diagnose and treat co-occurrent ADHD has just been published by the Royal College of Psychiatrists (RCPsych), the UK, based on literature review and experts' opinion. It includes adaptations of DSM-5 diagnostic criteria for application to adults with ID [46] (see ◘ Tables 17.1 and 17.2).

Attention deficit hyperactivity disorder (ADHD) is characterised by inattention or hyperactivity/ impulsivity or both.

There is growing evidence that people with ID are at a higher risk of comorbid ADHD compared with people without ID. In general, there is a strong association among ADHD, ID, problem behaviour, and ASD.

The onset of ADHD is in childhood, but in a proportion of cases, some symptoms continue into adulthood.

17.6 Clinical Symptoms

17.6.1 Inattention

Inability to stay focused on tasks, disorganisation, careless mistakes, difficulty following instructions, difficulties in listening, forgetfulness, losing materials, and avoidance of tasks needing sustained attention are symptoms that come under the inattention domain. Some of these symptoms are difficult to assess in people with ID. Therefore, symptoms of inattention can be easily missed or wrongly attributed to having the 'usual' inattention symptoms in people with ID. Inability to pay and sustain attention is a subjective complaint which people with ID may struggle to communicate. Observation of a person's distractibility that is not consistent with their level of development may help when considering the symptom of inattention in an individual with ID (see ◘ Table 17.1). A more pragmatic approach can be helpful when assessing an individual with ID for ADHD. Reports from colleagues, schools, or day centre staff can be invaluable in differentiating between a person with ID alone and a person with the same level of ID and ADHD. Difficulties in sustaining attention and distractibility were found to be the most commonly recognised DSM-5 [9] inattentive symptoms by clinicians diagnosing ADHD in people with ID [45, 46].

Table 17.1 Specific presentation of inattention in persons with ID and ADHD as compared to DSM-5 ADHD diagnostic criteria

DSM-5 criteria [9]	Specific presentation in persons with ID
Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or with other activities	Struggles to pay attention at school, work, home, and during occupational therapy and other activities
Often has trouble holding attention on tasks or play activities	Difficulty sustaining attention at work, home, and during occupational therapy and other activities
Often does not seem to listen when spoken to directly	Appears not to listen to the conversation, asks for the information again, cannot remember parts of the conversation
Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace, e.g. loses focus, side-tracked	Starts an activity but does not complete the task. Needs a lot of support and prompting to complete tasks
Often has trouble organising tasks and activities	Observation of a person's difficulty in planning simple tasks and following the steps required to complete tasks in the proper sequence, which is not consistent with their level of development. This symptom does not apply to persons with more severe ID, who are rarely assigned responsibility for organising chores or activities
Often avoids, dislikes, or is reluctant to do tasks that require mental effort over a long period of time (such as schoolwork or homework)	Struggles to complete a task or activity that takes a long period of time or involves concentration
Often loses things necessary for tasks and activities, e.g. school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones	Will leave belongings behind even when aware of what is needed for the day. Will not know where something is if it has not been put in its usual place
Is often easily distracted	Gets distracted by every little stimulus. Quickly switches from one task to the next and find it difficult to return to an activity in which they were previously engaged
Is often forgetful in daily activities	Forgets where they have put objects, including favourite items from everyday life, and how to carry out activities, particularly those that are not routine

Adapted from McCarthy et al.[47] and RCPsych [46]

Case Study 17.1

An 18-year-old man with severe ID and autism presents with a long-standing history of behavioural difficulties. He is supported 24 hours a day by caregivers. Assessing symptoms of inattention can be difficult in a person with severe ID. However, close observations by staff who look after him reported that he needs more one-to-one support to keep him focused on tasks compared with other people with a similar level of ID. He was also described as more distractible compared with others. Inattentive symptoms shown by this 18-year-old man can easily be attributed to the person's level of ID. It is challenging to assess whether a person's level of inattention is proportionate to their level of ID as there are no objective measures. This patient was diagnosed with ADHD and was given treatment for ADHD. There was a significant improvement in his level of attention. He was able to sit and enjoy activities. He started to engage in various outdoor activities which were not possible before treatment due to his behaviour. Fewer restrictions were needed to manage behavioural difficulties

Table 17.2 Specific presentation of hyperactivity and impulsivity in persons with ID and ADHD as compared to DSM-5 ADHD diagnostic criteria

DSM-5 criteria [9]	Specific presentation in persons with ID
Often fidgets, taps hands or feet, or squirms in seat	Often cannot be still; always moving around
Often leaves seat in situations when remaining seated is expected	Moves around a lot and finds it difficult to sit still for lengthy periods of time, even while eating or bathing
Often runs about or climbs in situations where it is not appropriate (adolescents or adults may be limited to feeling restless)	Moves around most of the time, frequently changes location or body position, or take objects, even in situations when it is particularly improper such as a waiting area or a public office; internal restlessness can lead to psychomotor agitation, escape, or aggressive behaviour
Often unable to play or take part quietly in leisure activities	Speaks loudly, emits noisy phonations, or behaves inappropriately during leisure activities
Is often 'on the go' acting as if 'driven by a motor'	Shows excessive energy, often moves around, is not able to sit in one place for long, likes to be outdoors most of the time engaging in activities
Often talks excessively	Talks a lot without taking turns or emits continuous phonations while other persons are trying to interact with him
Often blurts out answers before a question has been completed	Blurts out answer to any question asked or physically react before other persons complete their communicative act
Often has trouble waiting his/her turn	Becomes agitated or aggressive when asked to wait for any length of time. Not able to queue for activities, finds it hard to wait if their needs are not met immediately
Often interrupts or intrudes on others	Acts as though he/she lacks a sense of personal space, interrupting others' discussions and actions

Adapted from McCarthy et al.[47] and RCP [46]

17.6.2 Hyperactivity and Impulsivity

The symptoms of hyperactivity and impulsivity include overactivity, inability to sit in one place for long, frequent fidgeting, on the go, talking excessively, intruding into the space or conversations of other people, impatience, and the inability to wait and take a turn during a conversation. Hyperactivity may lead to aggression such as hitting, kicking, biting, pinching others and self, and also arguing with others by people who can speak. Again, these symptoms need to be developmentally inappropriate to consider the diagnosis of ADHD. In contrast to inattention, hyperactivity and impulsivity symptoms can be observed in a person with ID. For example, if they fidget most of the time, leave their seat in situations when they are expected to remain seated or are described as 'on the go'. However, examples such as excessive talking or blurting out answers may not be relevant to people with limited or non-verbal communication skills [35]. An individual's symptoms of impulsivity can be manifested as their inability to wait which can often lead to verbal or physical aggression, irritability, mood fluctuations, or self-harming behaviour [48]. 'Often leaving a situation when remaining seated is expected' and 'on the go' were found to be the most commonly recognised DSM-5 [9] hyperactivity symptoms in people with ADHD and ID [45] (see Table 17.2).

Although inattention is more prevalent in both the ID and the non-ID population, but

as hyperactivity/impulsiveness is associated with problem behaviour, they are more prevalent among the tertiary referrals in the ID clinics, possibly sometimes giving a false sense of a higher prevalence of hyperactivity symptoms in this population. However, hyperactivity symptoms and dysregulated affect cause more impairment and morbidity in people with ID [23].

Case Study 17.2

A 25-year-old man with moderate ID, autism, and anxiety disorder presents with challenging behaviour going back to early childhood. During the assessment of his behaviour, his mother reported how hyperactive he has been all his life. These symptoms were never mentioned in the past as his mother often considered his hyperactivity as part of his ID. Most professionals also overlooked his hyperactive behaviour. Further questions elicited symptoms such as his inability to sit in one place, how busy he is most of the time, and his impulsivity/impatience. A diagnosis of ADHD was made and treated which led to a clear improvement in his behaviour and improved his quality of life

17.7 Diagnostic Validity

The validity of an ADHD diagnosis in the presence of ID has been debated both in the literature and in clinical practice, and to some extent, this issue still remains unresolved. According to the older versions of the DSM [11], ADHD diagnosis could not be made in a person with ID. There are three main areas of confusion, namely (a) an overlap between ID and ADHD symptoms, (b) an overlap between ADHD symptoms and problem behaviour in ID, and (c) the validity of using ADHD diagnostic criteria for people with ID that have been developed based on the studies of people who do not have ID.

Both inattention and hyperactivity are non-specific symptoms that are found in many psychiatric disorders. These symptoms are also common in people with ID which may lead to a 'diagnostic overshadowing' [49] in that even when these symptoms are due to ADHD, they are wrongly attributed to the ID diagnosis. This may lead to an underdiagnosis of ADHD in the ID population. However, as both ID and ADHD are classified under the same hierarchical diagnostic category of 'neurodevelopmental disorder', some symptoms overlap will be expected. Similarly, both conditions may share some genetic as well as environmental aetiologies such as pregnancy related Foetal Alcohol Spectrum Disorder (FASD) or obstetric complication [50]. Underlying brain impairment has also been shown to be similar in both conditions affecting the frontal cortex, basal ganglion, and cerebellum [51]. One study has shown abnormalities in the posterior part of the corpus callosum in people with ADHD and ID associated with velocardiofacial syndrome [51]. However, in the absence of a control group, it is difficult to comment on the specificity of this finding in relation to a combined diagnosis of ID and ADHD.

To establish a separate diagnosis of ADHD in the presence of ID, one has to establish that inattention and hyperactivity/impulsive symptoms are more frequent and severe than what would be expected for the person's level of intellectual capacity. To do that one has to establish the age appropriateness of these symptoms, but there is debate as to whether this should be based on the chronological or developmental age of the person. Developmental age appropriateness may be difficult to establish. Other ways to distinguish the two diagnoses would be to look at the similarities or differences in their (a) symptom profile, (b) trajectory of symptoms, (c) level of associated impairment, (d) pattern of comorbidity, (e) family history, (f) laboratory findings, (g) neuropsychological findings, and (h) treatment response [52, 53].

Core symptoms of ADHD seem to be similar in the presence or absence of ID, but anxiety symptoms may be more prominent in the presence of ID [54]. The factor structure of the ADHD symptoms seems to be the same in the ID and the non-ID population. Using Conners' Parent Rating Scale (CPRS-R) [55],

Deb and colleagues [33] found three factors, namely, inattention, hyperactivity, and conduct disorder among children and adolescents with ID and ADHD. The same three factors were described by Conners and colleagues [55, 56] in the non-ID population with ADHD.

The trajectory of ADHD symptoms, by and large, seems to be similar in the ID and the non-ID population. Hyperactivity/impulsivity symptoms tend to appear at an early age and then diminish as the child grows old. On the other hand, inattention symptoms tend to appear later in childhood perhaps when the child is under academic pressure and tend to persist over time. In the ID population hyperactivity symptoms may be identified more in adulthood as they cause more problems for the service in the form of problem behaviour. In contrast, inattention symptoms may be detected more in the non-ID population in adulthood as they cause more impairment in the person's occupational and social life [57].

The DSM-5 [9] criteria stipulate that to confirm a diagnosis, ADHD symptoms must cause impairment in areas such as communication, daily living skills, social functioning, and educational/occupational achievement. However, the impairment has to be age-inappropriate, and in the case of ID, developmental age inappropriateness may not be easy to determine. However, people with ID who have a diagnosis of ADHD are shown to have more impairment compared with those who have ID but no ADHD and also who have ADHD in the absence of ID [58].

The most common comorbidity found with ADHD in the non-ID population is oppositional defiant disorder (ODD) [53]. The most common comorbidity with ADHD in the ID population is problem behaviour [16, 33]. Therefore, there is a similarity in the ADHD comorbidity pattern between ID and non-ID populations.

Although a number of family studies exist in the non-ID ADHD population, no such study exists involving ADHD in the ID population [59]. Therefore, it is impossible to draw any conclusion about the influence of family factors on ADHD in the ID population.

As for laboratory findings, although many molecular genetic studies are showing a strong genetic vulnerability for ADHD in the non-ID population [6], no such study exists involving people with ADHD and ID.

Similarly, although there are many studies of neuropsychological impairment associated with ADHD in the non-ID population, there is very little empirical evidence available to support any specific pattern of neuropsychological impairment associated with ADHD in ID children over and above the ID-related deficits [51]. One study has shown impaired sustained attention in ID in the presence of ADHD. However, some argue the validity of the assessment of attention in the presence of a global cognitive deficit as ID and attention may be perceived as part of the same overlapping dimension [50].

Similar treatment response to ADHD symptoms, particularly from psychostimulants such as methylphenidate has been shown in both non-ID and ID children and adolescents although the effect size seems smaller in ID children [60].

As problem behaviour is prevalent in people with ID (see ▶ Chap. 7), in many cases problem behaviour may be mistakenly diagnosed (false-positive diagnosis) as ADHD in people with ID. However, problem behaviour is a common co-occurrence of ADHD in both the ID and the non-ID population [16, 44]. Deb and colleagues [33] found conduct disorder is a common factor associated with ADHD among children with ID. However, if the problem behaviour is a comorbidity of ADHD, this has to be more prevalent than what is expected for the person's level of ID. Also, as Deb and colleagues' [33] factor analysis of Conners' Parent Rating Scale [61] items has shown that problem behaviour/conduct disorder is a separate and distinct factor from inattention and hyperactivity factors among ID children with an ADHD diagnosis, the presence of behaviour problem alone in the absence of any other definite ADHD symptoms is not sufficient to make a diagnosis of ADHD in a person with ID (see Case Studies 17.1 and 17.2).

A diagnosis of ADHD is made in the ID population based on the criteria that were originally developed for the non-ID ADHD population. For example, the validity of ADHD screening and diagnostic instruments used in the non-ID population have not been established in the ID population. However, Deb and colleagues [33] have shown that a commonly used screening tool for ADHD in the non-ID population, CPRS-R (Conners Parent Rating Scale-Revised) [55] scores may distinguish between children with ID and with and without ADHD but not the CTRS-R (Conners Teachers Rating Scale-Revised) [62] scores. However, there are many items in the scale such as 'forgets things she has already learned', 'poor spelling', 'spiteful or vindictive', 'not reading up to par', 'argues with adults', 'has difficulty waiting his/her turn', interrupts or intrudes others', 'does not follow through instructions', and 'fails to finish schoolwork' cannot be verified in people who have severe and profound ID and lack communication skills.

In Deb and colleagues' [33] study Conners Teacher's scale yielded a significantly lower score than the Parent's scale. This may reflect a genuine difference between the two scales as the items are not exactly identical in these two scales. It may also mean that whereas Conners Parent rating scale is to some extent validated in the ID population, Conners Teacher rating scale is not valid for use in the ID population. However, more practical reasons are that the children may behave differently in school and in home, because schools may provide a more structured environment and there may be different types of demand placed on children in different environments. Also, parents may perceive their children's behaviour as less of a problem than the teachers. On the other hand, some parents may suffer from burnout and perceive their children as more of a problem than the teachers do.

Therefore, multiple sources of data collection including the use of rating scales, and direct examination and interview of the child and her or his care giver as well as a history of the development of symptoms over time, the impact of symptoms on adaptive behaviour (communication, education/occupation, daily living skills, socialisation, etc.) are needed to reach a diagnosis of ADHD in people with ID.

- Diagnosis of ADHD in people with ID has gone through a long journey of diagnostic challenges. It has finally been accepted in the current diagnostic criteria such as ICD 10/11 [8, 10] and DSM-5 [9].

  The presence of other NDDs can make the diagnosis more challenging. Current diagnostic criteria need to be adapted when making a diagnosis of ADHD in people with ID.

  Certain criteria are not applicable for people with more severe ID [46].

  Functional impairment of ADHD in ID can be different from that of people without ID as societal and self-expectations are lower when a person has an ID.

17.8 Psychiatric Assessment

The diagnosis of ADHD in people with ID involves obtaining a detailed psychiatric and developmental history followed by a structured assessment of symptoms of inattention, hyperactivity, and impulsivity. People with ID often find it difficult to communicate their symptoms, therefore, collateral history from family and support staff would be invaluable. Observation of behaviour in different settings can also be helpful. The aim of the assessment is to determine if the person with ID is experiencing more inattention, hyperactive, or impulsivity symptoms than is expected for their developmental age, with associated functional impairment [63]. Functional impairment from ADHD in a person with ID can present in different ways, including hyperactivity presenting as challenging behaviour [64] which can impact on their access to activities, use of illicit drugs for self-medication, impulsive aggression, or not achieving their maximum potential. Rating scales for ADHD can supplement clinical findings; however, there are not many validated tools for ADHD in people with ID.

17.9 Rating Scales for ADHD in ID

Taylor and colleagues [65] completed a systematic review of 14 ADHD rating scales that are commonly used for non-ID adults. This review found that only Conners' Adult ADHD Rating Scale [66] and the Wender Utah Rating Scale (short version) [67] had robust psychometric properties and content validity. There is a growing need for a validated screening tool for ADHD in people with ID. The ability to screen may help to recognise ADHD more effectively in people with ID. A consensus-based structured diagnostic interview called DIVA-5-ID has been developed by an international group of experts which has been produced by the DIVA Foundation [68] to guide on assessing symptoms of ADHD in a person with ID using the DSM-5 [9] criteria. This instrument has been adapted from the DIVA-5 structured interview schedule, which was originally developed for the diagnosis of ADHD in the non-ID population. Although it is a useful tool in clinical practice, the true validity and psychometric properties of this instrument in the ID population have not been established yet.

17.10 Aetiology and Associated Conditions

Several genetic and chromosomal disorders are associated with ADHD (► Box 17.1) [69, 70]. It is, therefore, worth considering genetic testing for people with ID to understand the possible aetiology of the person's ID. Recognition of a genetic syndrome that is associated with ADHD can be helpful in the diagnostic process. Genetic syndromes highly associated with ADHD shift the diagnosis of ADHD from a phenomenological to an aetiological concept.

ADHD appears to have a multifactorial aetiology, and most of the risk factors discovered thus far appear to be non-specific. Risks such as chromosomal microdeletions, large, rare copy number variants, having a biological relative with a neurodevelopmental disorder, extreme early adversity, pre–/postnatal exposure to lead or other neurotoxins, preterm birth, and extremely low birth weight appear to affect a variety of neurodevelopmental and psychiatric conditions [71]. However, heritable components seem to play a relevant role in the aetiopathogenesis as siblings are reported to present twice the risk of having ADHD than the general population, and there is a much greater concordance in monozygotic twins than dizygotic [72].

More specific risks factors have been identified in few dopaminergic genes [dopamine active transporter gene (DAT1), dopamine D5 receptor gene (DRD5), and especially dopamine D4 receptor gene (DRD4)], catechol-O-methyltransferase gene (COMT), brain-specific angiogenesis inhibitor 1-associated protein 2 gene (BAIAP2). The functional polymorphism in exon III of the D4 receptor gene is associated with ADHD in different meta-analyses, although with substantial heterogeneity across studies [73–77]. COMT gene and its mutation were associated with decreased grey matter volume, cortical thickness, surface area abnormalities, antisocial behaviour, and high vulnerability to early-life negative events and environment in children with ADHD [71, 78–80]. Some isoforms of the BAIAP2 gene, which encodes for a protein that has been suggested to be involved in cerebral asymmetry at embryonic stages, have been repeatedly linked with ADHD-related cognitive and emotional dysfunctions, including issues of sustained attention, working memory, response inhibition, planning, and anger control [77, 81].

One other well-recognised condition associated with ADHD is foetal alcohol spectrum disorder (FASD). FASD is one of the causes of ID [82]. Hence, a detailed history of maternal use of alcohol during pregnancy to rule out FASD in people with ID is important. A diagnosis of FASD is associated with an increased risk for ADHD (Relative risk of 7.6) [83]. Therefore, the presence of FASD in a person with ID should raise the suspicion of ADHD. FASD is associated with a high prevalence of ADHD of up to 75% [84].

Certain genetic syndromes are associated with ADHD (see paragraph on associated conditions and ► Box 17.1), but most people with ID and ADHD do not have a specific genetic syndrome.

Box 17.1 Genetic Syndromes Associated with ADHD in People with ID

- Downs syndrome.
- 22q 11.2 deletion/velocardiofacial syndrome/DiGeorge syndrome.
- Smith-Magenis syndrome.
- Williams syndrome.
- Angelman syndrome.
- Fragile X/ataxia (FRAXT) (also FRAXA, FRAXE).
- Neurofibromatosis.
- Turner syndrome.
- Klinefelter syndrome.
- Jacobsen syndrome.
- Tuberous sclerosis.
- Foetal alcohol spectrum disorder.

It is important to have a good understanding of common coexistent NDDs with ADHD such as ASD and Tourette's syndrome as they add complexity to the clinical presentation. Hyperarousal and restricted and repetitive behaviours can present as hyperactivity in an individual with ASD. Sensory processing difficulties found in people with ASD can also make someone appear hyperactive and restless at times. Ability to differentiate and understand this comorbidity can help to create a bespoke formulation and treatment plan.

Problem behaviour is prevalent in people with ID (see ▶ Chap. 7), but the rate increases in the presence of ADHD. Both inattention and hyperactivity/impulsive symptoms could lead to problem behaviour either directly or indirectly. Therefore, in practice, it may be quite difficult to distinguish problem behaviour from ADHD in people with ID. In this context the developmental history, for example, the presence of ADHD symptoms in childhood before the onset of problem behaviour, and associated features of ADHD may help with the distinction. Because of these difficulties, some clinicians may go for a trial of psychostimulants to assess any advantage of these medications in improving problem behaviour, although the response to a psychostimulant does not necessarily clarify the diagnosis of ADHD.

In a study of 56,462 adult psychiatric patients, ADHD was diagnosed among 2.7% and ASD among 1.3% of the participants. ADHD was associated more with affective disorder and substance use, whereas ASD was associated more with psychosis. The diagnosis of personality disorder remained the same in ASD and ADHD psychiatric patients in the general population [85].

All these conditions add an additional layer of complexity for diagnosis, formulation, and treatment of ADHD in the ID population.

The aetiologies of ADHD are varied including many genetic disorders.

Comorbidity with other NDDs such as ID and ASD is common in ADHD.

Other psychiatric comorbidities such as affective disorder and substance misuse can also be associated with ADHD.

ADHD can often present as a problem behaviour in individuals with ID, so detailed assessment to rule in or out an ADHD diagnosis is vital given the availability of effective treatments.

17.11 Management of ADHD in ID

Management of ADHD in ID follows biopsychosocial principles. In practice, this means reviewing medication options, psychological strategies and optimising environmental factors (see ▶ Chap. 7).

In the UK, National Institute for Health and Care Excellence (NICE) [86] provides the following guidelines for a baseline assessment before starting a pharmacological treatment for ADHD.

Before starting medication for ADHD, children and adults with ADHD should have a full assessment, which should include:

1. A review to confirm they continue to meet the criteria for ADHD and need treatment.
2. A review of mental health and social circumstances, including:

- Presence of coexisting mental health and neurodevelopmental condition.
- Current educational or employment circumstances.
- Risk assessment for substance misuse and drug diversion.
- Care needs.

3. A review of physical health, including:
   - Medical history, taking into account conditions that may be contraindications for specific medicines.
   - Current medication.
   - Height and weight (measured and recorded against the normal range for age, height, and sex).
   - Baseline pulse and blood pressure (measured with an appropriately sized cuff and compared with the normal range for age).
   - A cardiovascular assessment.

An electrocardiogram (ECG) is not needed before starting stimulants, atomoxetine, or guanfacine unless the person has any of the features in the next paragraph, or a coexisting condition that is being treated with a medicine that may pose an increased cardiac risk. Concerns related to an increased risk of sudden cardiac mortality in adults treated for ADHD have been raised; however, observational studies have not consistently demonstrated this to be the case [87].

Individuals should be referred for a cardiology opinion before starting medication for ADHD if any of the following apply:

1. History of congenital heart disease or previous cardiac surgery.
2. History of sudden death in a first-degree relative under 40 years suggesting a cardiac disease.
3. Shortness of breath on exertion compared with peers.
4. Fainting on exertion or in response to fright or noise.
5. Palpitations that are rapid, regular, and start and stop suddenly (fleeting occasional bumps are usually ectopic and do not need investigation).
6. Chest pain suggesting a cardiac origin.
7. Signs of heart failure.
8. A murmur heard on cardiac examination.
9. Blood pressure that is classified as hypertensive for adults.

Refer to a paediatric hypertension specialist before starting medication for ADHD if blood pressure is consistently above the 95th centile for age and height for children and young people.

In the UK, NICE [86] also provides the following guideline for the choice of pharmacological treatment in the non-ID population, but the same guidelines could be applied to people with ID.

17.11.1 Medication Choice: Children Aged 5 Years and Over and Young People

Offer methylphenidate (either short or long acting) as the first-line pharmacological treatment for children aged 5 years and over and young people with ADHD.

Consider switching to lisdexamfetamine for children aged 5 years and over and young people who have had a 6-week trial of methylphenidate at an adequate dose and not derived enough benefit in terms of reduced ADHD symptoms and associated impairment.

Consider dexamfetamine for children aged 5 years and over and young people whose ADHD symptoms are responding to lisdexamfetamine but who cannot tolerate the longer effect profile.

Offer atomoxetine or guanfacine to children aged 5 years and over and young people if they cannot tolerate methylphenidate or lisdexamfetamine or their symptoms have not responded to separate 6-week trials of lisdexamfetamine and methylphenidate, having considered alternative preparations and adequate doses.

17.11.2 Medication Choice for Adults

Offer lisdexamfetamine or methylphenidate as a first-line pharmacological treatment for adults with ADHD.

Consider switching to lisdexamfetamine for adults who have had a 6-week trial of methylphenidate at an adequate dose but have not derived enough benefit in terms of reduced ADHD symptoms and associated impairment.

Consider switching to methylphenidate for adults who have had a 6-week trial of lisdexamfetamine at an adequate dose but have not derived enough benefit in terms of reduced ADHD symptoms and associated impairment.

Consider dexamfetamine for adults whose ADHD symptoms are responding to lisdexamfetamine but who cannot tolerate the longer effect profile.

Offer atomoxetine to adults if they cannot tolerate lisdexamfetamine or methylphenidate or their symptoms have not responded to separate 6-week trials of lisdexamfetamine and methylphenidate, having considered alternative preparations and adequate doses.

However, in the UK, the trend is to use atomoxetine either as a first-line or second-line treatment after methylphenidate in people with ID, particularly among adults.

17.11.3 Further Medication Choices

Obtain a second opinion or refer to a tertiary service if ADHD symptoms in a child aged 5 years or over, a young person, or an adult are unresponsive to one or more stimulants and one non-stimulant.

Do not offer any of the following medication for ADHD without advice from a tertiary ADHD service:

- Guanfacine for adults.
- Clonidine for children with ADHD and sleep disturbance, rages, or tics.
- Atypical antipsychotics in addition to stimulants for people with ADHD and coexisting pervasive aggression, rages, or irritability.
- Medication not included in recommendations.

17.11.4 Medication Choice: People with Coexisting Conditions

Offer the same medication choices to people with ADHD and anxiety disorder, tic disorder, or ASD as other people with ADHD.

Addressing an eventual comorbid anxiety disorder before taking ADHD medication is recommended since there is a risk of increased anxiety and deteriorating behaviour. When initiating ADHD medication, treat anxiety first or utilise medications/strategies to lessen anxiety. Stop ADHD medication if anxiety and associated problem behaviours increase, then continue when the person's anxiety is under control [46].

For children aged 5 years and over, young people, and adults with ADHD experiencing an acute psychotic or manic episode, stop any medication for ADHD and consider restarting or starting new ADHD medication after the episode has resolved, taking into account the individual circumstances, risks, and benefits of the ADHD medication.

17.11.5 Considerations When Prescribing ADHD Medication

When prescribing stimulants for ADHD, think about modified-release once-daily preparations for the following reasons:

1. Convenience.
2. Improving adherence.
3. Reducing stigma (because there is no need to take medication at school or in the workplace).
4. Reducing problems of storing and administering controlled drugs at school.
5. The risk of stimulant misuse and diversion with immediate-release preparations.
6. Their pharmacokinetic profiles.

Immediate-release preparations may be suitable if more flexible dosing regimens are needed, or during initial titration to determine correct dosing levels.

As we have recommended a lower starting dose and slower titration rate, a modified-release preparation may not be suitable as the starting option in many children and adults with ID.

When prescribing stimulants for ADHD, be aware that effect size, duration of effect, and adverse effects vary from person to person.

Think about using immediate- and modified-release preparations of stimulants to optimise effect (e.g. a modified-release preparation of methylphenidate in the morning and an immediate-release preparation of methylphenidate at another time of the day to extend the duration of effect).

Be cautious about prescribing stimulants for ADHD if there is a risk of diversion for cognitive enhancement or appetite suppression.

Do not offer immediate-release stimulants or modified-release stimulants that can be easily injected or insufflated if there is a risk of stimulant misuse or diversion.

Prescribers should be familiar with the requirements of controlled drug legislation governing the prescription and supply of stimulants.

17.12 Pharmacological Management

There are broadly two classes of medications used to treat ADHD: psychostimulants and non-psychostimulants. Cortese and colleagues [88] in their network meta-analysis found 133 double-blind placebo-controlled trials on ADHD medications in the non-ID population based on 10,068 children and adolescents and 8131 adults. However, there are only a limited number of studies on people with ID and ADHD [60]. All the major studies have ID as an exclusion criterion. Therefore, treatment recommendations for ADHD in people with ID are derived from studies from the non-ID population.

A recent systematic review on the effectiveness of methylphenidate in the management of ADHD in people with ID [60] found 13 RCTs, only one of which used parallel design, and the rest are small crossover trials. Overall the quality of evidence is poor. All RCTs included children and none are on adults. It seems that overall the effect size of methylphenidate in children with ID (average around 0.5) is lower than that in the children who do not have ID (average around 0.8–1.3).

Significant adverse effects included sleep difficulties and poor appetite along with weight loss. Other important adverse effects included irritability, social withdrawal, and increased motor activities including tic. The type and the rate of adverse effects among children with ID seem similar to those in the children who do not have an ID (average around 12–24%). Similarly, the placebo effect seen among children with ID seems to be similar to that in the children who do not have an ID (average around 12.5%).

In the past, there was concern that methylphenidate may worsen the symptoms of ASD. However, recent studies [89] showed that methylphenidate could be effective in the general non-ID population of children with ASD (effect size is around 0.5), similar to what has been reported in children with ID [60]. Although a proportion of participants showed adverse events mostly mild, overall it seems that generally methylphenidate was tolerated by most children with ASD. In fact, some studies have shown improvement in core ASD symptoms, such as social communication and self-regulation in children who were treated with methylphenidate [89].

There is some concern that methylphenidate may make epilepsy (which is common among people with ID) [90] worse and interact with antiepileptic medication, although small-scale studies did not show any such adverse effects. There is also some debate as to whether the level of ID is a modifying factor for response to treatment with methylphenidate although this has not been proven unequivocally. Apart from the core symptoms, methylphenidate seems to have some effect specifically on problem behaviour in children who have ADHD but not ID [91]. Among children with ADHD and ID, whereas some studies showed some improvement in problem

behaviour while treated with methylphenidate, other studies have failed to do so [60].

Although not conclusive, it is possible that methylphenidate may have a better effect at a higher dose but possibly at the expense of a higher rate of adverse effects. There is some doubt whether concomitant use of other psychotropic medication (which is common in people with ID) reduces the efficacy of methylphenidate [92]. It is also possible that by countering some of the adverse events such as weight loss and sleep impairment, antipsychotics may indirectly show a better result when used concomitantly with methylphenidate.

17.12.1 Psychostimulants

The most commonly used psychostimulants are methylphenidate and amphetamine. Both amphetamine and methylphenidate act as noradrenaline (norepinephrine) and dopamine reuptake inhibitors, and they both increase monoamine neurotransmitters in the prefrontal cortex. In addition, amphetamine releases dopamine to the synaptic cleft. Methylphenidate and lisdexamfetamine have a strong evidence base with many trials showing efficacy in non-ID people. There are no RCTs in adults with ID for stimulant medications [60, 88].

17.12.1.1 Methylphenidate

Tarrant and colleagues [60] in their systematic review on methylphenidate found only one good quality study parallel design RCT in children with ID. They found that overall the effect size of methylphenidate is lower (0.5) in children with ADHD and ID compared with children without ID [60]. The low response rate in people with ID could be due to various reasons. Aman and colleagues [93] suggested whether the low response rate is due to the use of low doses of methylphenidate in studies done in people with ID. Tarrant and colleagues [60] have cautioned that the findings from the systematic review should be used carefully as studies used in the review were of poor quality.

A crossover trial showed that methylphenidate was effective in reducing ADHD symptoms in four children with FASD [94]. A small crossover trial suggested that methylphenidate might improve cognition and ADHD symptoms in children with velocardiofacial syndrome [95].

17.12.1.2 Different Methylphenidate Preparations

This is the drug of the first choice. This is available as immediate-release and prolonged-release preparations.

Child 6–17 years: Initially 5 mgs one to two times a day, dose increased in steps of 5–10 mgs daily if required, at weekly intervals to a dose of 60 mgs daily, in two to three divided doses, up to 2.1 mgs/kg, higher dose, maximum of 90 mgs daily, under specialist supervision, for a month, to be discontinued if there is no response. If the effect wears off by bedtime with rebound hyperactivity, a bedtime dose may be appropriate (establish need with a trial bedtime dose).

Adults: Initially 5 mg two to three times a day, dose increased at weekly intervals according to response up to a maximum of 100 mgs daily in two to three divided doses, if the effect wears off in the evening with rebound hyperactivity, a bedtime dose may be appropriate. It may be necessary to establish the need with a trial bedtime dose.

Treatment may be established with a modified preparation that contains immediate and modified release components in different proportions to cover the day. The modified release preparations are given in the morning. When switching from immediate to modified release preparations, it is important to check product literature.

Common side effects include decreased appetite, hypertension, growth retardation in children, anxiety, arrhythmias, arthralgia, behavioural difficulties, depression, diarrhoea, dizziness, drowsiness, dry mouth, fever, gastrointestinal discomfort, headaches, nausea, palpitations, sleep problems, vomiting, and loss of weight.

Monitoring requirements: Pulse, blood pressure, psychiatric symptoms, appetite, weight,

and height should be recorded at the initiation of therapy, following each dose adjustment, and at least every 6 months thereafter.

Treatment cessation: avoid abrupt withdrawal.

Methylphenidate is available in short- and long-acting preparations. Short-acting preparations are effective for up to 4 hours. The duration of long-acting preparations varies according to the drug. Short- and long-acting methylphenidates are available in different brands. Ritalin and Medikinet are some of the short-acting brands available in the UK. Concerta XL, Medikinet XL, and Equasym XL are some of the commonly prescribed long-acting methylphenidate preparations in the UK. Concerta XL, Delmosart, and Xaggitin XL are available as 18, 27, 36, and 54 mgs tablets, while Equasym XL capsules are available as 5, 10, 20, 30, 40, 50, and 60 mgs capsules (British National Formulary, BNF 76; ► www.bnf.org). Concerta XL has 8–10-hour duration of action with 22% of the drug released immediately and the rest released slowly over next 8–10 hours. Medikinet XL has 6–8-hour duration of action with 50% of the drug released immediately and the rest released over next several hours. Equasym XL has a similar duration of action to Medikinet XL, but only 30% of the drug is released immediately with 70% released slowly. There are other different brands in the market with similar durations of actions and modified release preparations. These long-acting preparations help people to take one tablet a day as their effect lasts for several hours rather than having to take extra tablets to take to school, day centre, or work. For patients with swallowing difficulties, certain ADHD-modified release preparations (Medikinet XL) can be taken out of their capsules and sprinkled over food.

17.12.1.3 Dexamfetamine

Dexamfetamine is available as short- and long-acting preparations. Short-acting dexamfetamine acts for up to 4 hours. Therefore, several doses are needed to cover longer duration of symptom control. Long-acting preparation available in the UK is called lisdexamfetamine which lasts for up to 14 hours. Dexamfetamine sulphate is available as oral solution, tablets 5, 10, and 20 mgs and as modified release spansules 5, 10, and 15 mgs (BNF, 76; ► www.bnf.org).

Evidence base again is limited for dexamfetamine use in ID [96]. One Cochrane review [97] on amphetamine in children with ADHD and ID only found one study looking at 15 children. This study was limited for 1 week and did not find any difference between treatment and placebo-controlled group. Lack of evidence is again another limitation with regard to the use of dexamfetamine in people with ID.

A small crossover trial with methylphenidate, dextroamphetamine, and placebo suggested that methylphenidate might be more effective and safer than dextroamphetamine in boys with Fragile X syndrome (FXS) [98]. Another study described that dextroamphetamine reduced hyperactivity compared with placebo in a boy with a mild ID [99].

Child: 6–17 years: Initially 2.5 mgs two to three times a day increased in steps of 5 mgs/day weekly if necessary up to 1 mg/kg daily, maintenance dose to be given in two to four divided doses, up to 20 mgs daily: 40 mgs may be necessary in some children.

Adults: Initially 5 mgs twice daily, dose increased weekly depending on the response, maintenance dose in two to four divided doses, maximum 60 mgs per day.

Common side effects include abdominal pain, anxiety, decreased appetite, arrhythmias, joint pain, behaviour problems, depression, dry mouth, headache, altered mood, movement disorders, muscle cramps, nausea, palpitations, poor weight gain, sleep problems, vertigo, vomiting, and weight loss.

Monitoring requirements include growth in children, aggressive behaviour, or hostility. Pulse, blood pressure, psychiatric symptoms, appetite, height, and weight should be recorded at initiation, following each dose adjustment and at least after every 6 months thereafter. Treatment should not be withdrawn abruptly.

17.12.1.4 Lisdexamfetamine Mesilate

This is a prodrug of dexamfetamine.

Child: 6–17 years initially 30 mgs once daily, alternatively, initially 20 mgs once daily,

increased in steps of 10–20 mgs/day every week if required, dose to be taken in the morning, discontinue if the response is insufficient after 1 month; maximum dose 70 mgs per day.

Adult: Initially 30 mgs daily, increased in steps of 20 mgs/day every week if required, dose to be taken in the morning, discontinue if the response is insufficient after 1 month; maximum dose 70 mgs per day.

Common side effects include upper abdominal pain, anxiety, decreased appetite, behavioural problems, constipation or diarrhoea, dizziness, dry mouth, fatigue, feeling jittery, headache, sweating, poor sleep, mood alteration, movement disorders, nausea, palpitations, sexual dysfunction in adults, tachycardia, tremor, and weight loss.

Monitoring requirements are similar to methylphenidate and dexamfetamine and avoid abrupt withdrawal.

Lisdexamfetamine dimesylate is available as 20, 30, 40, 50, 60, and 70 mgs capsules (BNF, 76; ► www.bnf.org).

17.12.2 Non-stimulant Medication

17.12.2.1 Atomoxetine

Atomoxetine is an ADHD medication that acts as selective noradrenaline (norepinephrine) reuptake inhibitor. It is given once or twice a day and can take several weeks to reach plasma levels to lead to symptom improvement. Therefore, this contrasts with psychostimulant medications which can be taken or omitted when needed. Atomoxetine needs to be taken every day to get the maximum benefit. It has 24-hour symptom control which some patients prefer. In people with ID and ADHD, atomoxetine can also be considered as the first choice of medication especially if ADHD is associated with challenging behaviour throughout the day.

There are a limited number of studies on the use of atomoxetine in people with ID and ADHD. Current studies suggest a response rate of 50–65% for atomoxetine [100, 101]. In clinical samples, atomoxetine was reported to be one of the most commonly used ADHD medications in adults with ID [15]. Only two RCTs show the efficacy of atomoxetine in children with ASD and ADHD, a combination of parent training and atomoxetine being the most effective [96]. Atomoxetine was effective in reducing ADHD symptoms in children with ASD with/without ID in recent RCTs [102, 103]. Somnolence, fatigue, anorexia, nausea, and irritability were common adverse events.

Children 6–17 years and adults, weight up to 70 kg: Initially, 0.5 mg per kg daily for 7 days, the dose is increased by the response to 1.2 mg/kg/day weekly, can be given in two divided doses, last dose no later than early evening; up to a maximum of 1.8 mg/kg/day; maximum dose of 120 mgs daily.

Children 6–17 years and adults, weight above 70 kgs: start 40 mgs per day for 7 days, dose increased according to response, maintenance dose 80 mgs daily (adults can go up to 100 mgs/day), can be given in two divided doses, second dose early evening, maximum 120 mgs daily.

Doses above 100 mgs/day are not licenced in children, while those above 120 mgs/day are not licenced in adults.

Common side effects include abdominal pain, poor appetite, low mood, dizziness, feeling sleepy, anxiety, irritability, dry mouth, nausea, dyspepsia, flatulence, fatigue, sleepiness, palpitation, sweating, tachycardia, high blood pressure, tremor, vomiting, sexual dysfunction, rash, taste disturbance, dizziness, and urinary dysfunction.

Preparations: Oral solution: Strattera 4 mg/ml. Capsules: Strattera 10, 18, 25, 40, 60, 80, 100 mgs (BNF, 76; ► www.bnf.org).

17.12.2.2 Guanfacine

Guanfacine is an alpha-2 agonist with similar action to clonidine but with a longer duration of action. It is given once a day. A common side effect specifically related to guanfacine is sleepiness; as a result, it is administered at night. It may be helpful for patients with ADHD struggling with sleep. A small crossover trial of guanfacine in children with developmental disabilities showed benefits in improving hyperactivity and global functioning [104]. A recent large RCT in children with ASD (63% were with IQ < 70) showed that extended release of guanfacine was effective

in reducing hyperactivity/impulsivity and inattention with a large effect size (1.67) [105]. Drowsiness, fatigue, emotional fragility, and irritability were common adverse events.

The *main side effects* include nausea, gastrointestinal disturbances, negative impact on sleep, poor appetite, increased blood pressure, increased heart rate, and weight loss.

As many people with ID are highly sensitive to medications, the advice is to start medication at a lower dose and increase the dose slowly. Individuals with more severe ID may be unable to complain about their side effects; therefore, it is important to observe them closely to detect any side effects.

Monitoring of blood pressure and heart rate in adults due to the risk of increased blood pressure and heart rate is a requirement as per NICE [86] guidelines. Guanfacine can reduce blood pressure due to its mechanism of action. Weight monitoring is also required with height monitoring mainly for children. Blood pressure and heart rate monitoring in particular can be difficult in people with ID who are also challenging in their behaviour. A more balanced and pragmatic view needs to be taken and act in the best interests of the person with ID and ADHD in terms of starting and continuing ADHD medication in such individuals who lack the capacity to make treatment choices. Anecdotal evidence suggests that people with ID are more likely to engage in physical monitoring if their ADHD symptoms are better controlled with ADHD medications.

Increased anxiety is a known side effect of ADHD medications. This can be an issue in people with ID who are experiencing underlying anxiety symptoms especially if they have comorbid ASD. Educating families to monitor for symptoms of increased anxiety is important when starting ADHD medications. If there is a high risk of a further increase in anxiety symptoms, it is worth considering treatment for anxiety before or along with ADHD medications.

A small crossover trial showed clonidine was effective in reducing both inattentive and hyperactive/impulsive ADHD symptoms in children with ID [106]. Drowsiness, dry mouth, and anorexia were common adverse events. One small crossover trial has shown a better efficacy of risperidone than methylphenidate in improving ADHD symptoms in ID [107].

17.12.3 General Principles of Prescribing for People with ID

Starting on a smaller dose and gradually increasing the dose is the general recommendation for psychotropic prescribing in people with ID [108, 109] (see ▶ Chap. 11). It can help patients to tolerate side effects better and improve compliance. This may not be possible especially with slow-release ADHD medications as they cannot be broken into smaller doses than the recommended starting dose; however, non-stimulant medications such as atomoxetine can be started in smaller doses than the recommended BNF (BNF 67) starting dose. Some people with ID may find swallowing tablets or capsules difficult. In such situations, certain ADHD medications which come in liquid preparations can be used. The other strategy is to open capsules of modified ADHD medications and mix the granules with a food item. The medicinal leaflet needs to be followed in such instances. Atomoxetine is the only ADHD medication available in liquid form in the UK at present. Medikinet XL and lisdexamfetamine capsules can be opened and poured onto a food item.

17.13 Non-pharmacological Treatment

Non-pharmacological treatment options cover a wide range of interventions. Lack of studies in non-pharmacological treatment in people with ID can make treatment recommendations difficult for this patient group. However, management options used in the non-ID population can be adapted in people with ID on the premise that treatment principles are similar across both ID and non-ID groups for ADHD.

Despite challenges in building up a stringent evidence base, there is a wide range of

non-pharmacological management options available for ADHD treatment. This has led to difficulties in studying, analysing, and drawing conclusions on the effectiveness of individual strategies. However, on the contrary, a wide range of non-pharmacological interventions can be helpful for people who prefer non-pharmacological strategies. The other challenge for non-pharmacological treatment options is that potential adverse events are not recorded as part of the studies compared with detailed discussions of adverse events associated with pharmacological strategies.

Non-pharmacological options can be broadly divided into

1. Supporting an individual to manage symptoms of ADHD.
2. Reducing functional impairment secondary to ADHD.
3. Managing mental health conditions and emotional disorders secondary to ADHD.
4. Supporting families of children who have ADHD through psychoeducational programmes.

Some of the strategies discussed in the literature are cognitive behavioural therapy (CBT), dialectical behaviour therapy (DBT), coaching, mentoring and other counselling approaches, parent/family/carer training, psychoeducation, relaxation techniques, organisational skills/school or workplace targeted interventions, interventions to improve sleep, exercise, outdoor activities, non-specific supportive therapy, or combination of the above interventions. The use of one or more of these strategies is based on an individual's level of ID, support available to the person, availability of resources, and the environment the person lives in. For example, a person with mild ID and ADHD may be able to engage in CBT therapy adapted to their needs. Such individuals can also be supported through targeted interventions if in employment. Exercise and outdoor activities can be easily accessible depending on where the person lives, resources available, and the amount of support available to the individual especially if the person has moderate to severe ID. Relaxation strategies can be simplified and broken down into smaller steps to help people with any severity of ID.

There are two modes of treatment, namely pharmacological and non-pharmacological. ADHD medications available for children and adults without ID can be used in the ID population.

Psychostimulants are effective in treating ADHD symptoms in people with ID but relatively less effective than the general population.

The side effect profile is similar to that in the general population.

Non-pharmacological strategies can also be useful. There are many different non-pharmacological strategies. Interventions need to be tailored to the individual need [46].

Tip

Researchers and clinicians should pay more attention to the challenges in diagnosing and treating ADHD in persons with ID and/or ASD, with a special focus on person-centred outcomes and specific symptoms in individuals with more severe cognitive and communicative impairment.

Key Points

- There is growing evidence that people with ID are at a higher risk of comorbid ADHD compared with people without ID.
- Despite this much higher prevalence, there is minimal high-quality research specific to people with ID and low-functioning ASD in comparison to the general population.
- In people with ID and/or ASD, ADHD is frequently misdiagnosed, under-recognised, and improperly treated.
- The stringent use of categorical diagnostic criteria might limit the identification of the disorder since some criteria may not be applicable, particularly for those with more severe cognitive and communication impairment.
- Observation of a person's distractibility that is not consistent with their develop-

mental level may help when considering the symptom of inattention in an individual with ID and/or low-functioning ASD.

- In people with ID/ASD and more severe cognitive and communication impairment, hyperactivity and impulsivity can present with fidgeting most of the time, appearing 'on the go', and being unable to remain seated for a long time and wait for one's turn. Verbal or physical aggression, irritability, mood fluctuations, or self-harming behaviour are also possible expressions or consequences of these ADHD symptoms.
- ADHD appears to have a multifactorial aetiology with most of the risk factors discovered thus far resulting to be shared with many other psychiatric and neurodevelopmental disorders. More specific risk factors have been identified in few dopaminergic genes, catechol-O-methyltransferase gene, and brain-specific angiogenesis inhibitor 1-associated protein 2 gene. A well-recognised condition associated with ADHD is foetal alcohol spectrum disorder.
- ADHD therapy should be thorough, collaborative, and multimodal, with a variety of pharmacological and non-pharmacological options available to fit the individual requirements of the person with ID and/or ASD.

Learning Objectives

- To learn about definitions and diagnostic criteria of specific learning disorders within the main classification systems
- To understand difficulties of diagnosing a specific learning disorder in people with ID and ASD
- To learn about most appropriate assessment for every specific learning disorder
- To learn about definitions and diagnostic criteria of motor and communication disorders
- To understand specific characteristics of motor and communication disorders in persons with ID
- To gain a better understanding of the current state of research and its implications for the development of treatment and support methods for specific learning, motor, and communication disorders

18.1 Introduction

Developmental learning, communication, and motor disorders affect persons with intellectual disability (ID), autism spectrum disorders (ASD), and/or other neurodevelopmental disorders more often than neurotypical persons. These disorders, which occur during the first years of life, have a significant influence on the emotional and adaptive development of children and adolescents, but they also have considerable consequences throughout the whole lifespan of affected persons, influencing their lives and personalities. Some of these disorders can be effectively remediated if recognized and treated early. Others are chronic and necessitate the development of compensatory skills.

Specific learning disorders (SLDs) are conditions that cause a discrepancy between potential and actual levels of academic performance as predicted by the person's intellectual abilities. Learning disorders involve impairments or difficulties in concentration or attention, language development, or visual and aural information processing. These specific learning disorders should be distinguished from a global cognitive impairment as found in people with ID although they can coexist with ID.

Motor disorders are lifelong conditions that make it hard to learn motor skills and coordination and may cause a lack of intended movement or an excess of involuntary movement. Symptoms of motor disorders include tremors, jerks, twitches, spasms, contractions, or gait problems.

Communication disorders consist of an impairment in the ability to receive, send, process, and comprehend concepts or verbal, nonverbal, and graphic symbol systems. A communication disorder may be evident in the processes of hearing, language, or speech, or any combination of these, and may range in severity from mild to profound. Developmental communication disorders differ from acquired ones in that they express conditions of uneven development of communication skills, while acquired communication disorders come after development and are generally the result of traumatic brain injury or neurological disorders.

The phenomenology, classification, aetiology, and treatment outcomes of communication and motor problems in people with ID and/or ASD are still poorly understood. It is also difficult to sort out the numerous causal relationships between these disorders and the often co-occurring psychiatric disorders. The co-occurrence of specific learning, motor, and communication disorders cause significant adjunctive impairment and result in negative physical, psychological, and social consequences.

18.2 Specific Learning Disorders (Specific Developmental Disorders of Scholastic Skills)

Specific learning disorders (SLD) or developmental learning disorder (in ICD-11) [1] represents a group of disorders characterized by specific deficits in one domain of cognitive processing that manifest in persistent learning difficulties with significant interference with academic or occupational performance or with activities of daily life.

They are chronic disorders that modify their expression over time in relation to age and environmental requirements, manifesting with different characteristics over the course of development and the phases of scholastic learning. The term 'specific' refers to the fact that the impairment refers to specific cognitive domains and is not solely explained by ID (intellectual developmental disorder; IDD) or impairments of overall cognitive functioning. If an ID is present, a specific learning disorder can be adjunctively diagnosed only if the specific learning difficulties are more severe than those attributable to ID [2]. Specificity has to be ascertained also in presence of global developmental delay, hearing or visual disorders, neurological or motor disorders, lack of availability of education, lack of proficiency in the language of academic instruction, psychosocial adversity, etc.

SLDs occur early during the first years of formal schooling, with difficulty in learning, reading, writing, and mathematics. They are persistent, consequently also resistant to targeted educational interventions. These disorders, which do not depend on maturation processes, emerge when reading, writing, and mathematics are taught at school in an explicit manner, but could also manifest later, when the person can no longer compensate for the environmental requirements, for example due to the speed required or excessive academic demands. They are not due to lack of educational opportunity, ID, trauma or acquired brain-related diseases, or uncorrected visual or hearing impairment.

The neurobiological dysfunction underpinning the disorders interferes with the normal learning process of reading, writing, and mathematics and is influenced by environmental factors such as school, family, and social context, determining the phenotypic expression and a greater or lesser maladjustment [3].

Thus, it involves a neurobiological impairment of academic skills like reading, writing, and mathematics, which are considered as functional disabilities. These functional aspects weigh heavily on the organization of the day of students with SLD diagnoses, a day mainly occupied with schoolwork during school hours, but also on the time used in the afternoon or weekend for completing the schoolwork, limiting the time to dedicate to more recreational activities or sports, believed by many parents of SLD students to be a type of release valve necessary for maintaining their psychological health.

SLDs are typically diagnosed in childhood, but they often continue into adulthood influencing a wide range of occupational, relational, and mental health issues.

Compared with the previous edition of the DSM [4] and the ICD-10 [5], DSM-5 [2] sets out a single diagnostic category for SLDs. While in ICD-10 [5] we included specific disorder of reading (DD, developmental dyslexia, F81.0), the disorder of spelling (dysorthographia, F81.1), and specific disorder in mathematical abilities (dyscalculia, F81.2), in DSM-5 [2], the continuity of the disorders is highlighted, included in the single category of SLDs, but with the specification of different impairments such as reading impairments (included dyslexia), mathematical impairment (included dyscalculia), and impairment of written expression (included dysorthographia and dysgraphia). The ICD-11 classification differs significantly from the ICD-10 and is very much aligned with the DSM-5, dividing developmental learning disorder (6A03) into (0) with impairment in reading; (1) with impairment in written expression; (2) with impairment in mathematics; (3) with other specified impairment of learning; and (Z) unspecified (see Table 18.1).

According to the DSM-5, in people with ID the formulation of an adjunctive diagnosis of a specific learning disorder is possible only if the specific learning difficulties are more severe than those attributable to ID.

18.2.1 Prevalence

SLDs are one of the most common neurodevelopmental disorders (NDD), the prevalence of which is estimated as 5–15% in school-aged children across different languages and cultures, and approximately 4% in adults. These percentages vary from country to

Table 18.1 SLDs in ICD-10 [5], ICD-11 [1], and DSM-5 [2]

SLD	ICD-10	ICD-11	DSM-5
Dyslexia	F81.0 Specific reading disorder	6A03.0 Developmental learning disorder with impairment in reading	315.00 Specific learning disorder with impairment in reading
Dysorthographia	F81.1 Specific spelling disorder	6A03.1 Developmental learning disorder with impairment in written expression	315.2 Specific learning disorder with impairment in written expression
Dysgraphia	F81.8 Other developmental disorders of scholastic skills	6A03.3 Developmental learning disorder with other specified impairment of learning	315.2 Specific learning disorder with impairment in written expression
Dyscalculia	F81.2 Specific disorder of arithmetical skills	6A03.2 Developmental learning disorder with impairment in mathematics	315.1 impairment in mathematics

country, as they depend on the characteristics of the language studied (transparent language vs. opaque language and more or less regular spelling), on the varying definitions of SLD, and on the different methods and instruments used for diagnosis. The cut-off scores reported in the literature for dyscalculia diagnosis are also very variable, ranging from the 5th percentile [6] to the 46th, [7] so the reported prevalence is not uniform. The DSM-5 [2] reports the rate of dyslexia among 4–9%, while dyscalculia 3–7% [2].

There is a slight dominance among males compared with females (ratios range from about 2:1 to 3:1) [2, 8] probably because more males than females come to clinical attention for their behavioural manifestations, in particular, for the frequent comorbidity between SLD and attention deficit hyperactivity disorder (ADHD), a condition which itself is associated with a high rate of problem behaviour [9].

SLDs seem to be rather frequent also in children, adolescents, and adults with borderline intellectual functioning and mild ID, though an adjunctive diagnosis of a specific learning disorder requires special care and in-depth evaluation in these individuals [10]. In general, SLDs' prevalence is inversely correlated with IQ level, even when other factors such as age, gender, and socio-cultural context are taken into account [11].

Specific learning disorders occur early during the first years of formal schooling, with difficulty in learning, reading, writing, and arithmetic.

These disorders originate in childhood and often continue into adulthood among many.

These disorders seem to be prevalent among children and adults with borderline intellectual functioning and mild intellectual disabilities, although in these persons adjunctive diagnosis of a specific learning disorder requires particular attention and in-depth assessment [10].

18.2.2 Aetiopathogenesis

The identification of the causes of SLD is complicated by their heterogeneity and the influence of multiple neuropsychological factors [12, 13]. Nevertheless, most experts agree on the biological origin of the cognitive anomalies that underlie behavioural symptoms of the disorders. The biological origin includes the interaction of genetic, epigenetic, and environmental factors that affect the brain's ability to perceive or process verbal or nonverbal information efficiently and accurately [2]. For example, left temporo-parieto-occipital impairment is associated with dyslexia.

Particularly, functional neuroimaging studies identified hypoactivation of the left parieto-temporal and occipito-temporal regions in children and adults with SLDs when they perform reading-related tasks [14–20].

Although genetic abnormalities associated with SLDs are described in the literature, the 'dyslexia gene' has not yet been identified. SLDs seem to have complex multi-factorial aetiology [21] because it is believed that the transmission of the disorder does not occur according to the Mendelian inheritance model. Genes such as DYX1C1, DCDV2, KIAA0319, ROB01, C2Orf3, and MRPL19 are implicated as risk factors for dyslexia [22, 23]. The SLDs, like the other NDDs, have overlapping traits, which derive from the interaction among multiple genetic risk factors and the epigenetic regulation by environmental factors [24].

Neural plasticity is also affected by the quality of the external environment, both in terms of life experiences and biological factors, such as diet, drugs, endocrinal abnormalities, or pathogenic agents [25]. Risk factors for SLDs are divided into environmental, genetic, and physiological factors. Environmental factors include premature birth or very low birth weight, and prenatal exposure to nicotine. A family history of SLDs is frequently present in persons with SLDs. In fact, recent studies have revealed that the whole spectrum of SLDs is strongly determined by genetic predisposition with the highest risk among first-degree relatives [26, 27].

18.2.3 Criteria and Clinical Features

The diagnosis of an SLD in reading, writing, and arithmetic can be made based upon individually applied standardized methods for testing scholastic achievement and IQ. The evaluation is based on a variety of methods, including medical history, clinical interview, school report, teacher evaluation, rating scales, and psychometric tests. For individuals aged 17 years and older, standardized achievement measures and comprehensive clinical assessment may be substituted by a documented history of impairing learning difficulties.

In DSM-5 [2] the IQ discrepancy criterion was abandoned. To make a diagnosis of SLD, the impaired ability must be significantly lower than age and class attended (discrepancy criterion). In statistical terms, this corresponds to two standard deviations below the mean, or performance below the 5th percentile [5]. The results depend largely on the tests used, which vary according to country, but which must present adequate psychometric characteristics, with a good reference sample and valid and reliable norms.

The first diagnostic criterion of DSM-5 [2] (Criterion A) is that difficulties learning and using academic skills must be present for at least 6 months, despite targeted interventions. Indication of the number of months of persistence of the disorder and the resistance to the targeted intervention represent an important innovation compared with previous editions, consistent with the literature on response to intervention (RT) [28–30].

To make an SLD diagnosis, one of these symptoms must be present (a) slow or inaccurate word reading, (b) difficulty in reading comprehension, (c) difficulty in spelling (spelling errors), (d) difficulty in written expression (grammatical, punctuation, morphosyntactic errors), (e) difficulty in mastering the number sense, (f) arithmetical facts or calculation, and (g) difficulty with mathematical reasoning.

The second diagnostic criterion (Criterion B) relates to performance in the affected academic skill, which must be below those expected for the age. It is, therefore, necessary to verify a particularly low scholastic performance, for example in a person who requires specific skills, compared with others in which the student succeeds easily. The school achievements may also be adequate but obtained only with great effort and struggle and, therefore, are inconsistent with the time and effort dedicated to studying.

The learning difficulties cannot be due to atypical academic experiences, for example prolonged absences from school, frequent changes of school or teachers, inadequate teaching, or inadequate educational instruction. SLD

cannot be attributed to more general external factors, such as economic or environmental disadvantage, chronic absenteeism, or lack of education as typically provided in the individual's community context. Uncorrected visual or auditory acuity, other mental or motor or neurological disorders (e.g. paediatric stroke), psychosocial adversity that could cause academic difficulties must be excluded (Criterion D).

Academic skills and intelligence must be evaluated with individually administered standardized tests. In the case of borderline IQ (70–85), it is recommended to use a multicomponent test for intellectual assessment, since the cognitive profile is more informative than the mere IQ scores. The difficulties must interfere with academic or occupational performance and the activities of daily life.

The DSM-5 [2] describes three specific learning disorders, namely (a) impairment in reading, (b) impairment in the written expression, and (c) impairment in mathematics. Each disorder is described by subskills that must be recorded separately.

A disorder in reading (dyslexia) is characterized by (a) the inability to decode a text; (b) inaccurate or dysfluent loud reading, for example when words are read incorrectly or slowly and hesitantly, or when the child tries to guess words or has difficulty sounding out words (may add, omit, or substitute vowels or consonants); or (c) when there are difficulties in reading comprehension. Difficulties in understanding the relationships, inferences, or deeper meanings are included, even if reading is adequate. According to DSM-5 [2] and ICD-10 [5], the diagnosis of reading impairment can be made even if there is only impairment in comprehension of the text without difficulty in loud reading, but in some countries like Italy, the Consensus Conference promoted by the Italian National Institute of Health [3] recommend to diagnose dyslexia, not to include reading comprehension as a diagnostic parameter, since persons with comprehension problems but good decoding skills do not meet the criteria for dyslexia. For transparent languages such as Italian, for the diagnosis of dyslexia, it is recommended to consider reading fluency in addition to the parameter of accuracy as reported in the ICD-10 [5] criterion [31].

In adults, most common symptoms of dyslexia include visual problems while reading (high sensitivity to glare, the colour of the paper, font, etc.), difficulty focusing when reading such as losing place, confusing very similar words or letters when writing or reading, feeling like words are moving or jumbled up, finding reading very stressful, rarely or never reading for pleasure, difficulties with written communication or tests, difficulty writing down messages or reports, and confusing left and right, or struggling with spatial reasoning [32, 33].

Another disorder included in SLDs is dysorthography, characterized by impairment of orthographic skills and phonographic coding. In the DSM-5 [2] the impairment in written expression includes also errors in spelling, grammar, and punctuation, or poverty in organization and clarity of written expression.

There may be a disorder in numeracy and calculation skills (dyscalculia) when there are difficulties in mastering number sense, number facts, or calculation. The calculation is slow or incorrect, understanding of numbers is poor, arithmetic facts are not memorized, fingers are used to count instead of recalling the fact, and procedures are not automated. Difficulties in mathematical reasoning can be present, with difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems. Skills assessed with standardized tests must fall outside the limits of 2 standard deviations (SD) from the level expected based on the child's chronological age and his overall intellectual level, but no parameter (fluency, accuracy) is specified.

This lack of precise references, which includes calculation difficulties that are rather different from those characterizing a real disorder, is probably the cause of the extreme variability of the way dyscalculia is defined in scientific literature. Dyscalculia seems to fall at the highest severity end of a wide spectrum of mathematical difficulties. In addition, many studies confound exact and approximate numerical processing because they involve qualitatively different task designs [34].

It is difficult to establish a reliable prevalence rate for the impaired mathematical skills because of the heterogeneity of definitions, diagnostic criteria, and different assessment scales used across the studies [35–37], with a considerable increase when the discrepancy between intellectual efficiency and mathematical skill is not adequately considered and persons with ID are included [38]. Kaufmann [39] argues that in many studies on mathematical difficulties only a few participants show a real calculation disorder [35, 40]. Also, aetiopathological models of dyscalculia are contradictory. According to both the 'core deficit theory' [41] and the 'defective module hypothesis' [42], individuals with dyscalculia would suffer from impaired number processing due to a defective number sense, while the 'triple code model' argues for alterations in one or more of the three representational codes for number, which are Arabic digits, verbal number words, and analog non-symbolic magnitude representations, each subserved by functionally dissociated neural substrates [43]. A meta-analysis suggested that specific difficulty in number facts [44] or number processing [45] is particularly meaningful as a criterion.

- **DSM-5 [2] Describes Three Levels of Severity for SLDs, Namely Mild, Moderate, and Severe**

1. Mild: Some difficulties in learning skills in one or two academic domains, but of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.
2. Moderate: Marked difficulties in learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervention of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, in the workplace, or at home may be needed to complete activities accurately and efficiently.
3. Severe: Severe difficulties in learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, at school, or in the workplace, the individual may not be able to complete all activities efficiently [2].

The timeliness and adequacy of the rehabilitative measures, the IQ score (which in SLD may be at the mild ID end, but also above average), the areas involved in the disorder (one or more among reading, calculation, reading comprehension, expressive ability, graphic skill, spelling), and any contemporary presence of other disorders (most frequently, language and attention disorders) influence the severity of the disorder. The severity of impairment may vary from case to case and affect the academic skills by age in a different way.

There is high comorbidity among different types of learning disabilities (dyslexia, dysorthographia, dysgraphia, and dyscalculia), and they often co-occur with other NDDs, ADHD, communication disorders, developmental coordination disorder, ASD, and other mental disorders (anxiety disorders, depressive and bipolar disorders). In children with SLDs in multiple learning domains, both the rates and the types of psychopathology are higher than in children with an isolated SLD [46].

Dyslexia has particular comorbidity with ADHD, developmental dyscalculia, specific language impairments, and speech-sound disorders [47]. Overlap among various learning disorders leads to sharing of some risk factors among them, different according to the individual disorders involved [48]. Therefore, it becomes particularly difficult to clearly distinguish main symptoms from associated symptoms [49].

18.2.4 Specific Assessment

The assessment involves professionals with expertise in SLDs and psychological/cognitive assessment.

According to DSM-5 [2], low scores are at least one and a half standard deviations below the mean of the population by age, which is

below the 7th percentile, in one or more tests. In ICD-10 [5], this threshold is two standard deviations below the mean, or the 5th percentile.

To verify the reading impairment, it is necessary to use evidence that evaluates the word recognition, the ability to read out loud, and the ability to automatically understand what is read. Reading tests include a word, non-word, sentence, and passage reading. In childhood word and non-word reading tests show higher reliability and predictability as compared with whole text reading. In dyslexic and/or compensated adults use of non-word reading tests is recommended for its relevance in this particular population. Given that decoding may be slow or incorrect, it is necessary to measure both the parameters of speed and correctness. For a correct functional diagnosis, it is also necessary to make a qualitative analysis of the errors committed, to correctly attribute them to phonological, articulation, or lexical difficulties.

It is also important to verify expressive and receptive language skills, given that frequently, reading impairments are preceded by a history of speech and language disorders, which, during school age, may be compensated or still show some specific markers. To evaluate reading comprehension, it is necessary to use evidence that assumes autonomous reading by the person, usually including passages with questions and multiple-choice replies that the student must respond to. To distinguish how much a decoding difficulty affects fatigue, and thereby the correct comprehension of what was read, it is also useful to administer comprehension tests in listening form, read by the examiner.

To evaluate the impairment of writing skills, it is necessary to include dictations of words, sentences, or passages, checking that the spelling is correct. For the diagnosis of dysorthographia, the use of word and non-word dictation tests is recommended along with the production of written texts and sentences. In early school years, it is important to assess grapheme-phoneme conversion processes, while during primary school, assessment of spelling at the lexical level is becoming progressively more important. Errors in grapheme-phoneme conversion at the end of the primary school or later is a marker of a particularly severe disorder. To evaluate the correctness of the grammar and punctuation and the morphosyntactic aspects, it is also necessary to test spontaneous writing skill, which involves regulations for the number of words and sentences used, the expository richness (use of qualifying adjectives, personal pronouns, number of subordinations, adequate vocabulary, etc.), punctuation correctness.

To evaluate the calculation impairment, arithmetic tests must be used, that involve subtests on numerical ability, arithmetic facts, calculation, and mathematical problem-solving. These tests evaluate the concept of numbers, counting, reading and writing of numbers, repetition of numbers, semantic coding, ordering of numbers, and size comparison. With regard to calculation, it is necessary to involve written calculation tests, to evaluate the learning of the algorithm procedure, mental calculation with complex numbers to evaluate the ability for calculation strategies, mental calculations with small quantities to verify the learning of the so-called arithmetic facts, namely those calculations that, for their solution, do not require the application of the algorithm (e.g. sums and subtractions under ten), learning of multiplication tables. Murphy [35], Mazzocco [45], and Chong [50] suggest defining 'dyscalculia' only when the child's test performance level is lower than the 10th percentile in at least two specific tests of basic arithmetic skills. Children who score between 11th and 25th percentiles are considered 'low achievers', while those above the 25th percentile are considered 'typical achievers'. In these tests, it is necessary to evaluate the correctness, the number and type of errors made [7, 35, 51], and the speed of execution that, with age, becomes a significant parameter to highlight the presence of dyscalculia. It is also crucial to evaluate the persistence of immature computation strategies (e.g. long-term use of the fingers) [52].

As working memory and visuo-spatial skills support and facilitate the acquisition and consolidation of arithmetic skills [53], for the diagnosis of dyscalculia they must be investigated with standardized tests assessing [54] different types of dyscalculia. For example, different treatment programmes may be needed depending on the type of numerical cognition or procedural deficits.

Neither ICD-10 [5] nor DSM-5 [2] explicitly involves the diagnostic label of dysgraphia, that is difficulty in writing in the absence of a motor coordination disorder. To verify the presence of dysgraphia, it is, therefore, necessary to exclude this disorder and involve tests that evaluate both the quality of the written product and the speed of execution. For the ICD-10 [5], it is possible to use diagnostic code F81.8 'Other development disorders of scholastic skills'.

It is indisputable that to exclude the presence of an IDD, it is necessary to evaluate the intelligence through a standardized test that may be mono-component or multicomponent. There is a recent debate on how necessary it is to make a complete cognitive evaluation to diagnose a specific learning disorder [55].

Diagnosis of SLD includes cognitive, speech and language, medical, psychological, and educational assessment, which should be made by professionals with specific training and expertise.

18.2.5 Treatment

Early intervention is fundamental for all SLDs in order to prevent or limit maladaptive consequences in school and working career [56, 57] as well as psychological distress and risk of mental health issues [58, 59]. The effectiveness of rehabilitation programmes on reading, writing, calculation, and overall adaptive skills during the developmental age has been repeatedly proven, but evidence on long-term outcomes is lacking.

Numerous studies on the aetiopathogenesis of dyslexia in recent years have helped to identify a multifunctional deficit model [60, 61], but studies on treatment have been few [62], due to several factors such as the national health policies, considerable heterogeneity of interventions, and cost. Rehabilitation programmes vary from country to country, focusing more on correctness or speed depending on the characteristics of the language. In less regular spellings (as in English) correctness represents the main issue, while in regular spellings (as in the Italian language) it is the speed that has to be impaired more [63–65]. In general, studies on the enhancement of correctness are more numerous than those on speed [66–67]. The literature suggests that the skills to train in the presence of dyslexia are verbal working memory, meta-phonological skills (phonological processing), and rapid automatized naming (RAN). Proposed treatments are different according to the aetiopathogenetic theories (phonological awareness theory, rapid auditory processing theory, magnocellular-dorsal theory, attentional deficit theory) embraced by those who developed them.

Systematic reviews of the literature, with and without meta-analysis, show that specialist interventions aimed at improving the correctness and fluency of reading are effective. These include the reading of words isolated or inserted in a context as well as exercises on meta-phonology, grapheme-phoneme conversion, repeated readings, which must be done several times in a week for at least 20 min each, and for at least 15–20 sessions [68–74]. In transparent languages, such as Italian, fast reading of whole words or reading with facilitated syllables identification are effective, also through the use of modern technologies, which allow to realize remote rehabilitation programmes, reduce costs, and are more fun for kids [66, 67, 75–81]. Many studies show that increased letter spacing can facilitate reading in dyslexics with visual crowding deficits [82–90]. In recent years transcranial magnetic stimulation (TMS), particularly rapid-rate TMS has been successfully used for treating dyslexia and for improving reading performance by exciting or rebalancing underactive reading pathways in the brain [91–93]. Also, transcranial direct current stimulation is showing promising results [94].

Studies on the treatment of dysorthography (or spelling disorder) are even less than those for dyslexia, probably because dyslexia and dysorthography frequently co-occur and some prerequisite skills underlie both conditions [95–97]. However, this does not justify the lack of studies, given that spelling correctness also requires skills other than the recognition process, such as the ability to segment words into phonemes [98]. In fact, students who have spelling deficits do not necessarily have word recognition deficits [99].

Interventions on dysorthography must involve the various sub-lexical or lexical components or both [100]. Studies carried out on English- or German-speaking children have shown the effectiveness of interventions on both components, sub-lexical [101, 102] and lexical [103–105]. The effectiveness of treatments depends on many factors; the literature indicates that the most important are represented by the clarity of instructions, regularity of exercise repetition, and timeliness of feedbacks [106].

Computer-based programs seem to offer benefits beyond traditional interventions, especially for spelling in writing through word processing programs with speech synthesis, although the evidence is far from conclusive [107, 108].

Treatments for dyscalculia also vary depending on pathogenic models. The most common focus on the Approximate Number System [41] and the access deficit hypothesis [109].

Slowness with numerical magnitude processing is a crucial target for treatment, for both symbolic (digits) and non-symbolic (dots) number formats, although data are more consistent and robust across studies for symbolic numbers [110–112].

In addition to the duration (at least 20 sessions of 30 min each), other characteristics of the intervention proved highly relevant for effectiveness, such as the inclusion of direct and self-instruction (more than mediated instruction), use of adequate support tools (i.e. number line), and teacher experience. Computer-assisted interventions can improve motivation to practice, automatization of math facts, and direct feedback provision but showed smaller effects than traditional interventions with humans as teachers [113–117].

Early intervention is critical for all SLDs to avoid or reduce negative repercussions in academic and occupational career, as well as psychological distress and the likelihood of mental health problems.

Various treatments and support programmes are available for SLDs, showing a varied rate of success.

18.2.6 Prognosis

SLDs occur early during the first years of formal schooling and persist into adulthood. As for NDDs, their manifestation may change over time, determined in part by genetic and biological factors, and influenced by environmental aspects. Therefore, the progression depends both on the severity of the impairment and the general clinical situation and on the external stimuli that the student receives from school and family. The IQ score also has an influence, which, as a diagnostic criterion, must not be lower than 70, but that delineates very different profiles of function between students that have a medium-low IQ and those with a very high IQ. Early diagnosis and successive intervention are fundamental, differentiating the prognosis of children who are diagnosed in adolescence compared with those who receive early diagnoses. Subjects who have undergone a course of rehabilitation treatment may compensate for the initial learning difficulties, while some are resistant to treatment and continue, therefore, to have significant problems later in life [118, 28, 30].

In addition, comorbidities have to be considered as the sum of numerous disorders makes the situation more complex and does not favour a positive prognosis. In particular, the coexistence of SLD and ADHD is predictive of worsening results of mental health. The situation may be worsened by histories of scholastic failure, with early school leaving (dropout) and a greater probability of psychological disadvantage. Early school leaving and symptoms of depression lead to a higher suicide rate, while social and emotional support are predictive factors.

Tip

Researchers and clinicians should focus more on identifying and treating specific learning disorders in adults who have not previously received treatment.

The neurological, genetic, and cognitive basis of learning impairments should be addressed in future studies and prac-

tice, particularly in those who do not respond to typical treatments. A continued empirical study on the function of cognitive processes in detection and intervention is required. Interdisciplinary study based on a rigorous, scientific approach and focused on integrating information across domains will provide a better understanding of the communalities and distinctions between specific and non-specific developmental learning problems.

18.3 Motor Disorders

Developmental motor and coordination disorder represent a group of lifelong conditions characterized by difficulties in acquiring motor and coordination skills. They are not learning disorder, but they can impact learning and many associated activities. Children with these conditions may be substantially delayed in reaching motor milestones, make repetitive and involuntary movements, or have physical or verbal tics, which cause impairment and result in negative physical, psychological, and social consequences across the whole lifespan. Motor disorders frequently co-occur with intellectual disability and/or autism spectrum disorders, supporting the notion that motor, cognitive, and social-communication functioning are interrelated [119, 120].

The latest editions of the main classification systems of disorders and diseases (DSM-5 [2] and ICD-11 [1]) show significant changes in the consideration of developmental motor disorders compared with previous editions. The DSM-5 [2] created a new subcategory called 'Motor Disorders' under the new meta-structure called 'Neurodevelopmental Disorders', while in the DSM IV-TR [4], developmental coordination disorder, stereotypic movement disorder, and tic disorders were included under the cluster 'Disorders Usually First Diagnosed in Infancy, Childhood, and Adolescence', with only developmental coordination disorder being specified as a motor skills disorder. This new neurodevelopmental framework also blurred the hierarchy of a disorder in relation to another; for example, stereotypies occurring in children who are otherwise developing normally, which were referred to as primary, are no longer distinguished from those occurring in children who have developmental problems, which were referred to as secondary. Another significant change concerns tic disorders, for which the DSM-IV-TR [4] required the youth to be tic-free for no more than 3 months before being diagnosed. This requirement has been removed in the DSM-5 [2], which takes a more dimensional approach to diagnosis and, as a result, places a greater emphasis on the likelihood that tics might come and go in terms of frequency and incidence. In the DSM-5 'motor disorders' category includes developmental coordination disorder, stereotypic movement disorder, and tic disorders [2].

Within ICD-11, only the developmental motor coordination disorder and stereotyped movement disorder are included under the new chapter of 'neurodevelopmental disorders' (number 6), while primary tics or tic disorders are included in the chapter of 'diseases of the nervous system' (number 8), and more specifically in the subchapter named 'movement disorders', which also includes disorders as parkinsonism, choreiform disorders, dystonic disorders, or myoclonic disorders [1].

Concerns about the presence of a developmental motor disorder should be raised if the following developmental milestones are missing or delayed; (a) 4–6 months: sits with support, rolls, reaches out and grasps objects; (b) 6–9 months: crawls, sits without support, pulls to stand, transfer objects between hands; (c) 7–12 months: pincer grasp, walks with hands held; (d) 12–15 months: drinks from a cup, builds two-brick towers; (e) 18 months: walks up steps, walks independently, builds three-brick towers; (f) 2 years: kicks and throws a ball, jumps, runs, builds six-brick towers, uses spoons, turns pages, helps with dressing, draws circular scribbles; (g) 3 years: stands on one leg momentarily, eats with forks and spoons, draws circles; (h) 4 years: hops, can dress and undress, draws a person with head, body, and legs [121].

Motor disorders such as motor coordination difficulties, tic, and Tourette's syndrome are common in children and adults with intellectual disabilities.

18.3.1 Developmental Coordination Disorder

- **DSM-5 Diagnostic Criteria [2]**

A. The acquisition and execution of coordinated motor skills are substantially below that expected given the individual's chronological age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g. dropping or bumping into objects) as well as slowness and inaccuracy of motor skills (e.g. catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports).
B. The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronological age (e.g. self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play.
C. The onset of symptoms is in the developmental period.
D. The motor skills deficits are not better explained by intellectual disability or visual impairment and not attributable to a neurological condition affecting movement (e.g. cerebral palsy, muscular dystrophy, degenerative disorder).

The diagnosis is made by a comprehensive developmental and medical history, physical examination, school or workplace reports, and culturally appropriate standardized individual tests. Disorders that commonly occur with developmental coordination disorder include speech and language disorder, SLDs especially reading and writing, problems of attention including ADHD, ASD, disruptive and emotional problems, and joint hypermobility syndrome [2].

The diagnostic criteria exclude ID, but the two conditions appear together in several studies. Gillberg and colleagues [122] found that after adjusting for epilepsy, there remained a significant association between febrile seizures and ASD, developmental coordination disorder, and ID. Bernier and colleagues [123] were able to follow up two cohorts, one with 16 p11.2 deletion and the another with 16 p11.2 duplication, and study their early developmental trajectories and emergence of the phenotype. The most commonly diagnosed conditions for the deletion carriers were speech sound disorder (67%), developmental coordination disorder (67%), and language disorder (54%). For the duplication carriers, the most common diagnoses were developmental coordination disorder (56%) and ADHD (39%). Fifteen per cent of the deletion group and 22% of the duplication group also had an ID. Although the verbal IQ of duplication children with ID improved, they showed more motor skills problems over time ($P = 0.02$) and showed a trend toward increased challenges in daily living skills. There appeared to be a complex interplay of possibilities between the children developing ASD, motor disorders, or ID.

Barnevik Olsson and colleagues [124] presented the neuropsychiatric profiles of children aged 11 years with ASD, assessed before age 4.5 years, and after interventions. Developmental coordination disorder rates were equal in the average intelligence, borderline intelligence, and ID group. The authors make a very important point about ASD which is equally important about ID that it is rarely an isolated disorder but a co-occurring one.

Cunningham and colleagues [125] found that indicative developmental coordination disorder was associated with full-scale IQ children with 22q11.2DS ($P = 0.038$) which suggests that the observed coordination difficulties seen in this population can be partially explained by a general deficit in IQ. They suggest that this agrees with studies of children with developmental coordination disorder not selected for having a chromosomal disorder and suggest that within the ID population, the level of impairment is associated with motor dysfunction.

> Although the presence of ID is an exclusion criterion for the diagnosis of developmental coordination disorder, the two disorders have been found together in several studies.

18.3.2 Stereotypic Movement Disorder

According to ICD-11, stereotyped movement disorder is characterized by the presence of persistent voluntary, repetitive, apparently purposeless movements that are not caused by the direct physiological effects of a substance or medication, and markedly interferes with normal activities [1]. Like developmental coordination disorder, stereotypic movement disorder has an early onset during the developmental age but can continue across the whole lifespan [126]. Around 80% of children with complicated motor stereotypies show symptoms before the age of 24 months, 12% between the ages of 24 and 35 months, and 8% at the age of 36 months or beyond [127]. Stereotypic movement disorder affects more males than females [128].

Symptoms of stereotypic movement disorder include repetitive and involuntary motor behaviours like shaking, rocking, finger-flicking mannerisms, or hand flapping. Stereotyped movements with self-injury, such as head banging, face slapping, or self-biting, represent a specific sub-category of 'stereotyped movement disorder' within ICD-11 while they are considered as a specifier of a unique category of 'stereotypic movement disorder' in DSM-5. However, most of the international scientific community views self-injurious behaviour as a broad category of problem behaviours with a variety of aetiologies and explanatory hypotheses, including the possibility of underlying causative mechanisms that are more closely related to the spectrum of OCD/impulse dyscontrol than to stereotypic movement disorder [129]. For further details on self-injury see ► Chap. 7.

Youngsters with stereotypic movement disorder are unable to cease repeated motions even when distracted or given attention, although they can try to limit their movements by sitting on their hands or wrapping their arms in their clothing. Nevertheless, it is also possible that distraction may attenuate stereotypic movements to some extent and for a limited time.

In terms of body location, stereotypies frequently involve hands, arms, legs, the upper body, or the entire body, which represent quite different locations in respect to other repetitive movement disorders such as tic disorders, which commonly involve eyes, face, head, and shoulders. Stereotypies are also more stable, rhythmic, and long-lasting than tics, which tend to be variable, irregular, and quick. Also in contrast to tics, stereotypies are not accompanied by premonitory desires, prior sensations, or an inward desire to execute. Both could be precipitated or exacerbated by some psychological conditions such as distress, anxiety, excitement, focused concentration, or boredom, but stereotypic movements are also frequent when a person is immersed in an activity.

Stereotyped or repetitive motor movements can also be present in ASD and are not uncommon in persons with ID, especially in those with a moderate-to-severe degree of severity. In these cases, stereotypic movement disorder is diagnosed only when there is self-injury or when the stereotypic behaviours are sufficiently severe to constitute an adjunctive clinical focus. Further information on stereotypies associated with ID and ASD has been included in the ► Chaps. 6 and 16.

Despite the frequency of its occurrence, stereotypic movement disorder still presents diagnostic difficulties, confusion around comorbidities, and management uncertainty. Also, terminology, definition, and aetiology have been subject to recent debate [130].

18.3.3 Tic Disorders

A tic is a sudden, rapid, recurrent, non-rhythmic motor movement or vocalization. Tics are common in childhood and transient in most cases. The estimated prevalence of Tourette's syndrome ranges from 3 to 8 per 1000 school children with boys being more commonly affected than girls [2]. Onset of tics is typically between 4 and 6 years of age, peak severity occurs between 10 and 12 years, with a decline during adolescence. They can wax and wane and change muscle groups affected and patterns of vocalizations over time.

Tics can be simple or complex. Simple motor tics are of short duration and can include eye blinking, shoulder shrugging, and

extension of extremities. Simple vocal tics include throat clearing, sniffing, and grunting caused by the contraction of the diaphragm or the muscles of the oropharynx. Complex tics can appear purposeful. Complex tics are of longer duration and often include a combination of simple tics such as head turning and shoulder shrugging. They can appear purposeful, such as a tic like sexual gesture (copropraxia), tic like imitation of someone else's movements (echopraxia), tic like an imitation of what one has said (palilalia), and tic like an imitation of what someone else has said (echolalia), uttering socially unacceptable words (coprolalia). Coprolalia is an abrupt, sharp bark or grunt utterance and lacks the normal prosody of speech [2].

Tics are worsened by anxiety, stress, and exhaustion. Observing a gesture or sound in another person may precipitate tic which may be misconstrued as being purposeful by authority figures such as teachers.

The key DSM-5 [2] diagnostic criteria for different tic disorders are listed below.

Tourette's Disorder

A. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently.
B. The tics may wax and wane in frequency but have persisted for more than 1 year since the first tic onset.
C. Onset is before age 18 years.
D. The disturbance is not attributable to physiological effects of a substance (e.g. cocaine) or another medical condition (Huntington's disease, post viral encephalitis).

Persistent (Chronic) Motor or Vocal Tic Disorder

A. Single or multiple motor or vocal tics have been present during the illness, but not both vocal and motor.
B. The tics may wax and wane in frequency but have persisted for more than 1 year since the first tic onset.
C. Onset is before age 18 years.
D. The disturbance is not attributable to physiological effects of a substance (e.g. cocaine) or another medical condition (Huntington's disease, post viral encephalitis).
E. Criteria have never been met for Tourette's disorder.

Specify if with motor tics only or with vocal tics only.

Provisional Tic Disorder

A. Single or multiple motor and/or vocal tics.
B. The tics have been present for less than 1 year since the first tic onset.
C. Onset is before the age of 18 years.
D. The disturbance is not attributable to physiological effects of a substance (e.g. cocaine) or another medical condition (Huntington's disease, post viral encephalitis).
E. The criteria have never been met before for Tourette's disorder or persistent (chronic) motor or a vocal tic disorder.

Tic disorders are hierarchical in order, that is Tourette's disorder, followed by persistent (chronic) motor or vocal tic disorder, followed by provisional tic disorder followed by other specified or unspecified tic disorders, such that once a tic disorder at one level of the hierarchy has been diagnosed, a lower level diagnosis cannot be made.

Cervantes and Matson [131] found that people with autism and ID were significantly more likely to experience tics and stereotypies than people who only had ID. Tourette's disorder and ASD share clinical features and possibly an overlapping aetiology. Darrow and colleagues [132] recruited 535 participants with Tourette's disorder and 234 of their family members and got them to complete Social Responsiveness Scale (SRS), 2nd edition, to characterize ASD symptoms. More children with Tourette's disorder met cut-off criteria for ASD (22.8%) than adults (8.7%). The elevated rate in children was primarily due to high scores on the SRS Repetitive and Restricted Behaviours (RRB) subscale. Higher observed rates of ASD among children affected by Tourette's disorder may in part be due to difficulty in discriminating complex tics and OCD symptoms from ASD

symptoms. Careful examination of ASD-specific symptom patterns (social communication vs. repetitive behaviours) is essential.

Self-injurious behaviour has been reported in up to 60% of people with Tourette's disorder. Mathews and colleagues [133] found that 29% of their sample had self-injury and 4% had severe self-injury. Mild to moderate symptoms correlated with obsessive and compulsive symptoms, while severe self-injury was correlated with variables related to affect or impulse dysregulation.

In their cross-sectional study of a cohort of people with tuberous sclerosis, Raznahan and colleagues [134] found two people with a tic disorder; it is not clear whether they also had ID. Shelley and colleagues [135] reported a case of a young man with Smith-Magenis syndrome and Tourette disorder suggesting that the co-occurrence of the two conditions may reflect common endophenotypic mechanisms underpinning the complex genetic disorders.

Barabas and colleagues [136] reported three cases of people with Down syndrome who also had characteristic features of Tourette's disorder with multiple motor and vocal tics. Kerbeshian and Burd [137] examined the North Dakota Tourette Registry retrospectively and found that five people also had Down syndrome, out of 70 adults and 188 children and adolescents, which gave an association rate of 2% between Down syndrome and Tourette's disorder.

Tartaglia and colleagues [138] reported on medical and psychological aspects of XXYY syndrome having looked at a large cohort of 95 individuals from the USA, Canada, the UK, and Australia and found that 18.9% had a tic disorder.

Schneider and colleagues [139] described five male patients from three unrelated families with fragile X syndrome who presented with motor and phonic tics. Four of them fulfilled the criteria for the diagnosis of Tourette's disorder and the fifth for adult onset tic disorder. As the onset of tics in all the individuals was considerably later than usual, authors suggest testing for Fragile X syndrome in people with Tourette's disorder complicated by ID and dysmorphic features.

Treatment of Tic disorders include both pharmacological intervention such as risperidone, haloperidol, pimozide, aripiprazole, clonidine, and non-pharmacological interventions such as symptom focused behaviour therapy like habit reversal training and exposure and response prevention therapy [140].

Tics and stereotypies are more common in people with more complex neurodevelopmental disorders, such as those with co-occurring ID and ASD, than in people with ID alone.

18.4 Communication Disorders

People with mild and moderate ID are usually able to communicate using speech. Those with more severe degrees of ID may be able to utter single words, and caregivers use body language, pictures, signs, and other enhanced forms of communication to anticipate the needs of these people. Language disorder is strongly associated with other NDDs such as ADHD and ASD [2].

People with ID may have communication needs that must be fully recognized in order to understand how to support them. For example, articulation difficulties in expression may lead to stammering, slurred speech, echolalia (repeating the same word or repeating the last word that has been said to them), fluctuating pitch, and intonation. Restrictive speech and repetitive speech are common in people with ASD.

Communication impairments can be described in three aspects of communication. These are (a) comprehension (how much someone understands what is being spoken), (b) expression (how someone communicates their needs), and (c) social Interaction: how someone seeks interactions with others. Most people would be expected to have better understanding skills (comprehensive speech) than expressive speech. However, some people can understand more language than they can communicate themselves. Developmental language disorders are not always easily identified and might not become apparent until a child begins school. This can cause problems with academic performance and overall functioning.

18.4.1 Speech Sound Disorder

Speech sound production is the clear articulation of individual sounds that in combination produce spoken words. Learning to produce speech sounds clearly and later connect speech fluently are developmental skills that follow a pattern. Normally developing children may shorten words and syllables during this process but produce mostly intelligible speech by 3 years. Most speech sounds and most words should be pronounced accurately by the age of 7 years according to age and community norms with the most frequently misarticulated sounds being *l*, *r*, *s*, *z*, *th*, *ch*, *dzh*, and *zh*, up to the age of 8 years.

Speech sound production requires phonological knowledge of the sound and the ability to coordinate the movements of the jaw, tongue, and lips – the articulators with breathing and vocalizing. Children with speech sound disorder could have difficulties with knowing what the sound is and also with coordination, but the underlying causes could be heterogeneous. A diagnosis can be made only when the level of speech is not what would be expected at that developmental stage for the child. The examples are (a) no gestures or response to words at 9 months, (b) no babbled phrases at 12 months, (c) no clear words at 18 months, (d) has less than 50 words and does not produce 2 words sentences at 2 years, (e) does not ask 'what' and 'who' questions, does not use pronouns (e.g. 'I', 'me'), and does not understand 3 words commands at 3 years, and (f) does not ask 'why', 'when', and 'how' questions and cannot count up to 20 by age 4 years.

- **DSM-5 Diagnostic Criteria [2]**

A. Persistent difficulty with speech sound production that interferes with speech intelligibility or prevents verbal communication of messages.
B. The disturbance causes limitation in effective communication that interferes with social participation, academic achievement, or occupational performance, individually or in any combination.
C. The onset of symptoms is in the early developmental period.
D. The difficulties are not attributable to congenital or acquired conditions such as cerebral palsy, cleft palate, deafness or hearing loss, traumatic brain injury, or other neurological conditions.

In many children with ID conditions like cerebral palsy, cleft palate, hearing problem, and other neurological conditions will be present.

A study carried out in Edinburgh [141] found that in a large sample of ID adults, 12.7% had no speech and 53% had speech problems, primarily in the form of difficulties in intelligibility. Shriberg and colleagues [142] also found a high percentage (43%) of persistent speech errors in their Idiopathic ID group which would affect their intelligibility. Extensive work has been carried out in the acquisition of language by children with Down syndrome, and this shows differences emerging at the transition into first words with delays characteristic of developmentally younger children, while consonant errors, as well as phonological processes (patterns of sound errors such as deletion of final consonants), are similar to the patterns in younger typically developing children at similar mental age levels [143, 144]. Although children with Down syndrome use phonological processes or sound patterns that are similar to those used by typically developing children, they eliminate these processes at a slower rate. The boys with Down syndrome generally use reduced word shapes, by omitted syllables (e.g. 'bana' for 'banana'), reduced consonant clusters (e.g. 'bu' for 'blue'), and deleted consonants, e.g. spoo for spoon [145].

Delayed emergence of speech and restricted and atypical phoneme repertoires are common findings in people with 22q deletion syndrome which results in poor speech intelligibility, particularly in younger children. Although there is progression and improvement in speech in school age children, speech sounds deficits may persist into late childhood and adolescence. Common speech sound disorders include hypernasality, high pitch, dysphonia, restricted and delayed speech sound acquisition, articulation impairments, abnormal speech prosody, childhood apraxia of speech, and speech motor delay [146].

The FOX2P gene has been called the speech gene encoding a transcription factor involved in speech and language acquisition. There is increasing evidence that dysregulated FOXP2 activity may also be instrumental in human oncogenesis [147]. All FOXP2-related speech and language disorders, regardless of the underlying genetic alteration, have a core phenotype: childhood apraxia of speech (CAS), a disorder of speech motor programming or planning that affects the production, sequencing, timing, and stress of sounds, syllables, and words. All individuals with CAS (whether caused by an alteration of FOXP2 or of an unknown cause) have difficulties in automatically and accurately sequencing speech sounds into syllables, syllables into words, and words into sentences with the correct prosody [148]. Some of these individuals may have global developmental delay and ASD too.

Speech delay and articulation problems occur in children and adults with ASD. Rapin and colleagues [149] analysed language data of children with ASD and reported more than a quarter of the group as having phonological speech problems. Cleland and colleagues [150] found speech problems in 12% when assessing a group of children with ASD without ID; however, 41% of the children produced at least some speech errors. Similarly, Shriberg and colleagues [151] reported 'speech delay', defined as mainly phonological speech errors affecting intelligibility (but also including articulation errors) occurring in 15% of their sample of ASD children.

18.4.2 Childhood Onset Fluency Disorder (Stuttering)

Essentially, this is a disorder with a disturbance in the normal fluency and time patterning of speech which is inappropriate for the individual's age. It is characterized by frequent repetitions or prolongations of words or syllables and by other types of speech dysfluencies including broken words, audible or silent blocking, word substitutions to avoid difficult words, words produced with an excess of physical tension, and monosyllabic whole word repetitions. This may interfere with academic or occupational achievement and social interactions and is usually worse when there is pressure to communicate. It may be absent when talking to pets or inanimate objects or singing. The child may develop motor movements such as eye blinks, tics, tremors, etc. together with dysfluency. The onset of the condition can be insidious or sudden, with the age of onset ranging from 2 to 7 years. Longitudinal studies show that 65–85% of children recover from dysfluency, and severity of the disorder at age 8 years predicts recovery or persistence into adolescence and beyond [2].

DSM-5 Diagnostic Criteria [2]

A. Disturbances in the normal fluency and time patterning of speech that are inappropriate for the individual's age and language skills, persist over time, and are characterized by frequent and marked occurrences of one (or more) of the following:
   1. Sound and syllable repetitions.
   2. Sound prolongations of consonants as well as vowels.
   3. Broken words (e.g. pauses within a word).
   4. Audible or silent blocking (filled or unfilled pauses in speech).
   5. Circumlocutions (word substitutions to avoid problematic words).
   6. Words are pronounced with excessive physical tension.
   7. Monosyllabic whole word repetitions (e.g. 'I-I-I-I see him').

B. The disturbance causes anxiety about speaking or limitation in effective communication, social participation, or academic or occupational performance, individually or in any combination.

C. The onset of symptoms is in the early developmental period. (Note: Later onset cases are diagnosed as adult onset fluency disorder.)

D. The disturbance is not attributable to a speech motor or sensory deficit, dysfluency associated with neurological insult (e.g. stroke, tumour, trauma), or another medical condition and is not better explained by another mental disorder.

Data collected through Centres for Disease Control and Prevention indicate a prevalence rate of 1.6% of children between 3 and 17 years of age [152]. Stansfield [141] carried out a study on the prevalence of idiopathic dysfluency or stuttering in adults with ID using NHS and local authority provision in Edinburgh and found a total prevalence of 6.31% of speech dysfluency. Half of the dysfluent group had Down syndrome and they formed 14.7% of the Down syndrome group. Kent and Vorperian [153] have reviewed the studies on children with Down syndrome and concluded that stuttering has been demonstrated in 10–45%, on an average of 31% of individuals. Briley and Ellis [154] found that the presence of at least one disabling developmental condition was 5.5 times higher in children who stutter when compared with children who do not stutter. The presence of stuttering was also associated with higher odds of each of the following coexisting developmental and neurological conditions: ID (odds ratio [OR] = 6.67, p < 0.001), SLDs (OR = 5.45, $p < 0.001$), ADHD (OR = 3.09, $p < 0.001$), seizures (OR = 7.52, $p < 0.001$), ASD (OR = 5.48, $p < 0.001$), and any other developmental delay (OR = 7.10, $p < 0.001$).

Stuttered speech has been reported in people with Fragile X syndrome. Paul and colleagues [155] reported 2.9% stuttered syllables on average in the spontaneous speech of a group of adult males with fragile X, compared with 2.75% in a group with non-specific ID and 2% in a group with ASD. Ferrier and colleagues [156] reported a mean percentage of stuttering of 4.9% in fragile X syndrome, 1.6% in ASD, and 6.1% in Down syndrome. Van Borsel and Tetnowski [157] concluded that individuals with fragile X syndrome appear to have a higher prevalence of stuttering than non-specific forms of ID and ASD, but a lower prevalence than individuals diagnosed with Down syndrome.

Prader Willi syndrome is also associated with speech dysfluency. Van Borsel and Tetnowski [157] suggested that an in-depth analysis of the distribution of stuttering moments has been shown to differentiate the stuttering associated with Prader-Willi syndrome from developmental stuttering.

18.4.3 Social (Pragmatic) Communication Disorder

This condition is characterized by a primary difficulty with the pragmatics or social use of language and communication. The individual is unable to understand and follow social cues of verbal and nonverbal communication according to context and the needs of the listener or the situation, and follow the rules of conversation and storytelling. This could lead to functional limitations in effective communication, social participation, and developing social relationships, academic achievements, or occupational performance. The most common association is language impairment with a history of language delay. Individuals may avoid social interactions [2].

As the diagnosis is dependent on adequate language development, this disorder is rare before the age of 4 years. The outcome of the disorder is variable, with some children improving substantially, and others continuing to have difficulties into adulthood.

A diagnosis of social communication disorder can only be considered if the child did not display repetitive restricted patterns of behaviours, interests, and activities during the early developmental period. Social communication skills may also be deficient in individuals with ID, but a separate diagnosis is not made unless social communications are clearly in excess of the intellectual limitations [2].

- **DSM-5 Diagnostic Criteria [2]**

A. Persistent difficulties in the social use of verbal and nonverbal communication as manifested by all of the following:
   1. Deficits in using communication for social purposes, such as greeting and sharing information, in a manner that is appropriate for the social context.
   2. Impairment of the ability to change communication to match the context or the needs of the listener, such as speaking differently in a classroom rather than in a playground, talking differently to a child than an adult, and avoiding overly formal language.

3. Difficulties following rules of conversation and storytelling, such as turn taking in conversation, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signs to regulate interaction.
4. Difficulties understanding what is not explicitly stated (e.g. making inferences) and nonliteral or ambiguous meanings of language (e.g. idioms, humour, metaphors, multiple meanings that depend on the context for interpretation).

B. The deficits result in functional limitation in effective communication, social participation, social relationships, academic achievement, or occupational performance, individually or in combination.
C. The onset of the symptoms is in the early developmental period (but deficits may not become fully manifest until social communication demands exceed limited capacities).
D. Symptoms are not attributable to another medical or neurological condition or low abilities in the domain of word structure and grammar and are not better explained by autism spectrum disorder, intellectual disability (intellectual developmental disorder), global developmental delay, or another mental disorder.

Given that the concept has been recently expanded in DSM-5 [2], it will be necessary to examine and evaluate the validity of the criteria for the disorder before estimating the prevalence [158]. However, Ouss et al. [159] found that two of their patients with Dravet syndrome with ID also met the criteria for social communication disorder. Despite DSM-5 [2] excluding ID and ASD for the above diagnosis, the social communication disorder is very common in ASD and also to some extent in the ID population. It has been shown that prior to 2013, before social communication disorder was added to the DSM-5 as a stand-alone diagnosis, individuals with this condition would have been diagnosed with ASD, most often pervasive developmental disorder not otherwise specified or Asperger's syndrome [160].

18.4.4 Unspecified Communication Disorder

This category is applied to presentations in which there is a communication disorder significant enough to cause clinically significant distress or impairment in social, or other important areas of functioning but does not meet full criteria for any of the communication disorders or any of the disorders of the NDDs. DSM-5 [2] specifies that this category is used in situations when the clinician chooses not to specify the reason that the criteria are not met and includes presentations in which there is insufficient information to make a more specific diagnosis.

Stansfield [141] in the comprehensive prevalence study of health and local authority provision in Edinburgh found that 53% had speech problems including difficulties in intelligibility, comprehension, expressive language, voice, fluency, and no speech.

The role of functional communication assessment is highlighted by Cascella [161] in his review of standardized speech and language tests. He suggests that a functional assessment approach lets the clinician consider the variety of communication contexts in which the student participates (e.g. home, school, and community). When the context is considered, the speech and language practitioner can evaluate communication opportunities and teachers' and family members' expectations in any given situation. This can be used in other situations too (Table 18.2).

Children and adults with intellectual disabilities manifest various types of communication disorders including speech sound disorder, speech fluency disorder (stuttering), and social (pragmatic) communication disorder.

Table 18.2 Tips to improve communication with people who have mild to moderate ID and can speak *(see Deb & Iyer, 2005)* [162]

The nature of the person's relationship with the interviewer may influence the interview process.	Some may have set ways of responding to questions irrespective of their content. For example, they may answer 'yes' or alternatively 'no' to all questions irrespective of their contents. This may tell you they are not understanding what you are saying.	The tendency of the person with ID to echo the last option can be minimized by asking her/him to confirm both options and choose one.
Be aware that the person with ID may have negative experiences of the interview process.	Avoid closed questions and always use open questions.	Avoid complex phrasing and those involving abstract concepts such as 'extent', 'all the time', and 'low spirits'.
They may also be concerned about the consequences of the interview.	Establish first the person's preferred method of communication and inform other professionals about that.	Ask the person with intellectual disabilities to clarify statements using examples.
Wait for them to respond to your question and assess whether you feel they have understood you. If necessary, repeat the question.	Be flexible about the length of interviews, such as using several shorter interviews instead of one long interview.	Avoid double negatives. For example, 'You do not refuse medication, do you?' may be usefully phrased as 'Do you take your meds?'
Ensure you have made all reasonable adjustments for the interview.	Make sure you allow plenty of processing time when you have asked a question.	Events could be used as anchors to get a time frame. For example, 'Are you feeling sad since your birthday?'
Interview in an unfamiliar location may pose its own anxieties.	Start with easy questions to gain the person's confidence.	Use simple sentences using short words, in the present tense.
The interview may involve a change in routine which may precipitate unwanted behaviour.	Be patient and wait for the answer to the first question before moving to the next.	Watch out for non-verbal signs especially distress and discomfort.
Remember that sensory difficulties such as impaired hearing or vision are likely to affect the interview.	Be aware of body language. For example, during the discussion of a recent bereavement, an autistic person started to rock in his chair, which is an early sign of distress. You may need to stop the discussion or change the topic.	You should be aware of autistic masking where someone says something, but it is not exactly concise. The interviewer needs to use insight and interpretation to establish what the person actually means.
Reduce background noise, allow plenty of time and ensure you understand each individual's communicative needs, and try to establish eye contact to get their attention.	You can use reverse wording. For example, the question 'Do you have trouble sleeping?' can be followed by 'Do you sleep well?' in the latter part of the interview.	For example, BJ, a 13-year-old boy assessed for depression talked about having his 'tummy cut'. His mother clarified that this referred to his preoccupation with his weight of late. He had recently watched a programme on television about surgical treatments for obesity.

18.4.5 Strategies to Support People with ID Who Have Communication Difficulties

- **Useful Links**

► http://helensandersonassociates.co.uk/person-centred-practice/person-centred-thinking-tools/

Tips to improve communication with people who have severe to profound ID and cannot speak (► https://spectrom.wixsite.com/project).

People with severe and profound ID and without verbal skills may need to use non-verbal methods of communication. It is advisable to have a 'communication partner' usually the key care/support staff or a family member who has developed a good relationship with the person and has developed skills to communicate with the person non-verbally. This 'communication partner' can act as an interpreter and could inform other people, particularly professionals about the best way to communicate with the person with ID [163]. The person with ID may respond better to environmental cues such as a 'familiar voice', 'gesture', and 'touch'.

Following are the examples of non-verbal communication techniques that could be used (augmentative and alternative communication (AAC)/communication aids) [163].

► https://www.youtube.com/watch?v=YzVvYj1RfKI

- **Examples of AAC**

- *Signing* includes the use of signs and symbols to convey relevant key messages to aid comprehension. For example, signing 'we need to visit the park after you finish your lunch' would include signs 'lunch', 'shoes', and 'park'.
- *On-body singing* is used for people with visual impairments. Examples of this include placing one person's hand on top of or under the partner's hand so the communicative partner can read the signs.
- *Objects of references* include the use of objects to convey messages. For example, using a football to signify that the activity football game is about to take place.
- You can use *photos*, *pictures*, and *symbols* to convey any message. For example, you can use a photo of a relative to show that his or her relative has come to visit.
- Picture Exchange Communication System (*PECS*) is a training method that uses symbols to teach the person communication skills of increasing complexity. For example, the person first learns to use simple symbols for things she or he wants and then learns to use this in different settings. The person then learns to use multiple pictures to form sentences, expand their sentences, respond to questions, and comment on things.
- A person can communicate using their eyes to point to a specific symbol on an *E-tran* frame. For example, a person can look at food symbols to show that she or he wants to eat.
- *Talking mats* includes using symbols or pictures to communicate about a topic. For example, a person can stick symbols or pictures of how they feel about swimming, playing football, or any other activity if the topic is an activity.
- High-tech devices such as *VOCAs* can generate speech for people who have no means to communicate. For example, it can be used to inform support staff of what the person wants.
- *Intensive interaction* is a person-centred approach to enhance social communication, particularly among people who have severe and profound ID, sensory impairment, and autism. Following are the main principles on which this intervention is based.
  - Doing a sequence of activities with the person
  - Attending and concentrating
  - Taking turns in exchange for behaviour
  - Sharing personal space
  - Using and understanding eye contact (face and mind-reading)
  - Using and understanding facial expression (face and mind-reading)
  - Using and understanding physical contacts

- Using and understanding non-verbal communication
- Vocalizing and using vocalization meaningfully (including speech)
- Regulating and controlling arousal level
- Considering emotional and well-being issues

Here is a link for more information on intensive interaction: ► https://www.intensiveinteraction.org/

Use short videos and visual aids such as photographs, line drawings, visual scripts or social stories, and communication boards or PECS symbols.

Always seek the advice and support of an experienced professional such as a speech and language therapist specializing in ID to guide which of these approaches are likely to be the most successful with an individual.

Use '*Tools for talking*' to identify what the person with ID wants or needs to improve her or his quality of life. Tools for talking can be used for people from ethnic minorities and who have low communication skills.

► https://toolsfortalking.wordpress.com/resources/

Example of person-centred tools developed by Helen and Sanderson Associates to understand communication and communicate effectively.

► http://helensandersonassociates.co.uk/person-centred-practice/person-centred-thinking-tools/

Always try to understand and meet the needs of the person. If a person enjoys routine, then a visual timetable of the activities she or he will participate in may be created. The use of sign languages such as Makaton or British Sign Language, and objects of reference such as plates to signify dinner/lunch time is another option.

Pay attention to the body language of a person with ID. For example, you may identify a person who is about to display aggressive behaviour through cues such as fist clenching, lip biting, or stomping of feet. The facial expression, body posture, and tone of voice will provide many cues. Examples of positive cues include smiling, eye contact, relaxed body, responding well to social interaction, and so on. Examples of negative cues include restless, rigid body, feet tapping, slumped posture, a relaxed tone of voice, and so on.

Key Points

- Specific learning, motor, and communication disorders start at childhood and often persist into adulthood, with changes of symptomatology across time depending on age and environmental requirements.
- If an ID is present, a specific learning disorder can be diagnosed additionally only if the specific learning difficulties are more severe than those attributable to ID.
- Current classificatory systems introduced significant changes to diagnostic criteria of specific learning, motor, and communication disorders in comparison to previous editions.
- Specific learning disorders are among the most common neurodevelopmental disorders, with a prevalence of 5–15% in school-age children across different languages and cultures, and approximately 4% in adults.
- The identification of the causes of SLD is complicated by their heterogeneity. Nevertheless, most experts agree on a biological origin of the cognitive anomalies that underlie behavioural symptoms of the disorders.
- The assessment of SLDs should be made by specialists with appropriate training and expertise and address cognitive, speech and language, medical, psychological, and educational aspects.
- Early intervention is critical for all SLDs to avoid or reduce negative outcome.

- Various treatments and support programmes are available for SLDs, showing a varied rate of success.
- Children with motor disorders may be substantially delayed in reaching motor milestones, make repetitive and involuntary movements, or have physical or verbal tics, which cause impairment and result in negative physical, psychological, and social consequences across the whole lifespan.
- Motor disorders frequently co-occur with ID and/or ASD, supporting the notion that motor, cognitive, and social-communication functioning are interrelated.
- Stereotyped or repetitive motor movements represent a distinguishing feature of ASD and are not uncommon in persons with ID, especially in those with a moderate-to-severe degree of severity. In these cases, stereotypic movement disorder is diagnosed only when it is sufficiently severe to constitute an adjunctive clinical focus.
- Persons with more complicated neurodevelopmental disorders, such as ID and ASD co-occurring, have more tics and stereotyped or repetitive motor movements than people with ID alone.
- Speech sound disorder, speech fluency disorder (stuttering), and social (pragmatic) communication disorder are all common communication disorders in children and adults with ID.
